A similar approach may be applied when we try to construct fuzzy versions of the confidence intervals of the unknown parameter θ. Let us assume that we are able to find confidence intervals of θ using precise (crisp) statistical data. For example, let $[\underline{\pi}_l,+\infty)$, where $\underline{\pi}_l=\underline{\pi}_l(X_1,\dots,X_n;\delta)$, be the one-sided confidence interval for the parameter θ on the confidence level $1-\delta$. Kruse and Meyer [20] have shown that when we replace $\underline{\pi}_l$ with the lower limits of the α-cuts of its fuzzy version we obtain a proper confidence interval for the fuzzy perception of θ. These lower limits can be found for different values of $\alpha\in(0,1]$ from the formula [15]

$$\begin{aligned}\underline{\Pi}^L_\alpha &= \underline{\Pi}^L_\alpha(\mathcal{X}_1,\dots,\mathcal{X}_n;\delta)\\ &=\inf\big\{t\in\mathbb{R}:\forall i\in\{1,\dots n\}\ \exists x_i\in\mathcal{X}_{i,\alpha}\\ &\quad\text{such that }\underline{\pi}_l(x_1,\dots,x_n;\delta)\le t\big\}\end{aligned} \tag{9}$$

where $X_{i,\alpha}, i = 1, \ldots, n$ are respective α-cuts of the observed fuzzy data.

In a similar way we can define a fuzzy equivalent of the one-sided confidence interval $(-\infty, \overline{\pi}_u]$:

$$\begin{aligned}\overline{\Pi}_\alpha^U &= \overline{\Pi}_\alpha^U(\mathcal{X}_1, \ldots, \mathcal{X}_n; \delta) \\ &= \sup\big\{t \in \mathbb{R} : \forall i \in \{1, \ldots n\}\, \exists z_i \in X_{i,\alpha} \\ &\quad \text{such that } \overline{\pi}_u(z_1, \ldots, z_n; \delta) \geq t\big\} \qquad (10)\end{aligned}$$

where $\overline{\pi}_u(z_1, \ldots, z_n; \delta) = \underline{\pi}_l(z_1, \ldots, z_n; 1-\delta)$. Moreover, exactly the same approach can be applied when we look for two-sided confidence intervals.

Summing up this section we can say that when imprecise observations may be treated as fuzzy perceptions of precise but unobserved realizations of ordinary random variables the problem of point and interval estimation of the unknown parameters of the underlying probability distribution can be reduced to finding fuzzy versions of the formulae known from traditional mathematical statistics.

Fuzzy Statistical Tests

Testing statistical hypotheses is the second main branch of mathematical statistics. Tests of statistical hypotheses have to be applied if we want to make decisions based on the analysis of random data. When our decisions depend on the values of the parameters of probability distributions that describe observed statistical data we use parametric statistical methods. In such a case we test statistical hypotheses about the values of the parameters of probability distributions utilizing a well known equivalence between the set of values of the considered probability distribution parameter for which the null hypothesis is accepted and a certain confidence interval for this parameter. Kruse and Meyer [20] have shown that the same equivalence exists in the case of statistical tests with fuzzy data.

Let $\mathcal{X}_1, \ldots, \mathcal{X}_n$ denote a fuzzy sample, i. e. a fuzzy perception of the usual random sample $X_1, \ldots, X_n$, from the population with the distribution P_θ. Let δ be a given number from the interval $(0, 1)$. Grzegorzewski ([15]) proposed the following definition of the *fuzzy test* for vague data:

Definition 4 A function $\varphi : \left(\mathcal{F}_c(\mathbb{R})\right)^n \to \mathcal{F}(\{0,1\})$ is called a fuzzy test for the hypothesis H, at the significance level δ, if

$$\sup_{\alpha\in[0,1]} P\{\omega \in \Omega : \varphi_\alpha(\mathcal{X}_1(\omega), \ldots, \mathcal{X}_n(\omega)) \subseteq \{1\}\,|H\} \leq \delta, \qquad (11)$$

where φ_α is the α-level set (α-cut) of $\varphi(\mathcal{X}_1, \ldots, \mathcal{X}_n)$.

The fuzzy test defined above can be regarded as a family of classical tests $\{\varphi_\alpha : \alpha \in (0,1]\}$ for which the significance level is given as the upper bound of type I error for the whole family $\{\varphi_\alpha : \alpha \in (0,1]\}$.

In order to give an example of a fuzzy statistical test let us consider a following simple null hypothesis: $H : \theta = \theta_0$, against the composite two-sided alternative: $K : \theta \neq \theta_0$. Suppose we know a two-sided symmetrical confidence interval $[\pi_1, \pi_2]$ for θ, on a confidence level $1-\delta$, where $\pi_1 = \pi_1(X_1, \ldots, X_n; \delta/2)$ and $\pi_2 = \pi_2(X_1, \ldots, X_n; \delta/2)$ are the limits of the ordinary two-sided confidence interval. The fuzzy equivalent of this confidence interval can be calculated using the α-cuts $\Pi_\alpha = [\Pi_\alpha^L, \Pi_\alpha^U]$ for all $\alpha \in (0,1]$, where the limits of these α-cuts can be computed from Eq. (9)-(10) by replacing δ with $\delta/2$. The fuzzy two-sided statistical test for $H : \theta = \theta_0$, against $K : \theta \neq \theta_0$, on the significance level δ, has been defined by Grzegorzewski [15] as a function $\varphi : (\mathcal{F}_c(\mathbb{R}))^n \to \mathcal{F}(\{0,1\})$ with following α-cuts

$$\varphi_\alpha(X_1, \ldots, X_n) = \begin{cases} \{0\} & \text{if } \theta_0 \in (\Pi_\alpha \setminus (\neg\Pi)_\alpha)\,, \\ \{1\} & \text{if } \theta_0 \in ((\neg\Pi)_\alpha \setminus \Pi_\alpha)\,, \\ \{0,1\} & \text{if } \theta_0 \in (\Pi_\alpha \cap (\neg\Pi)_\alpha)\,, \\ \emptyset & \text{if } \theta_0 \notin (\Pi_\alpha \cup (\neg\Pi)_\alpha)\,, \end{cases} \qquad (12)$$

Similarly we may obtain fuzzy tests for one-sided hypotheses using the one-to-one correspondence between the acceptance regions of the tests designated for testing these hypotheses on the significance level δ and one-sided confidence intervals for the parameter θ on the confidence level $1-\delta$.

Grzegorzewski [15] has shown that the membership function of the fuzzy test for the hypothesis H against K is given by

$$\begin{aligned}\mu_\varphi(t) &= \mu_\Pi(\theta_0)I_{\{0\}}(t) + \mu_{\neg\Pi}(\theta_0)I_{\{1\}}(t) \\ &= \mu_\Pi(\theta_0)I_{\{0\}}(t) + (1-\mu_\Pi(\theta_0))I_{\{1\}}(t)\,,\ t \in \{0,1\}, \qquad (13)\end{aligned}$$

where Π is a fuzzy acceptance region depending on the considered hypotheses. Thus, the fuzzy fuzzy test defined by Eq. (12), contrary to the classical crisp test, does not lead to the binary decision – to accept or to reject the null hypothesis – but to a fuzzy decision. One may get $\mu_\varphi(0) = 1, \mu_\varphi(1) = 0$ which indicates that we should accept H, or $\mu_\varphi(0) = 0, \mu_\varphi(1) = 1$ which means the rejection of H. However, one may also get $\mu_\varphi(0) = \mu_0, \mu_\varphi(1) = 1 - \mu_0$, where $\mu_0 \in (0,1)$, which can be interpreted as a degree of conviction that we should accept (μ_0) or reject ($1-\mu_0$) the hypothesis H. Thus, in situation when μ_0 is neither 0 nor 1, a user must decide using other criteria whether to reject or to accept the considered hypothesis. There exist several approaches that are suitable for solving this problem. One of these approaches which is formulated in the language of the possibility theory has been proposed by Hryniewicz [16] who used the results of Dubois et al. [9] who proposed to use statistical confidence intervals of parameters of probability distributions for the construction of possibility distributions of these parameters. According to their approach, the family of two-sided confidence intervals

$$\begin{aligned}&[\pi_L(x_1,\ldots,x_n;1-\delta/2)\,,\\&\qquad\pi_U(x_1,\ldots,x_n;1-\delta/2)]\,,\qquad\delta\in(0,1)\end{aligned}\tag{14}$$

forms the *possibility distribution* $\tilde{\vartheta}$ of the estimated value of the unknown parameter ϑ. In a similar way it is possible to construct one-sided possibility distributions based on one-sided nested confidence intervals. Hryniewicz [16] proposed to compare this possibility distribution with a hypothetical value of the tested parameter. For this purpose he proposed to use the necessity of strict dominance measure introduced by Dubois and Prade [7] for measuring the necessity of the strict dominance relation $\tilde{A}\succ\tilde{B}$, where $\tilde{A}$ and $\tilde{B}$ are fuzzy sets. This measure, called the *Necessity of Strict Dominance* index (*NSD*), is defined as

$$\begin{aligned}NSD&=\mathrm{Ness}\left(\tilde{A}\succ\tilde{B}\right)\\&=1-\sup_{x,y;x\le y}\min\left\{\mu_A(x)\,,\mu_B(y)\right\}\,.\end{aligned}\tag{15}$$

Hryniewicz [16] has shown that in the classical case of precise statistical data and precisely defined statistical hypotheses the value of the *NSD* index is equal to the *p*-value of the test.

In case of fuzzy data the confidence intervals used for the construction of the possibility distribution of the estimated parameter θ can be replaced by their fuzzy equivalents presented in the previous sections of this article. In his paper Hryniewicz [16] assumes that the value of the significance level of the corresponding statistical test δ is equal to the possibility degree α that defines the respective α-cut of the possibility distribution of $\tilde{\theta}$. He also assumes that in the possibilistic analysis of statistical tests on the significance level δ we should take into account only those possible values of the fuzzy sample whose possibility is not smaller than δ. Thus, the α-cuts of the membership function $\mu_F(\theta)$ denoted by $\left[\mu_{F,L}^{(\alpha)},\mu_{F,U}^{(\alpha)}\right]$ are equivalent to the α-cuts of the respective fuzzy confidence intervals on a confidence level $1-\alpha$. Having the possibility distribution of the test statistic we can use Eq. (15) for the calculation of the degree on necessity that the considered statistical hypothesis has to be accepted. When we set a critical value for this characteristic we arrive at unequivocal (crisp) decisions. It is worthy to note that this approach has been generalized in [16] to the case of testing imprecisely defined hypothesis using fuzzy statistical data.

In the previous paragraphs we have presented fuzzy statistical tests when the class the underlying probability distribution belongs to is known. Verification of this assumption when the available statistical data are imprecise may be very difficult indeed. Therefore, it would be advisable to use fuzzy equivalents of non-parametric (distribution-free) statistical methods. Unfortunately, there exist only few papers devoted to such fuzzy tests. The most interesting result has been obtained by Denœux et al. [4] who proposed a general methodology for the construction of fuzzy tests based on rank statistics.

Statistical analysis of fuzzy random data can be also done in the Bayesian framework. First results presenting the Bayesian decision analysis for imprecise data were given in papers by Casals et al. [3] and Gil [11]. Other approaches have been proposed by such authors as Viertl [34], Frühwirth-Schnatter [10], and Taheri and Behboodian [32]. Comprehensive Bayesian model comprising fuzzy data, fuzzy hypotheses, and fuzzy utility function has been proposed in the paper by Hryniewicz [17].

Statistical Analysis of Existing Fuzzy-Valued Data

When imprecise statistical data correspond to intrinsic fuzzy-valued data we can treat them as observed values of fuzzy random variables in the sense of Puri and Ralescu. In the literature these data are often treated as categorical/ordinal/interval-valued ones. It should be emphasized that the model given by fuzzy random variables allows us to describe and handle these data in a more expressive scale and way (in contrast to just ranking or stating simply the interval support of the values). Thus, many statistical developments for real-valued data are based on distances/deviations between values rather than on the diversity of these values. The use of the fuzzy scale allows to consider metrics with a meaning similar to that for the real-valued case (i. e., distinguishing not only the ranks of variable values w.r.t. a certain criterion, but a physical distance between them).

The distance we will consider here is the one stated by Bertoluzza et al. [2], so that if $A,B\in\mathcal{F}_c(\mathbb{R})$

$$D_W^{\varphi}(A,B)=\sqrt{\int_{[0,1]}\left[\int_{[0,1]}\left[\mathrm{f}_A(\alpha,\lambda)-\mathrm{f}_B(\alpha,\lambda)\right]^2\,\mathrm{d}W(\lambda)\right]\mathrm{d}\varphi(\alpha)}\tag{16}$$

with $\mathrm{f}_A(\alpha, \lambda) = \lambda \cdot A_U(\alpha) + (1-\lambda) \cdot A_L(\alpha)$, where

- W and φ are normalized weighted measures on $[0,1]$ formalized as probability measures on $([0,1], \mathcal{B}_{[0,1]})$,
- W is associated with a non-degenerate distribution,
- φ is associated with a strictly increasing distribution function on $[0,1]$.

Remark It should be remarked on D_W^φ that

- W and φ have no stochastic meaning.
- To consider W is equivalents to consider a measure weighting points 0, 1 and a certain $t_0(W) \in (0,1)$; in case W is symmetric, then $t_0(W) = .5$.
- For each α, the choice of W allows us to weight
  - the effect of the distance between the "widths" of the α- levels (i. e., effect of the "shape" difference),
  - in comparison with the effect of the distance between their $t_0(W)$-points (i. e., effect of the "location" difference).
- The choice of φ allows us to weight the influence of each level (i. e., degree of "imprecision", "consensus", "subjectivity",...).
- D_W^φ is a versatile and operational in statistical developments with fuzzy numbers, and it behaves especially well when we consider least-squares approaches.

Since the concept of fuzzy random variable in Puri and Ralescu's sense has been properly stated in a probabilistic context as a random element (i. e., as a Borel-measurable function), concepts like independent and identically distributed fuzzy random variables make immediate sense. Furthermore, all the main ideas, aims and concepts, and several developments can be immediately considered to deal with fuzzy data when coming from fuzzy-valued Borel-measurable mappings. In this respect, notions like either unbiasedness or consistency of a "point" (fuzzy- or real- valued) estimator of a (fuzzy- or real- valued) 'parameter' associated with the distribution of the fuzzy random variable, or the p-value and power of a test concerning such a 'parameter', make the same sense as in the classical case.

Several developments have been made in connection with both estimation and testing of fuzzy- and real-valued parameters associated with the distribution of a fuzzy random variable in Puri and Ralescu's sense. We are now just recalling a few results concerning the "point" fuzzy estimation and testing of the population mean of a fuzzy random variable, which is formalized as follows:

Definition 5 (Puri & Ralescu, [31]) Given a probability space $(\Omega, \mathcal{A}, P)$ and an associated fuzzy random variable $\mathcal{X} : \Omega \to \mathcal{F}_c(\mathbb{R})$ such that $\max\{|\inf \mathcal{X}_0|, |\sup \mathcal{X}_0|\}$ is integrable, then, the **fuzzy expected value** (or **fuzzy mean**) of $\mathcal{X}$ is the fuzzy number $\tilde{E}(\mathcal{X}|P) \in \mathcal{F}_c(\mathbb{R})$ such that for all $\alpha \in [0,1]$

$$\begin{aligned}
&\left(\tilde{E}(\mathcal{X}|P)\right)_\alpha \\
&= \text{Aumann integral of } \mathcal{X}_\alpha \\
&= \big\{E(X|P) \big| X : \Omega \to \mathbb{R}, \\
&\qquad\qquad X \in L^1(\Omega, \mathcal{A}, P),\ X \in \mathcal{X}_\alpha \text{ a.s. } [P]\big\} \\
&= \left[E(\inf \mathcal{X}_\alpha|P), E(\sup \mathcal{X}_\alpha|P)\right] .
\end{aligned}$$

Remark 5 The fuzzy mean satisfies that

- If $\mathcal{X}(\Omega) = \{\tilde{x}_1, \ldots, \tilde{x}_m, \ldots\} \subset \mathcal{F}_c(\mathbb{R})$, then, it is coherent with fuzzy arithmetic, that is,

$$\begin{aligned}
\tilde{E}(\mathcal{X}|P) &= P(\{\omega \in \Omega \,|\, \mathcal{X}(\omega) = \tilde{x}_1\}) \cdot \tilde{x}_1 + \ldots \\
&\quad + P(\{\omega \in \Omega \,|\, \mathcal{X}(\omega) = \tilde{x}_m\}) \cdot \tilde{x}_m + \ldots
\end{aligned}$$

- Strong Laws of Large Numbers are satisfied for different metrics (like D_W^φ, and stronger ones), which also corroborates the suitability of the defined fuzzy mean as the stochastic limit of the sample ones.
- $\tilde{E}(\mathcal{X}|P)$ is the "Fréchet expectation" of $\mathcal{X}$ w.r.t. D_W^φ, i. e., for all $A \in \mathcal{F}_c(\mathbb{R})$:

$$E\left(\left[D_W^\varphi(\mathcal{X}, \tilde{E}(\mathcal{X}|P))\right]^2 \big| P\right) \le E\left(\left[D_W^\varphi(\mathcal{X}, A)\right]^2 \big| P\right) .$$

The interpretation of the fuzzy mean becomes more clear if we notice that for interval-valued random variables (i. e., random intervals) the expected value is given in a form of an interval with the lower limit equal to the expected value of the lower limits of observed random variables, and the upper limit equal to the expected value of the upper limits of observed random variables. Therefore, the expected value of the fuzzy random variable can be given as a nested set of such intervals represented by respective α-cuts, as it is formally described in the definition.

The definition of other characteristics describing fuzzy random variables may be much more complicated. For example, the definition of the variance requires the introduction of the "Fréchet expectation" (defined above), as it was proposed by Körner and Näther [24].

Fuzzy Estimation

Assume that we observe a fuzzy simple random sample $\mathcal{X}_1, \ldots, \mathcal{X}_n$ which is viewed now as an n-tuple of n independent fuzzy random variables which are identically distributed as $\mathcal{X}$. The associated ***fuzzy sample mean*** is the statistic given by

$$\overline{\mathcal{X}}_n = \frac{1}{n} \cdot [\mathcal{X}_1 + \ldots + \mathcal{X}n] \ .$$

Then, one can prove that (see Lubiano ([25])

Theorem 1 *The fuzzy sample mean satisfies that*

i) $\overline{\mathcal{X}}_n[\cdot]$ *in an "unbiased fuzzy-valued estimator" of* $\tilde{E}(\mathcal{X}|P)$ *(in the sense of the fuzzy expected value defined by Puri & Ralescu). For most of the metrics we can consider, it is also a 'strongly consistent' fuzzy-valued estimator of* $\tilde{E}(\mathcal{X}|P)$*.*

ii) One can quantify the mean squared-type error in the fuzzy estimation by considering the real-valued expected value $E\left(\left[D_W^{\varphi}(\overline{\mathcal{X}}_n, \tilde{E}(\mathcal{X}|P))\right]^2\right)$*.*

Actually, Lubiano et al. [26,27] proposed several developments in connection with the estimation and testing about the D_W^{φ}-mean squared error associated with the estimation of the population fuzzy means by means of the sample one.

Statistical Tests

One of the problems which has received a deep attention in connection with testing from fuzzy random variables in Puri and Ralescu's sense is that concerning two-sided tests about the mean of a fuzzy random variable (one-sample case). In order to define this problem one can decide which metrics could be used for measuring the distance between the hypothetical and observed fuzzy values of considered characteristics of the fuzzy random variables. In the case of the metrics defined by Eq. (16), the problem can be formalized as follows:

Given n independent observations from $\mathcal{X}$, $\mathcal{X}_1, \ldots, \mathcal{X}_n$, we wish to test the null hypothesis $H_0\colon \tilde{E}(\mathcal{X}|P) = A \in \mathcal{F}_c(\mathbb{R})$, which can be equivalently expressed as $H_0\colon D_W^{\varphi}\left(\tilde{E}(\mathcal{X}|P), A\right) = 0$.

Despite simple formulation of the testing problem the construction of statistical tests for the verification of hypotheses related to fuzzy mean values is not that simple. For example, an exact test has been developed in Montenegro et al. [28] for so called "normal" fuzzy random variables (in Puri and Ralescu's sense, [30]). Although the method is exact and easy-to-apply, the assumption of $\mathcal{X}$ being fuzzy "normal" ($\mathcal{X} = V + \mathcal{N}(0,1)$, with $V \in \mathcal{F}_c(\mathbb{R})$) is quite restrictive and often unrealistic, as it means that *all* observed fuzzy values are described by the same membership function shape with maybe different location.

In a more general case asymptotic tests based on Large Sample Theory have been developed for the same purpose. However, they are usually hardly applicable (except for some simple special cases) in practice. For example, the asymptotic distribution of the statistic proposed by Körner [23] involves unknown parameters such as correlations between random variables describing membership functions of observed fuzzy variables. In the paper by Montenegro et al. [28] devoted to the problem of testing the equality of two fuzzy mean values, it is assumed that $\mathcal{X}$ takes on a finite number of values, and large sample sizes would be required anyway in order to estimate unknown parameters of the model.

Simulation studies have been considered to analyze the extent and applicability of the asymptotic test by Montenegro et al. [28]. These studies have confirmed that in estimating the unknown parameters (the eigenvalues of a certain correlation matrix) entails a substantial loss of precision w.r.t. the nominal significance level. Based on this empirical conclusion, the use of D_W^{φ} and the Generalized Bootstrapped CLT (Giné and Zinn, [13]) allow us to consider bootstrap techniques in this context.

The bootstrap technique consists in taking random samples (i. e. re-sampling) from the original one and calculating the value of the considered statistic. By repeating this procedure many times we obtain the sample distribution of the test statistic which may be thus used for testing purposes. In case of fuzzy random data we get the following method proposed by González-Rodríguez et al. [14]:

Theorem 2 *Given a fuzzy random variable* $\mathcal{X}\colon \Omega \to \mathcal{F}_c(\mathbb{R})$ *associated with the probability space* $(\Omega, \mathcal{A}, P)$ *and such that*

- $\max\left\{(\inf \mathcal{X}_0)^2, (\sup \mathcal{X}_0)^2\right\}$ *is integrable ,*
- $\mathcal{X}_1, \ldots, \mathcal{X}_n$ *are i.i.d. as* $\mathcal{X}$ *,*
- $\mathcal{X}_1^*, \ldots, \mathcal{X}_n^*$ *is a bootstrap sample from* $\mathcal{X}_1, \ldots, \mathcal{X}_n$ *,*

then, to test H_0 *at the nominal significance level* $\alpha \in [0,1]$*,* H_0 *should be rejected whenever*

$$\frac{\left[D_W^{\varphi}\left(\overline{\mathcal{X}_n}, U\right)\right]^2}{\widehat{S}_n^2} > z_\alpha \ ,$$

where z_α *is the* $100(1-\alpha)$ *fractile of the bootstrap distribution of*

$$T_n = \left[D_W^{\varphi}\left(\overline{\mathcal{X}_n^*}, \overline{\mathcal{X}_n}\right)\right]^2 \Big/ \widehat{S}_n^{*\,2}$$

with

$$\overline{\mathcal{X}_n^*} = \sum_{i=1}^{n} \mathcal{X}_i^*/n, \quad \widehat{S}_n^{*\,2} = \sum_{i=1}^{n} \left[D_W^{\varphi}\left(\mathcal{X}_i^*, \overline{\mathcal{X}_n^*}\right)\right]^2/(n-1) \, .$$

Other bootstrap tests about means of fuzzy random variables which have been recently developed are the following ones:

- One-sided hypotheses tests in the one-sample case.
- Tests for the equality of means of two FRVs
  - for two independent samples
  - for two linked samples.
- Tests for the equality of means of J FRVs (ANOVA):
  - for J independent samples.

From comparative extensive simulation studies that have been performed recently at the University of Oviedo and the European Center for Soft Computing we can draw the following practical conclusions:

- For small/medium samples, the bootstrap method performs and behaves much better than the asymptotic one.
- For large sample sizes (over 300), the improvement is not that remarkable, but the bootstrap approach still provides the best approximation to the nominal significance level.

Taking into account that fuzzy statistical test for testing hypotheses about other characteristics of fuzzy random variables are even more complicated than the procedures designed for testing the hypotheses about mean values we can claim that the bootstrap technique is probably the most promising for dealing with random fuzzy observations.

Future Directions

Statistical analysis of imprecise data is still a developing area of science. Future directions of its development are tightly connected with the development of methods that may be used for the description of uncertainties of different types. It has been pointed out by P. Walley (see, e. g. [36] for a good overview) that traditional probability is not sufficient for good description of different types of uncertainty. Different mathematical models, such as e. g. Dempster–Schafer belief functions, possibility distributions, lower and upper probabilities, lower and upper previsions, and many others, have been proposed for this purpose. However, for the most general models describing uncertainty appropriate statistical methods have not been proposed yet. Therefore, statistical methods for handling very general imprecise data have to be developed in the future.

Another, but much more specific, future direction for the development of statistical analysis of imprecise data is related to the analysis of intrinsically fuzzy data. In contrast to the situation when fuzzy observations may be considered as fuzzy perceptions of real-valued observations, many notions known from traditional statistics are still waiting for their widely accepted definitions, and statistical methods of analysis.

The most challenging future direction is related to Zadeh's paradigm of "computing with words". First of all, we need operational methods for the representation of linguistic concepts which could be useful is statistical analysis of imprecisely reported (with words!) statistical data. Moreover, we also need methods for convincing presentation of the results of computations to users who have only limited knowledge of mathematics and statistics.

Article Outline

Glossary

Binary Two stars which orbit around each other.

Distribution function A density function in the six-dimensional phase space which gives the distribution of stars in a stellar system.

Fokker–Planck equation Partial differential equation for the thermal evolution of the distribution function of a stellar system, expressed in the form of the advection-diffusion equation in the phase space.

Monte-Carlo method The method to numerically follow the thermal evolution of stellar systems using Monte-Carlo integration of Fokker–Planck equation for the distribution function.

Relaxation The process which leads the system to thermal equilibrium. In the case of a stellar system, the main mechanism of relaxation is the gravitational encounter between stars.

Stellar systems A system composed of a large number of stars, i. e., particles which interact through mutual gravity.

Thermal stability Stability of the system against the re-distribution of the thermal energy.

Definition of the Subject

Most of astronomical objects are in the first approximation the collection of point mass particles (stars or planets). We call such systems stellar systems, and stellar dynamics is the theoretical framework for the study of such systems. Since the equation of motion for stellar systems with N stars is analytically solvable only for the case of $N = 2$, numerical integration of the orbit of stars has been very important tool for the study of stellar systems.

Introduction

Stellar Dynamics deals with the evolution of systems which consist of a large number of stars interacting with other stars through mutual gravitational force. Examples of such systems include star clusters, galaxies, clusters of galaxies. Star clusters consist of up to around 10 million stars. They are classified into two categories: open clusters and globular clusters. Open clusters are less massive and younger than globular clusters. Globular clusters in our galaxy are all very old (more than 10 Gyr) and fairly massive (more than 10^5 solar mass). Both types of clusters are compact, with the radius of the order of 10 parsec or less.

Galaxies are larger and more massive than star clusters. The total mass of our Galaxy is around 10^{12} solar mass. Around 80% of the total mass is in dark matter, the existence of which we only indirectly know through the measurement of the motions of visible matter such as gas or stars.

In the first approximation, stellar systems such as star clusters and galaxies are just a collection of a large number of point masses. Therefore, one might expect that a statistical description is applicable. In other words, one might expect that the behavior of the system is described by the statistical mechanics. If that were the case, however, the universe would look very different from its present form. All galaxies would look similar, and rather boring, without any structures such as spirals, bars, shells etc., which make the diversity of galaxies. In this article, we first review how the statistical description can be or cannot be applied to stellar systems, and then present an overview of our current understanding for the evolution of stellar systems. Then we discuss the numerical methods for N-body simulations. For a more complete coverage of the subject see textbooks [5,25].

Statistical Description

Thermal Stability and Gravothermal Catastrophe

There are two basic reasons why stellar systems cannot be described by statistical mechanics. The first one is that the thermal equilibrium state does not exist for stellar systems. An equilibrium state for a system of classical particles is given by the Maxwell-Boltzmann statistics. This means that the local velocity distribution is Maxwellian with a single temperature everywhere in the system. In other words, the velocity distribution function is given by

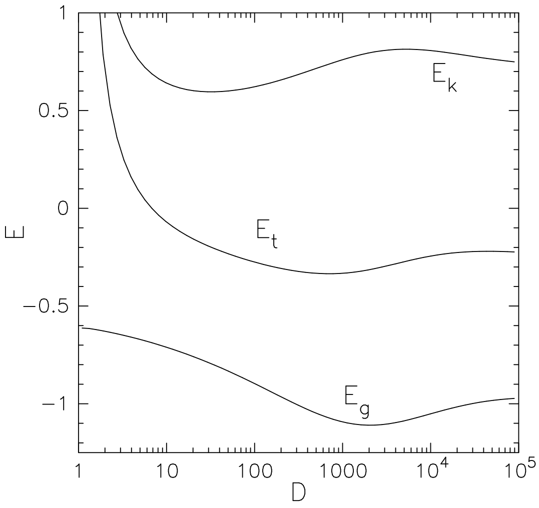
$$f_0(v) = \frac{n_f}{(2\pi\sigma^2)^{3/2}} \exp\left(\frac{-v^2/2}{\sigma^2}\right) , \qquad (1)$$

where n_f is the volume number density of particles and σ is the velocity dispersion.

However, with a stellar system, this Maxwellian distribution cannot be realized, simply because the stars with sufficiently high velocities will escape from the system. The depth of the gravitational potential of a stellar system is finite. Thus, if a star gained kinetic energy higher than that of the depth of the gravitational potential at its position, it would escape from the system.

As a thought experiment, we can think of a stellar system with a spherical adiabatic wall around it. The thermal equilibrium state of the stellar system can be described by that of an ideal gas, since the distribution function is Maxwellian for both cases. Therefore, even though we cannot apply the terms like pressure and temperature to stellar systems in general, we can apply these concepts to stellar systems in the thermal equilibrium, since the equilibrium distribution function is the same as that of an ideal gas with self gravity.

In this case, since the stars do not escape, the equilibrium state does exist. In the limit of very high temperature (large kinetic energy), the distribution of stars within the wall is uniform, with the number density of stars same everywhere. However, as we lower the temperature, the central density becomes higher due to the effect of self gravity. There must be a pressure gradient to support the gravity, and that means a density gradient should exist. However, this increase of density gradient means an increase of the



Stellar Dynamics, *N*-body Methods for, Figure 1
Energies as function of the ratio between the density at the center and that at the place of the wall, *D*. Three curves indicate the kinetic energy (*top*), total energy (*middle*) and gravitational energy (*bottom*), respectively

gravitational force, because more mass is concentrated to the center. Thus, if the increase of the gravitational force is larger than the increase of pressure, than the pressure gradient cannot support the system and there is no equilibrium state.

Figure 1 shows this phenomenon more clearly. Here, we plot the thermal energy (E_k), gravitational energy(E_g) and total energy ($E_t = E_k + E_g$) as a function of the ratio of the density at the center and that of just inside the wall. Here, for simplicity, we use the system of units where the radius of the wall R and mass of the gas M are both unity and the gravitational constant G is also unity. The limit as $D \to 1$ corresponds to infinite temperature. In this limit, the gravitational energy converges to -0.6, and the kinetic energy and total energy diverge. As we increase D, the kinetic energy decreases, gravitational energy increases, and the total energy decreases. However, at $D = 709$, the total energy E_t takes a minimum.

The fact that E_t takes a minimum means that this system has neutral stability against the perturbation which conserves the total energy, since an infinitesimal change of D in either direction does not change the total energy. In other words, for this system we can redistribute the thermal energy in such a way that after that perturbation is applied the system is still isothermal. For $D < 709$, when we change D the total energy also changes. In other words, if we redistribute the energy in any way, as far as we keep the total energy unchanged, the system cannot remain isothermal.

This change of behavior corresponds to a sign of the (second-order) variation of total entropy $\delta^2 S$. For $D < 709$, for any thermal perturbation, $\delta^2 S < 0$, and the second law of thermodynamics guarantees that the isothermal state is stable. However, for $D = 709$, there is one form of perturbation for which $\delta^2 S = 0$. For $D > 709$, there are one or more perturbations for which $\delta^2 S > 0$. In other words, the isothermal state is unstable for $D > 709$.

The eigenfunction which corresponds to $\delta^2 S = 0$ has a single node, which means it either transfers the thermal energy from central area to the outer area, or vise versa. The system shows neutral stability against this heat transfer. Thus, even though the thermal energy is moved, the system remains isothermal.

In the case of $D < 709$, any perturbation in the distribution of the thermal energy results in the heat flux which cancels out the perturbation. In the case of $D = 709$, there is one mode of perturbation for which there will be no heat flux. Finally, in the case of $D > 709$, there is at least one mode of perturbation, for which the resulting heat flows in the direction that enhances perturbation. Thus, if we remove some energy from the outer region and give it to the central region, the central region becomes cooler than the outer region, and therefore heat starts to flow inwards. This inward heat flow results in more cooling.

The reason why the central region cools when it gets more thermal energy is that it expands. As a result of the expansion, the gravitational attraction becomes weaker, and the central region can expand more. Through this additional expansion the central region lowers its temperature. In this case, however, the final state is another isothermal state with the same E_t but a smaller value of D. Since the minimum value of E_t corresponds to $D = 709$, for any other value of D, there is one value of D with same E_t which is thermally stable.

If the initial perturbation removes the thermal energy from the central region and deposits it to the outer region, the central region becomes hotter, and the heat starts to flow outwards. In this case, there is no stable final state, and the central region continues to contract and becomes hotter indefinitely. Exactly what happens depends on the efficiency of the heat transport.

Roughly speaking, if the thermal timescale is shorter in the center than in the outer region, as the central region contracts, the timescale becomes even shorter. In this case, the central density can reach infinity in a finite time. Of course, in this case, the mass of the region with infinite density should become zero. On the other hand, if the timescale is longer in the center, the timescale becomes even longer as the contraction proceeds, and the overall system contracts slowly. In the case of an ideal gas, the timescale is determined by the mechanism of the heat transfer.

In the case of stellar systems, heat transfer proceeds through close encounters between two stars. Since the rate of close encounters is directly proportional to the number density of stars, the thermal relaxation timescale is shorter for the central region, and becomes shorter as the central density goes up. This phenomenon is called "gravothermal catastrophe".

This gravothermal catastrophe occurs in real stellar systems without the adiabatic wall, since real stellar systems always have the temperature decreasing outward, which naturally drives the outward heat flux. Of course, the distribution function is not Maxwellian and one cannot strictly define the temperature. Even so, comparisons between numerical simulations with different approaches have shown that this picture gives a very good description.

Hachisu et al. [9] performed a simulation of the evolution of the self-gravitating gas system with several different forms of heat conductivity. They found that if the heat conductivity is such that the central thermal timescale is shorter than that of the outside region, the evolution of the system would become self-similar. In other words, the central region continues to shrink, leaving a power-law halo behind it. The mass of the core decreases in time and the central density reaches infinity within a finite time.

In the following, we give a simple explanation of this power-law behavior, following the description by Lynden-Bell and Eggleton [14]. Formally, a self-similar solution for a physical quantity y as a function of radius r and time t is expressed as

$$y(r,t) = y_0(t)y_*[r/r_0(t)] . \tag{2}$$

We can set $y_*(0) = 1$ without loss of generality. We can assume that in the limit of $r \to \infty$ there is no evolution, since the thermal timescale is longer at the outskirts. We can further assume that functions r_0 and y_0 are powers of the time t, since otherwise the self-similar solution cannot be constructed. Thus, if we express

$$r_0 = (t_0 - t)^\beta , \tag{3}$$

and

$$y_0 = (t_0 - t)^\gamma , \tag{4}$$

we have

$$y_0 = r_0^{\gamma/\beta} . \tag{5}$$

The ratio between the gravitational binding energy of the core and the thermal energy of the core should be constant. Therefore, we have

$$\sigma^2 \propto \frac{GM_c}{r_c} \sim \rho_0 r_0^2 . \tag{6}$$

If we express ρ_0 as

$$\rho_0 = r_0^\alpha , \tag{7}$$

we have

$$r_0 = (t_0 - t)^{2/(6+\alpha)} . \tag{8}$$

Lynden-Bell and Eggleton [14] numerically obtained the self-similar solution for the gaseous model with heat conductivity which they believed would mimic the radial energy transfer in an N-body system, and found that the self-similar solution has the characteristic power law index of

$$\rho = r^{-2.21} . \tag{9}$$

Henon [11] demonstrated that the N-body system would exhibit core collapse using Monte-Carlo calculation with 1000 shells. At that time, N-body simulation did show some collapse-like behavior, but it was difficult to see whether the collapse is really self-similar or not because of the limitation in the number of particles. The most beautiful demonstration of the self-similar nature of the collapse is by Cohn [6], who is the first to use the direct integration of the Fokker–Planck equation in the study of the thermal evolution of the globular clusters. He found the power index to be −2.23, which is strikingly close to the value obtained by the gas model calculation of Lynden-Bell and Eggleton [14].

In the study of the gravothermal catastrophe and self-similar solution, N-body simulation did not play a major role. This is partly because more approximate methods, such as the gaseous models and Fokker–Planck calculations, gave reasonable results, and partly because computer power available was quite limited in the 1980s.

Binary Formation and Gravothermal Oscillation

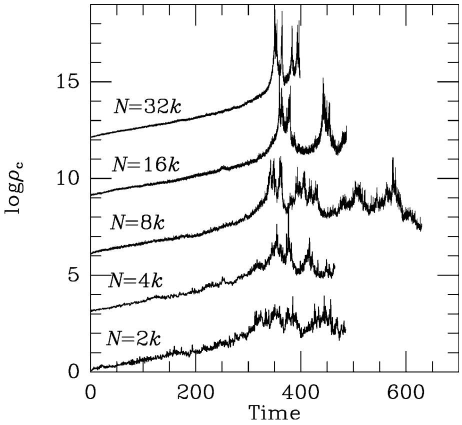
In the continuous limit, the central density diverges in a finite time, and at that time the core mass becomes zero. Since real stellar systems consist of stars with finite mass and finite size, the central density cannot reach infinity. One possibility is that stars start to physically collide, but there is another possibility.

When the central density becomes very high, the cross-section of the three-body close encounter, which causes the formation of a bound binary, becomes non-negligible.

The binding energy of the binary is transferred to the kinetic energy of the third particle and the center-of-mass motion of the binary. This is essentially the same as the nuclear fusion reaction. The difference is that in this case the interaction which makes the two stars bound is the same gravitational force which makes the entire system bound, and that means there is no ground state for a binary star. Thus, in theory, the binding energy of a binary star can become arbitrarily large. In practice, in real star clusters, there is a practical limit for the binding energy of a binary star. When a binary star interacts with another star, its center-of-mass motion acquires some energy, which is typically a fraction of its binding energy. When the kinetic energy of the center-of-mass motion becomes large enough, the binary would be ejected out the cluster. In fact, this ejection of the binary itself and the other star is the main channel which heats the central region of a star cluster.

This energy production by binaries halts the collapse. The collapse of the core is driven by the outward heat flux. If a sufficient amount of energy is generated in the core, the collapse is halted. In the case of a star, gravitational contraction of the star is halted by the energy production from the nuclear fusion reaction, and it becomes a main-sequence star.

In the case of a star cluster, it is possible to construct a steady-state solution quite similar to the main-sequence stage of a star [8,10]. However, it turned out that this steady-state solution is again thermally unstable [26]. This instability drives what is now called "gravothermal oscillation". This oscillation was first found in a gas sphere model, but then confirmed with Fokker–Planck (FP) calculations [7], and later with direct *N*-body simulations [16].



Stellar Dynamics, *N*-body Methods for, Figure 2
The time variation of the central density of simulated star clusters. (Reproduced from [16])

Figure 2 shows the time variation of the central density for simulations with 2–32k particles. The time is scaled so that the initial thermal relaxation time is the same for all runs. The curves are shifted vertically.

From Fig. 2 we can see that the oscillation is not strictly periodic. One reason is simply that the binary formation and its interaction with other stars is a stochastic process. The other reason is that, even in the continuous limit with a smooth and deterministic heating term, this oscillation is chaotic. Note that here what exhibits the chaotic behavior is the central density of the whole *N*-body system, which is a macroscopic variable of a system with large degrees of freedom.

Numerical Methods

In this section, we discuss the numerical methods used to obtain the solution of gravitational *N*-body problem. The problem itself is rather simple. We integrate the equation of motion for stars, using some numerical methods for the initial-value problem of ordinary differential equations. The calculation cost of the mutual gravitation interaction is $O(N^2)$ and dominate the calculation cost.

In practice, however, what is done is far more complex for a variety of reasons. Here, let us overview the approaches used.

First of all, for some problems, it is not necessary to calculate the interaction of all $N^2/2$ pairs at each timestep. There are several algorithms which reduce the calculation cost from $O(N^2)$ to $O(N \log N)$ or even $O(N)$. These algorithms include particle-mesh schemes, Barnes-Hut tree algorithm, and the Fast Multipole Method.

Secondly, it is not practical to apply the same timestep to all stars. While two stars undergo close encounters, their distance can become arbitrary small, depending on the impact parameter and the relative velocity. They have to be integrated with the adaptive timestep which can resolve their relative orbit. Moreover, as we discussed in Sect. "Statistical Description", many stellar systems tend to develop high-density cores, in which the stars orbit on a timescale much shorter than that of average stars. Also, in many stellar systems, interactions between binary stars (two stars orbiting around each other) and other stars play an important role, and the evolution of the binary orbit due to the interaction with other stars must be accurately integrated. The orbital timescale of binaries can become as small as a fraction of a second, while stars in globular clusters or galaxies have the orbital timescale much longer than one million years. Thus, it is clearly necessary to apply some algorithm with which we can change the timestep of individual stars individually.

Finally, an important characteristic of a stellar system is, from both the theoretical and practical point of views, that it is a Hamiltonian system with various symmetry and conservation laws. Numerical schemes which make use of these characteristics play important roles.

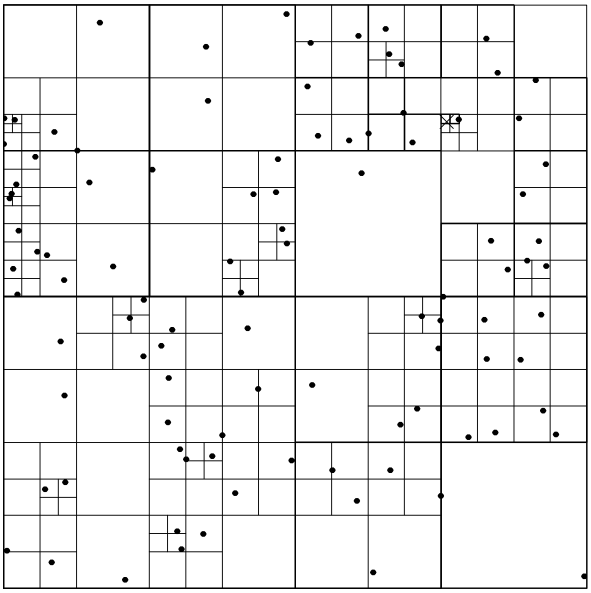
In the following, we briefly overview these schemes.

Fast Interaction Calculations

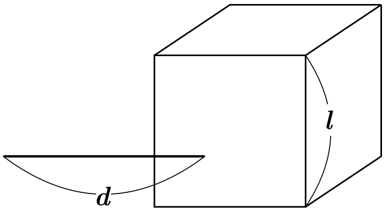
The basic idea of the tree code [4] is to replace the force from a group of distant particles with the force from their center of mass or by a multipole expansion. To ensure accuracy, we make groups for distant particles large and groups for nearby particles small.

We use a tree structure to construct the appropriate grouping for each particle. Before calculating the forces on particles, we first organize particles into a tree structure. Barnes and Hut [4] used an oct-tree based on the recursive subdivision of a cube into eight subcubes. We stop the recursive subdivision if the cube has only one particle (or no particles). See [15] for details concerning an efficient tree construction algorithm. Figure 3 shows the Barnes–Hut tree in two dimensional space.

After the tree is constructed, for each node of the tree, which corresponds to a cube of a certain size, we calculate the coefficient of the multipole expansion of the gravitational force exerted by particles in that cube. The fast algorithm was described in [12].



Stellar Dynamics, *N*-body Methods for, Figure 3
Barnes–Hut tree in two dimensions



Stellar Dynamics, *N*-body Methods for, Figure 4
Opening criterion for tree traversal

The force calculation is expressed as a recursive procedure. To calculate the force on a particle, we start from the root node, which corresponds to the total system. We calculate the distance between the node and the particle (d) and compare it with the size of the node (l). If they satisfy the convergence criterion

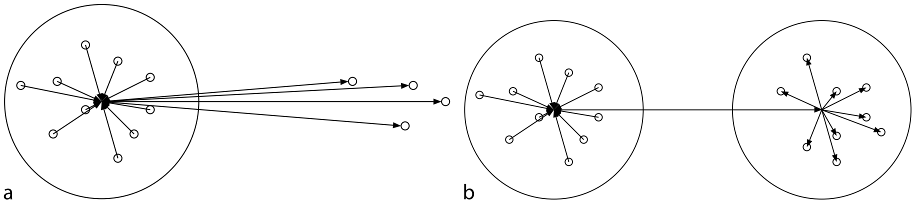
$$\frac{l}{d} < \theta \,, \tag{10}$$

where θ is the accuracy parameter, we calculate the force from that node to the particle using the coefficients of the multipole expansion. If criterion (10) is not satisfied, the force is calculated as a summation of the forces from eight sub-nodes.

Usually, we use the distance between the particle and the center of mass of the node to determine whether the force is accurate enough. When θ is very large, this criterion can cause unacceptably large error [21]. For most calculations, however, such a pathological situation is not realized.

The fast multipole algorithm (FMM) is in some sense a natural extension of the tree algorithm. In the tree algorithm, we use the multipole expansion to express the gravitational force for a group of stars with other stars sufficiently far away (Fig. 5a). In FMM, the forces on another group of stars are expressed in terms of one spherical harmonics expansion, and the forces on these stars are obtained by evaluating the expansion at the locations of stars. The tree-based recursive approach is now applied to both the path to calculate multipole expansions and the path to calculate the spherical harmonics expansions (usually called local expansions). This treatment removes the log N term in the calculation cost of the tree algorithm, since the cells of a given size do not directly interact with stars. They interact only with the cells of the same or similar sizes.

After the invention of the tree algorithm and FMM in the late 1980s, a large number of works followed on various topics such as the theoretical analysis of the algo-



Stellar Dynamics, *N*-body Methods for, Figure 5
Tree algorithm (a) and FMM (b)

rithms, efficient implementation, a fast method to translate multipole and local expansions, parallel implementation, etc. Some of these are covered in [19].

In many other fields of computational science, the Poisson equation associated with the distribution of particles is numerically solved using FFT. If the number of grid points one needs to resolve the potential field is of the same order or less than the number of particles, it is highly advantageous to use FFT, since the calculation cost of FFT is $O(M \log M)$, where M is the number of grid points, with relatively small coefficient. However, FFT requires that the grid is regular with equal spacing. Thus, FFT alone is not very suitable for astronomical simulations, where small-scale structures develop through gravitational instability. Recently, the combination of the tree algorithm and FFT potential solver has become the standard scheme for simulations which requires periodic boundary conditions (see, e. g., Yoshikawa and Fukushige [27]).

Individual Timestep Algorithms

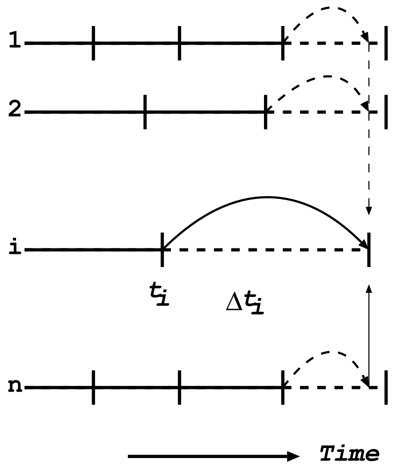
The individual timestep scheme [1,2] has been the only algorithm that can be used for simulations of gravitational many-body systems, such as open clusters, globular clusters and a system of planetesimals. In a simulation of these systems, we are interested in the change of orbit of each particle due to gravitational encounters with other particles, and the evolution of the total system driven by such changes. In that sense, simulation of these systems is similar to the molecular dynamics simulation, in which we are interested in the thermodynamical process.

In simulations of these collisional systems, we need to follow the changes of the orbit of a star due to individual encounters with a reasonable accuracy, since the encounters drive the evolution of the system. Therefore, we cannot use the softening parameter to simulate the evolution of these systems. In the study of the galaxies, for example, we can modify the $1/r$ potential to $1/\sqrt{r^2 + \epsilon^2}$, with small constant ϵ. This softened potential makes it possible to use a constant and global timestep. When we use a strict $1/r$ potential, the force between two particles changes very rapidly when two particles undergo a close encounter. Therefore, during a close encounter, the timestep should be sufficiently small to resolve this rapid change. Roughly speaking, the timestep is determined by the distance to the nearest neighbor. Therefore, if we integrate the system in lockstep, the timestep is determined by the pair of particles with minimum separation. Even in a nearly homogeneous system, the minimum separation is proportional to $N^{-2/3}$, and the dependence on N is stronger when the system is highly inhomogeneous [17].

To reduce the total calculation cost, Aarseth [1] developed an algorithm which assigns each particle its own timestep. In this individual timestep algorithm, each particle adjusts its timestep so that it satisfies the required accuracy. Thus, when two particles undergo a close encounter, although the timesteps of these particles shrink as required, the timesteps of other particles remain long. Makino and Hut [17] showed that the individual timestep scheme is faster than a shared timestep scheme by a factor in the range of $O(N^{1/3})$ and $O(N)$, depending on the distribution of particles.

In the individual timestep algorithm, each particle has its own timestep, and therefore its own time. To calculate the force on a particle due to other particles, we must know their positions at the time of the particle for which we calculate the force. To calculate the position of a particle at a time different from the time of the particle, Aarseth used a third order polynomial extrapolation. This polynomial is evaluated each time a pairwise force is calculated, therefore the calculation cost of the polynomial evaluation is of the same order as that of the force calculation itself. The basic algorithm looks like the following in the case of Aarseth's program, which uses a predictor-corrector scheme:

(a) Select particle i with a minimum $t_i + \Delta t_i$. Set the global time (t) to be this minimum, $t_i + \Delta t_i$.
(b) Predict the positions of all the particles at time t using the extrapolation polynomial.
(c) Calculate the acceleration (a_i) for particle i at time t, using the predicted positions.
(d) Apply the corrector for the position and velocity of particle i.
(e) Go back to step (a).



Stellar Dynamics, *N*-body Methods for, Figure 6
Schematic description of the individual timestep algorithm

Figure 6 illustrates how the individual timestep scheme works. When particle i is integrated from t_i to $t_i + \Delta t_i$, the positions of all other particles are predicted at that time, and forces from those particles are calculated using these predicted positions.

Not all time integration schemes can be used with this individual timestep, since the predicted values of the positions of all other particles need to be calculated at the time of the particle to be integrated. Most integration schemes do not provide the solutions at arbitrary points in time. For example, there is no simple way to obtain the approximate solution at the intermediate time with the usual Runge–Kutta schemes or extrapolation schemes.

For the treatment of binaries and small-N systems which can formed in larger stellar systems, see Aarseth [3].

Special Numerical Methods

A stellar system is a Hamiltonian system, and therefore the symplectic algorithms [22] can in principle be applied. These schemes show behavior much better than that of traditional schemes, and can dramatically reduce the integration error for long calculations. However, in practice there are a number of difficulties. One is that with symplectic schemes we cannot change timesteps [24]. There has been a number of works to make the symplectic scheme effectively work as variable-timestep scheme. Most of them rely on the partition of the potential energy term of the Hamiltonian into multiple parts with different timescales, and apply different timesteps to different parts of the potential term [20,23]. A very different approach is to use time-symmetric scheme instead of symplectic schemes. Symmetric schemes offer most of the practical advantages of symplectic schemes, and remain symmetric if we change the timestep. Here, the timestep must be calculated in such a way that does not destroy the time symmetry [13]. Recently, a way to combine this symmetric algorithm and the individual timestep algorithm was proposed [18].

Future Directions

In Sect. "Statistical Description" we over viewed the evolution of a system of point-mass particles. When we try to understand the evolution of real stellar systems such as globular clusters, open clusters and galactic nuclei, we need to take into account various effects which were neglected in Sect. "Statistical Description". For example, real stars are not point masses but have finite radii, and can physically collide with each other. In the case of normal stars like our sun in a galaxy, the chance that it will collide with its neighbors before the end of its lifetime is negligible. However, the number density of stars in the central regions of globular clusters or other massive star clusters can reach more than $10^6/\mathrm{pc}^3$, or about a million times that of the solar neighborhood. In such circumstances the collision is not rare. Also, individual stars have different masses. Even in the case of thermal equilibrium, stars with different masses have different spacial distribution, since the kinetic energy per unit mass is different. Thus, massive stars tend to lose their kinetic energy and segregate to the central region of the cluster, resulting in strong enhancement of collision rates between most massive stars in star clusters. To make things even more complex, each star evolves from the Main Sequence to giant, and depending on their masses, goes through Type II supernova and finally becomes a white dwarf, a neutron star, or a black hole. These stellar evolutions and stellar collisions, coupled with the stellar dynamics, makes stellar systems very interesting and an important research subject.

The ultimate research direction is to model all of these processes, stellar evolution, stellar collisions, stellar dynamics, and at some point the initial gas dynamics of star cluster formation, in one single unified simulation. From the viewpoint of the computational cost, such a simulation is not impossible, since the calculation cost of stellar dynamics is high and others are relatively minor. However, from the viewpoint of software engineering and physical modeling, we do not really know how we can actually develop and maintain a simulation program which can handle gravitational interaction between stars, evolution of individual stars, physical collisions and tidal interaction between stars, and other more complex things like the evolution of binary stars. MODEST (Modeling Dense Stellar systems)[1] is one of such efforts to develop a simulation code, or a loosely coupled collection of codes, to handle complex systems.

Article Outline

Glossary

A stochastic game A repeated interaction between several participants in which the underlying state of the environment changes stochastically, and it depends on the decisions of the participants.

A strategy A rule that dictates how a participant in an interaction makes his decisions as a function of the observed behavior of the other participants and of the evolution of the environment.

Evaluation of stage payoffs The way that a participant in a repeated interaction evaluates the stream of stage payoffs that he receives (or stage costs that he pays) along the interaction.

An equilibrium A collection of strategies, one for each player, such that each player maximizes (or minimizes, in case of stage costs) his evaluation of stage payoffs given the strategies of the other players.

A correlated equilibrium An equilibrium in an extended game in which at the outset of the game each player receives a private signal, and the vector of private signals is chosen according to a known joint probability distribution. In the extended game, a strategy of a player depends, in addition to past play, on the signal he received.

Definition of the Subject

Stochastic games, first introduced by Shapley [60], model dynamic interactions in which the environment changes in response to the behavior of the players. Formally, a stochastic game is a tuple $G = \langle N, S, (\mathcal{A}_i, A_i, u_i)_{i \in N}, q \rangle$ where

- N is a set of players.
- S is a state space. If S is uncountable, it is supplemented with a σ-algebra of measurable sets.
- For every player $i \in N$, $\mathcal{A}_i$ is a set of actions for that player, and $A_i \colon S \to \mathcal{A}_i$ is a set-valued (measurable) function that assigns to each state $s \in S$ the set of actions $A_i(s)$ that are available to player i in state s. If $\mathcal{A}_i$ is uncountable, it is supplemented with a σ-algebra of measurable sets. Denote $SA = \{(s, a) \colon s \in S, a =$

[1] http://www.manybody.org/modest/

$(a_i)_{i \in N}, a_i \in A_i(s) \;\; \forall i \in N\}$. This is the set of all possible *action profiles*.

- For every player $i \in N$, $u_i : SA \to \mathbf{R}$ is a (measurable) *stage payoff function* for player i.
- $q : SA \to \Delta(S)$ is a (measurable) *transition function*, where $\Delta(S)$ is the space of probability distributions over S.

The game starts at an initial state s^1, and is played as follows. At each stage $t \in \mathbf{N}$, each player $i \in N$ chooses an action $a_i^t \in A_i(s^t)$, receives the stage payoff $u_i(s^t, a^t)$, where $a^t = (a_i^t)_{i \in N}$, and the game moves to a new state s^{t+1} that is chosen according to the probability distribution $q(\cdot \mid s^t, a^t)$.

A few comments are in order.

1. A stochastic game lasts infinitely many stages. However, the model also captures finite interactions (of length t), by assuming the play moves, at stage t, to an absorbing state with payoff 0 to all players.
2. In particular, by setting $t = 1$, we see that stochastic games are a generalization of matrix games (games in normal formgames in normal form), which are played only once.
3. Stochastic games are also a generalization of repeated games, in which the players play the same matrix game over and over again. Indeed, a repeated game is equivalent to a stochastic game with a single state.
4. Stopping games are also a special case of stochastic games. In these games every player has two actions in all states, *continue* and *quit*. as long as all players choose *continue* the stage payoff is 0; once at least one player chooses *quit* the game moves to an absorbing state.
5. Markov decision problems (see, e. g., [49]) are stochastic games with a single player.
6. The transition function q governs the evolution of the game. It depends on the actions of all players and on the current state, so that all the players influence the evolution of the game.
7. The payoff function u_i of player i depends on the current state as well as on the actions chosen by all players. Thus, a player's payoff depends not only on that player's choice, but also on the behavior of the other players.
8. Though we refer to the functions $(u_i)_{i \in N}$ as "stage payoffs", with the implicit assumption that each player tries to maximize his payoff, in some applications these functions describe a stage *cost*, and then the implicit assumption is that each player tries to minimize his cost.
9. The action of a player at a given stage affects both his stage payoff and the evolution of the state variable, thereby affecting his future payoffs. These two, sometimes contradicting effects make the optimization problem of the players quite intricate, and the analysis of the game challenging.
10. The players receive a stage payoff at each stage. So far we did not mention how the players evaluate the infinite stream of stage payoffs that they receive, nor did we say what is their information at each stage: Do they observe the current state? Do they observe the actions of the other players? These issues will be discussed later.
11. The actions that are available to the players at each stage, the payoff functions, and the transition function, all depend on the current state, and not on past play (that is, past states that the game visited, and past actions that the players chose). This assumption is without loss of generality. Indeed, suppose that the actions available to the players at each stage, the payoff functions, and the transition function, all depend on past play, as well as on the current state. For every $t \in \mathbf{N}$ let H_t be the set of all possible *histories* of length t, that is, all sequences of the form $(s^1, a^1, s^2, a^2, \dots, s^t)$, where $s^k \in S$ for every $k = 2, 3, \dots, t$, $a^k = (a_i^k)_{i \in N}$ and a_i^k is an available action to player i at stage k, for every $k = 1, 2, \dots, t-1$. Then the game is equivalent to a game with state space $H := \bigcup_{t \in \mathbf{N}} H_t$, in which the state variable captures past play, and the state at stage t lies in H_t. In the new game, the sets of available actions, the payoff function, and the transition function, depend on the current state rather than on all past play.

The interested reader is referred to [20,42,72] for further reading on stochastic games. We now provide a few applications.

Example 1 (Capital Accumulation ([7,18,19,34,45])) Two (or more) agents jointly own a natural resource or a productive asset; at every period they have to decide the amount of the resource to consume. The amount that is not consumed grows by a known (or an unknown) fraction. Such a situation occurs, e. g., in fishery: Fishermen from various countries fish in the same area, and each country sets a quota for its fishermen. Here the state variable is the current amount of resource, the action set is the amount of resource to be exploited in the current period, and the transition is influenced by the decisions of all the players, as well as possibly by the random growth of the resource.

Example 2 (Taxation ([14,48])) A government sets a tax rate at every period. Each citizen decides at every period how much to work, and, from the total amount of money he or she has, how much to consume; the rest is saved for the next period, and grows by a known interest rate. Here the state is the amount of savings each citizen has, the stage payoff of a citizen depends on the amount of money that he consumed, on the amount of free time he has, and on the total amount of tax that the government collected. The stage payoff of the government may be the average stage payoff of the citizens, the amount of tax collected, or a mixture of the two.

Example 3 (Communication Network [58]) A single-cell system with one receiver and multiple uplink transmitters share a single, slotted, synchronous classical collision channel. Assume that all transmitted packets have the same length, and require one time unit, which is equal to one time slot, for transmission. Whenever a collision occurs, the users attempt to retransmit their packets in subsequent slots to resolve collision for reliable communication.

Here a state lists all relevant data for a given stage: e. g., the number of packets waiting at each transmitter, or the length of time each has been waiting to be transmitted. The players are the transmitters, and the action of each transmitter is which packet to transmit, if any. The stage cost may depend on the number of time slots that the transmitted packet waited, on the number of packets that have not been transmitted at that period, and possibly on additional variables. The transition depends on the actions chosen by the players, but it has a stochastic component, which captures the number of new packets that arrive at the various transmitters during every time slot.

Example 4 (Queues [1]) Individuals that require service have to choose whether to be served by a private slow service provider, or by a powerful public service provider. This situation arises, e. g., when jobs can be executed on either a slow personal computer or a fast mainframe. Here a state lists the current load of the public and private service providers, and the cost is the time to be served.

The importance of stochastic games stems from the wide range of applications they encompass. Many repeated interactions can be recast as stochastic games; the wide range of theoretical results that have been obtained provide insights that can help in analyzing specific situations and suggesting proper behavior to the participants. In certain classes of games algorithms that have been developed may be used to calculate such behavior.

Strategies, Evaluations and Equilibria

So far we have not described the information that the players have at each stage. In most of the chapter we assume that the players have complete information of past play; that is, at each stage t, they know the sequence $s^1, a^1, s^2, a^2, \dots, s^t$ of states that were visited in the past (including the current state) and the actions that were chosen by all players. This assumption is too strong for most applications, and in the sequel we will mention the consequences of its relaxation.

Since the players observe past play, a *pure strategy* for player i is a (measurable) function σ_i that assigns to every finite history $(s^1, a^1, s^2, a^2, \dots, s^t)$ an action $\sigma_i(s^1, a^1, s^2, a^2, \dots, s^t) \in A_i(s^t)$, with the interpretation that, at stage t, if the finite history $(s^1, a^1, s^2, a^2, \dots, s^t)$ occurred, player i plays the action $\sigma_i(s^1, a^1, s^2, a^2, \dots, s^t)$. If the player does not know the complete history, then a strategy for player i is a function that assigns to every possible information set, an action that is available to the player when the player has this information. A *mixed strategy* for player i is a probability distribution over the set of his pure strategies. The space of mixed strategies of player i is denoted by σ_i.

A simple class of strategies is the class of *stationary* strategies; a strategy σ_i for player i is *stationary* if $\sigma_i(s^1, a^1, s^2, a^2, \dots, s^t)$ depends only on the current state s^t, and not on past play $s^1, a^1, s^2, a^2, \dots, a^{t-1}$. A stationary strategy of player i can be identified with an element $x = (x_s)_{s\in S} \in \times_{s\in S} \Delta(A_i(s))$, with the interpretation that player i plays the mixed action x_s whenever the current state is s. Denote by $X_i = \times_{s\in S} \Delta(A_i(s))$ the space of stationary strategies of player i.

There are three common ways to evaluate the infinite stream of payoffs that the players receive in a stochastic game: The *finite-horizon evaluation*, in which a player considers the average payoff during the first T stages, the *discounted evaluation*, in which a player considers the discounted sum of his stage payoffs, and the *limsup evaluation*, in which a player considers the limsup of his long-run average payoffs. We now formally define these evaluations.

Every profile $\sigma = (\sigma_i)_{i\in N}$ of mixed strategies, together with the initial state, induces a probability distribution $\mathbf{P}_{s_1,\sigma}$ over the space of infinite plays $H_\infty := SA^{\mathbf{N}}$. We denote the corresponding expectation operator by $\mathbf{E}_{s_1,\sigma}$.

Definition 5 Let σ be a profile of mixed strategies. For every finite horizon $T \in \mathbf{N}$, the *T-stage payoff* under σ for player i is

$$\gamma_i^T(s_1, \sigma) := \mathbf{E}_{s_1,\sigma}\left[\frac{1}{T}\sum_{t=1}^{T} u_i(s^t, a^t)\right] .$$

For every discount factor $\lambda \in (0, 1]$, the λ-*discounted payoff* under σ for player i is

$$\gamma_i^\lambda(s_1, \sigma) := \mathbf{E}_{s_1,\sigma}\left[\lambda \sum_{t=1}^{\infty}(1-\lambda)^{t-1} u_i(s^t, a^t)\right] .$$

The *limsup payoff* under σ for player i is

$$\gamma_i^\infty(s_1, \sigma) := \mathbf{E}_{s_1,\sigma}\left[\limsup_{T\to\infty} \frac{1}{T}\sum_{t=1}^{T} u_i(s^t, a^t)\right] .$$

The T-stage payoff captures the situation in which the interaction lasts exactly T stages. The λ-discounted evaluation captures the situation in which the game lasts "many" stages, and the player discounts stage payoffs – it is better to receive \$1 today than tomorrow. The limsup payoff also captures the situation in which the game lasts "many" stages, but here the player does not discount his payoffs, and the payoff at each given stage is insignificant as compared to the payoff in all other stages. Equivalently, one could consider the liminf payoff in which the player considers the liminf of the long-run average payoffs.

As usual, an equilibrium is a vector of strategies such that no player can profit by a unilateral deviation. For every player i and every strategy profile $\sigma = (\sigma_i)_{i\in N}$ we denote the strategy profile of all other players, except player i, by $\sigma_{-i} = (\sigma_j)_{j\neq i}$.

Definition 6 Let $\varepsilon \geq 0$. A profile of strategies σ is a T-*stage* ε-*equilibrium* if

$$\gamma_i^T(s_1, \sigma) \geq \gamma_i^T(s_1, \sigma_i', \sigma_{-i}) - \varepsilon , \quad \forall s_1 \in S, \forall i \in N, \forall \sigma_i' \in \Sigma_i .$$

It is a λ-*discounted* ε-*equilibrium* if

$$\gamma_i^\lambda(s_1, \sigma) \geq \gamma_i^\lambda(s_1, \sigma_i', \sigma_{-i}) - \varepsilon , \quad \forall s_1 \in S, \forall i \in N, \forall \sigma_i' \in \Sigma_i .$$

It is a *limsup* ε-*equilibrium* if

$$\gamma_i^\infty(s_1, \sigma) \geq \gamma_i^\infty(s_1, \sigma_i', \sigma_{-i}) - \varepsilon , \quad \forall s_1 \in S, \forall i \in N, \forall \sigma_i' \in \Sigma_i .$$

The payoff that corresponds to an ε-equilibrium, that is, either one of the quantities $\gamma^T(s_1, \sigma)$, $\gamma^\lambda(s_1, \sigma)$ and $\gamma^\infty(s_1, \sigma)$, is called an ε-*equilibrium payoff* at the initial state s_1.

As we will see below, when both state and action spaces are finite, a T-stage and a λ-discounted 0-equilibrium exist. However, when the state or action spaces are infinite such a 0-equilibrium may fail to exist, yet ε-equilibria may exist for every $\varepsilon > 0$.

As the length of the game T varies, or as the discount factor λ varies, the equilibrium strategy profile varies as well. A strategy profile that is an ε-equilibrium for every T sufficiently large and for every λ sufficiently small is called a *uniform* ε-*equilibrium*.

Definition 7 Let $\varepsilon > 0$. A strategy profile σ is a *uniform* ε-*equilibrium* if there are $T_0 \in \mathbf{N}$ and $\lambda_0 \in (0, 1)$ such that for every $T \geq T_0$ the strategy profile σ is a T-stage ε-equilibrium, and for every $\lambda \in (0, \lambda_0)$ it is a λ-discounted ε-equilibrium.

If for every $\varepsilon > 0$ the game has a (T-stage, λ-discounted, limsup or uniform) ε-equilibrium with corresponding payoff g_ε, then any accumulation point of $(g_\varepsilon)_{\varepsilon>0}$ as ε goes to 0 is a (T-stage, λ-discounted, limsup or uniform) equilibrium payoff.

Zero-Sum Games

A two-player stochastic game is *zero-sum* if $u_1(s, a) + u_2(s, a) = 0$ for every $(s, a) \in SA$. As in matrix games, every two-player zero-sum stochastic game admits at most one equilibrium payoff at every initial state s_1, which is termed the *value* of the game at s_1. Each player's strategy which is part of an ε-equilibrium is termed ε-*optimal*. The definition of ε-equilibrium implies that an ε-optimal strategy guarantees the value up to ε; for example, in the T-stage evaluation, if σ_1 is an ε-optimal strategy of player 1, then for every strategy of player 2 we have

$$\gamma_1^T(s_1, \sigma_1, \sigma_2) \geq v^T(s_1) - \varepsilon ,$$

where $v^T(s_1)$ is the T-stage value at s_1.

In his seminal work, Shapley [60] presented the model of two-player zero-sum stochastic games with finite state and actions spaces, and proved the following.

Theorem 8 [60] *For every two-player zero-sum stochastic game, the λ-discounted value at every initial state exists. Moreover, both players have λ-discounted 0-optimal stationary strategies.*

Proof Let $\mathcal{V}$ be the space of all functions $v\colon S \to \mathbf{R}$. For every $v \in \mathcal{V}$ define a zero-sum matrix game $G_s^\lambda(v)$ as follows:

- The action spaces of the two players are $A_1(s)$ and $A_2(s)$ respectively.
- The payoff function (that player 2 pays player 1) is

$$\lambda u_1(s, a) + (1-\lambda)\sum_{s'\in S} q(s' \mid s, a) v(s') .$$

The game $G_s^\lambda(v)$ captures the situation in which, after the first stage, the game terminates with a terminal payoff $v(s')$, where s' is the state reached after stage 1. Define an operator $\varphi\colon \mathcal{V} \to \mathcal{V}$ as follows:

$$\varphi_s(v) = \mathrm{val}(G_s^\lambda(v)) \, ,$$

where $\mathrm{val}(G_s^\lambda(v))$ is the value of the matrix game $G_s^\lambda(v)$. Since the value operator is non-expansive, it follows that the operator φ is contracting: $\|\varphi(v) - \varphi(w)\|_\infty \leq (1 - \lambda)\|v - w\|_\infty$, so that this operator has a unique fixed point $\widehat{v}^\lambda$. One can show that the fixed point is the value of the stochastic game, and every strategy σ_i of player i in which he plays, after each finite history $(s^1, a^1, s^2, a^2, \ldots, s^t)$, an optimal mixed action in the matrix game $G_{s^t}^\lambda(\widehat{v}^\lambda)$, is a λ-discounted 0-optimal strategy in the stochastic game. □

Example 9 Consider the following two-player zero-sum game with three states, s_0, s_1 and s_2; each entry of the matrix indicates the payoff that player 2 (the column player) pays player 1 (the row player, the payoff is in the middle), and the transitions (which are deterministic, and are denoted at the top-right corner).

$$\begin{array}{c|c|c|} & L & R \\ \hline T & 0 \;\; s^2 & 1 \;\; s^1 \\ \hline B & 1 \;\; s^1 & 0 \;\; s^0 \\ \hline \end{array} \qquad \begin{array}{c|c|} & L \\ \hline T & 1 \;\; s^1 \\ \hline \end{array} \qquad \begin{array}{c|c|} & L \\ \hline T & 0 \;\; s^0 \\ \hline \end{array} \; .$$

State s_2 State s_1 State s_0

The states s_0 and s_1 are absorbing: Once the play reaches one of these states it never leaves it. State s_2 is non-absorbing. Stochastic games with a single non-absorbing state are called *absorbing games*. For every $v = (v_0, v_1, v_2) \in \mathcal{V} = \mathbf{R}^3$ the game $G_{s_2}^\lambda(v)$ is the following matrix game:

$$\begin{array}{c|c|c|} & L & R \\ \hline T & (1-\lambda)v_2 & \lambda + (1-\lambda)v_1 \\ \hline B & \lambda + (1-\lambda)v_1 & (1-\lambda)v_0 \\ \hline \end{array}$$

The game $G_{s_2}^\lambda$

$$\begin{array}{c|c|} & L \\ \hline T & \lambda + (1-\lambda)v_1 \\ \hline \end{array} \qquad \begin{array}{c|c|} & L \\ \hline T & (1-\lambda)v_0 \\ \hline \end{array} \; .$$

The game $G_{s_1}^\lambda$ The game $G_{s_0}^\lambda$

The unique fixed point of the operator $\mathrm{val}(G^\lambda)$ must satisfy

- $\widehat{v}_0 = \mathrm{val}(G_{s_0}^\lambda(\widehat{v}))$, so that $\widehat{v}_{s_0}^\lambda = \widehat{v}_0 = 0$;
- $\widehat{v}_1 = \mathrm{val}(G_{s_1}^\lambda(\widehat{v}))$, so that $\widehat{v}_{s_1}^\lambda = \widehat{v}_1 = 1$;
- $\widehat{v}_2 = \mathrm{val}(G_{s_1}^\lambda(\widehat{v}))$. By Theorem 8 both players have a stationary λ-discounted 0-optimal strategy. Denote by x (resp. y) a mixed action for player 1 (resp. player 2) that is part of a λ-discounted 0-optimal strategy at the state s_2. Since we know that in the fixed point $\widehat{v}_0 = 0$ and $\widehat{v}_1 = 1$, $\widehat{v}_2$ must be the unique solution of

  $$v_2 = y(1-\lambda)v_2 + (1-y) = y \, ,$$

  so that $\widehat{v}_{s_2}^\lambda = \widehat{v}_2 = (1 - \sqrt{\lambda})/(1 - \lambda)$. The 0-optimal strategy of player 2 at state s_2 is $y = \widehat{v}_2 = (1 - \sqrt{\lambda})/(1 - \lambda)$, and the 0-optimal strategy of player 1, $x = \widehat{v}_2 = (1 - \sqrt{\lambda})/(1 - \lambda)$, can be found by finding his 0-optimal strategy in $G_{s_2}^\lambda(\widehat{v})$.

Bewley and Kohlberg [11] proved that when the state and action spaces are finite, the function $\lambda \mapsto v_s^\lambda$, that assigns to every state s and every discount factor λ the λ-discounted value at the initial state s, is a *Puiseux function*, that is, it has a representation $v_s^\lambda = \sum_{k=K}^\infty a_k \lambda^{k/M}$ that is valid for every $\lambda \in (0, \lambda_0)$ for some $\lambda_0 > 0$, where M is a natural number, K is a non-negative integer, and $(a_k)_{k=K}^\infty$ are real numbers. In particular, the function $\lambda \mapsto v_s^\lambda$ is monotone in a neighborhood of 0, and its limit as λ goes to 0 exists. This result turned out to be crucial in subsequent study on games with finitely many states and actions.

Shapley's work has been extended to general state and action spaces; for a recent survey see [46]. The tools developed in [46], together with a dynamic programming argument, prove that under proper conditions on the payoff function and on the transitions the two-player zero-sum stochastic game has a T-stage value.

Maitra and Sudderth [35] proved that the limsup value exists in a very general setup. Their proof follows closely that of Martin [36] for the determinacy of Blackwell games.

The study of the uniform value emanated from an example, called the "Big Match", due to Gillette [28], that was solved by Blackwell and Ferguson [13].

Example 10 Consider the following stochastic game with two absorbing states and one non-absorbing state.

$$\begin{array}{c|c|c|} & L & R \\ \hline T & 0 \;\; s^2 & 1 \;\; s^2 \\ \hline B & 1 \;\; s^1 & 0 \;\; s^0 \\ \hline \end{array} \qquad \begin{array}{c|c|} & L \\ \hline T & 1 \;\; s^1 \\ \hline \end{array} \qquad \begin{array}{c|c|} & L \\ \hline T & 0 \;\; s^0 \\ \hline \end{array}$$

State s_2 State s_1 State s_0

Suppose the initial state is s_2. As long as player 1 plays T the play remains at s_2; once he plays B the play moves to either s_0 or s_1, and is effectively terminated. By finding the fixed point of the operator φ one can show that the discounted value at the initial state s_2 is $\frac{1}{2}$, and a λ-discounted stationary 0-optimal strategy for player 2 is[1] $[\frac{1}{2}(L), \frac{1}{2}(R)]$. Indeed, if player 1 plays T then the expected stage payoff is $\frac{1}{2}$ and play remains at s_2, while if player 1 plays B then the game moves to an absorbing state, and the expected stage payoff from that stage onwards is $\frac{1}{2}$. In particular, this strategy guarantees $\frac{1}{2}$ for player 2 both in the limsup evaluation and uniformly. A λ-discounted 0-optimal strategy for player 1 is $[\frac{1}{1+\lambda}(T), \frac{\lambda}{1+\lambda}(B)]$.

What can player 1 guarantee in the limsup evaluation and uniformly? If player 1 plays the stationary strategy $[x(T), (1-x)(B)]$ that plays at each stage the action T with probability x and the action B with probability $1-x$, then player 2 has a reply that ensures that the limsup payoff is 0: If $x = 1$ and player 2 always plays L, the payoff is 0 at each stage; if $x < 1$ and player 2 always plays R, the payoff is 1 until the play moves to s_0, and then it is 0 forever. Since player 1 plays the action B with probability $1-x > 0$ at each stage, the distribution of the stage in which play moves to s_0 is geometric. Therefore, the limsup payoff is 0, and if λ is sufficiently small, the discounted payoff is close to 0.

One can verify that if player 1 uses a bounded-recall strategy, that is, a strategy that uses only the last k actions that were played, player 2 has a reply that guarantees that the limsup payoff is 0, and the discounted payoff is close to 0, provided λ is close to 0. Thus, in the limsup payoff and uniformly finite memory cannot guarantee more than 0 in this game (see also [27]).

Intuitively, player 1 would like to condition the probability of playing T on the past behavior of player 2: If in the past player 2 played the action L more often than the action R, he would have liked to play T with higher probability; if in the past player 2 played the action R more often than the action L, he would have liked to play B with higher probability. Blackwell and Ferguson [13] constructed a family of good strategies $\{\sigma_1^M, M \in \mathbf{N}\}$ for player 1. The parameter M determines the amount that the strategy guarantees: The strategy σ_1^M guarantees a limsup payoff and a discounted payoff of $\frac{M}{2M+1}$, provided the discount factor is sufficiently low. In other words, player 1 cannot guarantee $\frac{1}{2}$, but he may guarantee an amount as close to $\frac{1}{2}$ as he wishes by choosing M to be sufficiently large. The strategy σ_1^M is defined as follows: At stage t, play B with probability $\frac{1}{(M+l_t-r_t)^2}$, where l_t is the number of stages up to stage t in which player 2 played L, and r_t is the number of stages up to stage t in which player 2 played R.

Since $r_t + l_t = t-1$ one has $r_t - l_t = 2r_t - (t-1)$. The quantity r_t is the total payoff that player 1 received in the first $t-1$ stages if player 1 played T in those stages (and the game was not absorbed). Thus, this total payoff is a linear function of the difference $r_t - l_t$. When presented this way, the strategy σ_1^M depends on that total payoff. Observe that as r_t increases, $r_t - l_t$ increases as well, and the probability to play B decreases.

Mertens and Neyman [38] generalized the idea presented at the end of Example 10 to stochastic games with finite state and action spaces.[2]

Theorem 11 *If the state and action spaces of a two-player zero-sum stochastic game are finite, the game has a uniform value v_s^0 at every initial state $s \in S$. Moreover, $v_s^0 = \lim_{\lambda\to 0} v_s^\lambda = \lim_{T\to\infty} v_s^T$.*

In their proof, Mertens and Neyman describe a uniform ε-optimal strategy. In this strategy the player keeps a parameter, λ_t, which is a fictitious discount factor to use at stage t. This parameter changes at each stage as a function of the stage payoff; if the stage payoff at stage t is high then $\lambda_{t+1} < \lambda_t$, whereas if the stage payoff at stage t is low then $\lambda_{t+1} > \lambda_t$. The intuition is as follows. As mentioned before, in stochastic games there are two forces that influence the player's behavior: He tries to get high stage payoffs, while keeping future prospects high (by playing in such a way that the next stage that is reached is favorable). When considering the λ-discounted payoff there is a clear comparison between the importance of the two forces: The weight of the stage payoff is λ and the weight of future prospects is $1-\lambda$; the lower the discount factor, the more weight is given to the future. When considering the uniform value (or the uniform equilibrium) the weight of the stage payoff is 0. However, if the player never attempts to receive a high stage payoff, the overall payoff in the game will not be high. Therefore, the player has a fictitious discount factor; if past payoffs are low and they do not meet the expectation, player 1 increases the weight of the stage payoff by increasing the fictitious discount factor; if past payoffs are high, player 1 increases the weight of the future by lowering this fictitious discount factor.

Multi-Player Games

Takahashi [75] and Fink [21] extended Shapley's [60] result to discounted equilibria in non-zero-sum games.

[1] That is, at each stage player 2 plays L with probability $\frac{1}{2}$ and R with probability $\frac{1}{2}$.

[2] Mertens and Neyman's [38] result actually holds in every stochastic game that satisfies a proper condition, which is always satisfied when the state and action spaces are finite.

Theorem 12 *Every stochastic game with finite state and action spaces has a λ-discounted equilibrium in stationary strategies.*

Proof The proof utilizes Kakutani's fixed point theorem [31]. Let $M = \max_{i,s,a} |u_i(s, a)|$ be a bound on the absolute values of the payoffs. Set $X = \times_{i \in N, s \in S} (\Delta(A_i(s)) \times [-M, M])$. A point $x = (x^A_{i,s}, x^V_{i,s})_{i \in N, s \in S} \in X$ is a collection of one mixed action and one payoff to each player at every state. For every $v = (v_i)_{i \in N} \in [-M, M]^{N \times S}$ and every $s \in S$ define a matrix game $G^\lambda_s(v)$ as follows:

- The action spaces of each player i is $A_i(s)$;
- The payoff to player i is

$$\lambda u_i(s, a) + (1 - \lambda) \sum_{s' \in S} q(s' \mid s, a) v_i(s') .$$

We define a set-valued function $\varphi \colon X \to X$ as follows.

- For every $i \in N$ and every $s \in S$, $\varphi^A_{i,s}$ is the set of all best responses of player i to the strategy vector $x_{-i,s} := (x_{j,s})_{j \neq i}$ in the game $G^\lambda_s(v)$. That is,

$$\varphi^A_{i,s}(x, v) := \Big\{ \operatorname{argmax}_{y_{i,s} \in \Delta(A_i(s))} \lambda r_i(s, y_{i,s}, x_{-i,s}) + (1 - \lambda) \sum_{s' \in S} q(s' \mid s, y_{i,s}, x_{-i,s}) v_{i,s'} \Big\} .$$

- For every $i \in N$ and every $s \in S$, $\varphi^V_{i,s}(x, v)$ is the maximal payoff for player i in the game $G^\lambda_s(v)$, when the other players play x_{-i}:

$$\varphi^V_s(x, v) := \max_{y_{i,s} \in \Delta(A_i(s))} \Bigg(\lambda r(s, y_{i,s}, x_{-i,s}) + (1 - \lambda) \times \sum_{s' \in S} q(s' \mid s, y_{i,s}, x_{-i,s}) v_{i,s'} \Bigg) .$$

The set-valued function φ has convex and non-empty values and its graph is closed, so that by Kakutani's fixed point theorem it has a fixed point. It turns out that every fixed point of φ defines a λ-discounted equilibrium in stationary strategies. □

This result has been extended to general state and action spaces by various authors. These results assume a strong continuity on either the payoff function or the transition function, see, e. g., [39,44,62].

As in the case of zero-sum games, a dynamic programming argument shows that under a strong continuity assumption on the payoff function or on the transitions a T-stage equilibrium exists.

Regarding the existence of the limsup equilibrium and uniform equilibrium little is known. The most significant result in this direction is Vieille [77,78], who proved that every two-player stochastic game with finite state and action spaces has a uniform ε-equilibrium for every $\varepsilon > 0$. This result has been proved for other classes of stochastic games, see, e. g., [6,24,25,61,63,65,76]. Several influential works in this area are [22,32,71,79]. Most of the papers mentioned above rely on the vanishing discount factor approach, which constructs a uniform ε-equilibrium by studying a sequence of λ-discounted equilibria as the discount factor goes to 0.

For games with general state and action spaces, a limsup equilibrium exists under an ergodicity assumption on the transitions, see e. g. Nowak [44], Remark 4 and Jaskiewicz and Nowak [30].

A game has perfect information if there are no simultaneous moves, and both players observe past play. Existence of equilibrium in this case was proven by Mertens [37] in a very general setup.

Correlated Equilibrium

The notion of correlated equilibrium was introduced by Aumann [8,9], see also Forges ► Correlated Equilibria and Communication in Games. A *correlated equilibrium* is an equilibrium of an extended game, in which each player receives at the outset of the game a private signal such that the vector of signals is chosen according to a known joint probability distribution. In repeated interactions, such as in stochastic games, there are two natural notions of correlated equilibria: (a) each player receives one signal at the outset of the game (*normal-form correlated equilibrium*); (b) each player receives a signal at each stage (*extensive-form correlated equilibrium*). It follows from Forges [26] that when the state and action sets are finite, the set of all correlated T-stage equilibrium payoffs (either normal-form or extensive-form) is a polytope.

Nowak and Raghavan [47] proved the existence of an extensive-form correlated discounted equilibrium under weak conditions on the state and action spaces. In their construction, the strategies of the players are stationary, and so is the distribution according to which the signals are chosen after each history; both depend only on the current state, rather than on the whole past play. Roughly, their approach is to apply Kakutani's fixed point theorem to the set-valued function that assigns to each game $G^\lambda_s(v)$ the set of all correlated equilibrium payoffs in this game, which is convex and compact.

Solan and Vielle [66] proved the existence of an extensive-form correlated uniform equilibrium payoff when the state and action spaces are finite. Their approach is to let each player play his uniform optimal strategy in a zero-sum game in which all other players try to minimize his payoff. Existence of a normal-form correlated equilibrium was proved for the class of absorbing games [68].

Solan [64] characterized the set of extensive-form correlated equilibrium payoffs for general state and action spaces and a general evaluation on the stage payoffs, and provided a sufficient condition that ensures that the set of normal-form correlated equilibrium payoffs coincides with the set of extensive-form correlated equilibrium payoffs.

Imperfect Monitoring

So far it has been assumed that at each stage the players know the past play. There are cases in which this assumption is too strong; in some cases players do not know the complete description of the current state (Examples 3 and 4), and in others players do not fully observe the actions of all other players (Examples 2, 3 and 4). For a most general description of stochastic games see Mertens, see Chapter IV in Sorin and Zamir [40] and Coulomb [17].

In the study of the discounted equilibrium, the T-stage equilibrium or the limsup equilibrium, one may consider the game as a one-shot game: The players simultaneously choose strategies, and the payoff is either the discounted payoff, the T-stage payoff or the limsup payoff. If the strategy spaces of the players are compact (e. g., if the state and action spaces are finite), and if the payoff is upper-semi-continuous in each player's strategy, keeping the strategies of the other players fixed, then an equilibrium exists. This approach can be used successfully for the discounted equilibrium or the T-stage equilibrium under weak conditions (see, e. g., [4]), and may be used for the limsup equilibrium under a proper ergodicity condition.

Whenever there exists an equilibrium in stationary strategies (e. g., a discounted equilibrium in games with finitely many states and actions) the only information that players need in order to follow the equilibrium strategies is the current state. In particular, they need not observe past actions of the other players. As we now show, in the "Big Match" (Example 10) the limsup value and the uniform value may fail to exist when each player does not observe the past actions of the other player.

Example 13 (Example 10: Continued.) Assume that no player observes the actions of the other player, and assume that the initial state is s_2. Player 2 can still guarantee $\frac{1}{2}$ in the limsup evaluation by playing the stationary strategy $[\frac{1}{2}(L), \frac{1}{2}(R)]$. One can show that for every strategy of player 2, player 1 has a reply such that the limsup payoff is at least $\frac{1}{2}$. In other words, $\inf_{\sigma_2} \sup_{\sigma_1} \gamma^{\infty}(s_2, \sigma_1, \sigma_2) = \frac{1}{2}$. We now argue that $\sup_{\sigma_1} \inf_{\sigma_2} \gamma^{\infty}(s_2, \sigma_1, \sigma_2) = 0$. Indeed, fix a strategy σ_1 for player 1, and $\varepsilon > 0$. Let θ be sufficiently large such that the probability that under σ_1 player 1 plays B for the first time after stage t is at most ε. Observe that as t increases, the probability that player 1 plays B for the first time after stage t decreases to 0, so that such a θ exists. Consider the following strategy σ_2 of player 2: Play R up to stage θ, and play L from stage $t + 1$ and on. By the definition of θ, either player 1 plays B before or at stage θ, and then the game moves to s_0, and the payoff is 0 at each stage thereafter, or player 1 plays T at each stage, and then the stage payoff after stage θ is 0, or, with probability less than ε, player 1 plays B for the first time after stage θ, the play moves to s_1, and the payoff is 1 thereafter. Thus, the limsup payoff is at most ε. A similar analysis shows that

$$\inf_{\sigma_2} \sup_{\sigma_1} \gamma^{\lambda}(s_2, \sigma_1, \sigma_2) = \tfrac{1}{2} \,,$$

$$\sup_{\sigma_1} \inf_{\sigma_2} \lim_{\lambda \to 0} \gamma^{\lambda}(s_2, \sigma_1, \sigma_2) = 0 \,,$$

so that the uniform value does not exist as well.

This example shows that in general the limsup value and the uniform value need not exist when the players do not observe past play. Though in general the value (and therefore also an equilibrium) need not exist, in many classes of stochastic games the value and an equilibrium do exist, even in the presence of imperfect monitoring.

Rosenberg et al. [55] and Renault [54] showed that the uniform value exists in the one player setup (Markov Decision Problem), in which the player receives partial information regarding the current state. Thus, a single decision maker who faces a dynamic situation and does not fully observe the state of the environment can play in such a way that guarantees high payoff, provided the interaction is sufficiently long or the discount factor is sufficiently low.

Altman et al. [5,6] and Flesch et al. [24] studied stochastic games in which each player has a "private" state, which only he can observe, and the state of the world is composed of the vector of private states. Altman et al. [5,6] studied the situation in which players do not observe the actions of the other players, and Flesch et al. [24] studied the situation in which players do observe each others payoffs. Such games arise naturally in wireless communication (see [5]); take for example several mobiles who periodically send information to a base station. The private state of a mobile may depend, e. g., on its exact physical environment, and it determines the power attenuation between the mobile and the base station. The throughput (the amount of bits per second) that a mobile can send to the base station depends on the power attenuations of all the mobiles. Finally, the stage payoff is the stage power consumption.

Rosenberg et al. [57] studied the extreme case of two player zero-sum games in which the players observe neither the current state nor the action of the other player, and proved that the uniform value does exist in two classes of games, which capture the behavior of certain communication protocols. Classes of games in which the actions are observed but the state is not observed were studied, e. g., by Sorin [69,70], Sorin and Zamir [74], Krausz and Rieder [33], Flesch et al. [23], Rosenberg et al. [56], Renault [52,53]. For additional results, see [16,73].

Algorithms

There are two kinds of algorithms: Those that terminate in a finite number of steps, and those that iterate and approximate solutions. Both kinds of algorithms were devised to calculate the value and optimal strategies (or equilibria) in stochastic games.

It is well known that the value of a two-player zero-sum matrix game and optimal strategies for the two players can be calculated efficiently using a linear program. Equilibria in two-player non-zero-sum games can be calculated by the Lemke–Howson algorithm, which is usually efficient, however, its worst running time is exponential in the number of pure strategies of the players [59]. Unfortunately, to date there are no efficient algorithms to calculate either the value in zero-sum stochastic games, or equilibria in non-zero-sum games. Moreover, in Example 9 the discounted value may be irrational for rational discount factors, even though the data of the game (payoffs and transitions) are rational, so it is not clear whether linear programming methods can be used to calculate the value of a stochastic game. Nevertheless, linear programming methods were used to calculate the discounted and uniform value of several classes of stochastic games, see [20,50]. Other methods that were used to calculate the value or equilibria in discounted stochastic games include fictitious play [80], value iterates, policy improvement, and general methods to find the maximum of a function (see [20,51]), a homotopy method [29], and algorithms to solve sentences in formal logic [15,67].

Additional and Future Directions

The research on stochastic games extends to additional directions than those mentioned in earlier sections. We mention a few here. Approximation of games with infinite state and action spaces by finite games was discussed by Whitt [81], and further developed by Nowak [43]. Stochastic games in continuous time have also been studied, as well as hybrid models that include both discrete and continuous aspects, see, e. g., [2,10].

Among the many directions of future research in this area, we will mention here but a few. One challenging question is the existence of a uniform equilibrium and a limsup equilibrium in multi-player stochastic games with finite state and action spaces. Another is the development of efficient algorithms that calculate the value of two-player zero-sum games. A third direction concerns the identification of applications that can be recast in the framework of stochastic games, and that can be successfully analyzed using the theoretical tools that the literature developed. Another problem that is of interest is the characterization of approachable and excludable sets in stochastic games with vector payoffs (see [12] for the presentation of matrix games with vector payoffs, and [41] for partial results regarding this problem).

Acknowledgments

I thank Eitan Altman, János Flesch, Yuval Heller, Jean-Jacques Herings, Ayala Mashiach-Yakovi, Andrzej Nowak, Ronald Peeters, T.E.S. Raghavan, Jérôme Renault, Nahum Shimkin, Robert Simon, Sylvain Sorin, William Sudderth, and Frank Thuijsman, for their comments on an earlier version of the entry.

Article Outline

Glossary

Bessel process The Bessel process operates in d dimensions and describes the radial distance r from the origin of a particle performing Brownian motion. The random motion is governed by the Langevin equation $\mathrm{d}r/\mathrm{d}t = \kappa(d-1)/2r + \xi$, where $\langle\xi\xi\rangle(t) = \kappa\delta(t)$. For $d \leq 2$ the motion is recurrent, i. e., returns to the origin; for $d > 2$ the motion goes off to infinity. In SLE the Bessel process describes the transition between simple curves and self-intersecting curves.

Brownian motion Brownian motion, B_t, is the scaling limit of random walk. Brownian motion is plane-filling, has the fractal dimension $D = 2$, and is described by the Langevin equation $\mathrm{d}B_t/\mathrm{d}t = \eta_t, \langle\eta_t\eta_s\rangle = \delta(t-s)$. B_t is characterized by i) the stationarity property, $B_{t+t'} - B_t$ and $B_{t'}$ identical in distribution and ii) the independence property, $B_{\Delta t'}$ and $B_{\Delta t}$ independent for $\Delta t \neq \Delta t'$. The correlations are given by

$\langle |B_t - B_s|^2 \rangle = |t - s|$ and B_t is distributed according to the Gaussian (normal) distribution $P(B, t) = (2\pi t)^{-1/2} \exp(-B^2/2t)$.

Chordal SLE In order to map the geometry of the growing hull to a real function by means of SLE one chooses a reference domain. Chordal SLE refers to the case where the SLE trace is grown between two boundary points, usually the origin and the point at infinity in the upper half complex plane.

Conformal invariance Conformal invariance or local scale invariance is a larger symmetry than scale invariance. Conformal invariance implies invariance under both a local rotation, translation, and dilatation. Conformal invariance is particularly powerful in 2D where a conformal transformation is implemented by an analytic function.

Conformal transformation A conformal transformation is a transformation which preserves angles but allows for rotation, dilatation, and translation. In an elastic medium picture a conformal transformation corresponds to translation, rotation, and compression (dilatation), but not shear. In 2D an analytic complex function $w = f(z)$ from the complex z plane to the complex w plane generates a conformal transformation.

Continuum limit The limit where a lattice model approaches a continuum model; also called the scaling limit. The resulting continuum field theories define the universality classes of the lattice models.

Correlation length The correlation length measures the size of correlations. At the critical point the correlation length diverges signaling that the system becomes scale invariant.

Critical curves Critical curves are domain walls or cluster boundaries at the critical point. Critical curves are scale invariant and characterized by a fractal dimension.

Exploration Domain walls at the critical point can mathematically be generated by an exploration process where the domain wall is initiated at a boundary point and constructed in steps across the domain. In the percolation case the local step is generated by 'flipping a coin', in the Ising case by evaluating the magnetization at the tip of the 'growing' domain wall. The construction by an exploration process is essential in generating a critical curve by stochastic Loewner evolution.

Fortuin–Kasteleyn representation (FK) Based on a high temperature expansion one can represent the configurations in the Ising, $O(n)$, and Potts models by means of the Fortuin–Kasteleyn representation in terms of random clusters. The FK transformation is essential in identifying random curves for the lattice models which then can be accessed by SLE in the scaling limit.

Fractal dimension Irregular objects can be characterized by a fractal dimension. The fractal dimension D is derived by covering the object with $N(\ell)$ intervals, disks, or spheres of linear dimension ℓ. By letting $\ell \to 0$ this definition resolves the fine scale fractal structure and the scaling relation $N(\ell) \propto (\ell)^{-D}$, or $D = -\lim_{\ell \to 0} \ln(N(\ell)/\ln(\ell)$, yields the fractal dimension. Examples of deterministic fractals are for example the Cantor set, the Koch curve, the Sierpinski gasket, and plane-filling Hilbert and Peano curves. Random walk and diffusion limited aggregation (DLA) are examples of random physical fractals.

Hulls For a self-intersecting SLE trace the trace and enclosed regions form a so-called hull. Points in the hull cannot be connected to infinity without crossing the trace. The growing hull of a self-intersecting SLE trace eventually exhausts the half plane.

Ising model The Ising model originates from the theory of magnetism and plays an important role in the theory of phase transitions and in general in statistical mechanics. The model is defined on a lattice where each lattice sites is endowed with a local spin variable assuming two distinct values. The spins interact by a short range exchange interaction. Above 1D the Ising model has a second order phase transition.

Locality In the percolation case the domain wall is constructed by an exploration process and a local rule for assigning the next step. This locality property is specific to percolation which has a geometric phase transition. In the SLE context the locality property implies $\kappa = 6$, i. e., the percolation case.

Loewner equation The Loewner equation is the first order nonlinear differential equation for the uniformizing map $g_t(z)$ which maps the complement of a growing hull or curve in the upper half plane back to the upper half plane. The geometrical properties of the hull is encoded in the real function a_t. The Loewner equation has the form $\mathrm{d}g_t/\mathrm{d}t = 2/(g_t - a_t)$.

Loewner evolution Loewner evolution refers to the parametrized map $g_t(z)$ which uniformizes the complement of a curve or hull, say in the upper half plane.

Loop erased random walk (LERW) Loop erased random walk is a variant of random walk where loops formed are removed as the walk progresses. LERW has a conformally invariant scaling limit and can be generated by SLE for $\kappa = 2$.

Markov property The Markov property refers to a stochastic process without memory. A typical example is random walk or in the scaling limit Brownian motion. The Markov property is essential for the application of SLE to domain walls in the scaling limit.

Measures For lattice systems one can define probability distributions according to the rules of statistical mechanics. In the scaling limit the distributions typically diverge and have to be replaced by the more abstract mathematical concept of probability measures.

$O(n)$ models The $O(n)$ model is a generalization of the Ising model. At each lattice site is associated an n-component spin variable. For $n = 1$ we recover the Ising model, $n = 2$ corresponds to the XY model, and $n = 3$ to the Heisenberg model.

Peano curve A Peano curve is a non-crossing curve which is dense in the plane, i. e., it gets arbitrarily close to every point. The Peano curve has the fractal dimension $D = 2$. In a SLE context a random Peano curve winds around a UST and corresponds to $\kappa = 8$.

Percolation Percolation on a lattice is constructed by filling lattice sites at random with a common probability p. At a critical concentration a spanning cluster extends across the system.

Potts model The Potts model is a generalization of the Ising model where the local lattice variable can assume q different values and where sites only interact when they are in the same Potts state. The Potts model has a FK cluster representation. The Ising model corresponds to $q = 2$; $q = 1$ corresponds to percolation and $q = 0$ to the UST.

Random walk Random walk is an ubiquitous phenomenon in nature. In random walk on a square lattice a particle jump from site to site with a given fixed probability. Each step is independent of the past history, there is no memory, this is the so-called Markov property. The random walk path or history is plane-filling and has the fractal dimension $D = 2$. The mean square displacement of random walk scales with the number of steps.

Restriction The restriction property in a SLE context implies that the measure on a curve in a domain D conditioned not to hit a bulge L is the same as the measure in the domain $D \setminus L$. The restriction property holds in the case of a uniform measure and applies to self-avoiding random walk.

Riemann's mapping theorem Riemann's mapping theorem states that an arbitrary simply connected domain D, i. e., without holes, can be mapped to another simply connected domain D' by means of a suitable complex function $g(z)$, i. e., $g(D) = D'$. Often the disk or half plane are used as reference domains. The mapping theorem does not make assumptions about the domain boundaries which can be fractal.

Scale invariance The scaling property refers to the case where a phenomenon is devoid of a characteristic scale or unit. Scale invariance is typically characterized by a power law behavior and critical exponents.

Scaling limit The limit where the lattice parameter in a lattice model approaches zero. The scaling limit is equivalent to the continuum limit.

Self-avoiding random walk (SAW) A self-avoiding random walk is a walk conditioned not to cross itself. SAW has been used to model polymers. SAW has a uniform probability measure and conforms in a SLE context to the restriction condition.

Stochastic Loewner evolution (SLE) Stochastic Loewner evolution is Loewner evolution driven by a real stochastic function a_t with a distribution given by 1D Brownian motion, i. e., $a_t = \sqrt{\kappa} B_t$. SLE is governed by the stochastic equation of motion $\mathrm{d}g_t/\mathrm{d}t = 2/(g_t - a_t)$.

Schramm's theorem Schramm's theorem refers to Schramm's derivation of SLE for LERW. Schramm showed that the scaling limit of LERW is described by SLE for $\kappa = 2$. Schramm also conjectured that the random Peano curve winding around an UST is described by SLE for $\kappa = 8$ and that percolation is described by SLE for $\kappa = 6$.

Uniformizing maps Conformal transformations which map a domain D to a standard reference domain, e. g., the half plane or the disk, are called uniformizing maps.

Uniform spanning tree (UST) A spanning tree is a collection of vertices and links forming a tree (no loops or cycles). A USF is a random tree picked among all spanning trees with equal probability.

Definition of the Subject

Stochastic Loewner evolution also called Schramm Loewner evolution (abbreviated, SLE) is a rigorous tool in mathematics and statistical physics for generating and studying scale invariant or fractal random curves in two dimensions (2D). The method is based on the older deterministic Loewner evolution introduced by Karl Löwner [64], who demonstrated that an arbitrary curve not crossing itself can be generated by a real function by means of a conformal transformation. A real function defined in one spatial dimension (1D) thus encodes a curve in 2D, in itself an intriguing result. In 2000 Oded Schramm [77] extended this method and demonstrated that driving the Loewner evolution by a 1D Brownian motion, the curves in the complex plane become scale invariant; the fractal dimension turns out to be determined by the strength of the Brownian motion.

The one parameter family of scale invariant curves generated by SLE is conjectured and has in some cases been proven to represent the continuum or scaling limit of a variety of interfaces and cluster boundaries in lattice models in statistical physics, ranging from self-avoiding random walks to percolation cluster boundaries, and Ising domain walls.

SLE operates in the 2D continuum where it generates extended scale invariant objects. SLE delimits scaling universality classes by a single parameter κ, the strength of the 1D Brownian drive, yielding the fractal dimension D of the scale invariant shapes according to the relation $D = 1 + \kappa/8$. Moreover, SLE provides the geometrical aspects of conformal field theory (CFT). The central charge c, delimiting scaling universality classes in CFT, is thus related to κ by means of the expression $c = (3\kappa - 8)(6 - \kappa)/2\kappa$.

Stochastic Loewner evolution derives its importance from the fact that it addresses the issue of extended random fractal shapes in 2D by direct analysis in the continuum. It thus supplements and extends earlier lattice results and also allows for the determination of new scaling exponents. From the point of view of conformal field theory based on the concept of a local field, operator expansions, and correlations, the geometrical approach afforded by SLE, directly addressing conformally invariant random shapes in the continuum, represents a novel point of view of maybe far reaching consequences; so far only explored in two dimensions.

Introduction

The field of SLE has mainly been driven by mathematicians presenting their results in long and difficult papers. There are, however, presently several excellent reviews of SLE both addressing the theoretical physics community [11,13,25,27,39,43] and the mathematical community [56,85], see also a complete biography up to 2003 [39]. The purpose of this article is to present a heuristic and simple discussion of some of the key aspects of SLE, for details and topics left out we refer the reader to the reviews mentioned above. However, in order to provide the necessary background and set the stage for SLE we begin with some general remarks on scaling in statistical physics.

General Remarks

In statistical physics we study macroscopic systems composed of many interacting components. In the limit of many degrees of freedom the macroscopic behavior roughly falls in two categories. In the most common case the macroscopic behavior is deterministic and governed by phenomenological theories like for example thermodynamics and hydrodynamics operating entirely on a macroscopic level. This behavior is basically a result of the law of large numbers, permitting an effective coarse graining and yielding for example a macroscopic density or velocity field [29]. In the other case, the macroscopic behavior is dominated by fluctuations and shows a random behavior [29,73]. Typical cases are random walk and equilibrium systems tuned to the critical point of a second order phase transition. Other random cases are for example self-organized critical systems purported to model earth quake dynamics, flicker noise and turbulence in fluids [5,40].

The distinction between the deterministic and random cases of macroscopic behavior is illustrated by the simple example of a biased random walk described by the Langevin equation $\mathrm{d}x(t)/\mathrm{d}t = v + \xi(t)$, $\langle\xi(t)\xi(0)\rangle \propto \delta(t)$. Here $x(t)$ is a macroscopic variable sampling the statistically independent microscopic steps $\xi(t)$; the velocity v is an imposed drift or bias. Averaging over the steps we obtain for the deviation of x, $R = [\langle x^2\rangle]^{1/2} = [(vt)^2 + t]^{1/2}$. For large t the deviation $R \sim \langle x\rangle = vt$ and the mean value or deterministic part dominates the behavior, the fluctuational or random part $R \sim t^{1/2}$ being subdominant. Fine tuning the random walk to vanishing bias $v = 0$ we have $\langle x\rangle = 0$ and $R \sim t^{1/2}$, i. e., the random fluctuations control the phenomenon.

The study of complexity encompasses a broader field than statistical physics and is concerned with the emergence of universal properties on a mesoscopic or macroscopic scale in large interacting systems. For example particle systems, networks in biology and sociology, cellular automata, etc. The class of complex systems generally falls in the category of random systems. The emergent properties are a result of many interacting agents or degrees of freedom and can in general not be directly inferred from the microscopic details. A major issue is thus the understanding of generic emerging properties of complex systems [45,70,83]. Here, however, the methods of statistical physics is an indispensable tool in the study of complexity.

The evolution of statistical physics, a branch of theoretical physics, has occurred in steps and is driven both by the introduction of new concepts and the concurrent development of new mathematical methods and techniques. A well-known case is the long standing problem of second order phase transitions or critical phenomena which gave way to a deeper understanding in the sixties and seventies and spun off the renormalization group techniques for the determination of critical exponents and universality classes [20,24,65,81,86].

Scaling Ideas

This brings us to the fundamental scaling ideas and techniques developed particularly in the context of critical phenomena in equilibrium systems and which now pervade a good part of theoretical physics and, moreover, play an important role in the analysis of complex systems in physical sciences [20,24,29]. Scaling is synonymous with no scale in the sense that a system exhibiting scale invariance is characterized by the absence of any particular scale or unit. Scaling occurs both in the space and/or time behavior and is typically characterized by power law dependencies controlled by scaling exponents.

A classical case is random walk discussed above, characterized by the Langevin equation $\mathrm{d}x/\mathrm{d}t = \xi(t)$, $\langle\xi\xi\rangle \sim \delta(t)$ [73]. Here the mean square displacement scales like $\langle x^2\rangle(t) \sim t^{2H}$, where H is the Hurst scaling exponent; for random walk $H = 1/2$ [32,68]. Correspondingly, the power spectrum $P(\omega) = |x_\omega|^2$, $x_\omega = \int \mathrm{d}t x(t) \exp(i\omega t)$, scales like $P(\omega) \sim \omega^{-1-2H}$, i. e., $P(\omega) \sim \omega^{-2}$ for random walk; we note that the underlying reason for the universal scaling behavior of random walk is the central limit theorem [37,73].

Scaling in Equilibrium

Scaling ideas and associated techniques first came to the forefront in statistical physics in the context of second order phase transitions or critical phenomena [20,24,29,65]. More specifically, consider the usual Ising model defined on a lattice with a local spin degrees of freedom, $\sigma_i = \pm 1$ at site i, subject to a short range interaction J favoring spin alignment. The Ising Hamiltonian has the form $H = -J\sum_{\langle ij\rangle}\sigma_i\sigma_j$, where $\langle ij\rangle$ indicates nearest neighbor sites. The thermodynamic phases are characterized by the order parameter $m = \langle\sigma_i\rangle$. Above one dimension the Ising model exhibits a second order phase transition at a finite critical temperature T_c. Above T_c the model is in a disordered paramagnetic state with $m = 0$ and only microscopic domain of ordered spins. Below T_c the model favors a ferromagnetic state with long range order and macroscopic domains of ordered spins, corresponding to $m \neq 0$; at $T = 0$ the model assumes the ferromagnetic ground state configuration with totally aligned spins. Regarding the spatial organization, the size of the domains of ordered spins is characterized by the correlation length $\xi(T)$. As we approach the critical point at T_c the order parameter vanishes $m \propto |T - T_c|^\beta$ with critical exponent β, but more significantly, the correlation length $\xi(T)$ diverges like $\xi(T) \sim |T - T_c|^{-\nu}$ with scaling exponent ν. This indicates that the system is scale invariant at T_c. Regarding the domains of ordered spins, the system is spatially self-similar on scales from the microscopic lattice distance to the system size; the system size diverging in the thermodynamic limit. The scaling behavior at the critical point T_c is an emergent property in the sense that the scaling exponents β and ν do not depend on microscopic details like the type of lattice, strength of interaction, etc., but only on the dimension of the system and the symmetry of the order parameter [72].

The diverging correlation length at the critical point is the central observation which in the 60-ties and 70-ties gave rise to a detailed understanding of critical phenomena, beginning with the coarse graining block scheme proposed by Kadanoff [41] and culminating with the development and application of field theoretical renormalization group techniques by Wilson and others [20,24,29,65,72,86].

For a diverging correlation length much larger than the lattice distance the local spin σ_i can be replaced by a coarse-grained local field $\phi(r)$ and the Ising Hamiltonian H by the Ginzburg–Landau functional $F = \int \mathrm{d}^d r[(\nabla\phi)^2 + R\phi^2 + U\phi^4]$, where the 'mass' term $R \sim |T - T_c|$. Consequently, the universality class of Ising-type models is described by a scalar field theory. The renormalization group techniques basically quantify the Kadanoff block construction in momentum space and extract scaling properties in an expansion about the upper critical dimension $d = 4$. To leading order in $4 - d$ one obtains $\beta = 1/2 - (4 - d)/6$ and $\nu = 1/2 + (4 - d)/12$. Alternatively, keeping the correlation length ξ fixed and letting the lattice distance approach zero, we obtain at T_c the so-called scaling limit or continuum limit of the Ising model. The Ising spin σ_i becomes a local field $\phi(r)$ and the weight of a configuration is determined by $\exp(-F)$. Note that in order to implement the scaling limit we must be at T_c. The two scenarios of a growing correlation length for fixed lattice distance implementing the Kadanoff construction and a fixed correlation length for a vanishing lattice distance yielding a continuum field theory are related by an overall scale transformation [86].

It is generally assumed that the global or nonlocal scale invariance at the critical point in the continuum limit can be extended to a local scale invariance including translation and rotation, that is an angle-preserving conformal transformation. This follows heuristically from an a local implementation of the Kadanoff coarse-graining block construction and applies to lattice models with short range interactions and discrete translational and rotational invariance [22,24]. The resulting continuum theories then fall in the category of conformal field theories (CFT).

In 2D the group of conformal transformations is particularly rich since it corresponds to the class of analytical functions $w = f(z)$, mapping the complex plane z to the complex plane w. The infinite group structure imposes sufficient constraints on the structure of conformal field theories in 2D that the scaling form of correlations, e. g., $\langle\phi\phi\rangle(r)$, and in particular the critical exponents can be determined explicitly [23,24]. On finds $\beta = 1/8$ and $\nu = 1$ for the order parameter and correlation length exponents, respectively, in accordance with lattice theory results [14]. Here we also mention the Coulomb gas method for the determination of critical exponents [71].

It is a common feature of both renormalization group calculations based on an expansion about a critical dimension and conformal field theory in 2D that the local field $\phi(r)$ and its correlations are the basic building blocks and that the critical properties are encoded in their scaling form, yielding critical exponents, scaling laws, scaling functions, etc. Notwithstanding the fact that the seminal Kadanoff construction [41] was based on a geometrical picture corresponding to coarse-graining the degrees of freedom over larger and larger scales, keeping track of ordered domains on all scales, the actual geometry of critical phenomena such as the scaling properties of critical clusters was not well-understood and seemed inaccessible in the continuum limit within the context of local field theories. Whereas it is not difficult to generate critical domain walls, interfaces, and clusters for lattice models with appropriate boundary conditions by means of standard Monte Carlo simulation techniques, the continuum or scaling limit of critical shapes appeared until recently, with a few exceptions, beyond present techniques.

Stochastic Loewner Evolution

Here stochastic Loewner evolution (SLE) represents a new insight in 2D critical phenomena with respect to a deeper understanding of scale invariant curves, clusters, and shapes. Also, there appears to be deep connections between SLE and conformal field theory.

SLE is an ingenious way of generating critical curves and shapes in the 2D continuum using conformal transformations. Let us mention a characteristic example. Consider an Ising model on a lattice in a chosen domain. Imposing spin up on a continuous part of the domain boundary and spin down on the remaining part of the boundary, it follows that a specific domain wall or interface will connect the two points on the boundary where a bond is broken. At low temperature the bond energies dominate and the free energy is lowest for a straight domain wall with few kinks. As we approach the critical point entropy or fluctuations come strongly into play and the domain wall meanders balancing energy and entropy. At the critical point the system becomes scale invariant with a diverging correlation length and likewise the domain wall becomes scale invariant, i. e., it has kinks on all scales larger that the lattice distance. In the continuum limit the Ising domain wall becomes a random fractal curve with a particular fractal dimension. Here SLE provides a direct analytical method in the continuum to generate such a random curve and, moreover, provides the fractal dimension in terms of the strength of the 1D random walk driving the SLE evolution.

Outline

The outline of the present article is as follows. In Sect. "Scaling" on scaling we introduce some of the basic models and concepts necessary for a discussion of SLE: A) Random walk, B) Percolation, C) Ising model, D) Critical curves and exploration, and E) Distributions, Markov properties, and measures. In Sect. "Conformal Invariance" we turn to the essential ingredient in SLE, namely, conformal invariance: A) Conformal maps and B) Measures and conformal invariance. Section "Loewner Evolution" is devoted to deterministic or classical Loewner evolution: A) Growing stick, B) Loewner equation and C) Exact solutions. In Sect. "Stochastic Loewner Evolution", constituting the core part of this article, we discuss stochastic Loewner evolution: A) Schramm's theorem, B) SLE properties, C) Curves, hulls, and the Bessel process and D) Fractal dimension. Section "Results and Discussion" is devoted to results and discussions: A) Phase transitions, locality, restriction, and duality, B) Loop erased random walk, C) Self-avoiding random walk, D) Percolation, E) Ising model and $O(n)$ models, F) SLE and conformal field theory, G) Application to 2D turbulence, H) Application to 2D spin glass and I) Further remarks. Finally, in Sect. "Future Directions" we discuss future directions of the field. The bibliography includes books, general reviews, and more technical papers.

Scaling

Stochastic Loewner evolution, has been applied to a host of lattice models proved or conjectured to possess scaling limits. However, for the present purpose we will focus on three lattice models: Random walk, Percolation, and the Ising model.

Random Walk

Random walk is a simple and much studied random process [4,32,73]. Consider an unbiased random walk in the plane composed of N steps, where the ith step, $\vec{\eta}_i$, is random, isotropic and uncorrelated, i. e., $\langle\vec{\eta}_i\rangle = 0$ and $\langle\eta_i^\alpha\eta_j^\beta\rangle \propto \delta_{\alpha\beta}\delta_{ij}$. For the end-to-end distance we have $\vec{x} = \sum_{i=1}^N \vec{\eta}_i$ and for the size $R = [\langle\vec{x}^2\rangle]^{1/2} \sim N^{1/2}$. Assuming one step pr unit time, $N \propto t$, we obtain $R \sim t^{1/2}$, characteristic of diffusive motion. Introducing the fractal dimension D by the usual box counting procedure [32,68]

$$N(R) \sim R^D\,, \tag{1}$$

where N is the number of boxes and R the size of the object, and covering the random walk we readily infer $D = 2$, i. e., the self-crossing random walk is plane-filling modulo the lattice distance. Introducing the scaling exponent ν according to $R \sim N^\nu$ we have for random walk $\nu = 1/2$; note that $D = 1/\nu$.

The scaling limit of unbiased random walk is Brownian motion (BM) [4] and is obtained by scaling the step size η down and the number of steps N up in such a manner that the size $R \sim N^{1/2}\eta$ stays constant. The resulting BM path is a continuous non-differentiable random curve with fractal dimension $D = 2$. The BM path is plane-filling and recurrent in 2D, i. e., it returns to a given point with probability one. Focusing on one of the independent cartesian components 1D BM, B_t, is also described by the Langevin equation

$$\frac{\mathrm{d}B_t}{\mathrm{d}t} = \eta_t\,, \quad \langle\eta_t\eta_s\rangle = \delta(t-s)\,, \tag{2}$$

where η_t is uncorrelated Gaussian white noise with a flat power spectrum. Integrating Eq. (2) B_t samples the step η_t and we find, assuming $B_0 = 0$, $B_t = \int_0^t \eta_{t'}\mathrm{d}t'$ from which we directly infer the fundamental properties of BM, namely, independence and stationarity,

$$B_{T+\Delta T} - B_T \approx B_{\Delta T}\,, \qquad \text{(stationarity)} \tag{3}$$

$$B_{\Delta T}, B_{\Delta T'} \ \text{ indep. for } \ \Delta T \neq \Delta T'\,, \quad \text{(independence)} \tag{4}$$

where $\approx$ indicates identical distributions. Moreover, the correlations are given by

$$\langle|B_t - B_s|^2\rangle = |t-s| \tag{5}$$

and B_t is distributed according to the normal (Gaussian) distribution $P(B,t) = (2\pi t)^{-1/2}\exp(-B^2/2t)$.

Whereas 1D BM drives SLE, 2D BM is not itself generated by SLE since the path is self-crossing on all scales; by construction SLE is limited to the generation of non-crossing random curves. However, variations of BM have played an important role in the development of SLE. We mention here the scaling limit of loop erased random walk (LERW) and self-avoiding random walk (SAW), to be discussed later.

Percolation

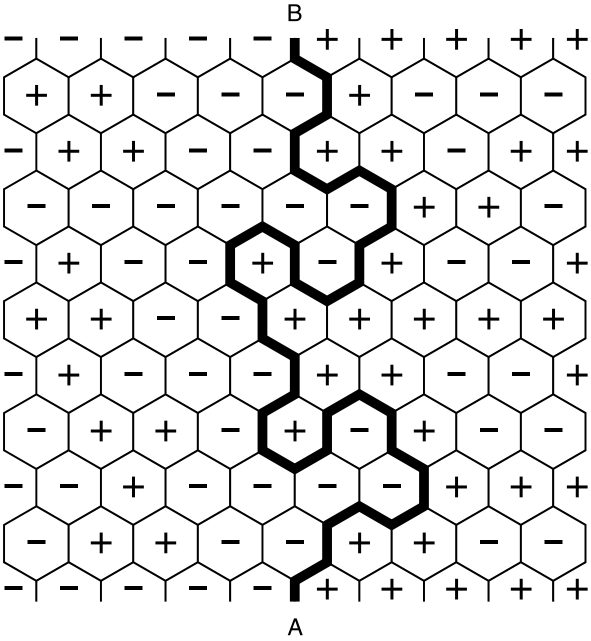
The phenomenon of percolation is relevant in the context of clustering, diffusion, fractals, phase transitions and disordered systems. As a result, percolation theory provides a theoretical and statistical background to many physical and natural sciences [82].

Percolation is the simplest lattice model exhibiting a geometrical phase transition. The site percolation model is constructed by occupying sites on a lattice with a given common probability p. Let an occupied site be denoted 'plus' and an 'empty' site denoted 'minus'. For p close to zero the sites are mainly unoccupied and the lattice is 'minus'. For p close to one the sites are predominantly occupied and the lattice is 'plus'. At a critical concentration p_c, the percolation threshold, an infinite cluster of 'plus' sites embedded in the 'minus' background extends across the lattice. In the scaling limit of vanishing lattice distance the critical cluster has a fractal boundary which can be accessed by SLE. Whereas the scaling properties of critical percolation clusters define a universality class and is independent of the lattice structure, the critical concentration p_c in general depends on the lattice. For site percolation on a triangular lattice the percolation threshold is known to be $p_c = 1/2$.

In Fig. 1 we depict a realization of site percolation on a triangular lattice in the upper half plane at the percolation threshold $p_c = 1/2$. The occupied sites are denoted 'plus', the empty sites 'minus'. By imposing appropriate boundary conditions we induce a meandering domain wall across the system from A to B. In the scaling limit the domain wall becomes a fractal non-crossing critical curve.

Ising Model

The Ising model is probably the simplest interacting many particle system in statistical physics [20,29,81]. The model has its origin in magnetism but has become of paradigmatic importance in the context of phase transitions. The model is defined on a lattice where each lattice site i is occupied by a single degree of freedom, a spin variable σ_i, assuming two values, $\sigma_i = \pm 1$, i. e., spin up or spin down.



Stochastic Loewner Evolution: Linking Universality, Criticality and Conformal Invariance in Complex Systems, Figure 1
We depict site percolation on a triangular lattice in the *upped half plane* at the percolation threshold. The critical concentration is $p_c = 1/2$. The occupied sites are denoted 'plus', the empty sites 'minus'. The boundary conditions enforce a meandering domain wall from *A* to *B*

In the ferromagnetic case considered here the spins interact via a short range exchange interaction J favoring parallel spin alignment. The model is described by the Ising Hamiltonian

$$H = -J \sum_{\langle ij \rangle} \sigma_i \sigma_j \,, \tag{6}$$

where $\langle ij \rangle$ indicates nearest neighbor spin sites i and j. The statistical weight or probability of a specific spin configuration $\{\sigma_i\}$ is determined by the Boltzmann factor

$$P(\{\sigma_i\}) = \exp[-H/kT]/Z \,, \tag{7}$$

where T is the temperature and k Boltzmann's constant. The partition function Z has the form

$$Z = \sum_{\{\sigma_i\}} \exp(-H/kT) \,, \tag{8}$$

yielding the thermodynamic free energy F according to $F = -kT \log Z$. The entropy is given by $S = -\mathrm{d}F/\mathrm{d}T$ and the energy follows from $F = E - TS$. The magnetization or order parameter and correlations are given by

$$m = \sum_{\{\sigma_i\}} \sigma_i P(\{\sigma_i\}) \quad \text{and} \quad \langle \sigma_i \sigma_j \rangle = \sum_{\{\sigma_i\}} \sigma_i \sigma_j P(\{\sigma_i\}) \,, \tag{9}$$

respectively.

The Ising model possesses a phase transition at a critical temperature T_c from a disordered paramagnetic phase above T_c with vanishing order parameter $m = 0$ to a ferromagnetic ordered phase below T_c with non-vanishing order parameter $m \neq 0$. At the critical temperature T_c the order parameter vanishes like $m \sim |T - T_c|^{\beta}$ with critical exponent β. The correlation function $\langle \sigma_i \sigma_j \rangle$ monitoring the spatial organization of ordered domains behaves like

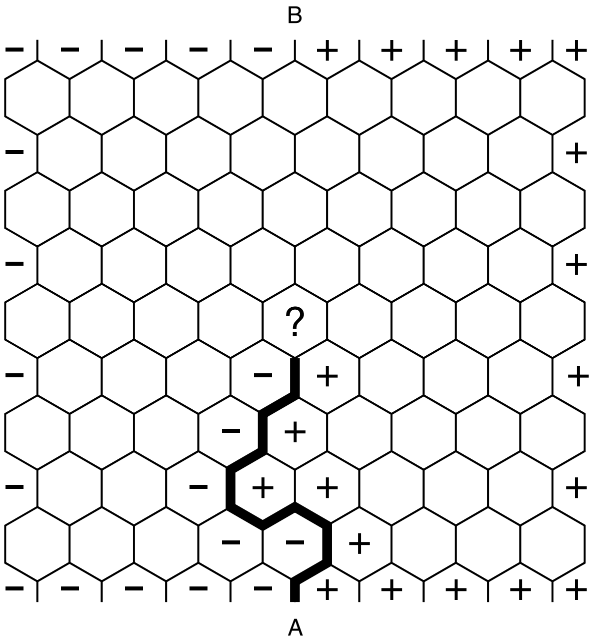
$$\langle \sigma_i \sigma_j \rangle \sim \frac{\exp[-|i-j|/\xi]}{|i-j|^{\eta}} \,, \tag{10}$$

where $|i - j|$ denotes the distance between position i and position j. The algebraic behavior is characterized by the critical exponent η and the correlation length ξ scales like $\xi \sim |T - T_c|^{-\nu}$ with critical exponent ν. At the critical point the correlation length ξ diverges and the Ising model becomes scale invariant with an algebraically decaying correlation function $\langle \sigma_i \sigma_j \rangle \sim |i - j|^{-\eta}$. Assigning 'plus' to spin up and 'minus' to spin down, Fig. 1 also illustrates a typical configuration of the 2D Ising model on a triangular lattice at the critical temperature, including an Ising domain wall from A to B.

Critical Curves – Exploration

In the percolation case at the percolation threshold a critical curve is induced by fixing the boundary conditions. Occupying sites from A to B along the right hand side of the boundary and assigning empty sites along the left hand side of the boundary from A to B a critical curve will meander across the system from A to B. Imagining painting the two sides of the curve, one side is painted with occupied sites, the other side with empty sites. Typically the curve meanders on all scales but by construction does not cross itself. For later purposes the configuration is depicted in Fig. 1.

In order to make contact with SLE we observe that a critical interface in the percolation case also can be constructed by an exploration process. We initiate the curve at the boundary point A and toss a coin. In the case of 'head' the site or hexagon in front is chosen to be occupied and the path bends left; in the event of 'tail' the hexagon in front is left unoccupied and the path bends right. In this manner a critical meandering non-crossing curve is generated terminating eventually at B. The percolation growth



Stochastic Loewner Evolution: Linking Universality, Criticality and Conformal Invariance in Complex Systems, Figure 2

We depict the growth process in the percolation case. The percolation threshold is at $p_c = 1/2$. The interface imposed by the boundary conditions originates at the boundary point *A* and progresses towards the boundary point *B*

process is depicted in Fig. 2, where we for clarity only have indicated the sites involved in the growth process. We note that since there is no interaction between the sites the path depends entirely on the local properties.

In the case of the Ising model a critical interface or domain walls at the critical point is again fixed by assigning appropriate boundary conditions with spin up along the boundary from A to B and spin down from B to A. The critical curve can be constructed in two ways: Globally or by an exploration process. In the global case we generate a spin configuration by means of a Monte Carlo simulation, i. e., perform a biased importance sampling implementing the probability distribution in Eq. (7), and identify a critical interface. Alternatively, we can generate an interface by an exploration process like in the percolation case, occupying a site i according to the weight $(1/2)(1 + \langle\sigma_i\rangle)$, where $\langle\sigma_i\rangle$ is evaluated in the domain with the spins along the interface fixed, see again Fig. 2.

Distributions – Markov Properties – Measures

In the case of random walk the number of walks of length L grows like μ^L, where μ is a lattice dependent number, i. e., at each step there are μ lattice-dependent choices for choosing a direction of the next step. Consequently, the weight or probability of a particular walk of length L is proportional to μ^{-L},

$$P(L) \sim \mu^{-L} \,, \tag{11}$$

and all walks of a given length have the same weight. We note here the important Markov property, characteristic of random walk, which can be formulated in the following manner. Assume that the first part γ' of the walk has taken place and thus conditions the remaining part γ of the walk. In a suggestive notation the conditional distribution is given by $P(\gamma|\gamma') = P(\gamma\gamma')/P(\gamma')$. The Markov property implies that the conditional probability is equal to the probability of the walk γ in a new domain where the first part of the walk γ' has been removed, i. e., the identity

$$P(\gamma|\gamma') = P'(\gamma) \,, \quad \text{(Markov property)} \tag{12}$$

where the prime refers to the new domain. The Markov property is self-evident for random walk and follows directly from Eq. (11), i. e., $P(\gamma|\gamma') = P(\gamma\gamma')/P(\gamma') = \mu^{-(L+L')}/\mu^{-L'} = \mu^{-L} = P'(\gamma)$, where L and L' are the lengths of segments γ' and γ, respectively.

In the scaling limit the lattice distance goes to zero whereas the length of the walk diverges. Consequently, the distribution diverges and must be replaced by an appropriate probability measure [4,13,43]. However, in order to define the probability distribution or measure in the scaling limit we shall assume that the Markov property continues to hold and interpret the P in Eq. (12) as probability measures. The Markov property is essential in carrying over the lattice probability distributions in the scaling limit.

For the critical interfaces defined by an exploration processes in the case of site percolation, the Markov property follows by inspection since the propagation of the interface is entirely determined by the local process of occupying the next site with probability 1/2. This locality property is specific for percolation which has a geometrical phase transition and does in the SLE context, to be discussed later, determine the scaling universality class.

In the case of an interface in the Ising model the Markov property also holds, but since the spins interact a little calculation is required [13]. Consider an interface γ defined by an exploration process. According to the rules of statistical mechanics the probability distribution for the interface γ is given by

$$P(\gamma) = \frac{Z(\gamma)}{Z} \,. \tag{13}$$

Here Z is the full partition function defined in Eq. (8) with appropriate boundary conditions imposed. $Z(\gamma)$ is the partial partition function with the spins associated with the interface γ fixed,

$$Z(\gamma) = \sum_{\{\sigma_i\},\gamma} \exp[-H(\gamma)/kT] \,. \tag{14}$$

The Hamiltonian $H(\gamma)$ inferred from Eq. (6) is the energy of a spin configuration with the spins determining γ fixed; $\{\sigma_i\},\gamma$ indicate the configurations to be summed over. Evidently, we have the identity $Z = \sum_\gamma Z(\gamma)$, i. e., $\sum_\gamma P(\gamma) = 1$.

Whereas in the random walk case we only considered an individual path and in the percolation case the interface only feels the nearby sites, an Ising interface is imbedded in the interacting spin systems and we have to define the Markov property more precisely with respect to a domain D. Consider an interface across the domain D from A to B and assume that the last part γ is conditioned on the determination of the first part γ', i. e., given by the distribution $P_D(\gamma|\gamma')$. Next imagine that we cut the domain D along the interface γ', i. e., break the interaction bonds between the spins determining γ'. The right and left face of γ' can then be considered part of the domain boundary and the Markov property states that the distribution of γ in the cut domain $D \setminus \gamma'$ (i. e., D minus γ') equals $P_D(\gamma|\gamma')$,

$$P_D(\gamma|\gamma') = P_{D\setminus\gamma'}(\gamma) \,. \quad \text{(Markov property)} \tag{15}$$

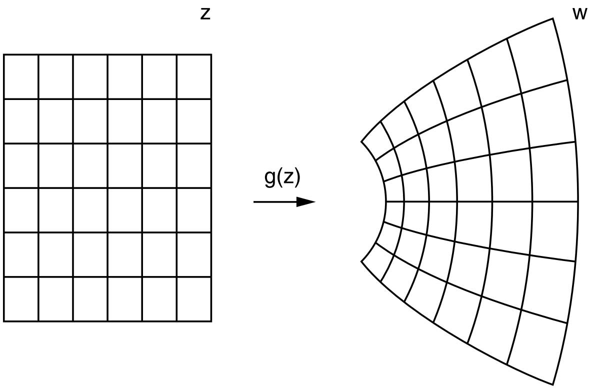
In order to demonstrate Eq. (15) we use the definition in Eq. (13). The conditional probability $P_D(\gamma|\gamma') = P_D(\gamma\gamma')/P_D(\gamma') = (Z_D(\gamma\gamma')/Z_D)/(Z_D(\gamma')/Z_D) = Z_D(\gamma\gamma')/Z_D(\gamma')$. Correspondingly, the distribution in the cut domain $D \setminus \gamma'$ is $P_{D\setminus\gamma'}(\gamma) = Z_{D\setminus\gamma'}(\gamma)/Z_{D\setminus\gamma'}$. However, it follows from the structure of the partition function in Eqs. (6–8) that $Z_{D\setminus\gamma'} = \exp[E(\gamma')/kT]Z_D(\gamma')$ and $Z_{D\setminus\gamma'}(\gamma) = \exp[E(\gamma')/kT]Z_D(\gamma\gamma')$, where $E(\gamma')$ is the energy of the broken bonds. By insertion the interface Boltzmann factors cancel out and we obtain Eq. (15) expressing the Markov property.

Conformal Invariance

In the complex plane analysis implies geometry. The representation of a complex number $z = x + iy$ directly associates complex function theory with 2D geometrical shapes. This connection is of importance in mathematical physics in for example 2D electrostatics and 2D hydrodynamics. In the context of SLE Riemann's mapping theorem plays an essential role [1].

Conformal Maps

Briefly, Riemann's mapping theorem [2] states that any simply connected domain, i. e., topologically deformable to a disk, in the complex plane z can be uniquely mapped to a unit disk $|w| < 1$ in the complex w plane by mean of a complex function $w = g(z)$. By combining complex functions we can map any simply connected domain to any other simply connected domain. For example, if $g_1(z)$ and $g_2(z)$ map domains D_1 and D_2 to the unit disk, respectively, then $g_2^{-1}(g_1(z))$ maps D_1 to D_2; here g_2^{-1} is the inverse function of g_2, i. e., $g_2^{-1}(g_2(z)) = z$. As an example, the transformation $g(z) = i(1 + z)/(1 - z)$ maps the the unit disk centered at the origin to the upper half plane. Likewise, the Möbius transformation $g(z) = (az + b)/(cz + d)$ determined by four real parameters, $ad - bc > 0$, maps the upper half plane onto itself. Conformal transformations are angle-preserving and basically correspond to a combination of a local rotation, local translation, and local dilatation. In terms of an elastic medium picture conformal transformations are equivalent to deformations without shear [54]. Expressing $g(z)$ in terms of its real and imaginary parts, $g(z) = u(x, y) + iv(x, y)$, the Cauchy–Riemann equations $\partial u/\partial x = \partial v/\partial y$ and $\partial u/\partial y = -\partial v/\partial x$ hold implying that u and v are harmonic functions satisfying Laplace's equations $\nabla^2 u = 0$ and $\nabla^2 v = 0$, $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$. In Fig. 3 we have depicted a conformal angle-preserving transformation effectuated by the complex function $g(z)$ from the complex z plane to the complex w plane.



Stochastic Loewner Evolution: Linking Universality, Criticality and Conformal Invariance in Complex Systems, Figure 3
We depict a conformal transformation from the complex z plane to the complex w plane. We note the angle-preserving property, i. e., a shear-free transformation. The map in the figure is given by $w = z^2$

Measures – Conformal Invariance

Whereas the Markov property discussed above holds for lattice curves even away from criticality, we here want to assume another property which only holds in the scaling limit at the critical point, namely conformal invariance. In the scaling limit we anticipate that the probability measure $P(\gamma)$ for an interface γ is invariant under a conformal transformation. More precisely, consider a lattice model, say the Ising or percolation model, and specify two domains D and D' on the lattice. Next, consider an interface, cluster boundary or domain wall γ from the boundary points A and B across the domain D. In terms of the partition functions the probability distribution for γ is given by Eq. (13). We now perform the scaling or continuum limit of the lattice model keeping the domains D and D' fixed. The continuous random interface approaches its scaling form and is characterized by the measure $P_D(\gamma)$. At the critical point we assume that the interface is scale invariant under the larger symmetry of conformal transformations. The next step is to consider a specific conformal transformation $g(z)$ which according to Riemann's theorem precisely maps domain D to domain D', i. e., $D' = g(D)$ and the interface to $g(\gamma)$. The assumption of conformal invariance then states that the probability measure P is invariant under this transformation expressing the scale invariance, i. e.,

$$P_D(\gamma) = P_{g(D)}(g(\gamma)) \, . \quad \text{(Conformal property)} \qquad (16)$$

Both the Markov property and the conformal property are sufficient in combination with Loewner evolution to determine the measures in the scaling limit.

Loewner Evolution

The original motivation of Loewner's work was to examine the so called Bieberbach conjecture which states that $|a_n| \leq n$ for the coefficients in the Taylor expansion $f(z) = \sum_{n=0} a_n z^z$, where $f(z)$ maps the unit disk to the complex plane. The conjecture was proposed in 1916 and finally proven in 1984 by de Branges [2,38,39]. For that purpose Loewner [64] considered growing parametrized conformal maps to a standard domain. In the present context Loewner's method allow us to access growing shapes in 2D in an indirect manner by means of a 'time dependent' conformal transformation $g_t(z)$.

Growing Stick

Before we address the derivation of the Loewner equation let us consider the specific conformal transformation

$$g_t(z) = \sqrt{z^2 + 4t} \, . \qquad (17)$$

For $t = 0$ we have $g_0(z) = z$, i. e., the identity map. Likewise, for $z \to \infty$ we obtain

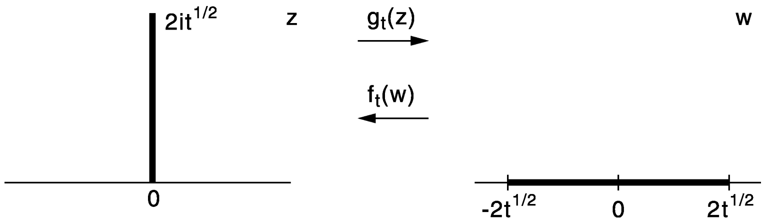
$$g_t(z) \sim z + \frac{2t}{z} \, , \qquad (18)$$

showing that far away in the complex plane we again have the identity map. The coefficient in the next leading term, C_t/z, is called the capacity C_t; here parametrized by the 'time variable', $t = C_t/2$. The map (17) has a branch point at $z = 2it^{1/2}$ and it follows by inspection that g_t maps the upper half plane minus a stick from the origin $\mathbf{0}$ to $2it^{1/2}$ back to the upper half plane. From the inverse map $f_t(w) = g_t^{-1}(w)$,

$$f_t(w) = \sqrt{w^2 - 4t} \, , \qquad (19)$$

we infer that the right face of the stick is mapped to the real axis from 0 to $2t^{1/2}$, the tip to the origin, and the left face to the interval $-2t^{1/2}$ to 0. Under the map the growing stick thus becomes part of the boundary in the w plane. The growing stick is depicted in Fig. 4.

The stick shows up as an imaginary contribution along the interval $-2t^{1/2}$ to $2t^{-1/2}$. More precisely, since $f_t(w)$ is analytic in the upper half plane, implementing the asymptotic behavior $f_t(w) \sim w$ for $w \to \infty$, and using Cauchy's



Stochastic Loewner Evolution: Linking Universality, Criticality and Conformal Invariance in Complex Systems, Figure 4

We depict the growing stick corresponding to the conformal transformation $w = \sqrt{z^2 + 4t}$. The vertical cut in the z plane extends from the origin to the point $(0, 2it^{1/2})$. The right and left faces of the cut are mapped to the real axis from $-2t^{1/2}$ to $+2t^{1/2}$, the endpoint to the origin, in the complex w plane

theorem, we obtain the dispersion relation or spectral representation

$$f_t(w) = w - \int \frac{\mathrm{d}\omega}{\pi} \frac{A_t(\omega)}{w-\omega} \,, \tag{20}$$

with spectral weight $A_t(\omega)$. In the case of the growing stick we find $A_t(\omega) = (4t - \omega^2)^{1/2}$ for $\omega^2 < 4t$ and otherwise $A_t(\omega) = 0$. Using $1/(\omega + i\epsilon) = \mathrm{P}\ 1/\omega - i\pi\delta(\omega)$ (P denotes principal value) we also have $\mathrm{Im} f_t(\omega) = A_t(\omega)$ and $\mathrm{Re} f_t(\omega) = \omega - \mathrm{P} \int (\mathrm{d}\omega'/\pi) A_t(\omega')/(\omega - \omega')$. The time dependent spectral weight $A_t(\omega)$ thus characterizes the growing stick. With the chosen parametrization we also have the sum rule

$$\int \frac{\mathrm{d}\omega}{\pi} A_t(\omega) = C_t = 2t \,. \tag{21}$$

Finally, we note that the map g_t satisfies the equation of motion

$$\frac{\mathrm{d}g_t(z)}{\mathrm{d}t} = \frac{2}{g_t(z)} \,, \tag{22}$$

i. e., solving Eq. (22) with the initial condition $g_0(z) = z$ and the boundary condition $g_t(z) \sim z$ for $z \to \infty$ we arrive at the map in Eq. (17).

Loewner Equation

The growing stick nicely illustrates the idea of accessing a growing shape indirectly by the application of Riemann's theorem mapping the domain adjacent to the shape to a standard reference domain, here the upper half plane. This so-called uniformizing map effectively absorbs the shape and encodes the information about the shape into the spectral weight $A_t(\omega)$ along the real axis.

Let us consider a general shape or hull $\mathbf{K_t}$ in the upper half plane $\mathbf{H}$. Together with the real axis the shape form part of the boundary of the domain $\mathbf{D}$. In other words, the domain in question is the upper half plane $\mathbf{H}$ with the shape $\mathbf{K_t}$ subtracted, $\mathbf{D} = \mathbf{H} \setminus \mathbf{K_t}$. Applying Riemann's theorem we map the simply connected domain $\mathbf{D}$ back to the upper half plane $\mathbf{H}$ by means of the conformal transformation $g_t(z)$, i. e., g_t absorbs the shape $\mathbf{K_t}$. Imagine that the shape grows a little bit further from $\mathbf{K_t}$ to $\mathbf{K}_{t+\delta t} = \mathbf{K_t} + \delta\mathbf{K_t}$, where $\mathbf{K_t}$ is now part of $\mathbf{K}_{t+\delta t}$; $\delta\mathbf{K_t}$ is the shape increment. Correspondingly, the map $g_{t+\delta t}$ is designed to absorb $\mathbf{K}_{t+\delta t}$, i. e., $\mathbf{H} \setminus \mathbf{K}_{t+\delta t} \to \mathbf{H}$ by means of the map $g_{t+\delta t}$. We now carry out the elimination in two ways. Either we absorb $\mathbf{K_t}$ by means of the map g_t and subsequently $\delta\mathbf{K_t}$ by means of the map δg_t or we absorb $\mathbf{K}_{t+\delta t}$ directly in one step by means of the map $g_{t+\delta t}$. Consequently, combining maps we have $g_{t+\delta t}(z) = \delta g_t(g_t(z))$ or $g_t(z) = \delta g_t^{-1}(g_{t+\delta t}(z))$. Since $\delta g_t^{-1}(w)$ is analytic in $\mathbf{H}$ we obtain the spectral representation

$$\delta g_t^{-1}(w) = w - \int \frac{\mathrm{d}\omega}{\pi} \frac{\delta A_t(\omega)}{w - \omega} \,, \tag{23}$$

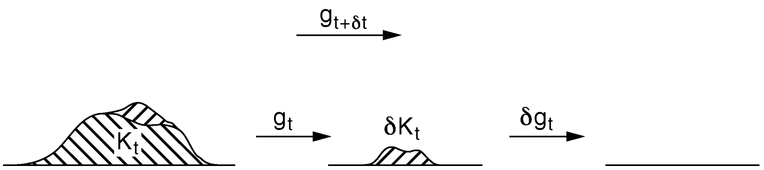
with infinitesimal spectral weight δA_t, or inserting $w = g_{t+\delta}(z)$

$$g_t(z) = g_{t+\delta t}(z) - \int \frac{\mathrm{d}\omega}{\pi} \frac{\delta A_t(\omega)}{g_{t+\delta t} - \omega} \,. \tag{24}$$

The last step is to set $\delta A_t(\omega) = \rho_t(\omega)\delta t$, yielding a differential equation for the evolution of the map g_t eliminating the shape $\mathbf{K_t}$,

$$\frac{\mathrm{d}g_t(z)}{\mathrm{d}t} = \int \frac{\mathrm{d}\omega}{\pi} \frac{\rho_t(\omega)}{g_t(z) - \omega} \,. \tag{25}$$

Specifying the weight or measure $\rho_t(\omega)$ along the real ω-axis this equation determines, through the uniformizing map g_t, how the shape $\mathbf{K_t}$ grows. The spectral weight encodes the 2D shape into the real function $\rho_t(\omega)$. Note that since $\rho_t(\omega)$ is not specified and can depend nonlinearly on the map, Eq. (25) still represent a highly nonlinear problem. Invoking the asymptotic condition $g_t(z) \sim z + C_t/z$, where C_t is the time dependent capacity we infer $\mathrm{d}C_t/\mathrm{d}t = \int (\mathrm{d}\omega/\pi)\rho_t(\omega)$ or since $\rho_t(\omega) = \mathrm{d}A_t(\omega)/\mathrm{d}t$ the sum rule in Eq. (21). The conformal mapping procedure is depicted in Fig. 5.



Stochastic Loewner Evolution: Linking Universality, Criticality and Conformal Invariance in Complex Systems, Figure 5

The combination of maps involved in the derivation of the Loewner equation. First the map g_t eliminates the hull K_t. Subject to the growth in the time interval δt the incremental hull δK_t is subsequently absorbed by the infinitesimal map δg_t. Correspondingly, the hull $K_{t+\delta t}$ is absorbed by the map $g_{t+\delta t}$ in one step

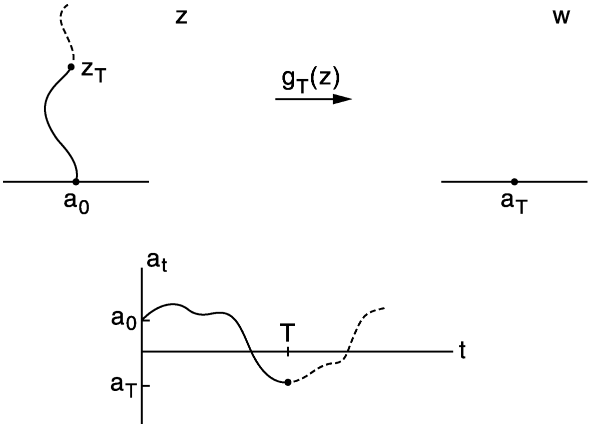
In the special case where the growth takes place at a point the equation simplifies considerably. Assuming that the spectral weight is concentrated at the point $\omega = a_t$, where a_t is a real function of t and setting $\rho_t(\omega) = 2\pi\delta(\omega - a_t)$ we arrive at the Loewner equation

$$\frac{\mathrm{d}g_t(z)}{\mathrm{d}t} = \frac{2}{g_t - a_t} . \tag{26}$$

The Loewner equation describes the growth of a curve or trace γ_t with endpoint z_t, $0 < t < \infty$, in the upper half complex z-plane. The time-dependent conformal transformation g_t maps the simply connected domain $\mathbf{H} \setminus \gamma_t$, i. e., the half plane excluding the curve γ_t back to the w half plane. At a given time instant t the tip of the curve z_t is determined by $g_t(z_t) = a_t$, i. e., the point where Eq. (26) develops a singularity. The topological properties and shape of the curve are encoded in the real function a_t which lives on the real axis in the w-plane. As a_t develops in time the tip of the curve z_t determined by $z_t = g_t^{-1}(a_t)$ traces out a curve. Since the domain $\mathbf{H} \setminus \gamma_\mathrm{t}$ must be simply connected for the Riemann theorem to apply the curve or trace cannot cross itself or cross the real axis. Whenever the curve touches or intersect itself or the real axis the enclosed part will be excluded from the domain. In other, words, during the time progression the curve effectively absorbs part of the upper half plane. It is a deep property of Loewner evolution that the topological properties of a 2D non-crossing curve are entirely encoded by the real function a_t. The encoding works both ways: A given 2D non-crossing curve γ_t corresponds to a specific real function a_t, a given real function a_t yields a specific 2D non-crossing curve γ_t. A continuous a_t will yield a continuous curve γ_t. A discontinuous a_t in general gives rise to branching. Whether or not the curve intersects or touches itself is determined by the singularity structure of the drive a_t. In the case where the Hölder condition $\lim_{\tau\to 0} |(a_{t+\tau} - a_\tau)/\tau^{1/2}|$ is greater that 4 we have self-intersection. Note again that since the curve is defined indirectly by the singularity structure in Eq. (26) we cannot easily identify a curve parametrization and for example determine a tangent vector, etc. The mechanism underlying the Loewner equation is shown in Fig. 6.

Exact Solutions

In a series of simple cases one can solve the Loewner equation analytically [42,44]. For vanishing drive $a_t = 0$ we obtain the growing vertical stick discussed above. Correspondingly, a constant drive $a_t = a$ yields a vertical stick growing up from the point a on the real axis.



Stochastic Loewner Evolution: Linking Universality, Criticality and Conformal Invariance in Complex Systems, Figure 6
The mechanism in the Loewner equation. The curve in the upper half complex z plane generated by the Loewner equation is mapped onto a finite but growing segment of the real axis of the complex w plane. The endpoint z_T is mapped to the real number a_T. As a_t develops in time and makes excursions along the real axis the endpoint z_t of the curve grows into the upper half plane

In the case of a linear drive $a_t = t$ the tip of the curve z_t is given by $z_t = 2 - 2\phi_t \cos\phi_t + 2i\phi_t$, where the phase ϕ_t is determined from the equations: $2\ln r_t - r_t \cos\phi_t = 2\ln 2 + t - 2$ and $r_t = 2\phi_t/\sin\phi_t$. By inspection $\phi_0 = 0$ and $\phi_\infty = \pi$. The curve thus approaches the asymptote $2\pi i$ for $t \to \infty$. For small t analysis yields $z_t \sim (2/3)t + 2i\sqrt{t}$, i. e., the trace approaches the origin with infinite slope. The square root drives $a_t = 2\sqrt{\kappa t}$ and $a_t = 2\sqrt{\kappa(1-t)}$, $0 < t < 1$ with a finite-time singularity can also be treated. In the first case, $a_t = 2\sqrt{\kappa t}$, the trace is a straight line $z_t = B\exp(i\phi)\sqrt{t}$ forming the angle ϕ with respect to the real axis. The amplitude B and phase ϕ depend on the parameter κ. The angle $\phi = (\pi/2)(1 - \kappa^{1/2}/(\kappa+4)^{1/2})$. For $\kappa = 0$, $\phi = \pi/2$ and we recover the perpendicular stick; for $\kappa \to \infty$, $\phi \to 0$ and the angle of intersection decreases to zero. In the second case, $a_t = 2\sqrt{\kappa(1-t)}$, the behavior of the trace is more complex. For $0 < \kappa < 4$ the trace forms a finite spiral in the upper half plane; for $\kappa = 4$ the trace has a glancing intersection with the real axis. For $4 < \kappa < \infty$ the trace hits the real axis in accordance with the Hölder condition discussed above.

Stochastic Loewner Evolution

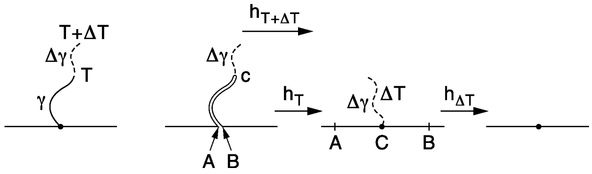
After these preliminaries we are in position to address stochastic Loewner evolution (SLE). The essential observation made by Oded Schramm [77] within the context of loop erased random walk was that the Markov and conformal properties of the measures or probability distributions for random curves generated by Loewner evolution imply that the random drive a_t must be proportional to an unbiased 1D Brownian motion.

Schramm's Theorem

The Loewner Equation (26) generates a non-crossing curve in the upper half plane $\mathbf{H}$ originating at the origin $\mathbf{O}$, given a continuous function a_t with initial value $a_0 = 0$. As a_t develops in time the tip of the curve z_t determined by the condition $g_t(z_t) = a_t$ traces out a curve or trace. In the case where a_t is a continuous random function the Loewner Equation (26) likewise becomes a stochastic equation of motion yielding a stochastic map $g_t(z)$. As a result the trace determined by $g_t(z_t) = a_t$ or $z_t = g_t^{-1}(a_t)$ is a random curve. The issue is to establish a contact between the exploration processes defining interfaces in the lattice models, the scaling limit of these curves, and the curves generated by SLE. In the scaling limit we thus invoke the two properties discussed above: i) the Markov property in Eq. (12) and ii) the conformal property in Eq. (16).

In order to demonstrate the surprising property that the Markov and conformal properties in combination imply that a_t must be a 1D Brownian motion we focus on chordal SLE which applies to a random curve or trace connecting two boundary points. Since the probability distribution or measure $P(\gamma)$ on the random curve γ using property ii) is assumed to be conformally invariant and since we by Riemann's theorem can map any simply connected domain to the upper half plane by mean of a conformal transformation, we are free to consider curves in the upper half plane from the origin $\mathbf{O}$ to ∞ parametrized with a time coordinate $0 < t < \infty$.

Imagine that we grow the curve from time $t = 0$ to time T driven by the function a_t, $0 < t < T$. The curve or trace is generated by the Loewner Equation (26) with boundary condition $a_0 = 0$ and the trace z_t by $g_t(z_t) = a_t$ or $z_t = g_t^{-1}(a_t)$. With the chosen time parametrization we have $g_t(z) \sim z + 2t/z$ for $z \to \infty$ in the upper half plane. The map g_t thus uniformizes the trace, i. e., the tip z_t is mapped to a_t on the real axis in the w-plane. In order to invoke the Markov property we let the curve grow the time increment ΔT corresponding to the curve segment $\Delta\gamma$. The Markov property then implies that the distribution on $\Delta\gamma$ conditioned on the distribution on γ is the same as the distribution on $\Delta\gamma$ in the cut domain $\mathbf{H} \setminus \gamma$, i. e., the domain with the curve γ deleted; this stage is illustrated in Fig. 7.



Stochastic Loewner Evolution: Linking Universality, Criticality and Conformal Invariance in Complex Systems, Figure 7
The figure depicts the construction in the derivation of SLE. The first step implements the Markov property by turning the curve γ into a cut. Subsequently, the conformal transformation h_T maps γ back to the origin. Finally, the map $h_{\Delta T}$ maps the segment $\Delta\gamma$ to the origin. The complete process is also implemented by $h_{T+\Delta T}$. The combination of the Markov property and conformal invariance implies that a_t performs a Brownian motion

Next, in order to implement the conformal property we shift the image by a_T in such a way that the curve segment $\Delta\gamma$ again starts at the origin $\mathbf{O}$. This is achieved by using the map $h_T = g_T - a_T$ which since $g_T(z_T) = a_T$ maps the tip z_T back to the origin; this construction is also depicted in Fig. 7. Moreover, the asymptotic behavior of h_T for large z is $h_T(z) \sim z - a_T - 2T/z$. Since the measure by assumption is unchanged under the conformal transformation h_T we infer that $\Delta\gamma$ growing the time ΔT from the origin has the same distribution as the segment $\Delta\gamma$ grown from time T to time $T + \Delta T$ conditioned on the segment γ grown up to time T. Moreover, since the segment γ from $\mathbf{O}(AB)$ to C subject to the Markov property has become part of the boundary, as shown in Fig. 7, we also infer that the measure on $\Delta\gamma$ is independent of the measure on γ. Finally, applying $h_{\Delta T}$ we map the segment $\Delta\gamma$ to the origin as a common reference point as indicated in Fig. 7.

Since the random curves are determined by the random maps g_t and h_t driven by the random function a_t the issue is how to transfer the properties of the measure on the curve determined by the Markov and conformal properties to the measure on the random driving function a_t.

In order to combine the Markov properties arising from the analysis of the lattice models and the conformal invariance pertaining to critical random curves, we carry out the following steps. First we grow the curve γ from the origin $\mathbf{O}$ to the tip z_T. Implying conformal invariance the curve is then uniformized back to the origin by means of h_T. The next step is to grow the curve segment $\Delta\gamma$ in time ΔT. This segment is subsequently absorbed by means of the map $h_{\Delta T}$. According to the Markov property the distribution of $\Delta\gamma$ from $\mathbf{O}$ to $z_{\Delta T}$ is the same as the distribution of $\Delta\gamma$ grown from T to $T + \Delta T$ conditioned on γ grown from 0 to T. Since the curve γ is determined by the map h_t the distribution is reflected in h_t. In particular, the stochastic properties of the curve is transferred to the random function a_t generating the curve by the Loewner evolution. The last step is now to observe that absorbing the segment $\Delta\gamma$ from **O** to $z_{\Delta T}$ by means of $h_{\Delta T}$ is the same transformation as first applying the inverse map h_T^{-1} followed by the map $h_{T+\Delta T}$; in both cases the end result is the absorption of the initial curve $\gamma + \Delta\gamma$, see Fig. 7. As regards the measure or distribution we have the equivalence $h_{\Delta T}(z) \approx h_{T+\Delta T}(h_T^{-1}(z))$. Using the asymptotic form $h_t(z) \sim z - a_t - 2t/z$ we obtain $a_{T+\Delta T} - a_T \approx a_{\Delta T}$; note that $\approx$ indicates identical distributions or measures.

In conclusion, the Markov property in combination with conformal invariance implies that $a_{T+\Delta T} - a_T$ is distributed like $a_{\Delta T}$ (stationarity) and that $a_{\Delta T}$ and $a_{\Delta T'}$ are independently distributed for non-overlapping time intervals ΔT and $\Delta T'$ (Markov property). Referring to Sect. "Scaling", A on Brownian motion as expressed in Eqs. (3) and (4), i. e., stationarity and independence, we infer that a_t is proportional to a Brownian motion of arbitrary strength κ, i. e., $a_t = \sqrt{\kappa} B_t$. Note that the reflection symmetry $x \to -x$ holding in the present context rules out a bias or drift in the 1D Brownian motion [13,27].

This is the basic conclusion reached by Schramm in the context of loop erased random walk. Driving Loewner evolution by means of 1D Brownian motion with different diffusion coefficient or strength κ we generate a one-parameter family of conformally invariant or scale invariant non-crossing random curves in the plane.

SLE Properties

Stochastic Loewner evolution is determined by the nonlinear stochastic equation of motion

$$\frac{\mathrm{d}g_t}{\mathrm{d}t} = \frac{2}{g_t - a_t} , \quad a_t = \sqrt{\kappa} B_t . \tag{27}$$

In the course of time a_t performs a 1D Brownian motion on the real axis starting at the origin $a_0 = 0$. a_t is a random continuous function of t and distributed according to $\sqrt{\kappa} B_t$. More precisely, a_t is given by the Gaussian distribution

$$P(a, t) = (2\pi t)^{-1/2} \exp[-a^2/2\kappa t] , \tag{28}$$

with correlations

$$\left\langle (a_t - a_s)^2 \right\rangle = \kappa |t - s| . \tag{29}$$

First we notice that a constant shift of the drive a_t, $a_t \to a_t + b$, is readily absorbed by a corresponding shift of the map, $g_t \to g_t + b$. Moreover, using the scaling property of Brownian motion, $B_{\lambda^2 t} = \lambda B_t$, following from e. g. Eq. (5), we have $a_{\lambda^2 t} = \lambda a_t$ and we conclude from Eq. (27) that $g_t(z)$ has the same distribution as $(1/\lambda) g_{\lambda^2 t}(\lambda z)$, i. e., $g_{\gamma^2 t}(\gamma z) \approx \gamma g_t(z)$. Note that this dilation invariance is consistent since the origin $z = 0$ and $z = \infty$, the endpoints of curves, are preserved. Note also that the strength of the drive κ is an essential parameter which cannot be scaled away.

Curves – Hulls – Bessel Process

For vanishing drive, $\kappa = 0$, the SLE yields a non random vertical line from $z = 0$, i. e., the growing stick discussed in Subsect. "Growing Stick". As we increase κ the curve becomes random with excursions to the right and to the left in the upper half plane. Up to a critical value of κ the random curve is simple; i. e., non-touching or non self-intersecting. At a critical value of κ the Brownian drive is so strong that the curve begins to intersect itself and the real axis. These intersection take place on all scales since the curve is self-similar or scale invariant. Denoting the curve by γ_t we observe that since Riemann's theorem uniformizing $\mathbf{H} \setminus \gamma_t$ to $\mathbf{H}$ only applies to a simply connected domain, the regions enclosed by the self-intersections do not become uniformized but are effectively removed from $\mathbf{H}$. The curve γ_t together with the enclosed parts is called the hull $\mathbf{K_t}$ and the mapping theorem applies to $\mathbf{H} \setminus \mathbf{K_t}$.

In order to analyze the critical value of κ we consider the stochastic equation for $h_t(z) = g_t(z) - a_t$. From Eq. (27) it follows that

$$\frac{\mathrm{d}h_t}{\mathrm{d}t} = \frac{2}{h_t} + \xi_t , \tag{30}$$

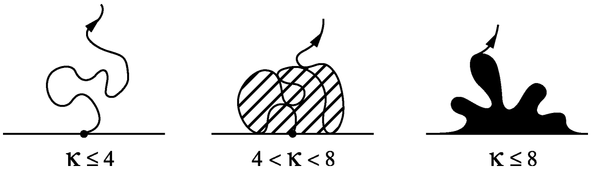
where $\xi_t = -\mathrm{d}a_t/\mathrm{d}t$ is white noise with correlations $\langle \xi_t \xi_s \rangle = \kappa\delta(t - s)$.

The nonlinear complex Langevin Equation (30) maps the tip of the curve z_t back to the origin. Likewise $\mathbf{H} \setminus \gamma_t$ is mapped onto $\mathbf{H}$. A point x on the real axis is mapped to $x_t = h_t(x)$ where x_t satisfies

$$\frac{\mathrm{d}x_t}{\mathrm{d}t} = \frac{2}{x_t} + \xi_t . \tag{31}$$

The Langevin Equation (31) is known as the Bessel equation and governs the radial distance R from the origin of a Brownian particle in d dimensions.

Introducing $R = (\sum_{i=1}^d B_i^2)^{1/2}$ where B_i, $i = 1, \dots d$, is a 1D Brownian motion with distribution $P(B, t) = (2\pi\kappa t)^{-1/2} \exp[-B^2/2\kappa t]$, we find $P(R, t) \propto (2\pi\kappa t)^{-d}$



Stochastic Loewner Evolution: Linking Universality, Criticality and Conformal Invariance in Complex Systems, Figure 8
The figures depict the phases of SLE. For $\kappa \leq 4$ the SLE trace is a simple non-intersecting scale invariant random curve from the origin to infinity with a fractal dimension between 1 and 3/2. For $4 < \kappa \leq 8$ the SLE curve is self-intersecting on all scales and also intersects the real axis on all scales. The curve together with the enclosed regions, the hull, eventually exhausts the upper half plane. The scale invariant hull has a fractal dimension ranging between 3/2 and 2. For $\kappa \geq 8$ the fractal dimension of the hull locks onto 2 and the scale invariant hull is dense and plane-filling

$R^{d-1}\exp[-R^2/2\kappa t]$ satisfying the Fokker–Planck equation $\partial P/\partial t = (\kappa/2)\partial^2 P/\partial R^2 - (\kappa(d-1)/2)\partial(P/R)/\partial R$, corresponding to the Langevin equation

$$\frac{\mathrm{d}R}{\mathrm{d}t} = \kappa\frac{d-1}{2R} + \xi_t\,. \tag{32}$$

For $d \leq 2$ Brownian motion is recurrent, i. e., the particle returns to the origin $R = 0$, for $d > 2$ the particle goes off to infinity. Referring to Eq. (31) and setting $\kappa(d-1)/2 = 2$ we obtain $\kappa = 4/(d-1)$, i. e., $R \to \infty$ for $\kappa < 4$ and $R \to 0$ for $\kappa > 4$.

Since the tip of the curve z_t is mapped to a_t, i. e., $h(z_t) = 0$, the case $x_t \to \infty$ for $\kappa < 4$ corresponds to a curve never intersecting the real axis, i. e., the curve is simple. For $\kappa > 4$ we have $x_t \to 0$ corresponding to the case where the tip z_t intersects the real axis forming a hull. Since the curve is self-similar the intersections takes place on all scales and eventually the whole upper half plane is engulfed by the hull.

The marginal value $\kappa = 4$ can also be inferred from a simple heuristic argument [27]. For small κ we can ignore the noise in Eq. (31)and the particle is repelled according to the solution $x_t^2 \sim 4t$. For large noise we ignore the nonlinear term and the noise can drive x_t to zero; we have $x_t^2 \sim \kappa t$. The balance is obtained for $\kappa = 4$.

In conclusion, for $\kappa \leq 4$ the curve is simple, for $\kappa > 4$ the curve intersects itself and the real axis infinitely many times on all scales, eventually the hull swallows the whole plane. For large κ the trace turns out to be plane-filling. The two cases $\kappa \leq 4$ and $\kappa > 4$ are depicted in Fig. 8.

Fractal Dimension

The SLE random curves are fractal. An important issue is thus the determination of the fractal dimension D in terms of the Brownian strength or SLE parameter κ. It has been shown that [15,16,74]

$$D = 1 + \frac{\kappa}{8} \quad \text{for } 0 \leq \kappa \leq 8\,, \tag{33}$$

for $\kappa \geq 8$ the fractal dimension locks onto 2 and the SLE curve is plane-filling.

In order to illustrate a typical SLE calculation we follow Cardy [27] in a heuristic derivation of Eq. (33). In order to evaluate D and in accordance with its definition [32,68] the standard procedure is to cover the object with disks of size ε and follow how the number of disks $N(\epsilon)$ of size ε scales with ε for small ε, i. e., $N(\epsilon) \propto \epsilon^{-D}$. However, since the SLE curve is random the argument has to be rephrased. Alternatively, we consider a disc of size ε located at a fixed position z and ask for the probability $P(z,\epsilon)$ that the SLE curve crosses the disk. The number of disks covering an area A is $N_A = A/\epsilon^2$, i. e., $P \propto \epsilon^{-D}/N_A$, and we infer $P(z,\epsilon) \propto \epsilon^{2-D}$, where D is the fractal dimension. Incorporating the Markov property we subject the curve to an infinitesimal conformal transformation, $h_{\delta t} = g_{\delta t} - a_{\delta t}$, transforming the point z to $w = g_{\delta t}(z) - a_{\delta t}$; moreover, all lengths are scaled by $|h'_{\delta t}(z)|$ [1]. Setting $z = x + iy$ and $w = x' + iy'$ we obtain expanding Eq. (30) $x' + iy' = 2\delta t/(x+iy) - \sqrt{\kappa}\delta B_t$ or $x' = x + 2x\delta t/(x^2+y^2) - \sqrt{\kappa}\delta B_t$, $y' = y - 2y\delta t/(x^2+y^2)$, $\epsilon' = (1 - |h_{\delta t}(z)|)\epsilon$, and $|h_{\delta t}| = 2(x^2-y^2)/(x^2+y^2)^2$. By conformal invariance the probability measure $P(x,y,\epsilon)$ is unchanged and we infer

$$P(x,y,\epsilon) = \langle P(x',y',\epsilon')\rangle_{\delta B}\,, \tag{34}$$

where we have averaged over the Brownian motion referring to the initial part of the curve which has been eliminated by the map $h_{\delta t}$. Expanding Eq. (34) to first order in δt and noting that $\langle(\delta B_t)^2\rangle = \delta t$ we arrive at a partial differential equation for $P(x,y,\epsilon)$

$$\left(\frac{2x}{x^2+y^2}\frac{\partial}{\partial x} - \frac{2y}{x^2+y^2}\frac{\partial}{\partial y} + \frac{\kappa}{2}\frac{\partial^2}{\partial x^2} - \frac{2(x^2-y^2)}{(x^2+y^2)^2}\epsilon\frac{\partial}{\partial\epsilon}\right)P = 0\,. \tag{35}$$

Since $P(x,y,\epsilon) \propto \epsilon^{2-D}$ we have $\epsilon\partial P/\partial\epsilon = (2-D)P$ and the determination of D is reduced to an eigenvalue problem. By inspection one finds

$$P \propto \epsilon^{1-\kappa/8} y^{(\kappa-8)^2/8\kappa}(x^2+y^2)^{(\kappa-8)/2\kappa}\,, \tag{36}$$

and we identify the fractal dimension $D = 1 + \kappa/8$ for $\kappa < 8$; for $\kappa > 8$ another solution yields $D = 2$.

Results and Discussion

Stochastic Loewner evolution based on Eq. (27) generates conformally invariant non-crossing random curves in the upper half plane starting at the origin and going off to infinity. This is the case of chordal SLE, where the random curve connects two boundary points (the origin **O** and infinity ∞). Another case is radial SLE for random curves connecting a boundary point and an interior point in a simply connected domain [13,27,43]. Radial SLE is governed by another stochastic equation and will not be discussed here.

Phase Transitions – Locality – Restriction – Duality

Phase Transitions SLE exhibits two phase transitions; for $\kappa = 4$ and $\kappa = 8$. For $0 < \kappa \leq 4$ the random curve is non-intersecting, i. e., a simple random continuous curve from **O** to ∞. For $4 < \kappa \leq 8$ the curve is self-intersecting on all scales. The curve together with the excluded regions form a hull which in the course of time absorbs the upper half plane. For κ just above 4 the half plane is eventually absorbed but the trace does not visit all regions, i. e., the hull is not dense. As we approach $\kappa = 8$ the trace becomes more dense and the hull becomes plane-filling. This is also reflected in the fractal dimension $D = 1 + \kappa/8$. For $\kappa > 8$ the hull is plane-filling, i. e., $D = 2$. As we increase the strength of the Brownian drive further the excursions of the trace to the right and left in the upper half plane become more pronounced and the hull becomes vertically compressed. These results have been obtained by Rohde and Schramm [74] and Lawler et al. [57]. The various phases of SLE are depicted in Fig. 8. In Fig. 9 we have depicted numerical renderings of SLE traces for various values of κ (with permission from V. Beffara, http://www.umpa.ens-lyon.fr/~vbeffara/simu.php).

Locality – Restriction In addition to the phase transitions at $\kappa = 4$ and $\kappa = 8$, there are special values of κ where SLE shows a behavior characteristic of the scaling limit of specific lattice models: The locality property for $\kappa = 6$ and the restriction property for $\kappa = 8/3$. The issue here is the influence of the boundary on the SLE trace.

To illustrate the locality property, consider for example the SLE trace originating at the origin and purporting to describe the scaling limit of a domain wall in the lattice model. Due to the long range correlations at the critical point it is intuitively clear that a deformation of the boundary, e. g., a bulge **L** on the real axis to the right of the origin, will influence the trace and push it to the left. A detailed analysis show that only for $\kappa = 6$ is the trace independent of a change of the boundary, i. e., the trace does not feel the boundary until it encounters a boundary point [59,63]. Returning to the lattice models the locality property for $\kappa = 6$ applies specifically to the percolation case where the interface generated by the exploration process is governed by a local rule and the model has a geometric phase transition.

The restriction property is less obvious to visualize but basically states that the distribution of traces conditioned not to hit a bulge **L** on the real axis away from the origin is the same as the distribution of traces in the domain where **L** is part of the boundary, i. e., in the domain $\mathbf{H} \setminus \mathbf{L}$. Analysis shows that the restriction property only applies in the case for $\kappa = 8/3$. Among the lattice models only the scaling limit of self-avoiding random walk (SAW), where the measure is uniform, conforms to the restriction property and thus corresponds to $\kappa = 8/3$ [63].

Duality For $\kappa > 4$ the SLE generates a hull of fractal dimension $D > 3/2$. The boundary, external perimeter, or frontier of the hull is again a simple conformally invariant random curve characterized by the fractal dimension $\bar{D}$. Using methods from 2D quantum gravity Duplantier [31] has proposed the relationship,

$$(D-1)(\bar{D}-1) = \tfrac{1}{4}\,, \tag{37}$$

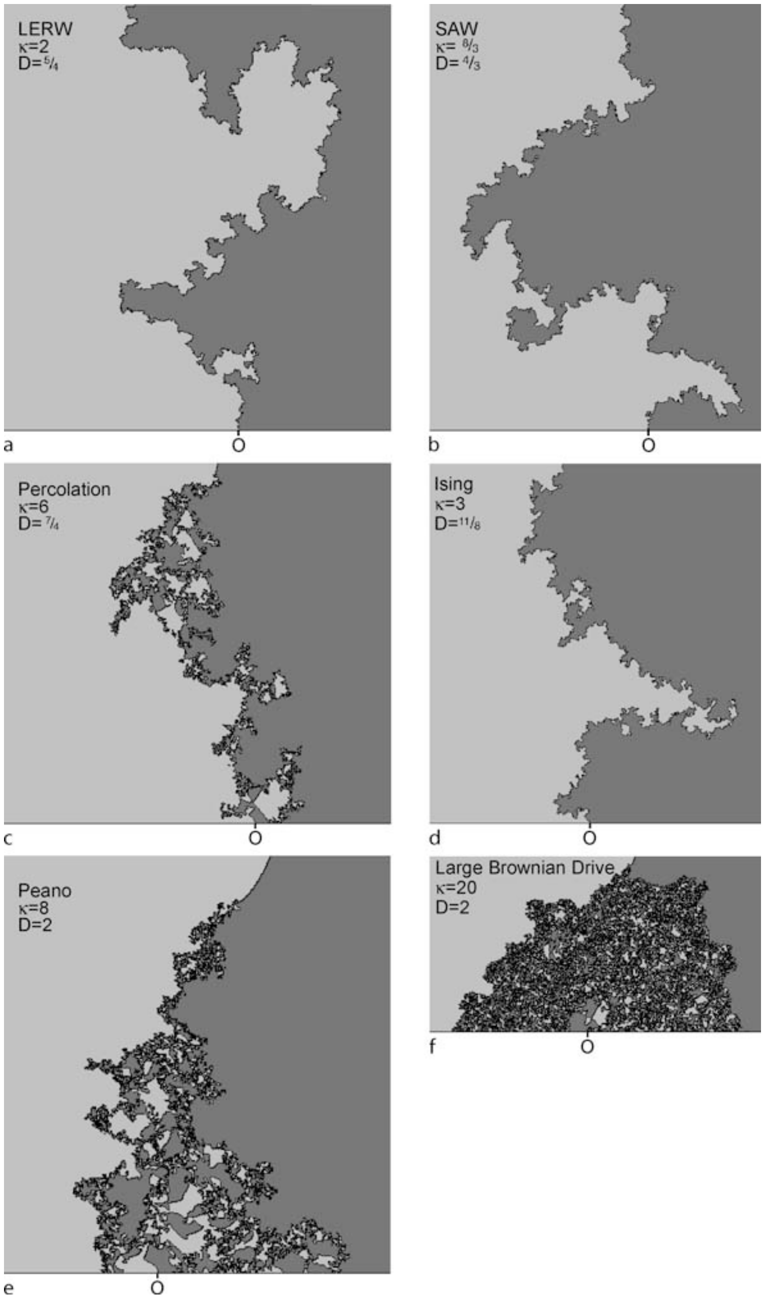
between the fractal dimension of the hull and its frontier. This result has been proved by Beffara for $\kappa = 6$, i. e., the percolation case [16]. Inserting in Eq. (33) we obtain for the corresponding SLE parameter the duality relation

$$\kappa\bar{\kappa} = 16\,. \tag{38}$$

Loop Erased Random Walk (LERW)

Whereas the scaling limit of random walk, i. e., Brownian motion, does not fall in the SLE category because of self-crossings rendering Riemann's mapping theorem inapplicable, variations of Brownian motion are described by SLE.

Loop erased random walk (LERW) where loops are removed along the way is by construction self-avoiding and was introduced as a simple model of a self-avoiding random walk. LERW was studied by Schramm in his pioneering work [77]. LERW has the Markov property and has been proved to be conformally invariant in the scaling limit and described by SLE for $\kappa = 2$ [57]. According to Eq. (33) LERW has the fractal dimension $D = 5/4$ [67]. Also, since $\kappa < 4$ LERW is non-intersecting. A simulation of LERW based on SLE is shown in Fig. 9a.



Stochastic Loewner Evolution: Linking Universality, Criticality and Conformal Invariance in Complex Systems, Figure 9
We depict a numerical rendering of SLE for a variety of κ values. In a we show loop erased random walk (LERW) for $\kappa = 2$ with fractal dimension $D = 5/4$. In b we illustrate the case of self-avoiding random walk (SAW) for $\kappa = 8/3$ and fractal dimension $D = 4/3$; both LERW and SAW have $\kappa > 4$ and are simple scale invariant random curves. In c we depict site percolation for $\kappa = 6$ with fractal dimension $D = 7/4$. Since $\kappa > 4$ the percolation case is self-intersecting and duality implies that the boundary or frontier of the hull is described by a SLE curve for $\kappa = 16/6 = 8/3$, i. e., the case of SAW. In d we show the Ising case for $\kappa = 3$ and fractal dimension $D = 11/8$. In e we depict the limiting case $\kappa = 8$ and fractal dimension $D = 2$. The hull is dense and plane-filling. The frontier of the hull corresponds to the SLE case $\kappa = 16/8 = 2$, i. e., the case of LERW. The so-called uniform spanning tree (UST) has the same properties as LERW and the SLE case for $\kappa = 8$ can thus be thought of as a random plane filling Peano curve wrapping around the UST. Finally, in f we show the SLE trace and hull for $\kappa = 20$ and $D = 2$. Because of the large Brownian excursions the plane-filling hull is vertically compressed (with permission from V. Beffara: http://www.umpa.ens-lyon.fr/~vbeffara/simu.php)

Self-Avoiding Random Walk (SAW)

Self-avoiding random walk (SAW) is a random walk conditioned not to cross itself. SAW has been used to model polymers in a dilute solution and has a uniform probability measure. Since SAW satisfies the restriction property it is conjectured in the scaling limit to fall in the SLE class with $\kappa = 8/3$ [46,47,48,61], yielding the fractal dimension $D = 4/3$. We note that Flory's mean field theory [30] for the size R of a polymer composed of N links (monomers) scales like $R \sim N^{\nu}$, where $\nu = 3/(2+d)$ for $d \leq 4$. By a box covering we infer $N \sim R^{D}$ where D is the fractal dimension, i. e., $D = (2+d)/3$. In $d = 2$ we obtain $D = 4/3$ in accordance with the SLE result. SLE induced SAW in the scaling limit is shown in Fig. 9b.

Percolation

The scaling limit of site percolation was conjectured by Schramm [77] to fall in the SLE class for $\kappa = 6$. Subsequently, the scaling limit of site percolation on a triangular lattice has been proved by Smirnov [78,80]. Percolation exhibits a geometrical phase transition. In the exploration process defining a critical interface the rule for propagation is entirely local. The lack of stiffness as for example in the Ising case to be discussed below results in a strongly meandering path winding back and in the scaling limit intersecting earlier part of the path. Since $\kappa > 4$ the path together with the enclosed part, i. e., the hull, eliminates the whole plane in the course of time. As discussed above the locality property is specific to percolation and yields $\kappa = 6$. The fractal dimension of the percolation interface is according to Eq. (33) $D = 7/4$. We note that D is close to 2, i. e., the percolation interface nearly covers the plane densely. A series of new results and a proof of Cardy's conjectured formula for the crossing probability have appeared; we refer to [13,27,43] for details. Using the duality relation (38) the frontier of the percolation hull is a simple SLE curve for $\kappa = 8/3$, corresponding to SAW. In Fig. 9c we have depicted a SLE generated percolation interface.

Ising Model – $O(n)$ Models

The Ising model in Eq. (6) is a special case of the $O(n)$ model defined by the Hamiltonian

$$H = -J \sum_{\langle ij \rangle} \vec{\sigma}_i \vec{\sigma}_j \,, \tag{39}$$

where $\vec{\sigma}_i = (\sigma_1, \ldots \sigma_n)$ is an n-component unit vector associated with the site i. For $n = 1$ we recover the Ising model, $n = 2$ is the XY-model [29], and $n = 3$ the Heisenberg model.

By means of the Fortuin–Kasteleyn (FK) transformation based on a high temperature expansion the configurations of the $O(n)$ model can be described by clusters or graphs on a dual lattice [35]. The crossing domain wall in Fig. 1 is thus a special case of a FK graph if we interpret the representation as a triangular Ising model. It has been conjectured that n is related to the SLE parameter κ by

$$n = -2\cos(4\pi/\kappa) \quad \text{for } 8/3 \leq \kappa \leq 4\,. \tag{40}$$

In the Ising case $n = 1$ and we have $\kappa = 3$ yielding the fractal dimension $D = 11/8$ for the Ising domain wall [84]. Since $\kappa < 4$ the Ising domain wall is non-intersecting. Unlike the percolation case, the Ising interface is stiffer due to the interaction. We also note that the scaling limit of spin cluster boundaries in the Ising model recently has been proved to correspond to SLE for $\kappa = 3$ [79]. The interface is shown in Fig. 9d.

SLE – Conformal Field Theory

Whereas conformal field theory (CFT) is based on the concept of a local field $\phi(r)$ and its correlations and therefore only accesses the underlying geometry indirectly through field correlations, SLE directly produces conformally invariant geometrical objects. A major issue is therefore the connection between CFT and SLE [6,7,26]. In CFT the central charge c plays an important role in delimiting the universality classes of the variety of lattice models yielding conformal field theories in the scaling limit. Percolation thus corresponds to the central charge $c = 0$, whereas the Ising model is associated with the central charge $c = 1/2$. It has been conjectured that the connection between the SLE parameter κ and the central charge c is given by

$$c = \frac{(6-\kappa)(3\kappa-8)}{2\kappa} = 1 - 6\frac{(\kappa-4)^2}{4\kappa}\,. \tag{41}$$

We note that $c < 1$ and, moreover, invariant under the duality transformation $\kappa \to 16/\kappa$.

SLE – 2D Turbulence

There is an interesting application of SLE ideas in the context of 2D turbulence. The issue here is to analyze conformal invariance by comparing the statistical properties of geometrical shapes like domain walls with SLE traces with the view of determining the SLE parameter κ and the corresponding universality class.

In 3D turbulence is governed by the incompressible Navies–Stokes equation for the velocity field. Since the viscosity is only effective at small length scales 3D turbulence is characterized by a cascade of kinetic energy $(1/2)v^2$ from large scales (driving scale) to small scales (dissipation scale). In the inertial regime the energy spectrum $E(k)$ (k is the wavenumber) is characterized by the celebrated Kolmogorov 5/3 law [46], $E(k) \propto k^{-5/3}$, indicating an underlying scale invariance in turbulence.

In 2D the cascade picture is different. Since both kinetic energy and squared vorticity (enstrophy) are conserved in the absence of dissipation and forcing, two cascades coexist [52,53]. A direct cascade to small scales for the squared vorticity $\omega^2 = (\nabla \times v)^2$ with scaling exponent -3 and an inverse cascade to larger scales for the kinetic energy $(1/2)v^2$ with Kolmogoroff scaling exponent $-5/3$. The system is thus characterized by a fine scale vorticity structure together with a large scale velocity structure. Moreover, we can assume that the vorticity structure is equipartitioned, i.e, in equilibrium.

In order to investigate whether the scale invariance of the small scale vorticity structure can be extended to conformal invariance Bernard et al. [17] have considered the statistics of the boundaries of vorticity clusters. By comparing the zero-vorticity isolines with SLE traces they find that cluster boundaries fall in the universality class corresponding to $\kappa = 6$, i. e., the case of percolation. Since 2D turbulence is a driven nonequilibrium system, this observation is very intriguing in particular since the correlations between vortices are long-ranged. A similar analysis [19] of the isolines in the inverse cascade in surface quasi-geostrophic turbulence corresponds to $\kappa = 4$, i. e., from Eq. (40) the domain walls in the equilibrium XY model for $n = 2$. For comments on the application of SLE in turbulence we refer to Cardy [28].

SLE – 2D Spin Glass

It is a standing issue whether conformal field theory can be applied to disordered systems, in particular systems with quenched disorder. In recent work Amoruso et al. [3] and Bernard et al. [18] have considered zero temperature domain walls in the Ising spin glass [34]; see also [33]. The Ising spin glass is an equilibrium system with quenched disorder. The system is described by the Hamiltonian $H = -\sum_{\langle ij\rangle} J_{ij}\sigma_i\sigma_j$, where the random exchange constants J_{ij} are picked from a Gaussian distribution with zero mean. The glass transition is at $T = 0$ and the system has a two-fold degenerate ground state. Inducing a scale invariant domain wall between the two ground states and comparing with an SLE trace, it is found that both the Markov and conformal properties are obeyed and that the universality class corresponds to $\kappa \approx 2.3$.

Further Remarks

In this discussion we have left out several topics which have played an important role in the development and applications of SLE. We mention some of them below.

There is an interesting connection between LERW and the so-called uniform spanning tree (UST) [13,43,57,77]. A spanning tree is a collection of vertices and edges which form a tree, i. e., without loops or cycles. A uniform spanning tree is a random spanning tree picked among all possible spanning trees with equal probability. Consider the unique path between two vertices on a UST. Since the path lives on a tree it is by construction non-crossing and it turns out that it has the same distribution as LERW. The winding random curve enclosing the UST can be visualized as a random plane-filling Peano curve. In the scaling limit the Peano curve is described by SLE for $\kappa = 8$ with fractal dimension $D = 2$.

The q-state Potts model [87] constitutes a generalization of the Ising model; here the lattice variable takes q values. The model is defined by the Hamiltonian $H = -J\sum_{\langle ij\rangle} \delta_{\sigma_i\sigma_j}$, where $\sigma_i = 1, \ldots q$; the Ising model obtains for $q = 2$. Applying the high temperature FK representation the configurations can be represented by loops and domain walls. From considerations involving the fractal dimension [76] it has been conjectured that domain walls in the scaling limit of the Potts model fall in the SLE category for $q = 2 + 2\cos(8\pi/\kappa)$, where $4 \leq \kappa \leq 8$. For $q = 2$ we recover the Ising case for $\kappa = 3$. In the limit $q \to 0$, the graph representation is equivalent to the uniform spanning tree described by SLE for $\kappa = 8$. For a numerical study of the three-state Potts model and its relation to SLE consult [36].

Standard SLE is driven by 1D Brownian motion producing a fractal curve. Ruskin et al. [75] have considered the case of adding a stable Lévy process with shape parameter α to the Brownian motion. Backing their analysis with numerics they find that the SLE trace branches and exhibit a 'phase transitions' related to self-intersections.

2D Brownian motion, the scaling limit of 2D random walk, is an incredibly complex fractal coil owing to the self-crossings on all scales. Although 2D Brownian motion because of self-crossing itself falls outside the SLE scheme, the outer frontier or perimeter of 2D random walk is a non-crossing and non-intersecting fractal curve which can be accessed by SLE. Verifying an earlier conjecture by Mandelbrot [68] it has been proven using SLE techniques [58] that the fractal dimension of the Brownian perimeter is $D = 4/3$, i.e, the same as the fractal dimension of self-avoiding random walk and the external perimeter of the percolation hull. Other characteristics of Brownian motion such as intersection exponents have also been obtained [59,60,62]; see also [66].

In recent work Zoia et al. [88] have considered the distribution of first passage times and distances along critical curves generated by SLE for different values of κ.

Future Directions

Stochastic Loewner evolution represents a major step in our understanding of fractal shapes in the 2D continuum limit. By combining the Markov property (stationarity) with conformal invariance SLE provides a minimal scheme for the generation of a one-parameter family of fractal curves. The SLE scheme also provides calculational tools which have led to a host of new results. SLE is a developing field and we can on the mathematical front anticipate progress and proofs of some yet unproved scaling limits, e. g., the scaling limit of the FK representation of the Potts model and the scaling limit of SAW.

On the more physical front many issues also remain open. First there is the fundamental issue of the connection between the hugely successful but non-rigorous CFT and SLE. Here progress is already under way. In a series of papers Bauer and Bernard [6,7,8,9,10,12] have shown how SLE results can be derived using CFT methods. Cardy [26] have considered a multiple SLE process and the connection to Dyson's Brownian process and random matrix theory. The analysis of the CFT–SLE connection still remains to be investigated further.

An obvious limitation of SLE is that it only addresses critical domain walls and not the full configuration of clusters and loops in for example the FK representation of the Potts model. In the case of critical percolation this problem has been addressed by Camia and Newman [21]. Another issue is how to provide SLE insight into spin correlations in the Potts or $O(n)$ models.

In the original formulation of SLE the Markov and conformal properties essentially requires a Brownian drive. It is clearly of interest to investigate the properties of random curves generated by other random drives. Such a program has been initiated by Ruskin et al. [75] who considered adding a Lévy drive to the Brownian drive; see also work by Kennedy [49,50].

Since the SLE trace lives in the infinite upper half plane the whole issue of finite size effects remain open. In ordinary critical phenomena the concept of a Kadanoff block construction and the diverging correlation length near the transition lead to a theory of finite size scaling and corrections to scaling which can be accessed numerically. It is an open problem how to develop a similar scheme for SLE.

In statistical physics it is customary and natural to associate a free energy to a domain wall and an interaction energy associated with several domain walls. These free energy considerations are entirely absent in the SLE framework which is based on conformal transformations. A major issue is thus: Where is the free energy in all this and how do we reintroduce and make use of ordinary physical considerations and estimates [69].

Article Outline

Glossary

Brownian dynamics A level of detail in which each molecule is represented by a point-like particle and molecules move in response to diffusion and collisions

Chemical Fokker–Planck equation (CFPE) Master equation for well-mixed systems that corresponds to the chemical Langevin equation

Chemical master equation (CME) Master equation for the probability that the system has specific integer copy numbers for each type of chemical species; it is exact for a well-mixed system

Chemical Langevin equation (CLE) Approximate stochastic differential equation for well-mixed systems which is based on continuous Gaussian statistics

Direct method An implementation of the Gillespie algorithm

Extrinsic noise In genetic noise studies, expression fluctuations of a gene that arise from upstream genes or global fluctuations

First-reaction method An implementation of the Gillespie algorithm

Gillespie algorithm Exact algorithm for simulating individual trajectories of the CME

Hybrid algorithms Algorithms that are designed to efficiently simulate systems that have multiple timescales

Individual-based spatial models Models that track individual molecules as they diffuse or react

Intrinsic noise Expression fluctuations of a gene that arise from that particular gene

Jump process A process in which the system abruptly changes from one state to another

Optimized direct method A computationally efficient implementation of the Gillespie algorithm

Population-based spatial models Models that track how many molecules of each chemical species are in various spatial compartments

Reaction channel A possible reaction between specified reactant and product chemical species (the terminology distinguishes this meaning from an individual reaction event between single molecules)

Reaction-diffusion equation Deterministic partial differential equation that combines mass action reaction kinetics and normal chemical diffusion

Reaction-diffusion master equation (RDME) Chemical master equation that accounts for diffusion as well as reactions

Reaction rate equation (RRE) Deterministic ordinary differential equation for the net production rate of each chemical species from chemical reactions

Spatial chemical Langevin equation Chemical Langevin equation that accounts for diffusion as well as reactions

Stochastic simulation algorithm (SSA) Alternative term for the Gillespie algorithm

Stoichiometric matrix (ν) Matrix that gives the net production of each chemical species, for each chemical reaction

Tau-leaping method Approximate simulation method for well-mixed systems in which molecule numbers are updated using discrete Poisson statistics

Well-mixed hypothesis Assumption that mixing processes occur faster than the relevant reaction processes

Definition of the Subject

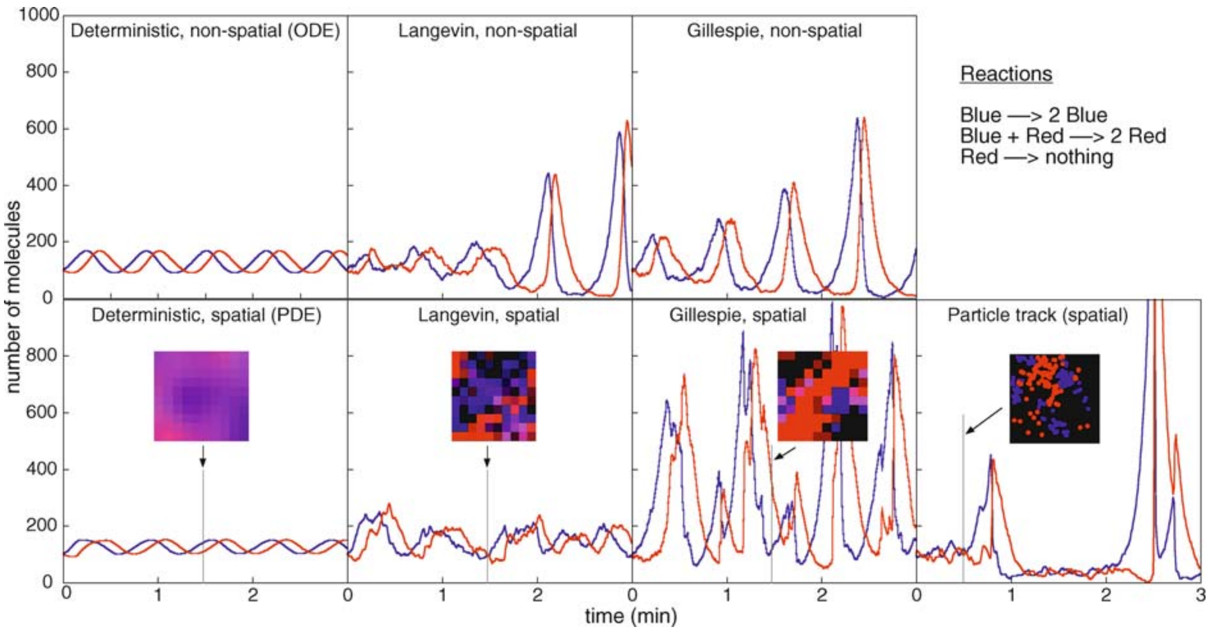
Many processes in cell biology, such as those that carry out metabolism, the cell cycle, and various types of signaling, are comprised of biochemical reaction networks. It has proven useful to study these networks using computer simulations because they allow us to quantitatively investigate hypotheses about the networks. Deterministic simulations are sufficient to predict average behaviors at the population level, but they cannot address questions about noise, random switching between stable states of the system, or the behaviors of systems with very few molecules of key species. These topics are investigated with stochastic simulations. In this article, we review the dominant types of stochastic simulation methods that are used to investigate biochemical reaction networks, as well as some of the results that have been found with them. As new biological experiments continue to reveal more detail about biological systems, and as computers continue to become more powerful, researchers will increasingly turn to simulation methods that can address stochastic and spatial details.

Introduction

Random events are ubiquitous throughout biology. Diffusion, chemical reactions, gene expression, homologous recombination, and most other fundamental biological processes are governed to a large extent by the inherently discrete and stochastic interactions of molecules [1]. In many cases, the random events that occur on very small length and time scales become averaged out when one focuses on larger length or time scales. However, there also exist many examples in which stochastic fluctuations at small scales propagate up to and then influence the system behavior at large scales. Examples range from the swimming trajectories of individual bacteria all the way up to the genetic diversity on which evolution depends.

Research on stochasticity in biochemical systems has received a great deal of attention lately, leading to many recent reviews [2,3,4,5,6,7,8,9]. One reason for its popularity is that the basic designs of many biochemical systems, such as metabolism, cell division, and chemotaxis, are becoming reasonably well understood. Starting from this understanding, researchers are delving deeper to examine the quantitative behaviors of these systems, including the roles of stochastic influences. Also, there is an increasing awareness of the importance of stochasticity in biological systems. For example, it has become clear that noisy gene expression is the rule rather than the exception [9]; this leads to important questions about non-genetic individuality and about biological robustness to gene expression noise. Thirdly, stochasticity is often investigated using computationally demanding simulations. Cheaper and faster computers, as well as improved simulation algorithms, are making it feasible for researchers to investigate more complex biochemical systems, at increasingly realistic levels of detail. Finally, and perhaps most importantly, the last ten years have witnessed incredible progress in experimental biochemical methods, some of which allow direct measurements of stochasticity on microscopic size scales. These methods include gene expression measurements [10,11], flow cytometry [12,13,14,15,16], single molecule detection methods [17,18,19,20], and applications of synthetic biology [21].

At the most fundamental level, the quantum mechanics that describe the dynamics of all physical systems are well-understood and completely deterministic [22]. It is



Stochastic Models of Biological Processes, Figure 1

Simulation results for a simple chemical oscillator using different simulation methods. The Lotka–Volterra system is shown, which shares key features with cellular oscillators such as circadian rhythms. *Insets* show the spatial distributions of molecules at the indicated times. In the *top panels*, note that stochasticity allows the system to drift to large amplitude oscillations and that the Langevin and Gillespie methods yield similar results. In the *bottom panels*, all of which were started with nearly homogeneous initial states, differences arise from the approximations: the PDE simulation has predictable oscillations due to the minimal stochasticity (which is only in the initial state); the Gillespie simulation has larger peaks than the Langevin one because it only allows integer numbers of molecules in each bin; and the particle tracking simulation shows larger and fewer bursts than does the Gillespie simulation because it accurately treats diffusion at all length scales (this difference was reduced with a spatial Gillespie simulation that used smaller subvolumes). Parameters: rate constants are 10 min^{-1}, 8000 nm^3 molec^{-1} min^{-1}, and 10 min^{-1}, for the respective reactions shown in the *top-right corner*, systems start with 100 of each *blue* and *red* molecules, their diffusion coefficients are 100 nm^2 min^{-1}, the volume is 100 nm high and wide by 10 nm deep, and the first three spatial simulations divide this volume into cubic subvolumes that are 10 nm on a side. This figure is reproduced from [8]

only when systems are observed that there arises unavoidable randomness, although these aspects of quantum mechanics remain murky and as close to philosophy as science. More importantly, essentially any system that is governed by nonlinear dynamics, including nearly all physical systems, rapidly becomes chaotic as the system size is increased beyond a few molecules, and thus becomes effectively unpredictable [23]. For all intents and purposes, the diffusive trajectories of individual molecules, and the probabilities of chemical reactions occurring between neighboring reactants at specific times, are fundamentally stochastic.

In the laboratory, partly by design, this stochasticity usually averages out. For systems comprised of many particles, diffusion is observed to be described well by Fick's law of diffusion and chemical reaction kinetics are described well by the deterministic reaction rate equations [24]. The situation is often different within biological cells for several reasons: (i) the program for cellular behavior, the genome, is present at low copy number and yet each gene governs the expression of possibly thousands of proteins, (ii) the low copy numbers of many proteins and mRNA transcripts within cells make random variation of their numbers a relatively large fraction of the total, (iii) stochasticity is often amplified during sequential biochemical steps, of which an especially important case is the sequence of DNA transcription followed by mRNA translation, and (iv) because of spatial organization within cells, it often takes very few proteins in specific locations to achieve large effects on the entire cell dynamics.

This review provides a broad account of stochastic modeling of biological processes. The emphasis is placed on stochastic processes at the cellular level although much of the work presented here also applies to other scales and systems. Our goal is to briefly familiarize the reader with the mathematical forms of the most important equations, the tools for analyzing and simulating them, and some applications for which they have been particularly successful. As shown below, the mathematics, the software implementation, and even the applications of modeling methods are often closely linked.

There are several ways to categorize stochastic biochemical modeling methods. A key designation is whether a method is spatial or non-spatial: spatial models treat spatial organization of proteins and membranes explicitly, whereas non-spatial models include an implicit assumption that mixing processes occur faster than the relevant reaction processes, which is called the *well-mixed hypothesis*. No single modeling method can efficiently capture stochastic dynamics over wide ranges of time scales, so separate methods have been developed that operate at levels of temporal detail that range from nanoseconds to hours. Hybrid simulators combine methods that operate at different timescales to allow the efficient simulation of systems that include both fast and slow processes. Whereas many modeling methods are designed solely to address the reactions in a biochemical reaction network, others also consider system boundaries, mechanics, or the multiple states that proteins can be in. Here, we present non-spatial modeling methods first, followed by spatial methods, with diversions along the way to touch on as many of the other topics as possible. Simulation results from many of the methods that are discussed are compared in Fig. 1, where it is seen that the differences can be quite significant.

Non-Spatial Stochastic Modeling

Deterministic Modeling and Notation

Before focusing on stochastic modeling, it is helpful to introduce the notation and some terminology by summarizing a few aspects of deterministic modeling. As applied to chemical reaction networks, deterministic modeling is based upon ordinary differential equations (ODEs) for the individual chemical reactions. Consider the generic elementary reversible reaction

$$A + B \underset{k_\mathrm{r}}{\overset{k_\mathrm{f}}{\rightleftharpoons}} C\,, \tag{1}$$

where k_f and k_r are the forward and reverse reaction rates, respectively. We assume that the system is kept well-mixed so that diffusion effects can be ignored. The reaction rate equations for components A, B, and C are the ODEs

$$\frac{\mathrm{d}[A]}{\mathrm{d}t} = \frac{\mathrm{d}[B]}{\mathrm{d}t} = -k_\mathrm{f}[A][B] + k_\mathrm{r}[C]\,, \tag{2a}$$

$$\frac{\mathrm{d}[C]}{\mathrm{d}t} = k_\mathrm{f}[A][B] - k_\mathrm{r}[C]\,. \tag{2b}$$

More complex reaction networks are expressed analogously, with one equation for each chemical species and with terms in the equations that represent chemical reactions. From these equations, the reactions can be simulated to show how the concentrations change over time. Or, after setting the left sides of the equations to zero, they can be solved to yield the steady-state chemical concentrations. One can also investigate the dynamic or steady-state behaviors as the reaction rate parameters (k_f and k_r), or initial concentrations, are varied [25]; this can yield phase diagrams for the reactions and additional insight.

It is helpful to generalize the rate equations given above to make them more convenient for computational or analytical work and to show their forms more clearly. First, each chemical concentration is replaced by the variable $Z_i(t)$, where i is an index for A, B, or C and the time-dependence is written out explicitly. Next, the product terms in the equations are replaced by the functions $\tilde{a}_\mathrm{f}(\mathbf{Z}(t))$ and $\tilde{a}_\mathrm{r}(\mathbf{Z}(t))$ for the forward and reverse reactions, respectively; the tildes indicate that molecule quantities are given as concentrations rather than as molecule numbers. These functions are called the *reaction propensities*. Finally, the '+' or '–' signs show the reaction stoichiometry. They are replaced by $\nu_{\mathrm{f}i}$ and $\nu_{\mathrm{r}i}$ for the forward and reverse reactions, respectively, which are elements of the so-called *stoichiometric matrix* (throughout this review, we follow Gillespie's notation [6]). In this example, one unit of each A and B are lost in a unit amount of forward reaction ($\nu_{\mathrm{f}A} = \nu_{\mathrm{f}B} = -1$) as one unit of C is formed ($\nu_{\mathrm{f}C} = 1$); the $\nu_{\mathrm{r}i}$ values have the opposite signs. With these substitutions, the rate equations become

$$\frac{\mathrm{d}Z_i(t)}{\mathrm{d}t} = \nu_{\mathrm{f}i}\,\tilde{a}_\mathrm{f}(\mathbf{Z}(t)) + \nu_{\mathrm{r}i}\,\tilde{a}_\mathrm{r}(\mathbf{Z}(t))\,, \tag{3a}$$

$$\tilde{a}_\mathrm{f}(\mathbf{Z}(t)) = k_\mathrm{f} Z_A Z_B\,, \tag{3b}$$

$$\tilde{a}_\mathrm{r}(\mathbf{Z}(t)) = k_\mathrm{r} Z_C\,. \tag{3c}$$

These equations are trivially extended to arbitrarily large reaction networks. Consider a system with N chemical species that can react via M different *reaction channels* (a "reaction channel" is simply unambiguous terminology for a reaction between specific reactant and product chemical species). The dynamics of this system are given with the *reaction rate equation* (RRE):

$$\frac{\mathrm{d}Z_i(t)}{\mathrm{d}t} = \sum_{j=1}^{M} \nu_{ji}\,\tilde{a}_j(\mathbf{Z}(t))\,. \tag{4}$$

The reaction propensity equations are typically the products of reaction rate constants and the appropriate chemical concentrations, as shown above (Eq. (3b) and (3c)), but they may also describe non-elementary processes such as Michaelis–Menten kinetics. It is worth noting that the state of the system, at any point in time, is fully expressed with the vector $\mathbf{Z}(t)$. This means that the entire trajectory of the system can be deterministically calculated from the RRE and any single $\mathbf{Z}(t)$ snapshot.

The RRE is at the heart of many branches of quantitative biochemistry and systems biology. A great deal of metabolic theory is based on either the steady-state solutions of the RRE, or the set of steady-state solutions that are possible, given only knowledge of the stoichiometric matrix [26,27,28,29]. Studies of biochemical oscillations [25], including the cell cycle [30,31], circadian rhythms [32,33], and certain spatial patterns [34,35] are usually based on the dynamics of the deterministic RRE. Research on biochemical switches, as are found in prion diseases [36], developmental processes [37], and some protein kinase cascades [38], often focuses on the multiple steady-state solutions of the RRE [39]. Deterministic modeling has been, and still is, the conventional modeling method for most biological systems.

The Chemical Master Equation

Although the RRE is tremendously useful, it cannot address the stochastic processes that are inherent to biochemical systems. This is because the RRE arises from a series of approximations to a more physically rigorous stochastic model of chemical reactions [40,41].

As above, we assume that diffusive processes are much faster than reactive ones [8], which allows us to ignore spatial organization (this assumption is usually valid for genetic and metabolic networks, but often invalid for signaling networks). Nevertheless, the stochasticity of diffusion plays an essential role because it makes the precise timing of individual reactions effectively random. These reactions occur in abrupt transitions, in which reactants are converted effectively instantaneously into products, making this a type of *jump process*. Also, random diffusion causes the system to rapidly lose any memory of its prior states, and thus of the sequence of reactions that led up to the current state. This independence of the system dynamics on its history, called the Markov property, implies that the probability that a specific reaction occurs depends only on the state of the system at that time [41].

Because of the random reaction timing, reactant concentrations do not follow the deterministic trajectory that is predicted by the RRE. Instead, many concentration trajectories are possible, of which a single effectively random one actually occurs. There are two primary ways to investigate the possible trajectories with computational methods. One can simultaneously track the probability of every possible outcome or one can simulate many independent stochastic trajectories and then analyze them as one would with several repetitions of an experiment. These methods are described in this and subsequent sections, respectively.

To mathematically track the probability that the system is in each possible state, it is helpful to first replace the vector of chemical concentrations that was introduced earlier, $\mathbf{Z}(t)$, with a vector of integer-valued molecule numbers, $\mathbf{X}(t)$. These are related to each other, within round-off error, through the volume of the system, which is given as Ω,

$$\mathbf{X}(t) \simeq \Omega \mathbf{Z}(t) \,. \tag{5}$$

The state of the stochastic system is fully captured by $\mathbf{X}(t)$. The probability that the system is in state $\mathbf{x}$ at time t, given that it started in state $\mathbf{x}_0$ at time t_0, is written as $P(\mathbf{x}, t \mid \mathbf{x}_0, t_0)$. This probability changes over time because chemical reactions can transfer the system either into this state from other ones, or out of this state and into others. These possible transitions are combined to yield the *chemical master equation* (CME) [6,42]:

$$\frac{\partial P(\mathbf{x}, t \mid \mathbf{x}_0, t_0)}{\partial t} = \sum_{j=1}^{M} \Big[a_j(\mathbf{x} - \underline{\boldsymbol{\nu}}_j)\, P(\mathbf{x} - \boldsymbol{\nu}_j, t \mid \mathbf{x}_0, t_0) - a_j(\mathbf{x})\, P(\mathbf{x}, t \mid \mathbf{x}_0, t_0) \Big] \,. \tag{6}$$

The sum is over the reaction channels that can occur in the system. The two terms within brackets give the rate at which the probability of being in state $\mathbf{x}$ increases or decreases over time because of reactions into or out of state $\mathbf{x}$, respectively. These are proportional to the reaction propensities for the respective reactions. They are also proportional to the probability that the system was in the starting state, because the system can only leave a state if it was there in the first place.

The reaction propensity $a_j(\mathbf{x})$, given here without a tilde because it is for molecule numbers rather than concentrations, is a probability density: $a_j(\mathbf{x})\mathrm{d}t$ is the probability that exactly one reaction of type j will occur in a system in state $\mathbf{x}$ within the next $\mathrm{d}t$ amount of time. This microscopic propensity function is as central to stochastic chemical kinetics as its macroscopic analog is to the reaction rate equation. However, the microscopic propensity rests on a solid microphysical basis, and has in fact been shown to have an exact solution for a well-stirred thermally-equilibrated gas-phase system [43]. For such a system, the propensity function is

$$a_j = h_j c_j \,, \tag{7}$$

where h_j is the number of distinct combinations of individual reactants for reaction j and c_j is the probability density for one of those reactions to occur. That is, $c_j(t)\mathrm{d}t$ is the probability that a randomly selected set of reactants for reaction j will collide and react in the next infinitesimal time interval dt. For a variety of reaction mechanisms, the c_j values can be calculated quite accurately from only the physical properties of the system [43].

The primary approximation made for the CME is that the reactive system is well-mixed. This implies both that there is no spatial organization and that there are no significant correlations between successive reactions (the Markov property). Examples of correlated reactions include metabolite channeling, which is the transfer of a metabolite from one enzyme to the next before it has a chance to equilibrate into the cytoplasm [44], and geminate recombinations, which are multiple bindings between molecules that bind reversibly [45]. The well-mixed statement also encompasses the assumption that the system is isothermal, which is typically the case in biological systems.

Because the CME becomes computationally intractable with any but the simplest systems, some recent work has focused on efficient solution methods. An algorithm called the finite state projection method accomplishes this by projecting a matrix form of the CME onto a smaller space [46,47]. By choosing the size of the projection space, the accuracy can be adapted to any level of precision. Less formal methods for state-space reduction of the CME have been proposed as well [48]. Another method uses a sparse grid, which can work efficiently for up to 10 proteins [49]. Work has also gone into separations of the CME into fast and slow components, as described in the section on hybrid methods [42,50,51].

Applications of the Chemical Master Equation

The solution of the CME suffers from the so-called "curse of dimensionality" as the size of the state space, and hence the number of equations, increases exponentially with the number of chemical species involved. Except for very small and simple systems, it is extremely difficult to obtain solutions of the CME, either analytically or numerically. However, a few papers do report quite interesting results from direct simulations of the CME.

The master equation was used to investigate the dynamics of transiently denatured segments of double stranded DNA [52]. The authors derived the dynamics, formation rates, and lifetimes of these "bubbles", which can be compared to fluorescence correlation microscopy experiments of fluorescently tagged base pairs [53]. In another use of the CME, studies on molecular motors [54,55] demonstrate how the load-velocity curve, including rectified motion, arises from nucleotide triphosphate binding free energies. These works more fully investigate ideas on thermal ratchets that were presented previously [56]. A particularly intriguing study on the copy number control system for bacterial plasmids [57] showed that stochasticity in a regulatory portion of a system can actually decrease the stochasticity elsewhere in the system. This "stochastic-focusing" changes the behaviors of gradual-response systems towards those of threshold systems [58,59] in a manner that is analogous to the oscillation enhancement that stochastic resonance can create in oscillating systems [60]. These results contradict the widely held belief that an increase in stochasticity in one portion of a system will necessarily increase the stochasticity everywhere downstream of it. Studies of simple signal transduction motifs have shown how the predictions of the RRE can be qualitatively wrong compared to the CME treatment in that the stochastic systems might be bistable or oscillate when the deterministic system has one stable state [40,61]. Many of these studies that used the CME also used other theoretical techniques as well, which allow fruitful comparisons between the methods.

The Gillespie Algorithm

Because of the challenges in working with the CME, it is most often investigated using a Monte Carlo approach in which individual sample trajectories are simulated. These simulations can be exact or approximate. In this context, "exact" means that if the simulation were run many times, the distribution of simulated trajectories would agree exactly with that which would be predicted by an analytical solution, were it obtainable, of the chemical master equation. Exactness implies nothing about the validity of the CME or about the limitations of the computational accuracy (such as round-off errors and imperfect pseudo-random number generators), but only that no further approximations are made beyond those that are assumed by the CME.

In 1976, Gillespie introduced an exact algorithm for simulating the CME [6,62,63] which is called the *stochastic simulation algorithm* (SSA) in his papers, but is better known as the *Gillespie algorithm*. This algorithm cycles through three portions: (i) generate the time step until the next reaction, (ii) determine which reaction that will be, and (iii) execute the reaction by advancing the time and molecule counts to reflect it. The Gillespie algorithm was introduced with two varieties, called the *direct method* and the *first-reaction method*. In the former, the time step to the next reaction, τ, and the reaction number, j, are chosen from the following probability distributions:

$$P(\tau) = a\mathrm{e}^{-a\tau}\,, \tag{8a}$$

$$P(j) = \frac{a_j(\mathbf{X})}{a}\,. \tag{8b}$$

The variable a represents the summed reaction propensity,

$$a \equiv \sum_j a_j(\mathbf{X})\,. \tag{8c}$$

In the first-reaction method, a time step, τ_j, is generated for each possible reaction channel. Again, these are exponentially distributed random numbers,

$$\tau_j = a_j(\mathbf{X})\,\mathrm{e}^{-a_j(\mathbf{X})\tau}\,. \tag{9}$$

The smallest of these time steps is chosen as the next simulation time step, while its subscript dictates the reaction channel that is executed at that time. The direct method is usually preferred because it is a little easier to program and runs slightly faster with a simple implementation. However, the latter has been favored as a basis for improvements on computational efficiency.

The exactness of the Gillespie algorithm comes at the cost of its being computationally demanding. Even if one simulation can be performed reasonably quickly, such as in a few minutes, this can still be too slow to investigate the behaviors of hundreds of mutant cells or to explore different regions of parameter space. Thus, much effort has been devoted to improving the efficiency of the Gillespie algorithm, while still maintaining exactness. These methods are all based upon either the direct method or the first-reaction method, but are carefully designed, usually with priority queues or other indexing methods, so that internal variables are recalculated as infrequently as possible [6,64,65,66,67]. Of these, it appears that the *optimized direct method* is probably best for most practical problems [66]. Because the faster methods are significantly more difficult to program than the original ones, both sets of methods are still commonly used.

The computational intensity of the Gillespie algorithm, even with more efficient implementations, makes it difficult to perform sensitivity analyzes. In these analyzes, one investigates the extent to which the results depend upon input parameters, which can helpful for determining which parameters need additional experimental investigation or which are particularly important for system control. An algorithm for stochastic sensitivity analysis was recently developed and applied to biochemical reaction networks [68]. It involves the addition of just two steps to the basic loop of the Gillespie algorithm.

Another difficulty of the Gillespie algorithm, which also applies to simulations of the RRE and other algorithms presented below, is called *combinatorial explosion*. Suppose a scaffold protein has several sites with which it can bind other proteins, and suppose that each of those proteins can bind to none, one, or two phosphate groups (this is the situation for the Ste5 protein in the yeast pheromone response pathway [69]). There are clearly a tremendous number of possible binding states that the scaffold protein can be in, each of which has to be treated as a separate chemical species. Just listing all of these states is tedious, and simulating their reaction dynamics with the Gillespie algorithm is very slow. One solution is to not list every possibility when the simulation starts, but to create states when they are needed and to destroy them when they are no longer required [65]. Another option is to use an algorithm that is implemented in a program called StochSim [70,71]. Unlike the Gillespie algorithm, this one does not stochastically choose reactions to execute, but it instead chooses reactant pairs from the pool of existing molecules. A probabilistic scheme is used to determine if these reactants should be made to react with each other.

What if the system volume changes as a function of time? This might seem like an unusual concern, but it occurs during cell growth (and cell division) and it affects the reaction propensities. The necessary modifications to the Gillespie algorithm were recently derived, which are likely to be particularly useful for relatively slow processes, such as protein production from infrequently expressed genes [72].

Applications of the Gillespie Algorithm

Models based on the Gillespie algorithm have provided critical insights into the stochastic nature of gene expression [3,73,74]. In particular, fluctuations in the rates of gene transcription are amplified at the translation stage to yield highly erratic time patterns of protein production [75]. When multiple regulatory proteins act together, or compete with each other, this randomness is amplified further because of the random sequence of protein bursts [75]. These effects were shown to stochastically switch a model of phage-λ between the bistable lysis and lysogeny states [76], with results that are consistent with experimental ones. Stochastic gene expression is also used by many pathogenic organisms to randomly switch their surface features so they can evade host responses [77], may be used by the HIV virus to stochastically delay viral expression long enough for transformation of its activated T-cell host to a memory cell and thereby trap HIV as a latent phage [16], can establish asymmetries that determine cell differentiation [78], and can cause circadian clocks to lose synchrony [21,79]. In fluctuating environments, stochastic gene expression can permit an isogenic bacterial population to grow faster than it would if all individuals were phenotypically homogeneous [77,80,81].

From combined modeling and experimental approaches, the dominant noise sources in the stochastic expression of a specific gene are: (i) the expression fluctuations of that particular gene, which is called the *intrinsic noise*, (ii) noise that is transmitted to it from upstream genes, and (iii) global noise that affects all genes. The latter two sources are often combined and called *extrinsic noise*, which is the total noise source that is extrinsic to that specific gene [12,74,82,83,84]. Noise arises at both the transcription and translation stages, for which the relative importance depends on the strength of the promoter and on whether prokaryotic or eukaryotic transcriptional machinery is used [14,15,75,85,86]. Direct measurements of gene expression have generally confirmed the predictions made by stochastic simulations [11,12,13,15,17,18,21,87].

Gene expression appears to be unavoidably stochastic, and this randomness is usually amplified at each stage, so how does biology function reliably amidst all the noise? This is a central topic of many papers on biological robustness [5,9,88,89,90,91], several of which use the Gillespie algorithm or other types of stochastic modeling. One answer is that many reaction network structures are inherently less susceptible to noise than others. These include ones in which the reaction rates do not depend on the number of mRNA transcripts [92], certain scale-free reaction networks [93], and networks that are designed to function near saturation [94] (analogous to binary logic). Secondly, there are several mechanisms for biological robustness to noise, including negative feedback, integral feedback [95], checkpoints, and redundancy [9]. Because gene expression noise is usually detrimental to biological function, it has been suggested that there is active selection for robustness mechanisms [96,97].

Approximate Stochastic Methods

Because every reaction is simulated individually in the Gillespie algorithm, it is unavoidably computationally demanding, even with the algorithmic methods that have been developed to speed it up. To address this, several approximate methods have been developed.

The most accurate of these approximate methods is called the *tau-leaping* method [6,98,99,100]. In contrast to the Gillespie algorithm, the τ-leaping method uses a simulation time step which is long enough that many individual reactions are likely to occur during the time interval. The reaction propensities ought to change slightly as each reaction occurs to reflect the new chemical populations, although this algorithm uses the assumption that changes within a single time step are negligible. This is the sole approximation made for the τ-leaping method. Each reaction is considered to be an independent event (a consequence of both the well-mixed hypothesis and the constant reaction propensities), so the number of reactions that occur during time step τ for reaction channel j is a Poisson-distributed random variable; it is denoted k_j and has a mean value equal to the reaction propensity $a_j(\mathbf{X}(t))$. The formula used by τ-leaping that updates the system state over one time step is

$$\mathbf{X}(t+\tau) = \mathbf{X}(t) + \sum_{j=1}^{M} k_j \boldsymbol{\nu}_j \,. \tag{10}$$

The algorithm alternates steps in which the state of the system is updated and those in which new reaction propensities are calculated.

As the time step is reduced to zero, the τ-leaping simulation method approaches that of the Gillespie algorithm, although with more computational overhead. In the other direction, increasing the time step makes the simulation becomes more and more approximate. It has been suggested that τ should be chosen by first predicting the change in molecular populations over time using deterministic methods; then, the time step is chosen so that no molecular species is likely to change its population during this time step by more than some pre-determined fraction of its total population [98]. A difficulty that can occur with τ-leaping (which is also an issue with ODE integration), is that it is possible for a molecular species to be assigned a negative population. Several methods have been proposed to avoid this problem, some of which are also able to improve the performance of the algorithm in other ways as well [101,102,103]. Despite several papers on the development of τ-leaping, this method has yet to be applied to novel biological problems.

Two additional approximations allow the application of many more theoretical methods. First, the vector that defines the state of the system, $\mathbf{X}(t)$, is allowed to take on real values as well as integer values. As one would expect, this is usually a reasonable assumption for large chemical populations and a poor assumption for low copy numbers. In particular, it can a very poor approximation in cases where there might become no copies of a chemical species at all; an approximate value of, say, 0.01 protein copies can lead a system to entirely different outcomes than one would find with exactly 0 copies. The second approximation is to replace the Poisson-distributed random variables that were used in the τ-leaping algorithm with Gaussian-distributed random variables [104]. The effect of this change again decreases as the copy numbers of chemical species are increased. It also decreases as longer time steps are used because that leads to more individual chemical reactions per time step. These approximations allow the updating equation of the τ-leaping algorithm to be replaced by a stochastic differential equation called the *chemical Langevin equation* [105,106,107] (CLE),

$$\frac{\mathrm{d}X_i(t)}{\mathrm{d}t} = \sum_{j=1}^{M} \nu_{ji}\, a_j(\mathbf{X}(t)) + \sum_{j=1}^{M} \Gamma_j(t)\, \nu_{ji} \sqrt{a_j(\mathbf{X}(t))}\,. \quad (11)$$

The first term is simply the reaction rate equation that is given above (Eq. (4)), but for molecule counts rather than concentrations. The second term adds Gaussian noise to the deterministic result, where $\Gamma_j(t)$ represents a temporally uncorrelated, statistically independent Gaussian white noise with mean 0 and variance 1. In other words, the integral of $\Gamma_j(t)$ is a one-dimensional continuous random walk. The chemical Langevin equation describes a continuous Markov process which is an approximation of the jump Markov process that underlies the chemical master equation. Simulations with the CLE, which are based on an equation that is quite similar to Eq. (11) [106], yield single stochastic trajectories of the system state, much like simulations with the Gillespie algorithm or the τ-leaping method.

Alternatively, instead of following a single system as it moves along one of its many possible stochastic trajectories, it is possible to focus on a single portion of the state space to see how likely it is that the system will be in this region of state space as a function of time. This latter picture is described by *chemical Fokker–Planck equation* [41,105,107] (CFPE),

$$\begin{aligned}\frac{\partial P(\mathbf{x},t \mid \mathbf{x}_0,t_0)}{\partial t} &= \\ &-\sum_{i=1}^{N} \frac{\partial}{\partial x_i}\left[\left(\sum_{j=1}^{M} \nu_{ji} a_j(\mathbf{x})\right) P(\mathbf{x},t \mid \mathbf{x}_0,t_0)\right] \\ &+ \frac{1}{2}\sum_{i=1}^{N} \frac{\partial^2}{\partial x_i^2}\left[\left(\sum_{j=1}^{M} \nu_{ji}^2 a_j(\mathbf{x})\right) P(\mathbf{x},t \mid \mathbf{x}_0,t_0)\right] \\ &+ \sum_{\substack{i,i'=1 \\ i<i'}}^{N} \frac{\partial^2}{\partial x_i \partial x_{i'}}\left[\left(\sum_{j=1}^{M} \nu_{ji}\nu_{ji'} a_j(\mathbf{x})\right) P(\mathbf{x},t \mid \mathbf{x}_0,t_0)\right]. \end{aligned} \quad (12)$$

The first term, often called the drift term, arises from the deterministic behavior of the system. The latter two terms, collectively called the diffusion term, represent the stochastic deviations away from deterministic behavior. Because the CFPE represents continuous processes, it is significantly more analytically tractable than the chemical master equation.

To compute the probabilities of possible system behaviors using the CFPE, state space is usually discretized into a grid and then the CFPE is integrated using standard numerical methods [108,109]. This analysis method is similar to that employed for the CME, but is usually less computationally demanding because the discretized state space is typically significantly coarser. Nevertheless, the dimensionality of state space still increases exponentially with additional chemical species, so the CFPE still suffers from the curse of dimensionality.

Applications of Approximate Stochastic Methods

Perhaps because stochastic simulations are still a relatively new field of study, many studies with the CLE and CFPE focus more on the mathematical techniques than on the biological applications [109,110,111,112,113]. The approximate CLE and CFPE have been shown to yield results that are in good agreement with exact simulations for a reversible isomerization reaction, even with very few molecules [107].

The CLE was used to analytically investigate the role of noise-induced phenomena in enzymatic futile cycles, which is a motif that is common to many biochemical networks [61]. The analysis indicated that the presence of external noise is sufficient to induce switching bistability in the system, a phenomenon that is often attributed to feedback loops [25]. In combination with experimental data, the CLE was also used to show that translational efficiency is the predominant source of intracellular noise for a single-gene system [15]. The Fokker–Planck equation has been used to model cell growth [111,112] and cell migration [113,114]. Of particular interest, the Fokker–Planck equation has provided a convenient framework to describe the behaviors of molecular motors [109]. A motor protein is approximated as a diffusion particle in a periodic asymmetric free-energy surface. Under the input of chemical energy, the motor switches stochastically between different potentials that describe distinct biochemical states of the motor. The model has been used to explain key experimental observations for molecular motors, most notably for the F_1F_0-ATPase system [115] and a bacterial flagellar motor [109,116].

Hybrid Algorithms

Systems that involve multiple time scales provide major simulation challenges. If the fast time scale is simulated with high precision, then the simulation takes too long for the dynamics of the slow one to be observed with any reasonable efficiency. On the other hand, if the simulation time steps are optimized for the slow timescale, then they are too long for the fast reactions and numerical errors become problematic. In the language of differential equations, these are stiff systems which require special solution techniques. For stochastic simulations with multiple timescales, several methods have been developed recently.

One class of hybrid methods focuses on new mathematics to allow approximations of the Gillespie algorithm, or related algorithms, to function with reasonable accuracy over a wide range of timescales [42,50,51,117,118,119,120,121]. The other class generally involves the coupling of multiple simulators, usually including ODE, Langevin, and/or Gillespie; the high-population molecular species are simulated with less stochastic detail and the low-population species are simulated with more stochastic detail [122,123].

Spatial Stochastic Modeling

Most biological systems are highly organized. For example, *Escherichia coli* bacteria have helical cytoskeletons, polar-localized proteins, centrally positioned chromosomes, and elaborate flagellar motor complexes. Eukaryotes are even more organized, with elaborate organelles, microtubules and other complex cytoskeletal elements, motor proteins that shuttle back and forth, and carefully controlled cell shapes. Even phages display remarkable order in the way the DNA is packed into the outer shell. Where does this order come from? And how does this order influence the biochemical reaction network? These questions are being investigated with new imaging experiments [124,212] and with new computer simulation methods that can account for spatial heterogeneity. These spatial simulation methods are the focus of this section.

Spatial simulations have been used to investigate a wide variety of topics. These include: morphogen gradients across *Drosophila* and *Xenopus* oocytes [125,126,127], the *Escherichia coli* cell division plane localization system [128,129,130,131,132,133,134] (see Sect. "Box 1: The *E. Coli* Min System"), intracellular signaling [135,136,137,138], and rebinding of ligands to receptor complexes [139,140,141].

As described above, many successful biochemical models do not account for spatial heterogeneity; in fact, non-spatial models are in the vast majority. Typically, non-spatial models get away with ignoring space because they model dynamics that occur more slowly than the time it takes for a molecule to diffuse across a cell, because they investigate processes that are not intrinsically spatial, and because they do not demand high quantitative accuracy. As the tools are becoming available, including both fast computers and new software algorithms [45,142,143,144], the interest in including spatial detail is increasing. These spatial models can be either deterministic or stochastic, of which our primary focus is on the latter ones.

As with the non-spatial methods that are described above, stochastic effects in spatial models arise from the discreteness of molecules. This leads to fluctuations in the numbers of molecules, which are typically on the order of the square root of the number of molecules in the appropriate characteristic volume (near steady-state and equilibrium points, but frequently greater near critical points). In spatial models, the characteristic length scale is no longer the size of the entire system but is dictated by the length scale of the spatial heterogeneity. With the shorter length scale, the characteristic volume size is reduced, fewer molecules are in these volumes, and stochastic effects increase. Thus, stochastic simulations can be required for spatial models, even if they were not needed for the corresponding non-spatial model. There are also other good reasons to model stochastic effects in spatial simulations. Many spatial phenomena, such as noise that arises from ligand rebinding [141], cannot be adequately treated without considering the detailed molecular interactions. Finally, a model is only as good as its weakest aspect. If one increases the accuracy of a model in one way, such as by accurately treating either space or stochastics, then the benefits may not be realized until the other aspect is addressed as well.

Schemes for investigating a chemical system with spatial and stochastic detail can be classified by whether they consider molecules within populations or as individuals. In the former case, space is divided it into small subvolumes, whereas in the latter, space is continuous. These classes are described in detail below. Another approach is lattice-based methods [145,146,147,148,149]. However, we do not discuss them here because they are rarely used for quantitative modeling. Furthermore, the underlying lattice geometry usually affects the results, thus making them less realistic.

Population-Based Spatial Models

In a top-down approach towards spatial modeling, one starts with a simple, deterministic, macroscopic description and then adds successive layers of detail. In this case, the natural starting point is with the standard textbook descriptions of chemical reactions and diffusion [24]. Reactions are described with mass action reaction kinetics expressed with the reaction rate equation that was discussed above (Eq. (4)). Diffusion is described with the diffusion equation [24], also called Fick's second law of diffusion, which is

$$\frac{\partial Z_i(\mathbf{r},t)}{\partial t} = D_i \nabla^2 Z_i(\mathbf{r},t)\,. \tag{13}$$

In an extension of the definition given before, $Z_i(\mathbf{r},t)$ is the concentration of component i at the 3-dimensional position $\mathbf{r}$ and time t. D_i is the diffusion coefficient for component i.

Because reactions and diffusion occur simultaneously, the respective equations are combined to express the simultaneous effects of both processes to yield the *reaction-diffusion equation*,

$$\frac{\partial Z_i(\mathbf{r},t)}{\partial t} = \sum_{j=1}^{M} \nu_{ji}\,\tilde{a}_j(\mathbf{Z}(\mathbf{r},t)) + D_i \nabla^2 Z_i(\mathbf{r},t)\,. \tag{14}$$

This partial differential equation (PDE) underlies a great deal of theory on chemical and biological pattern formation [126,136,150,151]. The Virtual Cell computer program [152] is general-purpose software that simulates the reaction-diffusion equation. It has been used primarily to explore spatial effects in intracellular signaling [153,154,155].

The reaction-diffusion equation is deterministic, so it captures neither the discreteness of reaction events nor the Brownian motion processes that underlie diffusion. It is possible to add this stochasticity directly into the deterministic theory but that would create a set of coupled stochastic scalar field equations, which would be extraordinarily complicated. Neither the deterministic nor the stochastic PDEs are tractable to work with analytically for any but the very simplest systems except, perhaps, in steady-state. Thus, most analysis is either computational or approximate.

In most such analyses, the equations are first simplified by dividing the system volume into an array of small cubic subvolumes, each with width l. This spatial discretization changes the diffusion portion of the reaction-diffusion equation into a discrete form:

$$\frac{\mathrm{d}Z_{i,k}(t)}{\mathrm{d}t} = \sum_{j=1}^{M} \nu_{ji}\,\tilde{a}_j(\mathbf{Z}_k(t)) + \frac{D_i}{l^2}\sum_{k'}\left[Z_{i,k'}(t) - Z_{i,k}(t)\right]\,. \tag{15}$$

The index k denotes the subvolume number, much as $\mathbf{r}$ represented the spatial location. The latter summation in this discrete reaction-diffusion equation extends over all nearest neighbors of subvolume k, denoted by k'. Because the description of space was changed from continuous states to discrete states, much like the discrete kinds of molecules that are labeled by the index i, diffusion is now formally identical to reactions. The "reaction rate constant" for diffusion [156] between one subvolume and its neighbor is D_i/l^2. Because of this mathematical equivalence, much of the following discussion on the stochastic simulation of the reaction-diffusion equation parallels the discussion presented earlier on non-spatial stochastic simulations.

The first spatial stochastic equation that we present is the one that accounts for the least detail. It is the *spatial chemical Langevin equation*, which results from adding white Gaussian noise to the discrete reaction-diffusion equation. It is

$$\begin{aligned}\frac{\mathrm{d}Z_{i,k}(t)}{\mathrm{d}t} = {} & \sum_{j=1}^{M} \nu_{ji}\left[\tilde{a}_j(\mathbf{Z}_k(t)) + \Gamma_j(t)\sqrt{\tilde{a}_j(\mathbf{Z}_k(t))}\right] \\ & + \sum_{k'}\left\{\frac{D_i}{l^2}\left[Z_{i,k'}(t) - Z_{i,k}(t)\right]\right. \\ & \left. + \Gamma_{k'}(t)\sqrt{\frac{D_i}{l^2}}\left[\sqrt{Z_{i,k'}(t)} - \sqrt{Z_{i,k}(t)}\right]\right\}\,. \end{aligned} \tag{16}$$

In an extension to what was presented before, $\Gamma_j(t)$ and $\Gamma_{k'}(t)$ represent temporally uncorrelated, statistically independent Gaussian white noises [106]. This is a specific example of the more general multivariate Langevin equation; it, and the multivariate Fokker–Planck equation, have been explored in depth [41,105]. However, the more specific spatial chemical Langevin equation has essentially never been used, investigated mathematically, or simulated. The sole exception that we are aware of was its simulation for a figure for a tutorial article [8] (those results are reproduced in Fig. 1).

The spatial chemical Langevin equation captures stochasticity reasonably accurately for systems in which there are many molecules per subvolume but not for those with few molecules per subvolume. Errors arise both because Gaussian white noise is the incorrect fluctuation distribution [100,104] and because it treats molecule amounts as continuously variable quantities. These are addressed by moving to the next level of detail in which the continuous molecular concentrations are replaced by discrete numbers of molecules. This changes the temporally continuous reaction and diffusion processes to stochastic jump processes. The *reaction-diffusion master equation* [156,157,158,159] (RDME) describes the time dependence of the system at this level of description. It is

$$\frac{\mathrm{d}P(\mathbf{x},t)}{\mathrm{d}t} = \sum_{j=1}^{M}\Big[a_j(\mathbf{x}-\underline{\boldsymbol{\nu}}_j)P(\mathbf{x}-\boldsymbol{\nu}_j,t) - a_j(\mathbf{x})P(\mathbf{x},t)\Big] + \sum_{i=1}^{N}\frac{D_i}{l^2}\sum_{k,k'}\Big[(X_{i,k}+1)\,P(\ldots,X_{i,k}+1, X_{i,k'}-1,\ldots,t) - X_{i,k}P(\mathbf{x},t)\Big]\,. \tag{17}$$

$P(\mathbf{x},t)$ is the probability that the system is in state $\mathbf{X}=\mathbf{x}$ at time t, $X_{i,k}$ is the number of molecules of type i in subvolume k, $\mathbf{X}$ is the vector of all $X_{i,k}$ values, and a_j is the propensity of reaction j.

The RDME expresses as much detail as is possible through these successive improvements of the reaction-diffusion equation. It is tempting to think of it as the fundamental equation for reactions and diffusion, and thus the basis for a statistical theory of chemistry. In fact, it is sufficiently accurate for most systems, but it nevertheless involves approximations that can be important in some situations. Firstly, neither of the starting equations, which are mass action kinetics and Fickian diffusion, are completely accurate even for very large systems. Mass action kinetics does not address the increased reaction rates that occur on extremely short time scales, which arise from reduced spatial correlations [160,161]. Nor does it address the geminate recombinations that can occur between the products of a dissociation reaction [162,163]. The diffusion equation is usually quite accurate for dilute solutions but fails for highly crowded ones [164,165], including most biological systems [166]. Secondly, the discretization of space into small subvolumes can also lead to inaccuracies, or exacerbate the inaccuracies just mentioned. The subvolume sizes must not be so small that they impinge on the microscopic details of the reaction or diffusion processes. This means that they need to be significantly larger than single molecules and larger than the mean free path lengths of diffusion [156,167]. Conversely, the subvolumes must not be so large that there would be appreciable concentration gradients across them. This means that the subvolume width needs to be less than the reactant correlation length. The correlation length is hard to predict but is at least as large as the average distance that a reactant travels before it reacts, called the reactive mean free path [156,167].

The RDME is even more intractable than the non-spatial chemical master equation because of the addition of spatial states and the many transitions that can occur between the spatial states. These additional states and transitions also make stochastic simulations of the RDME with Gillespie's direct algorithm extremely slow [157]. Several faster algorithms have been developed to address this problem. The "next reaction method" of Gibson and Bruck [64] was adapted to spatial simulations [168], and then further improved, to yield the "next subvolume method" [132,142]. Also, a fast version of the direct method [169] has been developed for spatial simulations [167]. All of these methods yield exactly the same results as Gillespie's original methods [62,63] but use carefully optimized data structures to minimize the number of computations.

A separate challenge with simulating the RDME concerns the cubical subvolumes into which space was discretized. Biological systems rarely have square corners, so the basic theory requires adaptation to account for realistic boundaries. In one approach, the mathematics was developed for dividing boundary subvolumes into two separate portions [170]. Using another approach, the theory was developed for curved surfaces, which was implemented in the MesoRD program [132,171]. Although it has not been developed yet, it has been proposed that automatic mesh refinement could simultaneously account for complex boundaries and lead to significant computational efficiencies [167].

Along with simulations of the *E. coli* Min system, presented in Sect. "Box 1: The E. Coli Min System", population-based spatial stochastic models have been used for a variety of test systems. In the first implementation of a spatial Gillespie algorithm, Stundzia and Lumsden used a one-dimensional simulation to demonstrate stochastic calcium wave propagation [157]. Elf and Ehrenberg showed that spatial and stochastic effects can cause an intrinsically bistable system to lose its global hysteresis through the formation of spatial domains [142]. In a third study, Isaacson and Peskin demonstrated their method for simulating porous boundaries with a model that includes transcription, translation, and nuclear membrane transport [170].

Individual-Based Spatial Models

In a bottom-up approach to spatial modeling, one starts with a very detailed consideration and then makes successive approximations. A convenient place to start is by considering every individual molecule in the system, along with some of the molecular structures. The motions of these molecules are governed by physical forces including steric repulsion, bond mechanics, and electrostatics. The simulation of the motions that result from these forces is called molecular dynamics [172]. Molecular dynamics can yield very accurate results but is so computationally intensive that it is rarely used for more than hundreds of cubic nanometers of volume or more than tens of nanoseconds of time. These size and time scales are too confining for studying biochemical reaction networks, so approximations are made.

At the Smoluchowski level of detail, all solvent molecules are ignored, solute molecules are treated as spheres, diffusion proceeds stochastically, and molecular rotation, molecular momentum, and long-range intermolecular forces are all ignored. This is a vast simplification, but is often valid. It is usually reasonably accurate for size scales that are larger than a few nanometers and for timescales that are longer than a few nanoseconds, constraints that are acceptable for an enormous range of chemical and biological phenomena.

For diffusion at the Smoluchowski level of detail, the effects of solvent-solute interactions on the solute motion are approximated by assuming that solute molecules diffuse with mathematically ideal Brownian motion [173,174]. This is a key approximation that replaces the deterministic molecular motions that result from solvent collisions with stochastic trajectories. It is often the only source of stochasticity in the theory, or in simulations that derive from this individual-based approach. More precisely, the position of molecule i at time t is given with the probability density $p_i(\mathbf{r}, t)$, which evolves over time according to the master equation

$$\frac{\partial p_i(\mathbf{r}, t)}{\partial t} = D_i \nabla^2 p_i(\mathbf{r}, t) \,. \tag{18}$$

This equation is nearly identical to the diffusion equation, given above (Eq. (13)), differing only in the definitions of the variables and the interpretation. Now, it is not a population of molecules that diffuse, but the positional probability density for a single molecule.

Because it is so simple, the diffusion master equation is analytically tractable, in contrast to the other master equations that were discussed. One result is an entire body of analytical theory on diffusion-influenced reactions [160,175]. Nevertheless, it too becomes unmanageable for systems that have several interacting molecules, so it is simulated with a technique called *Brownian dynamics* [176,177,178,179,180]. In this method, molecules have well-defined point-like positions which are updated at each simulation time step using random displacements. The displacements are chosen by solving the diffusion master equation for molecule i, which is taken to be at the well-defined position $\mathbf{r}_0$ at time t_0. One simulation time step later, at time $t_0 + \Delta t$, the probability density for the molecule's position is found to be a 3-dimensional Gaussian density that is centered at $\mathbf{r}_0$,

$$p_i(r, \Delta t) = \frac{1}{s_i^3 (2\pi)^{3/2}} \exp\left[-\frac{(\mathbf{r}-\mathbf{r}_0)^2}{2 s_i^2}\right] . \tag{19a}$$

The standard deviation of this Gaussian, called the root mean square step length, is

$$s_i = \sqrt{2 D_i \Delta t} \,. \tag{19b}$$

Brownian dynamics simulations provide accuracy that is below that of molecular dynamics, but still captures single molecule behavior.

Brownian dynamics has been used extensively for examining the rates of diffusion-influenced chemical reactions in solution [139,177,179,180,181,182] and for the rates of binding between ligands and receptor arrays [139, 141,178,183,184]. In these studies, simulated molecules diffuse in solution; at the moment that a reactant pair, or a ligand and its cognate receptor, come into contact, they undergo a chemical reaction. While diffusing, intermolecular forces are often ignored, although some studies account for these interactions as well [185,186].

To achieve the necessary level of detail, Brownian dynamics simulations usually use very short simulation time steps, often on the order of picoseconds [139]. Adaptive time steps, such that time steps are long when reactants are widely separated and short when they are close, can speed simulations up by several orders of magnitude, but are easy to implement only if there is just one diffusing particle present in the simulation volume [141]. A more sophisticated method that has the same general goal of computational efficiency is called Green's function reaction dynamics [143,187,188] (GFRD). In GFRD, which works with any number of molecules, the system is inspected to see how soon the next molecular collision or reaction could occur. The system is then advanced to that time using a single simulation time step, the event is executed if appropriate, and the cycle repeats. Yet another method, used in a program written by one of us (SSA) called Smoldyn, achieves computational efficiency by modifying the effective radii of simulated molecules so that the same reaction rate is achieved with long simulation time steps as with short ones [45,189,190]. This method does not achieve the same spatial or temporal precision as classical Brownian dynamics or GFRD, but the level of detail is still more than adequate for most biological applications and has been shown to be indistinguishable from more accurate simulations in many cases [191].

Technically, all of these algorithms execute Brownian dynamics. However, the term "Brownian dynamics" is typically used to describe highly detailed studies in which reaction rates, rebinding dynamics, or similar phenomena are found from fundamental molecular properties such as molecular radii and intermolecular forces. In contrast, GFRD and the methods used in Smoldyn are more often used to determine system-level behaviors from known or estimated reaction rates. These are more often called particle-based stochastic simulation methods [192].

MCell is another program that performs particle-based stochastic simulations [144]. Unlike the others, it cannot simulate reactions that occur in free solution, but instead only treats reactions at surfaces. Despite the decrease of versatility, it is still useful for studying a wide variety of biological phenomena [193,194,195]; in particular, it was developed to investigate the neuromuscular junction [196,197,198]. In MCell, surface-bound receptors are not modeled as single molecules as they would be in Smoldyn or GFRD methods, but as a uniform binding probability that applies to an entire surface tile. This decreases the spatial resolution some, but increases the computational efficiency.

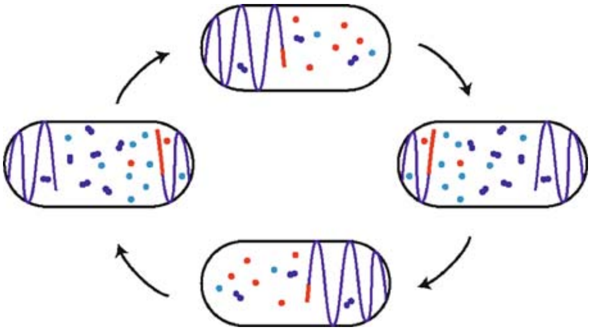
Future Directions

The classic advice of using the right tool for the job is as true in biochemical modeling as it is elsewhere. Several modeling tools have been presented here. Deterministic ordinary differential equation models are simple, easy to use, and can be analyzed with many powerful theoretical and analytical methods. They are the right tool for systems that can be treated as being well-mixed and that are both large enough and sufficiently far from critical points that stochastic effects are unimportant. In contrast, systems that include low copy numbers of important components, and/or that can be triggered by random events, require stochastic modeling methods for their investigation. These include integration of the chemical master equation and random sampling of the stochastic trajectories using the Gillespie algorithm, both of which are exact methods. Approximate methods include τ-leaping stochastic simulations, integration of the chemical Fokker–Planck equation, and sampling with the chemical Langevin equation. Of these, the Gillespie algorithm has proven to be the most popular. Finally, if the system cannot be considered to be well-mixed, then yet different tools are needed. These include spatial variants of the same list of simulation methods, including partial differential equations for deterministic simulations and a spatial Gillespie algorithm for stochastic simulations. Particle-tracking simulation methods allow an even greater degree of detail.

In general, more detailed simulation methods yield more accurate results and are based more closely on underlying processes and less on phenomenological descriptions. However, they are also more computationally intensive and require more model parameters. This parametrization poses a significant problem for current models because the necessary quantitative experimental data are typically only marginally adequate or are completely non-existent. For an ODE model, it is sometimes possible to address this problem by exploring model behaviors over wide ranges of parameter space, from which one can draw phase diagrams that graphically depict how the model behaves for different parameter choices. From this, one can sometimes constrain parameters or gain additional insight into the model; for example, Tyson showed how two enzyme concentrations can be used to regulate the cell cycle, bringing an oocyte from metaphase arrest to autonomous oscillations, and on to growth-controlled cell division [30]. Because of the computational demands of spatial and stochastic models, as well as the richer behavior possibilities, it is much more difficult to explore parameter space with these more complex models. Thus, much work is needed on this topic.

More generally, the mathematical infrastructure for designing and interpreting stochastic models lags far behind that for non-spatial deterministic models. This poses some challenges for theorists. For example, what new theories and graphical tools will help scientists gain intuition into the dynamics of stochastic systems? and what are the controlling elements of stochastic systems? The theory is even more unexplored when spatial organization is considered as well. Nevertheless, spatial considerations are essential because no biological life has been found that is well-mixed; instead, a tremendous amount of biochemical activity involves membranes, polymers, protein scaffolds, large multimeric complexes, and other spatial structures. Theories that address these topics will not be as elegant as those that focus on the chemical master equation, but biology is not always elegant either.

Although research on stochastic modeling of biochemistry grew slowly from the 1950s to the 1990s, the pace has accelerated dramatically during the last 10 to 15 years. This acceleration will likely continue for many more years, in response to the faster computers that become available every year and to the ever-increasing complexity of biochemical data. With this growth, stochastic modeling may open up entire new ways to understand cell biology.



Stochastic Models of Biological Processes, Figure 2

Diagram of the *E. coli* Min system, which is used to position the cell division plane at the cell center. *Dots* represent cytoplasmic proteins, while *curved lines* represent helical membrane-bound protein polymers. *Colors* identify the proteins: *light blue* for MinD bound to ADP, *dark blue* for MinD protein bound to ATP, and *red* for MinE. The system dynamics are summarized in the text of Sect. "Box 1: The E. Coli Min System"

Box 1: The *E. Coli* Min System

The *E. coli* Min system has served as a proving ground for spatial stochastic simulation methods. The Min system is used by *E. coli*, in conjunction with other systems, to position the cell division plane accurately at the cell center [131]. The system is comprised of the proteins MinC, MinD and MinE, which oscillate back and forth across the cell, from one pole to the other, with a period of about 40s (Fig. 2). Of these, only MinD and MinE are required for the oscillation, making this a relatively simple system that exhibits remarkably interesting dynamics. Cytoplasmic MinD proteins bind ATP, dimerize, and polymerize on the inside of the cell membrane to form long helical structures that extend outwards from one of the two cell poles. When MinE binds to the cell-center end of a MinD polymer, it activates ATP hydrolysis which depolymerizes the terminal subunit. As MinE progressively disassembles a MinD polymer at one end of the cell, it reassembles again from the opposite pole to start the next oscillation cycle. The oscillating Min proteins continually inhibit cell division plane formation near the poles using MinC, which colocalizes with MinD, thus only permitting cell division at the cell center.

This system was explored for several years with deterministic reaction-diffusion models [128,199,200]. One of these models, by Howard, Rutenberg, and de Vet [199], was also explored by the same group using a one-dimensional population-based stochastic method [129] (it uses discrete particle numbers and fixed time steps, thus conceptually placing it between the spatial Langevin and spatial Gillespie methods). The authors found that stochastic effects were essential for generating oscillations in some parameter regimes, in a spatial version of stochastic resonance [60,201]. These models helped direct new experiments [202,203,204,205] that clarified the processes of the system.

Building on the prior models and the new experimental data, Huang, Meir, and Wingreen [130] developed a new reaction-diffusion model that was more closely connected with the biology than were previous models and that accounted for several mutant phenotypes. This model became the basis of several stochastic simulations. The spatial Gillespie method was employed by Fange and Elf [132] using their MesoRD program. They showed that a stochastic model can account for a "spotty" phenotype and for oscillations in spherical mutant cells, neither of which can be explained by the deterministic model. The MCell particle-tracking program was used by Kerr and coworkers [133] to show that the Min system alone is insufficient to center the cell division plane with high accuracy.

Yet unexplained with these simulations were convincing experimental results that MinD forms polymers on the cell membrane [205,206,207]. These were explored with another particle-tracking model [208], using a method based on Smoluchowski dynamics [45]. Although this group did simulate spontaneous polymer formation, they observed many randomly oriented short filaments, in contrast to the few helical polymers that are observed experimentally. This inherent difficulty with the reaction-diffusion model [209], whether deterministic or stochastic, has led to several studies that have focused specifically on the polymer dynamics and shapes [134,210,211].

The *E. coli* Min system is already well on its way to becoming the prototypical system for studying spatial biochemical dynamics, much as *E. coli* chemotaxis has become the prototypical system for investigating bacterial signaling.

Article Outline

Glossary

Wiener process A *Wiener process* is a continuous time stochastic process $w = \{w(t)\,;\, t \in \mathbb{R}\}$ with continuous sample paths and stationary independent increments of zero mean and finite variance. The variance of the increments $w(t) - w(s)$ must then have the form $\sigma^2(t-s)$ and $w(t) - w(s)$ must have a Gaussian distribution with mean zero (Levy's theorem [30]). The Wiener process is *normalized* (or *standard*) if $\sigma^2 = 1$.

A *p-dimensional* Wiener process is a vector stochastic process having p components, w_k; $k = 1, \dots, p$, which are independent Wiener processes. A *wide-sense* p-dimensional normalized Wiener process is a continuous time stochastic process $w = \{w(t)\,;\ t \in \mathbb{R}\}$ which is continuous in mean square and has stationary orthogonal increments; i. e.,

$$\mathbb{E}\{[w(t_1) - w(s_1)][w(t_2) - w(s_2)]'\} = I_p|[s_1,\ t_1] \cap [s_2,\ t_2]|$$

where $\mathbb{E}$ denotes expectation, I_p is the $p \times p$ identity matrix, the prime denotes transpose and $|\cdot|$ denotes length (Lebesgue measure). This is a weaker concept than that of a Wiener process.

A Wiener process with $w(0) = 0$ is sometimes called a *Brownian motion process*. Usually a Brownian motion is only defined on the half line $\mathbb{R}_+$.

Wiener processes and stochastic integrals with respect to a Wiener process, introduced by Wiener and Itô, are the basic building blocks of *stochastic calculus* [14,25]. Since stochastic integrals only depend on the increments of w, it is immaterial whether an arbitrary random vector is added to w. The equivalence class of (wide sense) Wiener processes differing from each other by the addition of an arbitrary (constant) random vector of finite variance (e. g. $w(0)$), will still be called a Wiener process and denoted by the symbol dw.

White noise Continuous time *white noise* is the formal time derivative of a Wiener process. This derivative must be understood in a suitable distributional sense since it fails to exist as a limit in any of the standard senses of probability theory.

Much more standard is the notion of *discrete-time* (strict or wide-sense) normalized *white noise process*. It is a sequence of independent equally distributed (respectively orthogonal) random vectors $w = \{w(t)\,;\ t \in \mathbb{Z}\}$ with unit variance; i. e.,

$$\mathbb{E}\{w(t)w(s)'\} = I\delta_{ts} := \begin{cases} I & \text{if } s = t \\ 0 & \text{if } s \neq t\,. \end{cases}$$

This last condition alone characterizes wide-sense white noise. We shall always require that w should have zero mean.

Stochastic differential and difference equations

Stochastic differential equations are equations that define pathwise a continuous time stochastic process x by "local" evolution laws of the type

$$\mathrm{d}x(t) = f(x)\mathrm{d}t + G(x)\mathrm{d}w(t)\,,$$

where dw is a vector Wiener process. The equation should in reality be interpreted as an integral equation, the last term being a stochastic integral in the sense of Itô, see [14,25]. Under certain growth conditions on the coefficients the equation can be shown to have a unique solution which, in case f and G depend pointwise on $x(t)$, is a continuous Markov process, in fact a *diffusion process*.

In discrete time ($t \in \mathbb{Z}$) a *stochastic difference equation* is an object of the type

$$x(t+1) = f(x(t))\mathrm{d}t + G(x(t))w(t)$$

where now w is white noise. The solution of an equation of this type is a (discrete-time) Markov process.

Stochastic dynamical systems In continuous time, a (finite-dimensional) *stochastic system* is a pair (x, y) of vector, say n and m dimensional, stochastic processes satisfying equations of the type

$$\begin{aligned} \mathrm{d}x(t) &= f(x(t))\mathrm{d}t + G(x(t))\mathrm{d}w(t) \\ \mathrm{d}y(t) &= h(x(t))\mathrm{d}t + J(x(t))\mathrm{d}w(t)\,. \end{aligned}$$

The process x, which is Markov, is called the *state* of the system while y is the *output* process. The differential notation in the second equation is merely to allow a possible additive white noise component in the output process so y is actually the integral of the variable which would physically be called the output of the system. If there is no additive white noise component ($J \equiv 0$) this trick is unnecessary and the output variable is simply expressed as a memoryless function of the state, $\mathrm{d}y/\mathrm{d}t = h(x(t))$. A similar definition, with the obvious modifications, serves to introduce the concept of discrete-time stochastic systems.

The probabilistic essence of the concept of stochastic system is more generally captured in terms of *conditional independence* of the sigma-algebras induced by the underlying processes. From this it can be clearly seen that the state process at time t plays the role of *dynamic memory* of the system: the future and the past of the output and of the state sigma-algebras are conditionally independent given the present state $x(t)$. For a formal definition the reader is for example referred to p. 219 in [51]. We shall introduce these concepts in a wide-sense context later on.

Introduction

In this article we discuss some general ideas which motivate the use of stochastic dynamical models in applied sciences. We discuss the inherent mathematical problem of stochastic model building, called *stochastic realization* and the statistical problem of *(dynamic) system identification*, i. e. procedures for estimating dynamic stochastic models starting from observed data. We shall in particular discuss linear stochastic state-space models with random inputs, their construction and the relevant identification techniques. We shall assume that the reader has some general background on stationary stochastic processes, statistics [12] and linear system theory as for example exposed in the textbook [24].

There are no physical laws telling us how to obtain stochastic descriptions of nature. The laws of mechanics, electromagnetism, fluid dynamics etc. are, by nature, essentially deterministic. A fundamental empirical observation is that stochastic models generally come about as *aggregate* descriptions of complicated large deterministic systems. Think for example of describing mathematically the outcome of a dice-throwing experiment. Doing this by the laws of physics involves an enormous number of complicated factors such as the mechanics of a cubic-shaped rigid body flying in the air after an initial impulse applied on a specific region of one of its six faces. To describe the trajectory (i. e. the motion of the barycenter, the body orientation and the angular momenta) one should take into account, besides gravity, lift phenomena due to portance, drag, added-mass effects etc., describing the interaction with the surrounding fluid. Then one should describe the discontinuous mechanics of the dice landing on an elastic surface etc. Modeling all of this by the known laws of physics is perhaps possible and we may in principle be able to set up a set of algebraic-differential equations allowing us to predict exactly (or "almost exactly") which upper face of the dice will eventually show. This however, provided we knew an enormous number of geometrical and physical parameters of the system such as, for example, the dimensions of the dice, its initial position and orientation, its mass and moments of inertia, the location, direction and strength of the initial impulse, the density of the air surrounding the trajectory (depending on the temperature, humidity etc.), the possible air convection phenomena, the mechanical structure and geometry of the landing medium, etc. Indeed, this predictive model based on the (deterministic) laws of physics would require a very large number of equations and involve an unimaginable detailed prior knowledge of the parameters of the experiment. Trivially, the rudimentary stochastic model consisting of a probability distribution on the six possible outcomes $\{1, 2, \dots, 6\}$, although not allowing an "exact", i. e. "deterministic" prediction of the outcome, is incomparably simpler. One could venture to say that most stochastic models used in science and engineering come about, for the same reason, as simple aggregate descriptions of complicated deterministic systems. Thermodynamics, to name just one of the most conspicuous instances of this phenomenon, can be seen as stochastic aggregation of large ensembles of microscopic particles evolving in time according to the deterministic laws of mechanics [28,43].

Simplification is payed in terms of uncertainty and the predictions based on stochastic aggregate models are by nature uncertain. The modeling process hence requires us to quantify the uncertainty of aggregate modes. In a more precise sense, we should investigate their mathematical structure and describe how to construct them. This will be one of the main concerns of this article.

A Brownian Particle in a Heat Bath

The process of constructing aggregate models can be elucidated by a famous example, the *Ford–Kac–Mazur model* [20] which is probably the simplest explicitly solvable example of a problem of this nature.

Consider the problem of describing the dynamics of a particle, called the *Brownian particle*, coupled to a "heat bath" consisting of a very large number of identical particles obeying the laws of classical Hamiltonian mechanics and moving under the influence of a quadratic potential. Mathematically, the ensemble can be described as a large number of coupled harmonic oscillators. The Brownian particle is the only particle of the ensemble which is assumed to be accessible to external observation. One assumes that the macroscopic observables of the system are the relative position $q(t)$ and/or the momentum $p(t)$ of the Brownian particle, at each instant of time.

It is shown in [20] that in the limit when the number of particles in the heat bath tends to infinity, the motion of the Brownian particle is governed (exactly!) by the stochastic differential equations,

$$\dot{q}(t) = p(t) \tag{1}$$

$$dp(t) = -ap(t)\mathrm{d}t + k\mathrm{d}w(t)\,, \quad a > 0 \tag{2}$$

the second of which is the ubiquitous *Langevin equation* of statistical physics. This equation contains a dynamical *friction term*, $(-ap(t))$, and a forcing function term $w(t)$ which is described mathematically as a Wiener process. Physically, these terms can be interpreted as the influence of the surrounding medium on the observed particle, the friction accounting for the energy transferred from the particle to the heat bath and the forcing term $w(t)$ representing the sum of infinitesimal "random shocks" inflicted to the particle by the surrounding medium.

The stochastic process describing the temporal evolution of the observables $q(t)$ and $p(t)$ is a Markov diffusion process (in fact, both $p(t)$ and the two-dimensional vector process $[q(t)\ p(t)]$ are Markov). The evolution of the macroscopic observables is hence *dissipative*, because of the friction term, and *irreversible*, since diffusion processes evolve in time by the action of a semigroup which cannot be inverted to become a group. This is in accordance with the basic postulates of (macroscopic) thermodynamics.

The Ford–Kac–Mazur example can be generalized [48,49,50,52]. Assume a microscopic system described by a Hamiltonian H on the phase space Ω, a smooth manifold of very large dimension $2N$. The solution of the Hamilton equations determines the phase of the system, say configurations and momenta $z(t) := [q(t)\ \ p(t)]'$ at each time t, uniquely in terms of the initial value $z(0) \in \Omega$. The correspondence defines a flow $z(t) = \Phi(t)z(0)$ on the phase space which leaves invariant the total energy, $H(z(t))$, of the system. The microscopic evolution is in this sense, reversible and conservative. However, microscopic phenomena are *complex* in the sense that they involve an enormous number of interacting components and it is impossible to keep track of the dynamics of such a complex system. One must then resort to a statistical description.

A probability distribution on Ω which is *invariant for the Hamiltonian flow* $U(t)$ defines "thermal equilibrium". It is known that in a finite-dimensional space any absolutely continuous $U(t)$-invariant probability measure admits a one parameter family of densities $\rho(z)$ of the Maxwell–Boltzmann type, equal to a normalization constant times $\exp[-\frac{1}{2\beta}H(z)]$, $\beta > 0$, being interpreted as the "absolute temperature". For a quadratic Hamiltonian in a linear phase space these distributions are Gaussian. The choice of an initial phase $z(0)$ of a system in thermal equilibrium can then be interpreted as a random choice of an elementary event in the elementary outcome space $\{\Omega,\ \rho\}$.

It follows that in thermal equilibrium any observable; i. e. any measurable function $h\colon \Omega \to \mathbb{R}$ on the phase space can be regarded as a random variable. In fact, once combined with the (measure-preserving) Hamiltonian flow $z(t) = U(t)z(0)$, any measurable observable defines a *stationary stochastic process*. In general, the time evolution of any finite, say m-dimensional, family of observables $\{h_1, \dots, h_m\}$ can be identified with a vector-valued m-dimensional stationary process $\{y(t)\}$ on Ω, with components

$$y_k(t, z(0)) := h_k(U(t)z(0)) \tag{3}$$

where $z(0) \in \Omega$ is the elementary event and $U(t)$ the measure preserving group of transformations on the underlying probability space.

The main point of this story is that the "randomization" of the phase space may, under certain conditions, lead to a description of certain observable processes $\{y(t)\}$ of (3) by a stochastic dynamical model of a *much simpler structure than the microscopic deterministic Hamiltonian description*. These could for example be representations of $\{y(t)\}$ of the type $y(t) = h(x(t))$ where $\{x(t)\}$ a finite dimensional, say $\mathbb{R}^n$-valued Markov process and h is a suitable function $h\colon \mathbb{R}^n \to \mathbb{R}^m$. This description, in case the Markovian representation has a smaller complexity (dimension) than that of the microscopic description, would precisely meet both the general physical plausibility for a thermodynamic description and the mathematical requirement of reduction of complexity.

Remark 1 This view generalizes the way of conceiving stochastic aggregation in the physical literature, e.g [31,32], where it is generally required that the observables themselves should be Markov and satisfy a Langevin equation.

In general the requirement that the observables should themselves be Markov processes is seldom a reasonable one. For example, in the Brownian particle example the macroscopic observable $q(t)$ by itself need *not* satisfy any stochastic differential equation. Formally, $q(t)$ is just a memoryless function of a two-dimensional Markov process $x(t) := [q(t)\ p(t)]'$ and it is instead the "thermodynamic state" $x(t)$ which satisfies a stochastic differential equation.

Stochastic Realization

Stochastic realization is the abstract version of the aggregation problem mentioned above. One studies the problem of representing an m-dimensional stationary process $\{y(t)\}$ as a *memoryless function of a Markov process*. In this setting the physical phase space and the Hamiltonian group $\{U_t\}$ are generalized to an abstract probability space and to a measure preserving one-parameter group of transformations mapping Ω onto itself (the shift group of the process). In this article we shall assume that $\{y(t)\}$ is smooth with continuous values but the problem area also concerns stationary finite state-processes, see [5,19,46,66], which have important applications in communications and biology. In the present context, the question is when does a given stationary, m-dimensional, stochastic process $\{y(t)\}$ admit representations of the type $y(t) = h(x(t))$ where $\{x(t)\}$ is a Markov diffusion process taking values on a finite-dimensional state space X and h is say a continuous function from X to $\mathbb{R}^m$.

Since a smooth Markov diffusion process $\{x(t)\}$ is a solution of a stochastic differential equation (Chap. VI, Par. 3 in [14]), any such process must admit representations as the output of a stochastic dynamical system of the type

$$\mathrm{d}x(t) = f(x(t))\mathrm{d}t + G(x(t))\mathrm{d}w(t) \tag{4}$$

$$y(t) = h(x(t)) \tag{5}$$

where $\{w(t)\}$ is a vector m Wiener process. This stochastic dynamical system generalizes the Langevin equation representation. For a Gaussian mean square continuous stationary process, the representation simplifies to a linear model of the form

$$\mathrm{d}x(t) = Ax(t)\mathrm{d}t + B\mathrm{d}w(t) \tag{6}$$

$$y(t) = Cx(t) \tag{7}$$

where A, B, C are constant matrices of appropriate dimensions. There may be a need for introducing an additive noise term also in the second (output) equation when the process y has stationary increments, a situation more general than stationarity, see [37].

Representations as the output of a stochastic dynamical system are called *stochastic realizations* or *state-space realizations* of the process y and the Markov process $x(t)$ is accordingly called the *state process* of y, or of the realization.

Signal descriptions by a finite dimensional stochastic realization can be transformed into other equivalent forms such as ARMA models etc., which are also widely used in the engineering and econometric literature. It should be stressed that, irrespective of which particular equivalent form of the stochastic model, virtually all sequential signal processing, prediction and control algorithms (Kalman filtering to name just the most popular) require availability of a finite-dimensional realization of one form or another. Hence signal representation by a stochastic system is indeed a crucial prerequisite for system analysis and design in engineering and applied sciences.

A substantial amount of literature on the stochastic realization problem has appeared in the last four decades. The stationary (and stationary increments) Gaussian case is now covered by a rather complete linear theory, and is surveyed e. g. in [35,37]. For a more up to date account, see the forthcoming book [41]. The nonlinear realization problem is still underdeveloped, see [45,51,62].

Wide-Sense Stochastic Realization

We shall discuss only the wide-sense version of the realization problem, where random variables and processes are described in terms of first- and second-order moments. Since first- and second-order moments individuate a Gaussian distribution uniquely, the theory will in particular cover the Gaussian case. Hereafter, wide-sense stationarity will be simply referred to as stationarity. Also, a "wide-sense Markov process" will simply be called a "Markov process".

The wide-sense realization problem may look like a very particular modeling problem to deal with, but it is completely solvable and is general enough to reveal quite explicitly some of the important features of the solution set of stochastic realizations, some of which are quite unexpected. It is also motivated by its wide applicability since most times in practice the only reasonable way to describe a priori random phenomena is by second-order moments, say by covariances or spectra.

We advise the reader that in many applied fields one may want to construct dynamical system models involving also exogenous input (or decision) variables. The stochastic realization problem of constructing linear state-space representations of a stationary process with inputs has been studied in [11,53,54,55]. In the last two references one may find also material related to the germane problem of *identification with inputs*.

For reasons of space limitations we shall not touch upon this subject. A pointer to the relevant identification literature will be given in the final section of the article.

We shall discuss in some detail only stochastic realization of *discrete-time* random processes. An analogous (and in fact somewhat simpler) treatment can be given for continuous time processes [35] but we choose discrete-time since this theory makes contact with system identification which we shall discuss later in the section entitled "Dynamical System Identification".

Given a vector (say m-dimensional) wide-sense stationary purely nondeterministic (purely nondeterministic will be abbreviated to p.n.d. in the following; this property is called *linear regularity* in the Russian literature, see [57]) process $y = \{y(t)\}$ with $t \in \mathbb{Z}$ (the integers), one wants to find representations of y in terms of a finite dimensional Markov process. In other words one wants to find linear representations of the stationary process y, of the form

$$x(t+1) = Ax(t) + Bw(t) \tag{8a}$$

$$y(t) = Cx(t) + Dw(t) \tag{8b}$$

and procedures for constructing them. Here $\{w(t)\}$ is a vector, p-dimensional normalized white noise process, i. e. $\mathbb{E}\{w(t)w(s)'\} = I\delta(t-s)$, $\mathbb{E}\{w(t)\} = 0$, δ being the Kronecker delta function. Note that a white noise w could be seen as a (degenerate) kind of Markov process. The reason for having the term $Dw(t)$ in (8b) is to avoid the presence of such degenerate components in the dynamic equation for the state process x which would artificially increase its dimension. With this convention, in the extreme circumstance where $y = w$, the state dimension (of a minimal realization) is zero.

The linear representation (8a) involves auxiliary variables, i. e. random quantities which are not given as a part of the original data, especially the n-dimensional state process x (a stationary Markov process) and the generating white noise w. The peculiar properties of these processes actually embody the desired system structure (8a). Constructing these auxiliary processes is an essential part of the realization problem.

We shall restrict ourselves to representations (8a) for which

- (A,B,C) is a minimal triplet; i. e. (A, B) is a reachable pair and (A, C) is an observable pair, see e. g. [24] for these notions;
- $\begin{bmatrix} B \\ D \end{bmatrix}$ has independent columns.

These are classical conditions of nonredundancy of the model [24] and entail no loss of generality. From standard spectral representation theory, see e. g., Chap. 1 in [57], it follows that Eq. (8a) admits stationary solutions if and only if the rows of the $n \times p$ matrix $(e^{i\theta}I - A)^{-1}B$ are square integrable functions of $\theta \in [-\pi, \pi]$. This is equivalent to the absence of poles of the function $z \to (zI - A)^{-1}B$ on the unit circle. Equivalently, the eigenvalues of A of modulus one, if any, must be "unreachable" for the pair (A, B).

When eigenvalues on the unit circle are present, to guarantee stationarity they must be simple roots of the minimal polynomial of A. These eigenvalues, necessarily in even number say $2k$, give then rise to a sum of k uncorrelated sinusoidal oscillations with random amplitude, the so-called *purely deterministic* component of the process. This purely deterministic component of the stationary Markov process x obeys a fixed undriven (i. e. deterministic) linear difference equation of the type $x(t+1) = A_o x(t)$, which is the restriction of (8a) to the modulus one eigenspace of A. The initial conditions are random variables independent of the driving noise w. Since there is no stochastic forcing term in this restricted state equation, it follows that the presence of a purely deterministic component in the Markov process necessarily implies that the pair (A, B) must be nonreachable. The first of the two conditions of nonredundancy listed above hence excludes the presence of a purely deterministic component in the state, and therefore also in the output process y.

From this discussion it is immediately seen that there are stationary solutions x of the difference Eq. (8a) which are p.n.d. Markov processes if and only if A does not have eigenvalues of modulus one; i. e.

$$|\lambda(A)| \neq 1 \,. \tag{9}$$

When $|\lambda(A)| < 1$, the representation (8a) is called *forward* or *causal*. When $|\lambda(A)| > 1$ the representation is called *backward* or *anticausal*. Traditionally the causality of a representation, i. e. the condition $|\lambda(A)| < 1$ has been regarded as being equivalent to stationarity. In fact, stationarity permits a whole family of representations (8a) of the (same) process x, where the matrices A can have very different spectra. Formulas for computing a backward representation starting from a forward one or vice versa are given in [34,36]. The two representations (in particular the relative A matrices) are related by a particular family of *linear state feedback* transformations [47].

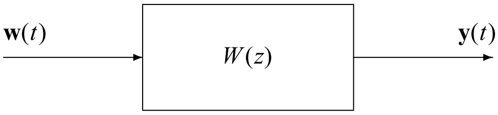
The *covariance function* of a zero-mean wide sense stationary process y is the $m \times m$ matrix function $k \mapsto \Lambda_k$, defined by

$$\Lambda_k := \mathbb{E}\{y(t+k)y(t)'\} = \mathbb{E}\{y(k)y(0)'\} \qquad k \in \mathbb{Z} \,.$$

This matrix function will be the initial data of our problem. Since y is p.n.d. the function Λ admits a Fourier transform called the *spectral density* matrix of y, given by

$$\Phi(z) = \sum_{t=-\infty}^{\infty} \Lambda_t z^{-t}$$

where $z = e^{i\theta}$; $\theta \in [-\pi, \pi]$. It is easy to see that the spectral density matrix of a process admitting a state-space realization (8a) must be a rational function of z. This fact follows easily by eliminating the variable x in (8a) and thereby expressing y as the output of a linear filter as in Fig. 1 below whose transfer function $W(z) = C(zI - A)^{-1}B + D$ is a rational function of z, and then using the classical Kintchine and Wiener formula for the spectrum of a filtered



Stochastic Noises, Observation, Identification and Realization with, Figure 1
Shaping filter representation of a stochastic process

stationary process [28,69] so that,

$$\Phi(z) = W(z)W(1/z)' \,. \tag{10}$$

Hence we have

Proposition 1 *The transfer function $W(z) = C(zI - A)^{-1}B + D$ of any state space representation (8a) of the stationary process y, is a* spectral factor *of Φ, in the sense that it satisfies the spectral factorization equation (10).*

It is easy and instructive to check this directly. Supposing that one has a *causal* realization (8a), one can compute for $k \geq 0$,

$$\begin{aligned}\Lambda_k &= \mathbb{E}[\, CA^k x(t) \\ &+ \sum_{s=0}^{k-1} CA^{k-1-s}Bw(t+s) + Dw(t+k)\,] \\ &\qquad\qquad [Cx(t) + Dw(t)]' \end{aligned} \tag{11}$$

$$= CA^{k-1}\bar{C}' + \frac{1}{2}\Lambda_0\delta(t) \,, \tag{12}$$

where $\bar{C}' = \mathbb{E}x(t+1)y(t)'$ and $\Lambda_0 = \mathbb{E}y(t)y(t)'$. By identifying terms, these matrices can be expressed directly in terms of the realization parameters A, B, C, D, by

$$P = APA' + BB' \tag{13a}$$

$$\bar{C}' = APC' + BD' \tag{13b}$$

$$\Lambda_0 = CPC' + DD' \tag{13c}$$

the matrix $P = \mathbb{E}x(t)x(t)'$ being the covariance matrix of the state process. Note that P obeys Eq. (13a) since by causality ($|\lambda(A)| < 1$) $x(t)$ is a function of the infinite past $\{w(s);\ s < t\}$ and hence is uncorrelated with $w(t)$ so that the two terms in the right hand side of (8a) are also uncorrelated and their variances add. In fact, by reachability of the model, P is actually (symmetric and) positive definite.

Now, introduce the decomposition

$$\Phi(z) = \Phi_+(z) + \Phi_+(1/z)' \tag{14}$$

where $\Phi_+(z) = \frac{1}{2}\Lambda_0 + \Lambda_1 z^{-1} + \Lambda_2 z^{-2} + \cdots$ is analytic outside of the unit circle. Clearly $\Phi_+(z)$ must be the Fourier transform of the "causal" tract of the covariance function Λ, computed in (12). Hence

$$\Phi_+(z) = C(zI - A)^{-1}\bar{C}' + \frac{1}{2}\Lambda_0 \,. \tag{15}$$

This shows that the spectrum of a process y described by a state-space model (8a), besides being a rational function of z, is directly expressible in parametric form in terms of the parameters of a causal realization. This explicit computation of the spectrum seems to be due to R.E. Kalman and B.D.O. Anderson [4,21].

"Classical" stochastic realization theory, developed in the late 1960s [3,4,17], deals with the inverse problem of computing the parameters A, B, C, D of a state space realization starting from the spectrum (or, equivalently, of the covariance function) of a stationary process y. Of course one assumes here that y is p.n.d. and has a spectral density Φ which is a rational function of $z = e^{j\theta}$.

This inverse problem is just a parametric version of the spectral factorization problem: Given a rational spectrum $\Phi(z)$ one looks for rational spectral factors parametrized as $W(z) = C(zI - A)^{-1}B + D$, solutions of (10). Since rational factors of a given spectral density matrix are in general infinitely many, one must preliminarily single out the interesting solutions by imposing certain restrictions. One very reasonable restriction which is imposed on the solutions of (10) is that the spectral factors should be of *minimal degree*. The degree of a proper rational matrix function is by definition the dimension n of the state of a minimal realization. Minimal degree (for short, *minimal*) spectral factors must have a degree which is exactly one half of the degree of the spectral density matrix $\Phi(z)$.

The solution of the inverse problem is described in the following proposition.

Proposition 2 *Assume the spectrum is given in the parametric form (15) where $|\lambda(A)| < 1$ and $(A, C, \bar{C}')$ is a minimal triplet of dimension n. Then the minimal degree spectral factors of $\Phi(z)$,* analytic in$\{|z| > 1\}$, *are in one-to-one correspondence with the symmetric $n \times n$ matrices P solving the* Linear Matrix Inequality *(LMI)*

$$M(P) := \begin{bmatrix} P - APA' & \bar{C}' - APC' \\ \bar{C} - CPA' & \Lambda_0 - CPC' \end{bmatrix} \geq 0 \tag{16}$$

where the symbol $\geq$ means positive semidefinite. The correspondence is to be understood in the following sense:

Corresponding to each solution $P = P'$ of (16), consider the full column rank matrix factor $\begin{bmatrix} B \\ D \end{bmatrix}$ of $M(P)$,

$$M(P) = \begin{bmatrix} B \\ D \end{bmatrix} [B'D'] \tag{17}$$

(this factor is unique modulo right multiplication by orthogonal matrices) and form the rational matrix

$$W(z) := C(zI - A)^{-1}B + D \,. \tag{18}$$

Then (18) is a minimal realization of a minimal analytic spectral factor of $\Phi(z)$ and all minimal analytic factors can be obtained in this way.

Note that any matrix P solving the LMI satisfies the system (12) and hence can be interpreted as the state covariance of a causal realization of y. It follows that any P solving the LMI is necessarily positive definite.

In fact it has been shown [17] that the set of symmetric solutions to the LMI (16)

$$\mathcal{P} := \{P = P' \, ; \, M(P) \geq 0\}$$

is a closed, bounded and convex set with maximal and minimal elements $P_-, \, P_+ \in \mathcal{P}$ which satisfy

$$P_- \leq P \leq P_+ \quad \text{for all} \ \ P \in \mathcal{P}$$

where $P_1 \leq P_2$ means that $P_2 - P_1 \geq 0$ (is positive semidefinite).

The existence of solutions to the LMI is equivalent to the property of $\Phi_+(z)$ defined in (14) of being a *positive-real matrix function*, namely that Φ_+ should be analytic in $\{|z| > 1\}$ and that $\Re e \, \Phi_+(e^{j\theta}) \geq 0$. The second condition is automatically satisfied when Φ admits spectral factors since

$$2\Re e \, \Phi_+(e^{j\theta}) = W(e^{j\theta}) W(e^{j\theta})^* \geq 0$$

(the star meaning complex conjugate transpose). This property can be characterized in general, for not necessarily stable representations, by the so-called *positive-real lemma* discovered in the 1960s by Kalman, Yakubovich, and Popov [22,56,71] in the context of dissipative systems and stability theory. The first application of the Kalman–Yakubovich–Popov theory to factorization of spectral density functions and to stochastic realization (called *stationary covariance generation*) is due to B.D.O. Anderson [3,4]. Far reaching generalizations to not necessarily stable systems have been pursued by J.C. Willems in his widely quoted paper [70]. The terminology "positive real" derives from network synthesis.

Under certain conditions on the zeros of the spectrum, discussed e. g. in [18], the matrix $\Delta(P) := \Lambda_0 - CPC'$ is nonsingular (and hence positive definite) for all $P \in \mathcal{P}$. In this case (16) is equivalent to the nonnegativity of the Schur complement of $\Delta(P)$ in the matrix $M(P)$, which can be written

$$P - APA' - (\bar{C}' - APC')\Delta(P)^{-1}(\bar{C}' - APC')' \leq 0 \, . \quad (19)$$

This is the *Algebraic Riccati Inequality* (ARI) of spectral factorization, first analyzed in the work of [3,17]. The solutions of the ARI with equality sign; i. e. the solutions of the Algebraic Riccati Equation (ARE)

$$P - APA' - (\bar{C}' - APC')\Delta(P)^{-1}(\bar{C}' - APC')' = 0 \quad (20)$$

make $M(P)$ of minimal rank $m = \dim y$ and hence correspond to *square spectral factors* (18). These spectral factors all have the same denominator matrix A and hence only differ by the location of their zeros. In particular one may show that $P_-, \, P_+$ solve the ARE and the two spectral factors W_- and W_+ corresponding to $P_-, \, P_+$ (are square and) have all of their zeros inside and respectively outside of the unit circle. In other words, W_- is the *minimum phase* and W_+ the *maximum phase* spectral factor. These spectral factors are essentially unique. All other square spectral factors are obtained (in rough terms) by "flipping" some of the zeros of W_- to their reciprocals outside of the unit circle. The maximum phase factor, W_+, is obtained by flipping *all* of the zeros of W_- to their reciprocals. More information on the zero structure of the minimal spectral factors can be found in [39].

In the next section we shall analyze in more detail the correspondence between spectral factors and stochastic realizations. As we shall see, for square spectral factors this correspondence is one-to-one and hence this particular class of stochastic realizations, for which $\dim w = \dim y = m$ can be classified according to their zero location.

The LMI plays an important role in many areas of system theory such as stability theory, dissipative systems and is central in H^∞ control and estimation theory. It seems to be much less appreciated in the scientific community that it plays a very basic role in modeling of stationary random signals as well. As we shall see in the next section certain solutions of the LMI (or of the ARI) have special probabilistic properties and are related to Kalman-filter or "innovations-type" realizations.

Geometric Stochastic Realization

The classical stationary covariance realization theory of the previous section is purely distributional as it says nothing about representation of random quantities in a truly probabilistic sense (i. e. how to generate the random variables or the sample paths of a given process, not just its covariance function). This was implicitly pointed out by Kalman already in [23]. In the last decades a *geometric coordinate-free* approach to stochastic modeling has been put forward in a series of papers by Lindquist, Picci, Ruckebusch et al. [33,34,35,58,59,60] which aims at the representation of random processes in this more specific sense. This motivation is also present in the early papers by Akaike [1,2].

A main point of the geometric approach is to provide procedures for the construction of the random quantities defining a stochastic state-space realization. In particular the *state space* of a realization is defined in terms of the conditional independence relation between past and future of the signals involved. This relation is intrinsically *coordinate-free* and in the present setting involves only linear subspaces of a given ambient Hilbert space of random variables, typically made of linear functionals of the variables of the process y to be modeled (but in some situations other random data may be used to construct the model).

Constructing the State Space of a Stationary Process

The theme of this section will be a review of geometric realization theory for the stochastic process y. The geometric theory centers on the idea of *Markovian Splitting Subspace* for the process y. This concept is the probabilistic analog of the deterministic notion of state space of a dynamical system and captures at an abstract level the property of "dynamic memory" that the state variables have in deterministic dynamical system theory. Once a stochastic state space is given the construction of the auxiliary random quantities which enter in a state space model and in particular the state process is fairly obvious. The state vector $x(t)$ of a particular realization can be regarded just as a particular basis for the state space, hence once a state-space is constructed, finding state equations is just a matter of choosing a basis and computing coordinates.

Notation 1 *In what follows the symbols* $\vee$, $+$ *and* $\oplus$ *will denote vector sum,* direct *vector sum and* orthogonal *vector sum of subspaces, the symbol* $\mathbf{x}^{\perp}$ *will denote the orthogonal complement of a (closed) subspace* $\mathbf{X}$ *of a Hilbert space with respect to some predefined ambient space. Given a collection* $\{X_\alpha \mid \alpha \in A\}$ *of subsets of a Hilbert space* $\mathbf{H}$ *we shall denote by* $\overline{\text{span}}\{X_\alpha \mid \alpha \in A\}$ *the closure in* $\mathbf{H}$ *of the linear (real) vector space generated by the collection. The orthogonal projection onto the subspace* $\mathbf{X}$ *will be denoted by the symbol* $\mathbb{E}(\cdot \mid \mathbf{X})$ *or by the shorthand* $\mathbb{E}^{\mathbf{X}}$*. The notation* $\mathbb{E}(z \mid \mathbf{X})$ *will be used also when* z *is vector-valued. The symbol will then denote the vector with components* $E(z_k \mid \mathbf{X})$, $k = 1, \ldots$*. For vector quantities,* $|v|$ *will denote Euclidean length (or absolute value in the scalar case).*

Let y be a zero mean stationary vector process with finite second-order moments defined on some underlying probability space $\{\Omega, \mathcal{A}, \mu\}$ and let $L^2\{\Omega, \mathcal{A}, \mu\}$ denote the Hilbert space of second-order random variables defined on Ω, endowed with the inner product $< \xi, \eta >= \mathbb{E}\{\xi\eta\}$. Let $\mathbf{H}(y)$ be the (closed) linear subspace of $L^2\{\Omega, \mathcal{A}, \mu\}$, linearly generated by the variables of the process; i. e.

$$\mathbf{H}(y) := \overline{\text{span}}\{y_k(t)\,; k = 1, 2, \ldots, m;\ t \in \mathbb{Z}\}\,.$$

If y is generated by a linear model of the type (8a) this Hilbert space will in general be a proper subspace of the space $\mathbf{H}(w)$, generated by the input white noise of the model (8a). All random variables of the stochastic system (8a) belong to $\mathbf{H}(w)$ and for this reason $\mathbf{H}(w)$ is called the *ambient space* of the model. By stationarity of w, $\mathbf{H}(w)$ comes naturally equipped with a unitary operator U, called the *shift* of w, such that $Uw_i(t) = w_i(t+1)$ for $i = 1, 2, \ldots, p$ and all $t \in \mathbb{Z}$ (stationarity). Note that the family $\left\{U^t; t \in \mathbb{Z}\right\}$ forms a one parameter group of unitary operators on the ambient space; in particular, $U^{-t} = (U^*)^t$. The pair $(\mathbf{H}(w), U)$ is also called a *stationary Hilbert space*. Clearly the processes x and y will also be stationary with respect to U.

The *past* and *future* subspaces (at time zero) of a stationary process are

$$\mathbf{H}^-(y) := \overline{\text{span}}\{y_k(t)\,; k = 1, 2, \ldots, m;\ t < 0\}$$
$$\mathbf{H}^+(y) := \overline{\text{span}}\{y_k(t)\,; k = 1, 2, \ldots, m;\ t \geq 0\}\,.$$

Because of stationarity everything propagates in time by the action of the unitary group, e. g. the past and future at time t are obtained as $\mathbf{H}_t^-(y) = U^t\mathbf{H}^-(y)$ and $\mathbf{H}_t^+(y) = U^t\mathbf{H}^+(y)$. For this reason the geometric definitions and constructions to follow, although valid for an arbitrary time instant will usually be referred to the time instant $t = 0$.

Let $\mathbf{X}$ be a subspace of some large stationary Hilbert space $\mathbf{H}$ of wide-sense random variables containing $\mathbf{H}(y)$. Define

$$\mathbf{X}_t := U^t\mathbf{X}, \quad \mathbf{X}_t^- := \vee_{s \leq t}\mathbf{X}_s, \quad \mathbf{X}_t^+ := \vee_{s \geq t}\mathbf{X}_s.$$

Definition 1 A *Markovian Splitting Subspace* $\mathbf{X}$ for the process y is a subspace of $\mathbf{H}$ making the vector sums $\mathbf{H}(y)^- \vee \mathbf{X}^-$ and $\mathbf{H}(y)^+ \vee \mathbf{X}^+$ conditionally orthogonal (i. e. conditionally uncorrelated) given $\mathbf{X}$, denoted,

$$\mathbf{H}(y)^- \vee \mathbf{X}^- \perp \mathbf{H}(y)^+ \vee \mathbf{X}^+ \mid \mathbf{X}. \tag{21}$$

The conditional orthogonality condition (21) can be equivalently written as

$$\mathbb{E}[\mathbf{H}(y)^+ \vee \mathbf{X}^+ \mid \mathbf{H}(y)^- \vee \mathbf{X}^-] = \mathbb{E}[\mathbf{H}(y)^+ \vee \mathbf{X}^+ \mid \mathbf{X}] \tag{22}$$

$$\mathbb{E}[\mathbf{H}(y)^- \vee \mathbf{X}^- \mid \mathbf{H}(y)^+ \vee \mathbf{X}^+] = \mathbb{E}[\mathbf{H}(y)^- \vee \mathbf{X}^- \mid \mathbf{X}] \tag{23}$$

which formalize the intuitive meaning of the splitting subspace $\mathbf{X}$ as a dynamic memory of the past (future) for the purpose of predicting the joint future (past). It follows in particular that $\mathbb{X}$ is Markovian (i. e. $\mathbf{X}^- \perp \mathbf{X}^+ \mid \mathbf{X}$) and any basis vector $x := [x_1, x_2, \ldots, x_n]'$ in a (finite-dimensional) Markovian splitting subspace $\mathbf{X}$ generates a stationary Markov process $x(t) := U^t x$, $t \in \mathbb{Z}$ which, as we shall see in a moment, serves as a *state* for the process y.

The subspace $\mathbf{X}$ is called *proper*, or *p.n.d.* if

$$\cap_t \mathbf{Y}_t^- \vee \mathbf{X}_t^- = \{0\}, \text{ and } \cap_t \mathbf{H}(y)_t^+ \vee \mathbf{X}_t^+ = \{0\}\,.$$

Obviously for the existence of proper splitting subspaces y must also be purely nondeterministic [57]. Properness is, by the Wold decomposition theorem, equivalent to the existence of two vector white noise processes w and $\bar{w}$ such that,

$$\mathbf{H}(y)^- \vee \mathbf{X}^- = \mathbf{H}^-(w)\,, \quad \mathbf{H}(y)^+ \vee \mathbf{X}^+ = \mathbf{H}^+(\bar{w})\,.$$

If $\mathbf{X}$ is proper, every Markov process $x(t) := U^t x$ is purely nondeterministic.

The subspaces

$$\mathbf{S} := \mathbf{H}(y)^- \vee \mathbf{X}^- \quad \text{and} \quad \bar{\mathbf{S}} := \mathbf{Y}^+ \vee \mathbf{X}^+ \tag{24}$$

associated to a Markovian Splitting subspace $\mathbf{X}$, play an important role in the geometric theory of stochastic systems. They are called the *scattering pair* of $\mathbf{X}$ as they can be seen to form an incoming–outgoing pair in the sense of Lax–Phillips Scattering Theory [29].

Definition 2 Given a stationary Hilbert space $(\mathbf{H}, U)$ containing $\mathbf{H}(y)$, a *scattering pair* for the process y is a pair of subspaces $(\mathbf{S}, \bar{\mathbf{S}})$ satisfying the following conditions for a stationary process,

1. $U^*\mathbf{S} \subset \mathbf{S}$ and $U\bar{\mathbf{S}} \subset \bar{\mathbf{S}}$, i. e. $\mathbf{S}$ and $\bar{\mathbf{S}}$ are invariant for the left and right shift semigroups (this means that $\mathbf{S}_t$ is increasing and $\bar{\mathbf{S}}_t$ is decreasing with time).
2. $\mathbf{S} \vee \bar{\mathbf{S}} = \mathbf{H}$
3. $\mathbf{S} \supset \mathbf{H}(y)^-$ and $\bar{\mathbf{S}} \supset \mathbf{H}(y)^+$
4. $\mathbf{S}^\perp \subset \bar{\mathbf{S}}$ or, equivalently, $\bar{\mathbf{S}}^\perp \subset \mathbf{S}$

The following representation Theorem provides the link between Markovian splitting subspaces and scattering pairs.

Theorem 1 ([35]) *The intersection*

$$\mathbf{X} = \mathbf{S} \cap \bar{\mathbf{S}} \tag{25}$$

of any scattering pair of subspaces of $\mathbf{H}$ *is a Markovian splitting subspace. Conversely every Markovian splitting subspace can be represented as the intersection of a scattering pair. The correspondence* $\mathbf{X} \leftrightarrow (\mathbf{S}, \bar{\mathbf{S}})$ *is one-to-one, the scattering pair corresponding to* $\mathbf{X}$ *being given by*

$$\mathbf{S} = \mathbf{H}(y)^- \vee \mathbf{X}^- \qquad \bar{\mathbf{S}} = \mathbf{H}(y)^+ \vee \mathbf{X}^+\,. \tag{26}$$

The process of forming scattering pairs associated to $\mathbf{X}$ should be thought of as an "extension" of the past and future spaces of y. The rationale for this extension is that scattering pairs have an extremely simple splitting geometry due to the fact that

$$\mathbf{S} \perp \bar{\mathbf{S}} \mid \mathbf{S} \cap \bar{\mathbf{S}} \tag{27}$$

equivalent to

$$\mathbf{S} \vee \bar{\mathbf{S}} = \bar{\mathbf{S}}^\perp \oplus (\mathbf{S} \cap \bar{\mathbf{S}}) \oplus \mathbf{S}^\perp \tag{28}$$

which is called *perpendicular intersection*. It is easy to show that Property (4) in the definition of a scattering pair is actually equivalent to perpendicular intersection. This property of conditional orthogonality given the intersection can also be seen as a natural generalization of the Markov property. Indeed for a Markovian family of subspaces $\mathbf{X} = \mathbf{X}^- \cap \mathbf{X}^+$ and $\mathbf{S} = \mathbf{X}^-$, $\bar{\mathbf{S}} = \mathbf{X}^+$ intersect perpendicularly with intersection $\mathbf{X}$.

Note that $\mathbf{A} \perp \mathbf{B} \mid \mathbf{X} \Rightarrow \mathbf{A} \cap \mathbf{B} \subset \mathbf{X}$ but the inclusion of the intersection in the splitting subspace $\mathbf{X}$ is only *proper* in general. For perpendicularly intersecting subspaces, the intersection is actually the *unique minimal subspace* making them conditionally orthogonal.

Theorem 1 is the fundamental device for the construction and classification of Markovian splitting subspaces.

Denote by $\mathbf{W}_t, \bar{\mathbf{W}}_t$ the (wandering) subspaces spanned by the components, at time t, of the generating noises $w(t)$ and $\bar{w}(t)$, of the scattering pair of $\mathbf{X}$. Since

$$\mathbf{S}_{t+1} = \mathbf{S}_t \oplus \mathbf{W}_t\,, \tag{29}$$

we can write,

$$\mathbf{X}_{t+1} = \mathbf{S}_{t+1} \cap \bar{\mathbf{S}}_{t+1} \subset (\mathbf{S}_t \cap \bar{\mathbf{S}}_{t+1}) \oplus (\mathbf{W}_t \cap \bar{\mathbf{S}}_{t+1}) \tag{30}$$

Since $\bar{\mathbf{S}}_t$ is decreasing in time, we have $\mathbf{S}_t \cap \bar{\mathbf{S}}_{t+1} \subset \mathbf{X}_t$ and by projecting the shifted basis $Ux(t) := x(t+1)$, onto the last orthogonal direct sum above, the time evolution of any basis vector $x(t) := [x_1(t), x_2(t), \ldots, x_n(t)]'$ in $\mathbf{X}_t$, is described by a linear equation of the type

$$x(t+1) = Ax(t) + Bw(t)\,.$$

It is also easy to see that, by the p.n.d. property, A must have all its eigenvalues strictly inside of the unit circle. Naturally, by decomposing instead $\bar{\mathbf{S}}_{t-1} = \bar{\mathbf{S}}_t \oplus \bar{\mathbf{W}}_t$ one could have obtained a *backward difference equation* model for the Markov process x, driven by the backward generating noise $\bar{w}$.

To complete the representation, note that by definition of the past space, $y(t) \in (\mathbf{S}_{t+1} \cap \bar{\mathbf{S}}_t)$. Inserting the decomposition (29) and projecting $y(t)$, leads to a state-output equation of the form

$$y(t) = Cx(t) + Dw(t) .$$

Here one could also obtain a state-output equation driven by the backward noise $\bar{w}$, the same noise driving the backward state model obtained before.

As we have just seen, any basis in a Markovian splitting subspaces produces a stochastic realization of y. It is easy to reverse the implication. In fact the following fundamental characterization holds.

Theorem 2 ([33,37]) *The state space* $\mathbf{X} = \text{span}\{x_1(0), x_2(0), \dots, x_n(0)\}$ *of any stochastic realization (8a) is a Markovian splitting subspace for the process y.*

Conversely, given a finite-dimensional Markovian splitting subspace $\mathbf{X}$*, to any choice of basis* $x(0) = [\, x_1(0), x_2(0), \dots, x_n(0)\,]'$ *in* $\mathbf{X}$ *there corresponds a stochastic realization of y of the type (8a).*

Once a basis in $\mathbf{X}$ is available, there are obvious formulas to compute the parameters $(A, C, \bar{C})$ of the corresponding stochastic realization, namely

$$A = \mathbb{E}x(t+1)x(t)'\, P^{-1} \tag{31}$$

$$C = \mathbb{E}y(t)x(t)'\, P^{-1} \tag{32}$$

$$\bar{C} = \mathbb{E}y(t-1)x(t)' \tag{33}$$

where $P = \mathbb{E}x(t)x(t)'$ is the state covariance matrix (i. e. the Gramian matrix of the basis). The matrices B and D, however, are related to the (unobservable) generating white noise w and require the solution of the LMI. This abstract procedure which permits us to compute the parameters of a stochastic realization once the state has been constructed, can be rendered quite concrete and forms the conceptual basis of subspace identification.

Stochastic realizations are called *internal* when $\mathbf{H} = \mathbf{H}(y)$, i. e. the state space is built from the Hilbert space made just of the linear statistics of the process y. For identification the only realizations of interest are the internal ones.

A central problem of geometric realization theory is to construct and to classify all minimal state spaces, i. e. the minimal Markovian splitting subspaces for the process y.

The obvious ordering of subspaces of $\mathbf{H}$ by inclusion, induces an ordering on the family of Markovian splitting subspaces. The notion of minimality is most naturally defined with respect to this ordering. Note that this definition is independent of assumptions of finite-dimensionality and applies also to infinite-dimensional Markovian splitting subspaces, i. e. to situations where comparing dimension would not make much sense.

Definition 3 A Markovian splitting subspace is *minimal* if it does not contain (properly) other Markovian splitting subspaces.

The study of minimality forms an elegant chapter of stochastic system theory. There are several known geometric and algebraic characterizations of minimality of splitting subspaces and of the corresponding stochastic state-space realizations. Since, however, the discussion of this topic would take us too far from the main theme of the paper we shall refer the reader to the literature [35,37].

Contrary to the deterministic situation minimal Markovian splitting subspaces are *nonunique*. Two very important examples are the *forward and backward predictor spaces* (at time zero):

$$\mathbf{X}_{-} := \mathrm{E}^{\mathbf{H}^{-}}\mathbf{H}^{+} \quad \mathbf{X}_{+} := \mathrm{E}^{\mathbf{H}^{+}}\mathbf{H}^{-} \tag{34}$$

for which we have the following characterization [35].

Proposition 3 *The subspaces* $\mathbf{X}_{-}$ *and* $\mathbf{X}_{+}$ *are minimal Markovian splitting subspaces contained in the past* $\mathbf{H}^{-}$*, and, respectively, in the future* $\mathbf{H}^{+}$*, of the process y.*

A basis in the forward predictor space $\mathbf{X}_{-}$ originates a stationary state-space model in which the state variables are linear functionals of the past history of the process y, i. e. $x(t) \in \mathbf{H}_t^{-}(y)$. In other words the state coincides with its best estimate (the orthogonal projection), $E[x(t) \mid \mathbf{H}_t^{-}(y)]$ given the past of y. It follows that the dynamical equations (8a) describe in this case a steady-state Kalman predictor and the input white noise $w = w_{-}$ is the steady state *innovation process* of y.

Before closing this section we should remark that a scattering picture emerges also in some of the early papers on the "unitary dilation" approach to statistical mechanics, e. g. [31,32]. It is remarkable that the abstract scattering picture described in this section makes contact with this literature. The dilation approach, however, deals (in our language) with the reverse problem of describing the stationary shift group starting from (Markov) processes which are described by a Langevin-type equation. This is a curious and (in our view) somewhat unnatural point of view which apparently does not lead to capture the phenomenon of *nonuniqueness of the macroscopic description* of the observables. Whether this has any physical relevance is however not clear to us.

Dynamical System Identification

System identification is the problem of describing an observed time series (e. g. a sequence of real numbers representing stock prices, temperatures in a room, sampled audio or video signals, etc.) by a linear dynamic model, in particular by a state-space model of the type (8a). It is a widely accepted viewpoint that system identification should be regarded as a *statistical* problem [40,42]. This is so because the experimental data which one wants to model very often come from complicated, often unknown, nonlinear physical phenomena subject to unknown interactions with the environment, and it would in general be impossible to attempt a "physical" modelization from first principles. Consequently the models describing the data should be stochastic. The general goal is to get accurate models which are as simple as possible. The problem can then be approached from (at least) two conceptually different viewpoints.

Identification by Parametric Optimization

This is the mainstream "optimization" approach, based on the principle of minimizing a suitable measure of discrepancy between the observed data and the data predicted by a probability law underlying a certain chosen model class. Well-known examples of distance functions are the *likelihood function*, or the average squared *prediction-error* of the observed data corresponding to a particular model. Except for rather trivial model classes, these distance functions depend nonlinearly on the model parameters and the minimization can only be done numerically. Hence the optimization approach leads to iterative algorithms in the parameter space, say in the space of minimal (A, B, C, D) matrix quadruples which parametrize a chosen model class. In spite of the fact that this has been almost the only accepted paradigm in system identification for many decades, [42,61], this approach has several drawbacks, including the need of unique parametrization of multivariable models, the fact that the cost function generally has complicated local minima which, for moderate or large dimension of the model are very difficult to detect, and the inherent insensitivity of the cost to variations of some parameters and the corresponding ill-posedness of the estimation problem.

It seems that these limitations are a consequence of the intrinsically "blind" philosophy which underlies setting the problem as a parameter optimization problem. Almost all problems of controller and/or estimator design could in principle be formulated just as parametric optimization after choosing a certain family of parametric structures for the controller or the estimator. Pushing this philosophy to the extreme, in principle one would not need the maximum principle, Kalman filtering, H^∞ theory, etc. (in fact one would not need system and control theory altogether), since everything could be reduced to a nonlinear programming problem in a suitable space of controller or estimator parameters. It is dubious however, whether any real progress in the field of control and estimation could have occurred by following this type of paradigm.

Identification by Stochastic Realization

This is commonly referred to as "subspace methods" identification or "subspace identification" *tout-court*. Subspace identification is essentially a sample version of stochastic realization. Under a reasonable assumption of second-order ergodicity of the process y which has produced the observed data, one can set up a "sample" counterpart of the abstract Hilbert space operations of stochastic realization theory. In this setting the geometric operations of stochastic realization can be translated into statistical operations on the observed data. One obtains a statistical theory of model building which is in a sense perfectly isomorphic to the abstract probabilistic realization theory. The main point is the idea of constructing first a (sample) *state space* for the process y, starting from certain vector spaces, called the *future* and *past* spaces associated with the observations. According to the recipe of (34) the state space is constructed by orthogonal projection of the future onto the past, as seen in the previous section. Successively, a well conditioned basis is chosen in the state space e. g. by principal components (canonical correlation) analysis. Once a "robust" basis; i. e. a state vector, is chosen, the parameters $A, C, \bar{C}$ of the model are computed by formulas analogous to (31),(32),(33). The final step of finding the B and D matrices requires solving a Riccati equation.

By similarity with realization theory, one recognizes that the inherent nonlinearity of model identification has to do with the quadratic nature of the spectral factorization problem. As we have seen, spectral factorization for state-space models involves the solution of a Riccati equation (or more generally of a linear matrix inequality), a problem which has been the object of intensive theoretical and numerical studies in the past three decades. The nonlinearity of the stochastic system identification problem is hence of a well-known and well-understood kind and is much better dealt with by the explicit methods of Riccati solution developed in system theory rather than by nonspecific optimization algorithms. This has allowed a systematic introduction of very reliable and efficient numerical linear algebra tools to solve the problem. The "subspace" approach has been suggested more or less implicitly by several authors in the past [6,13,15,44] but is first clearly presented in [63]. Various extensions to cover identification of systems with inputs have appeared since this paper and there is now a large literature on the subject. For references we refer the reader to the recently published book [27].

Since the optimization approach is well covered in the literature, we shall just analyze subspace identification below.

The Hilbert Space of a Time Series

The crucial conceptual step in subspace identification is a proper identification of the Hilbert space of random data in which modeling takes place. We shall briefly illustrate this point, following [38].

We shall initially consider an idealized situation in which the observed data (time series)

$$\{y_0, y_1, \ldots, y_t, \ldots\} \qquad y_t \in \mathbb{R}^m \tag{35}$$

is infinitely long.

We shall assume that the limit for $N \to \infty$ and for any $\tau \geq 0$, of the time averages

$$\frac{1}{N+1} \sum_{t=0}^{N} y_{t+\tau} y_t' \tag{36}$$

exists. It can be shown that this limit is a function $\tau \to \Lambda_\tau$ of *positive type*. In the continuous-time setting, functions admitting an "ergodic" limit of the sample correlation function (36), have been studied in depth by Wiener in his famous work on Generalized Harmonic Analysis. Although a systematic translation of the continuous-time results of Wiener into discrete-time seems not to be available in the literature, it is quite evident that a totally analogous set of results holds also for discrete-time signals. In particular it is rather easy to show, by adapting Wiener's proof for continuous time, that the limits of the time averages (36) form a matrix function Λ of positive type, in other words a *bona-fide stationary covariance matrix*, see [67,68] which can then be identified with the "true" covariance function of an underlying stochastic process.

The assumption actually implies that

$$\frac{1}{N+1} \sum_{t=t_0}^{N+t_0} y_{t+\tau} y_t' \to \Lambda_\tau \tag{37}$$

for arbitrary t_0, which can be read as a kind of "statistical regularity" of the (future) data. The ergodicity (36) is of course unverifiable in practice as it says something about data which have not been observed yet. Some assumption of this sort about the mechanism generating future data seems however to be necessary to even formulate the identification problem. We shall call Λ the *true covariance* of the time series $\{y_t\}$.

Now, for each $t \in \mathbb{Z}_+$ define the $m \times \infty$ matrices

$$\mathbb{y}(t) := [y_t, y_{t+1}, y_{t+2}, \ldots] \tag{38}$$

and consider the sequence $\mathbb{y} := \{\mathbb{y}(t) \mid t \in \mathbb{Z}_+\}$. We shall make this sequence of semi-infinite matrices into an object isomorphic to the stationary processes y.

Define the vector space $\mathbb{Y}$ of scalar semi-infinite real sequences obtained as finite linear combinations of the rows of y,

$$\mathbb{Y} := \left\{ \sum a_k' \mathbb{y}(t_k); \quad a_k \in \mathbb{R}^m,\ t_k \in \mathbb{Z}_+ \right\} \tag{39}$$

This space can be naturally made into an inner product space in the following way.

First, define the bilinear form $\langle \cdot, \cdot \rangle$ on the generators by letting

$$\langle a'\mathbb{y}(k), b'\mathbb{y}(j) \rangle := \lim_{N\to\infty} \frac{1}{N+1} \sum_{t=0}^{N} a' y_{t+k} y_{t+j}' b = a' \Lambda_{k-j} b, \tag{40}$$

for $a, b \in \mathbb{R}^m$, and then extend it by linearity to all elements of $\mathbb{Y}$.

Let $\mathbf{a} := \{a_k, k \in \mathbb{Z}_+\}$ be a sequence of vectors $a_k \in \mathbb{R}^m$, with compact support in $\mathbb{Z}_+$, and let $\mathbb{a}' := \{a_k'\}$. A generic element ξ of the vector space $\mathbb{Y}$ can be represented as

$$\xi = \sum_k a_k' \mathbb{y}(k) = \mathbf{a}' \mathbb{y}$$

Let us assume that the infinite block-symmetric Toeplitz matrix

$$T = \begin{bmatrix} \Lambda_0 & \Lambda_1 & \ldots & \Lambda_k & \ldots \\ \Lambda_1' & \Lambda_0 & \Lambda_1 & \ldots & \ldots \\ \vdots & & \ddots & & \vdots \\ \Lambda_k' & & & \Lambda_0 & \\ \ldots & & & & \end{bmatrix} \tag{41}$$

constructed from the "true" covariance sequence $\{\Lambda_0, \Lambda_1, \ldots, \Lambda_k, \ldots\}$ of the data, is positive definite. Since the bilinear form (40) on $\mathbb{Y}$ can be represented by the quadratic form

$$\langle \xi, \eta \rangle = \langle \mathbf{a}'\mathbb{y}, \mathbf{b}'\mathbb{y} \rangle = \sum_{kj} a_k' \Lambda_{k-j} b_j = \mathbf{a}' T \mathbf{b}$$

it can be seen that the bilinear form is nondegenerate (unless $\Lambda = 0$ identically) and defines a bona-fide inner product. As usual one identifies elements whose difference has norm zero (this means $\langle \xi, \xi \rangle = 0 \Leftrightarrow \xi = 0$).

By closing the vector space $\mathbb{Y}$ with respect to the norm induced by the inner product (40), one obtains a real Hilbert space of semi-infinite sequences which hereafter we shall still denote $\mathbb{Y}$. This is the basic data space on which our models will be defined.

The *shift operator* U operates on the family of semi-infinite matrices (38), by the rule

$$Ua'\mathbb{y}(t) = a'\mathbb{y}(t+1) \qquad t \in \mathbb{Z}\,, \quad a \in \mathbb{R}^m$$

It is easy to see that U is a linear map which is isometric with respect to the inner product (40) and can be extended by linearity to all of $\mathbb{Y}$. This Hilbert space framework for time series was introduced in [38]. It is shown in this reference that the "stationary Hilbert space" $(\mathbb{Y}, U)$ is isomorphic to the standard stochastic Hilbert space setup in the L^2 theory of second-order stationary random processes. By virtue of this isomorphism one can formally think of the observed time series (35) as an ergodic sample path of some Gaussian stationary stochastic process $\mathbf{y}$ defined on a true probability space, having covariance matrices equal to the limit Λ of the sum (36) as $N \to \infty$.

Linear functions and operators on the "tail sequences" $\mathbb{y}(t)$ correspond to the same linear functions and operators on the random variables of the process y. In particular the second-order moments of y can be computed in terms of the tail sequences $\mathbb{y}$, by substituting expectations with ergodic limits of the type (40). Since second-order properties are all what matters in our setting, one may even regard the tail sequence $\mathbb{y}$ of (38) as being the *same object* as the underlying stochastic process y. The usual probabilistic language can be adopted in the present setting provided one identifies real random variables as semi-infinite strings of numbers having the "ergodic property" described at the beginning of this section. The inner product of two semi-infinite strings ξ and η in $\mathbb{Y}$ corresponds in particular to the expectation $\mathbb{E}\{\xi\eta\}$; i. e.

$$\langle \xi, \eta \rangle = \mathbb{E}\{\xi\eta\}. \tag{42}$$

This unification of language permits us to carry over in its entirety the geometric theory of stochastic realization derived in the abstract L^2 setting to the time series framework. In particular, the *past* and *future* subspaces of the "processes" $\mathbb{y}$ at time t are defined as the closure of the linear vector spaces spanned by the relative past or future "random variables" $\mathbb{y}(t)$, in the metric of the Hilbert space $\mathbb{Y}$. The only difference to keep in mind here is the different interpretation that representation formulas like (8a) have in this context. The equalities involved in the representation

$$\begin{cases} x(t+1) = Ax(t) + Bw(t) \\ y(t) = Cx(t) + Dw(t) \end{cases} \tag{43}$$

are now to be understood in the sense of equalities of elements of $\mathbb{Y}$, i. e. as asymptotic equality of sequences in the sense of Cesàro limits. In particular the equality signs in the model (43) do not necessarily imply that the same relations hold for the sample values y_t, x_t, w_t at a particular instant of time t. This is in a certain sense similar to the "with probability one" interpretation of the equality sign to be given to the model (43) in case the variables are bona-fide random variables in a probability space.

Consider the orthogonal projection $\mathbb{E}[\,\xi \mid \mathbf{X}]$ of a (row) random variable ξ onto a subspace $\mathbf{X}$ of the space $\mathbb{Y}$. In the probabilistic L^2 setting this has the well-known interpretation of wide-sense conditional expectation given the random variables in $\mathbf{X}$ (a true conditional expectation, in the case of Gaussian distributions). In this setting the projection operator has an immediate and useful *statistical* meaning.

Assume for simplicity that $\mathbf{X}$ is given as the rowspace of some matrix of generators X, then the projection $\mathbb{E}[\,\xi \mid \mathbf{X}]$ has exactly the familiar aspect of the least squares formula expressing the best approximation of the vector ξ as a linear combination of the rows of X. For, writing $\mathbb{E}[\,\xi \mid X\,]$ to denote the projection expressed (perhaps nonuniquely) in terms of the rows of X, the classical linear "conditional expectation" formula leads to

$$\mathbb{E}[\,\xi \mid X\,] = \xi X'[XX']^{\sharp} X\,, \tag{44}$$

which is the universally known "least squares" formula of statistics. The pseudoinverse $\sharp$ can be substituted by a true inverse in case the rows of X are linearly independent.

The Question of Statistical Efficiency

There are questions about the statistical significance (what are the uncertainty bounds on the parameters and on the estimated transfer functions etc.) which are easily and naturally addressed in the optimization framework but harder to be addressed in the subspace/realization approach to identification. The main difference with the mainstream statistical approach is that the estimation of $(A, C, \bar{C})$ is not done *directly* by optimizing a likelihood or other distance functions but by just matching second-order moments, i. e. by solving the Eqs. (46).

This way of proceeding can be seen as an instance of *estimation by the method of moments* described in the statistical textbooks e. g. p. 497 in [12], a very old idea used extensively by K. Pearson in the beginning of the last century. The underlying estimation principle is that the parameter estimates should match exactly the sample second-order moments and is close in spirit to the wide-sense setting that we are working in. It does not involve optimality or minimal distance criteria between the "true" and the model distributions. For this reason it is generally claimed in the literature that one should expect better results (in the sense of smaller asymptotic variance of the estimates) by optimization methods. However, a proof that subspace methods can be efficient (under certain conditions which will be too long to report here) has appeared recently [8].

Usable expressions for the asymptotic covariance of the parameter estimates are given in [9]. The arguments in the derivations are, however, far from trivial.

Subspace Algorithms

Most standard algorithms for subspace identification can be shown to be essentially equivalent to the following three-step procedure (see e. g. [6,38]),

1. The first step is the estimation of a *finite* sequence of sample covariance matrices

$$\{\hat{\Lambda}_0, \hat{\Lambda}_1, \dots, \hat{\Lambda}_\nu\} \tag{45}$$

   from the observed data. Since the data are necessarily finite, ν must be also finite (and in general small compared to the data length).
2. The second step is identification of a rational model for the covariance sequence. This is a *minimal partial realization* (also called "rational extension") problem. Given a finite set of experimental covariance data one is asked to find a minimal value of n and a *minimal* triplet of matrices $(A, C, \bar{C})$, of dimensions $n \times n$, $m \times n$ and $m \times n$ respectively, such that

$$\hat{\Lambda}_k = CA^{k-1}\bar{C}' \qquad k = 1, \dots, \nu. \tag{46}$$

   Recall that $(A, C, \bar{C}')$ is a *minimal triplet*, in the sense of deterministic linear system theory, if the pairs of matrices (A, C) and $(A, \bar{C}')$ are an observable and, respectively, a reachable pair, see e. g. [24]. There are well-known algorithms for computing minimal partial realizations (see e. g. [72] for an efficient algorithm) thereby producing "estimates" of the parameters $(A, C, \bar{C})$ of a minimal realization of a rational spectral density matrix of the process.
3. The third step is to compute, starting from the realization of the rational spectrum estimated in step two, a stationary state-space model. Typically one is interested in the innovation model. This is accomplished by computing the minimal solution P_- of the Linear Matrix Inequality (16), or, equivalently, the minimal solution of the associated algebraic Riccati equation.

A warning is in order concerning the practical use of these algorithms in that some nontrivial mathematical questions related to positivity of the estimated spectrum are often overlooked in the implementation. This issue is thoroughly discussed in [38] and here we shall just give a short summary.

In determining a minimal triplet $(A, C, \bar{C})$ interpolating the partial sequence (45) so that $CA^{k-1}\bar{C}' = \hat{\Lambda}_k \quad k = 1, 2, \dots, \nu$, we also completely determine the infinite sequence

$$\{\hat{\Lambda}_0, \hat{\Lambda}_1, \hat{\Lambda}_2, \hat{\Lambda}_3, \dots\} \tag{47}$$

by setting $\hat{\Lambda}_k = CA^{k-1}\bar{C}'$ for $k = \nu+1, \nu+2, \dots$. This sequence is called a *minimal rational extension* of the finite sequence (45). The attribute "rational" is due to the fact that

$$\begin{aligned}\hat{\Phi}_+(z) &:= \frac{1}{2}\hat{\Lambda}_0 + \hat{\Lambda}_1 z^{-1} + \hat{\Lambda}_2 z^{-2} + \dots \\ &= \frac{1}{2}\hat{\Lambda}_0 + C(zI - A)^{-1}\bar{C}'\end{aligned} \tag{48}$$

is a rational function. In order for (47) to be a bona fide covariance sequence, however, it is necessary that the *infinite* block-Toeplitz matrix obtained by extending the finite matrix

$$T_\nu = \begin{bmatrix} \hat{\Lambda}_0 & \hat{\Lambda}_1 & \hat{\Lambda}_2 & \cdots & \hat{\Lambda}_\nu \\ \hat{\Lambda}_1' & \hat{\Lambda}_0 & \hat{\Lambda}_1 & \cdots & \hat{\Lambda}_{\nu_1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \hat{\Lambda}_\nu' & \hat{\Lambda}_{\nu-1}' & \hat{\Lambda}_{\nu-2} & \dots & \hat{\Lambda}_0 \end{bmatrix} \tag{49}$$

using the rational extension sequence (47), should be nonnegative definite. Equivalently, the spectral density function corresponding to (47)

$$\hat{\Phi}(z) = \hat{\Lambda}_0 + \sum_{k=1}^{\infty} \hat{\Lambda}_k (z^k + z^{-k}) = \hat{\Phi}_+(z) + \hat{\Phi}_+(z^{-1})' \tag{50}$$

should be nonnegative definite on the unit circle. This is equivalent to the function $\hat{\Phi}_+(z)$ being *positive real*. Consequently, the partial realization needs to be done subject to the extra constraint of positivity.

The constraint of positivity is a rather tricky one and in some of the methods described in the literature it is disregarded. For this reason some subspace algorithms may fail to provide a positive extension and hence may lead to data $(A, C, \bar{C})$ for which there are no solutions of the LMI and hence to totally inconsistent results.

It is important to appreciate the fact that the problem of positivity of the extension has little to do with the noise or sample variability of the covariance data and is present equally well for any *finite* covariance sequence extracted from a true (infinitely long) rational covariance sequence. For there is no guarantee that, even in this idealized situation, the order of a minimal rational extension (47) of the finite covariance subsequence would be sufficiently large to equal the order of the infinite sequence and hence to generate a positive extension. A minimal partial realization may well fail to be positive because its order is too low to guarantee positivity. It is shown in [38] that there are relatively "large" sets of data (45) for which this happens and the matrix A may even fail to be stable [7].

Future Directions

Because of the pervasive presence of fast digital computers in modern society, we are witnessing a sharp change of paradigms in the analysis, design, prediction and control of both man made and natural (say biological, economical etc) systems. Because of the tremendous computing capabilities at our disposal nowadays, stochastic modeling, realization and identification have become an essential ingredient of modern applied sciences. In particular modeling and simulation of complex technological, biological, economic, and environmental systems is becoming more and more essential for understanding the behavior and for prediction and control of these systems. New problems continually arise and much work remains to be done.

We just mention here problems where there is a need of modeling the effect of *input* or *decision variables*, possibly in the presence of feedback. Such *Input–Output* models have important applications in many applied areas such as control of industrial processes, econometrics, etc. There is a large body of results concerning stochastic realization and subspace identification of systems with inputs which we could not discuss in this article, see [10,11,26,27,53,54,55,64,65]. The area is important for applications and still needs research. Modeling and realization of finite state processes and of certain classes of highly non-Gaussian signals is needed in diverse applications such as source coding, image processing, and computer vision.

Article Outline

Glossary

Fokker–Planck equation A partial differential equation of the second order for the time evolution of the probability density function of a stochastic process. It resembles a diffusion equation, but has an extra term which represents the deterministic aspects of the process.

Langevin equation A stochastic differential equation of the simplest kind: linear and with an additive Gaussian white noise. Introduced by Langevin [30] in 1908 to describe Brownian motion; many stochastic differential equations in physics go by this name.

Markov process A stochastic process in which the current state of the system is only determined from its state in the immediate past, and not by its entire history.

Markov chain A Markov process where both the states and the time are discrete and where the process is stationary.

Master equation The equation describing a continuous-time Markov chain.

Stochastic process A sequence of stochastic variables. This sequence is usually a time-sequence, but could also be spatial.

Stochastic variable A random variable. This is a function which maps outcomes to numbers (real or integer).

Definition of the Subject

The most common type of stochastic process comprises of a set of random variables $\{x(t)\}$, where t represents the time which may be real or integer valued. Other types of stochastic process are possible, for instance when the stochastic variable depends on the spatial position $\mathbf{r}$, as well as, or instead of, t. Since in the study of complex systems we will predominantly be interested in applications relating to stochastic dynamics, we will suppose that it depends only on t. One of the earliest investigations of a stochastic process was carried out by Bachelier [2], who used the idea of a random walk to analyze stock market fluctuations. The problem of a random walk was more generally discussed by Pearson [42], and applied to the investigation of Brownian motion by Einstein [8,9], Smoluchowski [54] and Langevin [30]. The example of a random walk illustrates the fact that in addition to time being discrete or continuous, the stochastic variable itself can be discrete (for instance, the walker moves with fixed step size in one dimension) or continuous (for instance, the velocity of a Brownian particle). The modeling of the process may lead to an equation for the stochastic variable, such as a stochastic differential equation, or for an equation which predicts how the probability density function (pdf) for the stochastic variable changes in time. Stochastic processes are ubiquitous in the physical, biological and social sciences; they may come about through the perception of very complicated processes being essentially random (the toss of a coin, roll of a die, birth or death of individuals in populations), the inclusion of diverse and poorly characterized effects external to the system under consideration, or thermal fluctuations, among others.

Introduction

Deterministic dynamical processes are typically formulated as a set of rules which allow for the state of the system at time $t+1$ (or $t+\delta t$) to be found from the state of the system at time t. By contrast, for stochastic systems, we can only specify the probability of finding the system in a given state. If this only depends on the state of the system at the previous time step, but not those before this, the stochastic process is said to be Markov. Fortunately many stochastic processes are Markovian to a very good approximation, since the theory of non-Markov processes is considerably more complicated than Markov processes and much less well developed. In this article we will deal almost exclusively with Markov processes.

The mathematical definition of a Markov process follows from the definition of the hierarchy of pdfs for a given process. This involves the joint pdfs $P(x_1, t_1; x_2, t_2; \ldots; x_n, t_n)$, which are the probability that the system is in state x_1 at time t_1, state x_2 at time t_2,..., and state x_n at time t_n, and also the conditional pdfs $P(x_1, t_1; \ldots; x_m, t_m | x_{m+1}, t_{m+1}; \ldots; x_n, t_n)$, which are the probability that the system is in state x_1 at time $t_1, \ldots, x_m$ at time t_m, *given* that it was in state x_{m+1} at time $t_{m+1}, \ldots, x_n$ at time t_n. These pdfs are all non-negative and normalizable, and relations exist between them due to symmetry and reduction (integration over some of the state variables). Nevertheless, for a general non-Markov process, a whole family of these pdfs will be required to specify the process. On the other hand, for a Markov process the history of the system, apart from the immediate past, is forgotten, and so $P(x_1, t_1; \ldots; x_m, t_m | x_{m+1}, t_{m+1}; \ldots; x_n, t_n) = P(x_1, t_1; \ldots, x_m; t_m | x_{m+1}, t_{m+1})$. A direct consequence of this is that the whole hierarchy of pdfs can be determined from only two of them: $P(x,t)$ and $P(x,t|x',t')$. The hierarchy of defining equations then collapses to only two:

$$P(x_2, t_2) = \int \mathrm{d}x_1 P(x_2, t_2 | x_1, t_1) P(x_1, t_1) \quad (1)$$

and

$$P(x_3, t_3 | x_1, t_1) = \int \mathrm{d}x_2 P(x_3, t_3 | x_2, t_2) P(x_2, t_2 | x_1, t_1)\,, \quad t_1 < t_2 < t_3\,. \quad (2)$$

The pdf $P(x,t|x',t')$ is referred to as the transition probability and Eq. (2) as the Chapman–Kolmogorov equation. While the pdfs for a Markov process must obey Eqs. (1) and (2), the converse also holds: any two non-negative functions $P(x,t)$ and $P(x,t|x',t')$ which satisfy Eqs. (1) and (2), uniquely define a Markov process.

We will begin our discussion in Sect. "Markov Chains" with what is probably the simplest class of Markov processes: the case when both the state space and time are discrete. These are called Markov chains and were first investigated, for a finite number of states, by Markov [32] in 1906. The extension to an infinite number of states was carried out by Kolmogorov [27] in 1936. If time is continuous, an analogous formalism may be developed, which will be discussed in Sect. "The Master Equation". In physics the equation describing the time evolution of the pdf in this case is called the master equation and was introduced by Pauli [41] in 1928, in connection with the approach to equilibrium for quantum systems, and also by Nordsieck, Lamb and Uhlenbeck [39] in 1940, in connection with fluctuations in cosmic ray physics. The term "master equation" refers to that fact that many of the quantities of interest can be derived from this equation. The connection with previous work on Markov processes was clarified by Siegert [49] in 1949.

In many instances when the master equation cannot be solved exactly, it is useful to approximate it by a rather coarser description of the system, known as the Fokker–Planck equation. This approach will be discussed in Sect. "The Fokker–Planck Equation". This equation was used in its linear form by Rayleigh [44], Einstein [8,9], Smoluchowski [54,55], and Fokker [14], but it was Planck [43] who derived the general nonlinear form from a master equation in 1917, and Kolmogorov who made the procedure rigorous in 1931. All the descriptions which we have mentioned so far have been based on the time evolution of the pdfs. An alternative specification is to give the time evolution of the stochastic variables themselves. This will necessarily involve random variables appearing in the equations describing this evolution, and they will therefore be *stochastic differential equations*. The classic example is the Langevin equation [30] used to describe Brownian motion. This equation is linear and can therefore be solved exactly. The Langevin approach, and its relation to the Fokker–Planck equation is described in Sect. "Stochastic Differential Equations".

A good summary of the understanding of stochastic processes that had been gained by the mid-1950s is given in the book edited by Wax. This covers the basics of the subject, and what is discussed in the first six sections of this article. The article by Chandrasekhar [4], first published in 1943, and reprinted in Wax, gives an extensive bibliography of stochastic problems in physics before 1943. Since then the applications of the subject have grown enormously, and the equations modeling these systems have correspondingly become more complex. We illustrate some of the procedures which have been developed to deal with these equations in the next two sections. In Sect. "Path Integrals" we discuss how the path-integral formalism may be applied to stochastic processes and in Sect. "System Size Expansion" we describe how master equations can be analyzed when the size of the system is large. We end with a look forward to the future in Sect. "Future Directions".

Markov Chains

The simplest version of the Markov process is when both the states and the time are discrete, and when the stochastic process is *stationary*. When the states are discrete we will denote them by n or m, rather than x, which we reserve for continuous state variables. In this notation the two Eqs. (1) and (2) governing Markov processes read

$$P(n_2, t_2) = \sum_{n_1} P(n_2, t_2 | n_1, t_1) P(n_1, t_1) \tag{3}$$

$$P(n_3, t_3 | n_1, t_1) = \sum_{n_2} P(n_3, t_3 | n_2, t_2) P(n_2, t_2 | n_1, t_1) \,, \quad t_1 < t_2 < t_3 \,. \tag{4}$$

A stationary process is one in which the conditional pdf $P(n, t|n', t')$ only depends on the time difference $(t - t')$. For such processes, when time is discrete so that $t = t' + 1, t' + 2, \ldots$, we may write $P(n, t' + k|n', t')$ as $p^{(k)}_{n\,n'}$. The most elementary form of the Chapman–Kolmogorov equation (4) may then be expressed as

$$p^{(2)}_{n\,m} = \sum_{n'} p^{(1)}_{n\,n'} p^{(1)}_{n'\,m} \,. \tag{5}$$

This corresponds to the matrix multiplication of $p^{(1)}$ with itself, and therefore $p^{(2)}$ is simply $(p^{(1)})^2$. In the same way $p^{(k)} = (p^{(1)})^k$, and from now on we drop the superscript on $p^{(1)}$ and denote the matrix by $\mathcal{P}$. The entries of $\mathcal{P}$ are non-negative, with the sum of entries in each column being equal to unity, since

$$\sum_{n} p_{n\,n'} = \sum_{n} P(n, t+1|n', t) = 1 \,. \tag{6}$$

Such matrices are called *stochastic matrices*. From Eq. (5) it is clear that $\mathcal{P}^2$ is also a stochastic matrix, and by induction it follows that $\mathcal{P}^k$ is a stochastic matrix if $\mathcal{P}$ is.

The other defining relation for a Markov process, Eq. (3), now becomes

$$P(n, t+1) = \sum_{n'} p_{n\,n'} P(n', t) \,. \tag{7}$$

This relation defines a *Markov chain*. It has two ingredients: the probability that the system is in state n at time t, $P(n, t)$ – which is usually what we are trying to determine, and the stochastic matrix with entries $p_{n\,n'}$ which gives the probabilities of transitions from the state n' to the state n. The transition probabilities are typically given; they define the model. Note that in many texts the probability of making a transition from n' to n is written as $p_{n'\,n}$, not $p_{n\,n'}$. If we write $P(n, t)$ as a vector $\mathbf{P}(t)$, then we may write Eq. (7) as $\mathbf{P}(t+1) = \mathcal{P}\mathbf{P}(t)$. Therefore,

$$\mathbf{P}(t) = \mathcal{P}\mathbf{P}(t-1) = \mathcal{P}\mathcal{P}\mathbf{P}(t-2) = \cdots = \mathcal{P}^t\mathbf{P}(0) \,, \tag{8}$$

and so if the initial state of the system $\mathbf{P}(0)$ is given, then we can find the state of the system at time t ($\mathbf{P}(t)$) by matrix multiplication by the tth power of the transition matrix.

Examples of Markov Chains

1. *A one-dimensional random walk*. The most widely known example of a Markov chain is a random walk on the real axis, where the walker takes single steps between integers on the line. The simplest version is where the walker has to move during every time interval:

$$p_{n\,n'} = \begin{cases} p \,, & \text{if} \quad n = n' + 1 \\ q \,, & \text{if} \quad n = n' - 1 \\ 0 \,, & \text{otherwise} \,, \end{cases} \tag{9}$$

where $p + q = 1$. There are many variants. For instance, the walker could have a non-zero probability of staying put, in which case $p_{n\,n} = r$, with $p + q + r = 1$. The walk could be heterogeneous, in which case p and q (and r), could depend on n'. If there are boundaries, the boundary conditions have to be given. The most common two are *absorbing boundaries* defined by

$$\begin{aligned} p_{n+1\,n} &= p \,, \quad p_{n-1\,n} = q \,, \quad (n = 2, \ldots, N-1) \\ p_{11} &= 1 \,, \quad p_{NN} = 1 \,, \\ p_{n\,n'} &= 0 \,, \quad \text{otherwise} \,, \end{aligned} \tag{10}$$

and *reflecting boundaries* defined by

$$\begin{aligned} p_{n+1\,n} &= p\,, \quad p_{n-1\,n} = q\,, \quad (n = 2,\dots,N-1) \\ p_{21} &= p\,, \quad p_{N-1\,N} = q\,, \\ p_{11} &= q\,, \quad p_{NN} = p\,, \\ p_{n\,n'} &= 0\,, \quad \text{otherwise}\,. \end{aligned} \tag{11}$$

With absorbing boundaries (10), if we reach the state 1 or N, we can never leave it, since we stay there with probability 1. When the boundary is reflecting, we can never move beyond it; the only options are to move back towards the other boundary, or stay put. Well known examples of absorbing boundaries include the gambler's ruin problem, where a gambler bets a given amount against the house at each time step and can win with a probability p. Here the absorbing boundary is situated at $n = 0$. Eventually he will arrive at the state $n = 0$, where is has no money left, and so cannot re-enter the game. Birth/death processes will also have absorbing states at $n = 0$: if n is the number of individuals at a given time, and p is the probability of a birth and q of a death, then if there are no individuals left ($n = 0$), none can be born. This condition will be automatically applied if the transition probabilities are proportional to the number of individuals in the population.

2. *The Ehrenfest urn* This Markov chain was introduced by the Ehrenfests [7] in 1907, to illustrate the approach to equilibrium in a gas. Two containers, A and B, contain molecules of the same gas, the sum of the number of molecules in A and B being fixed to be N. At time t a molecule is removed at random from the containers and put into the other. If n' is the number of molecules in container A at a certain time, then at the next time step the transition probabilities will be:

$$p_{n\,n'} = \begin{cases} \frac{n'}{N}\,, & \text{if} \quad n' = n+1 \\ (1 - \frac{n'}{N})\,, & \text{if} \quad n' = n-1 \\ 0\,, & \text{otherwise}\,. \end{cases} \tag{12}$$

This is clearly a heterogeneous random walk of the type (9), and another interpretation of this model is as a random walk, but with a central force.

The most frequently asked question concerning Markov chains is: what is their eventual fate; how does the system behave at large time? Clearly if it tends towards a non-trivial stationary state, $P_{\text{st}}(n)$, then from Eq. (7):

$$P_{\text{st}}(n) = \sum_{n'} p_{n\,n'} P_{\text{st}}(n')\,, \tag{13}$$

and so $P_{\text{st}}(n)$ is a right eigenvector of $\mathcal{P}$ with unit eigenvalue. It follows from the properties of a general stochastic matrix that the eigenvalues of a stochastic matrix are such that $|\lambda| \le 1$ [15]. Furthermore every stochastic matrix has an eigenvalue equal to 1, however it may not be simple – there may be a multiplicity of unit eigenvalues. The classification of Markov chains can be used to decide which of these possibilities is the case. For example, Markov chains may be reducible or irreducible, and states recurrent or transient. We shall not discuss this in detail; Feller [10] gives a clear account of this classification and Cox and Miller [5] explore the consequences for the nature of the eigenvalues. Instead we will examine a specific example, that of the Ehrenfest urn introduced above, and focus on the explicit calculation of the eigenvalues and eigenvectors in that case.

Suppose that $\Psi^{(k)}$ and $\Theta^{(k)}$ are the right- and left-eigenvectors of $\mathcal{P}$, respectively, corresponding to the eigenvalue $\lambda^{(k)}$, so that $\Theta^{(k)}.\,\Psi^{(\ell)} = \delta_{k\,\ell}$. Then, in general, and for the Ehrenfest urn in particular,

$$\mathcal{P}^t_{n\,n'} = \sum_{k=0}^{N} \psi^{(k)}_n \left(\lambda^{(k)}\right)^t \theta^{(k)}_{n'}\,, \tag{14}$$

where $\psi^{(k)}_n$ is the nth component of the vector $\Psi^{(k)}$ and similarly for the left-eigenvector. The eigenvalues and eigenvectors for the Ehrenfest urn can be found exactly (Kac [23]; see also Krafft and Schaefer [28]). The eigenvalues are $\lambda^{(k)} = 1 - (2k/N)$, $k = 0,\dots,N$. Thus in this case there is a single eigenvalue $\lambda = 1$. The corresponding right-eigenvector, which gives the stationary state, is a binomial distribution:

$$P_{\text{st}}(n) = \psi^{(0)}_n = \frac{N!}{n!(N-n)!}\,\frac{1}{2^N}\,. \tag{15}$$

The left-eigenvector is $\theta^{(0)}_n = 1$ for all n. The other eigenvectors have the form $\theta^{(k)}_n = a_{kn}$ and $\psi^{(k)}_n = a_{kn} P_{\text{st}}(n)$, where the a_{kn} are the Krawtchouk polynomials [1]. Clearly, $a_{0n} = 1$, and the first non-trivial polynomial is $a_{1n} = \sqrt{N}[1 - (2n/N)]$. Therefore, for a suitable choice of initial conditions and using Eq. (8), the large t behavior of the Ehrenfest urn can be found from

$$\mathcal{P}^t_{n\,n'} \approx P_{\text{st}}(n) \left\{ 1 + c_{n\,n'} \left(1 - \frac{2}{N}\right)^t \right\}\,, \tag{16}$$

where $c_{n\,n'} = N[1 - (2n/N)][1 - (2n'/N)]$.

The Master Equation

The master equation is a Markov chain in the limit where time is continuous. To derive it we will assume that the states are discrete (the derivation is essentially identical if they are continuous) and write down the Chapman–Kolmogorov equation (4) in the form:

$$P(n,t+\Delta t|n_0,t_0) = \sum_{n'} P(n,t+\Delta t|n',t)P(n',t|n_0,t_0)\,. \tag{17}$$

We consider only stationary processes, so that we may take $t_0 = 0$ without loss of generality and $P(n, t + \Delta t|n', t)$ is independent of t. We now assume that

$$P(n,t+\Delta t|n',t) = \begin{cases} 1-\kappa(n)\Delta t + o(\Delta t)\,, & \text{if } n = n' \\ T(n|n')\Delta t + o(\Delta t)\,, & \text{if } n \neq n'\,, \end{cases} \tag{18}$$

where $o(\Delta t)$ means that $o(\Delta t)/\Delta t$ tends to zero as $\Delta t \to 0$. This reasonable: after a very short times the transition probability to stay put is unity minus a term of order Δt and the transition probabilities to move to any other state is of order Δt, but this is still an additional assumption on the process. The quantity $T(n|n')$ is the transition rate, and is only defined for $n \neq n'$. Since $\sum_n P(n, t + \Delta t|n', t) = 1$ for all n', we have that

$$\kappa(n') = \sum_{n\neq n'} T(n|n')\,. \tag{19}$$

Substituting Eq. (18) into Eq. (17), and making use of Eq. (19) we find that

$$\begin{aligned}&\frac{P(n,t+\Delta t|n_0,0) - P(n,t|n_0,0)}{\Delta t} \\ &= \sum_{n'\neq n} \left[T(n|n')P(n',t|n_0,0)\right] \\ &\quad - P(n,t|n_0,0)\sum_{n'\neq n}\left[T(n'|n)\right] + \frac{o(\Delta t)}{\Delta t}\,. \end{aligned} \tag{20}$$

Taking the limit $\Delta t \to 0$ gives *the master equation* for how the probability of finding the system in state n at time t changes with time:

$$\frac{\mathrm{d}P(n,t)}{\mathrm{d}t} = \sum_{n'\neq n} T(n|n')\,P(n',t) - \sum_{n'\neq n} T(n'|n)\,P(n,t)\,. \tag{21}$$

We have dropped the initial conditions, assuming that they are understood. It should be noticed that an analogous analysis starting from Eq. (3), rather than Eq. (4), may be carried out, leading to identical equations for $P(n, t|n_0, 0)$ and $P(n, t)$. If the state space is continuous the master equation reads

$$\frac{\partial P(x,t)}{\partial t} = \int \mathrm{d}x' \left[T(x|x')\,P(x',t) - T(x'|x)\,P(x,t)\right]\,. \tag{22}$$

In most applications transitions only take place between states whose label differs by one. That is, $T(n|n')$ and $T(n'|n)$ are zero unless $n' = n + 1$ and $n' = n - 1$. These are called *one-step processes*. For such processes the master equation takes the simpler form

$$\begin{aligned}\frac{\mathrm{d}P(n,t)}{\mathrm{d}t} &= T(n|n+1)P(n+1,t) \\ &\quad + T(n|n-1)P(n-1,t) \\ &\quad - \left[T(n-1|n) + T(n+1|n)\right]P(n,t)\,. \end{aligned} \tag{23}$$

For simplicity let us write

$$g_n = T(n+1|n) \quad \text{and} \quad r_n = T(n-1|n)\,, \tag{24}$$

then the master equation may be written as

$$\begin{aligned}\frac{\mathrm{d}P(n,t)}{\mathrm{d}t} &= r_{n+1}P(n+1,t) + g_{n-1}P(n-1,t) \\ &\quad - \left[r_n + g_n\right]P(n,t)\,. \end{aligned} \tag{25}$$

Examples of Master Equations

1. *The simple birth–death process*. For a population of simple organisms, for example a colony of bacteria, it might be reasonable to assume that the rate of birth of new bacteria is proportional to the number present at that time, and similarly for the rate of death. This is clearly a Markov process with $g_n = bn$ and $r_n = dn$, where b and d are rate constants. A variant is to include "immigrants" coming into the population from the outside at a constant rate c, so that $g_n = bn + c$.

   In this example g_n and r_n are linear in n. Such *linear one-step processes* can be solved by the introduction of the generating function $F(z, t) = \sum_n P(n, t)z^n$. This converts the master equation (which is a differential-difference equation) into a partial differential equation for $F(z, t)$ which can be solved if the process is linear. The simplest case of a pure death process ($b = c = 0$ in the above) can illustrate the general procedure. By rescaling the time ($t = \tau/d$), we may write the master equation in the very simple form

$$\frac{\mathrm{d}P(n,\tau)}{\mathrm{d}\tau} = (n+1)\,P(n+1,\tau) - n\,P(n,\tau)\,.$$

Multiplying this equation by z^n and summing over all $n \geq 0$ gives

$$\begin{aligned}&\frac{\partial}{\partial \tau}\left\{\sum_{n=0}^{\infty} z^n P(n,\tau)\right\}\\&= \sum_{n=0}^{\infty}(n+1)z^n P(n+1,\tau) - \sum_{n=1}^{\infty} n z^n P(n,\tau)\\&= \sum_{m=1}^{\infty} m z^{m-1} P(m,\tau) - z\sum_{n=1}^{\infty} n z^{n-1} P(n,\tau)\,,\end{aligned}$$

that is,

$$\frac{\partial F}{\partial \tau} = (1-z)\,\frac{\partial F}{\partial z}\,.$$

A change of variable to $\xi = (1-z)\mathrm{e}^{-\tau}$ and $\eta = \tau$ shows F to be a function of ξ only: $F(z,\tau) = \phi([1-z]\mathrm{e}^{-\tau})$. The function ϕ may be determined from the initial condition. For instance, if $P(n,0) = \delta_{n\,N}$, then $F(z,0) = z^N$ and so $\phi(\xi) = (1-\xi)^N$. This gives the solution for F to be

$$F(z,\tau) = \left[\left(1-\mathrm{e}^{-\tau}\right) + z\mathrm{e}^{-\tau}\right]^N\,.$$

In this case F can easily be expanded as a power series in z, and the $P(n,\tau)$ read off, but even if this is difficult, the moments of the distribution can be readily found by differentiation with respect to z and then setting $z = 1$. It should now be clear why F is called a generating function. In the general case the partial differential equation for F may be solved by standard methods [50]. The solution for a birth–death process without immigration is given in the book by Reichl [45]. The solution with immigration was first given by Kendall [25], who also introduced the technique of the generating function as a method of solution of the master equation.

2. *The Moran model of genetic drift*. Stochastic processes occur extensively in population genetics. The simplest, and most widely known, is a model of genetic drift introduced by Fisher [13] and Wright [58], in which a population of individuals in generation t mate randomly to produce the new generation $t+1$. We assume, for simplicity, that each individual has only one gene of a particular type, and that this may exist in one of two forms (alleles) denoted by A and B. The Wright–Fisher model is based on the sampling of the gene pool at generation t, which consists of n genes of type A and $(N-n)$ genes of type B, to produce the next generation of N genes. Although this may be formulated as a Markov chain, neither Fisher nor Wright did so; this was first carried out by Malécot [31] in 1944. Here we will describe a variant of the model introduced by Moran [36,37], which is a one-step process and can be formulated as a master equation.
The Moran model does not have non-overlapping generations, as in the Wright–Fisher model, and is more akin to a birth–death process where birth and death are coupled. At a given time, two individuals are sampled with replacement: one is designated the parent which is copied to create an offspring and the other is sacrificed to make way for the new offspring. Clearly if a B (chosen with probability $(N-n)/N$) is sacrificed and an A (chosen with probability n/N) is copied, this gives a contribution to $T(n+1|n)$. If the choice is that with A and B interchanged, this gives a contribution to $T(n-1|n)$. The transition rates for the Moran model are thus

$$\begin{aligned}T(n+1|n) &= \beta\left(1-\frac{n}{N}\right)\left(\frac{n}{N}\right)\,,\\T(n-1|n) &= \beta\left(\frac{n}{N}\right)\left(1-\frac{n}{N}\right)\,,\end{aligned}\qquad(26)$$

where β is a rate constant, which may be absorbed into the time t.
This may be extended in various ways. For example, mutations may be included: $A \overset{u}{\rightarrow} B$ and $B \overset{v}{\rightarrow} A$. With probability $(1-u-v)$ the offspring is taken to be a copy of the parent without mutation, as previously described. For the rest of the time (that is, with probability $u+v$), a mutation occurs. If the parent is an A, the offspring becomes a B with probability $u/(u+v)$, and if the parent is a B, the offspring becomes an A with probability $v/(u+v)$. This leads to the transition rates

$$\begin{aligned}T(n+1|n) &= (1-u-v)\left(1-\frac{n}{N}\right)\left(\frac{n}{N}\right)\\&\qquad + v\left(1-\frac{n}{N}\right)\,,\\T(n-1|n) &= (1-u-v)\left(1-\frac{n}{N}\right)\left(\frac{n}{N}\right)+u\left(\frac{n}{N}\right).\end{aligned}\qquad(27)$$

The master equation for the Moran model will be discussed again in the next section.

3. *Competition in a single species model*. The birth–death process described in Example 1 can be generalized to more complex ecological situations. As it stands it consists of the two processes $A \overset{d}{\rightarrow} E$ and $A \overset{b}{\rightarrow} A + A$ representing death and birth respectively. Here A represents an individual and E is a null state. To model the finite resources available in a given patch, we

put a limit on the number of allowed individuals: $n = 0, 1, \ldots, N$. We can also only allow a birth if enough space and/or other resources are available: $A + E \xrightarrow{b} A + A$ and include competition for these resources: $A + A \xrightarrow{c} A + E$. Since the probability of obtaining an A when sampling the patch is n/N and of obtaining an E is $(N - n)/N$, the birth term is now proportional to $n(N - n)/[N(N - 1)]$ and the competition term proportional to $n(n - 1)/[N(N - 1)]$. This gives the transition rates to be

$$\begin{aligned} T(n+1|n) &= \frac{2bn(N-n)}{N(N-1)}\,, \\ T(n-1|n) &= \frac{cn(n-1)}{N(N-1)} + \frac{dn}{N}\,. \end{aligned} \tag{28}$$

This approach can be extended to more than one species, for instance competition between and within two species [34] or predator-prey interactions [35]. In these cases the state space is multi-dimensional: $\mathbf{n} = (n_1, n_2, \ldots)$. The master equation still has the form (21), but with n replaced everywhere by the vector $\mathbf{n}$.

Whether or not a stationary state of the master equation exists depends on the nature of the boundary conditions. There are many types of boundary conditions, but two are particularly important. If the boundaries are reflecting, then the probability current vanishes there. If they are absorbing, then the probability of being at the boundary is zero. In the former case probability is conserved, in the latter case it is not, and leaks out of the system.

So to find a non-zero pdf as $t \to \infty$ (a stationary distribution) we therefore assume that the system lies within two reflecting boundaries. For a one-step process, the net flow of probability from the state n to the state $n + 1$, is $J(n, t) = g_n P(n, t) - r_{n+1} P(n + 1, t)$, where $J(n, t)$ is the probability current. The master Eq. (25) may be written as

$$\frac{\mathrm{d}P(n,t)}{\mathrm{d}t} = J(n-1,t) - J(n,t)\,.$$

For a stationary state, the left-hand side of this equation is zero, and the currents will be time-independent. Therefore $J(n - 1) = J(n)$ for all n, that is, all the currents are equal. Since the current vanishes at the boundaries, this constant must be zero. Therefore, for reflecting boundary conditions, $r_{n+1} P_{\mathrm{st}}(n + 1) = g_n P_{\mathrm{st}}(n)$ for all n. If we suppose that one boundary is at $n = 0$ and the other at $n = N$, then we have that $P_{\mathrm{st}}(1) = (g_0/r_1)P_{\mathrm{st}}(0)$, $P_{\mathrm{st}}(2) = (g_1/r_2)P_{\mathrm{st}}(1), \ldots,$ which implies $P_{\mathrm{st}}(2) = (g_1 g_0)/(r_2 r_1) P_{\mathrm{st}}(0), \ldots$ Iterating, the stationary state can be expressed as a simple product:

$$P_{\mathrm{st}}(n) = \frac{g_{n-1} g_{n-2} \ldots g_0}{r_n r_{n-1} \ldots r_1} P_{\mathrm{st}}(0)\,, \quad n = 1, \ldots, N\,. \tag{29}$$

The constant $P_{\mathrm{st}}(0)$ is determined by normalization:

$$\begin{aligned} \sum_{n=0}^{N} P_{\mathrm{st}}(n) &= P_{\mathrm{st}}(0) + \sum_{n>0} P_{\mathrm{st}}(n) = 1 \\ \Rightarrow (P_{\mathrm{st}}(0))^{-1} &= 1 + \sum_{n=1}^{N} \frac{g_{n-1} g_{n-2} \ldots g_0}{r_n r_{n-1} \ldots r_1}\,. \end{aligned} \tag{30}$$

As an example, we return to the Ehrenfest urn (12), which in the language of the master equation is defined by $g_n = (N - n)/N$ and $r_n = n/N$ (any overall rate may be absorbed into the time, and this is irrelevant as far as the stationary state is concerned). Here $n = 0, 1, \ldots, N$ and the molecules never go outside this range, so the boundaries are reflecting. Applying Eqs. (29) and (30) shows that the stationary state is the binomial distribution given by Eq. (15).

The Fokker–Planck Equation

The Fokker–Planck equation describes stochastic processes at a more coarse grained level than those that we have discussed so far. It only involves continuous stochastic variables; these could be for instance the fraction of individuals or genes of a certain kind in a population, whereas the master equation recognized the individuals or genes as discrete entities. To obtain the Fokker–Planck equation we first derive the Kramers–Moyal expansion [29,38].

We begin by defining the *jump moments* for the system:

$$M_\ell(x, t, \Delta t) = \int \mathrm{d}\xi \;(\xi - x)^\ell \, P(\xi, t + \Delta t | x, t)\,. \tag{31}$$

We will assume that these are known, that is, they can be obtained by some other means. They will, however, only be required in the limit of small Δt.

The starting point for the derivation is the Chapman–Kolmogorov equation (4), with the choice of variables analogous to that used in Eq. (17) for the discrete case:

$$P(x, t + \Delta t) = \int \mathrm{d}x' P(x, t + \Delta t | x', t)\, P(x', t)\,, \tag{32}$$

again dropping the dependence on the initial conditions. The integrand may be written as

$$\begin{aligned} & P(x,t+\Delta t|x',t)\,P(x',t) \\ & = P([x-\Delta x]+\Delta x, t+\Delta t|[x-\Delta x],t)P([x-\Delta x],t) \\ & = \sum_{\ell=0}^{\infty}\frac{(-1)^{\ell}}{\ell!}(\Delta x)^{\ell} \\ & \qquad \cdot \frac{\partial^{\ell}}{\partial x^{\ell}}\{P(x+\Delta x, t+\Delta t|x,t)P(x,t)\}\ , \end{aligned} \tag{33}$$

where $\Delta x = x - x'$. Integrating over x' gives for Eq. (32):

$$P(x,t+\Delta t) = \sum_{\ell=0}^{\infty}\frac{(-1)^{\ell}}{\ell!}\frac{\partial^{\ell}}{\partial x^{\ell}}\{M_{\ell}(x,t,\Delta t)P(x,t)\}\ . \tag{34}$$

Since $P(\xi,t|x,t) = \delta(\xi - x)$, it follows from Eq. (31), that $\lim_{\Delta t\to 0} M_{\ell}(x,t,\Delta t) = 0$ for $\ell \geq 1$. Also $M_0(x,t,\Delta t) = 1$. Bearing these results in mind, we will now assume that the jump moments for $\ell \geq 1$ take the form

$$M_{\ell}(x,t,\Delta t) = D^{(\ell)}(x,t)\Delta t + o(\Delta t)\ . \tag{35}$$

Substituting this into Eq. (34), dividing by Δt and taking the limit $\Delta t \to 0$ gives

$$\frac{\partial P}{\partial t} = \sum_{\ell=1}^{\infty}\frac{(-1)^{\ell}}{\ell!}\frac{\partial^{\ell}}{\partial x^{\ell}}\left\{D^{(\ell)}(x,t)P(x,t)\right\}\ . \tag{36}$$

Equation (36) is the Kramers–Moyal expansion. So far nothing has been assumed other than the Markov property and the existence of Taylor series expansions. However, in many situations, examination of the jump moments reveal that in a suitable approximation they may be neglected for $\ell > 2$. In this case, we may truncate the Kramers–Moyal expansion (36) at second order and obtain the *Fokker–Planck equation*:

$$\frac{\partial P}{\partial t} = -\frac{\partial}{\partial x}\left[A(x,t)P(x,t)\right] + \frac{1}{2}\frac{\partial^2}{\partial x^2}\left[B(x,t)P(x,t)\right]\ , \tag{37}$$

where $A = D^{(1)}$ and $B = D^{(2)}$ are independent of t if the process is stationary.

To calculate the jump moments (31), it is convenient to write them in terms of the underlying stochastic process $x(t)$. We use the notation

$$\langle x(t)\rangle_{x(t_0)=x_0} = \int \mathrm{d}x\, xP(x,t|x_0,t_0)\,, \tag{38}$$

for the mean of the stochastic variable at time t, conditional on the value of $x(t)$ being given to be x_0 at time t_0. With this notation $x(t)$ denotes the process and the angle brackets are averages over realizations of this process. More generally, we may define $\langle f(x(t))\rangle$ in a similar way, and in particular the jump moments are given by

$$M_{\ell}(x,t,\Delta t) = \langle (x(t+\Delta t)-x)^{\ell}\rangle_{x(t)=x}\ . \tag{39}$$

Examples of Fokker–Planck Equations

1. *Simple diffusion*. For the simple symmetric random walk, $g_n = 1$ and $r_n = 1$ when expressed in the language of the master equation (after a rescaling of the time so that the rates may taken to be equal to unity). From Eqs. (18) and (19) we find that for a one-step stationary process,

$$\begin{aligned} & \langle (n(t+\Delta t)-n)^{\ell}\rangle_{n(t)=n} \\ & = \begin{cases} (g_n - r_n)\,\Delta t + o\,(\Delta t)\ , & \text{if } \ell \text{ is odd} \\ (g_n + r_n)\,\Delta t + o\,(\Delta t)\ , & \text{if } \ell \text{ is even}\,, \end{cases} \end{aligned} \tag{40}$$

   and so for the symmetric random walk the odd moments all vanish, and the even moments are equal to $2\Delta t + o(\Delta t)$. We now make the approximation which will yield the Fokker–Planck equation: we let $x = nL$, where L is the step size, and let $L \to 0$. Since, for ℓ even, $\langle (x(t+\Delta t)-x)^{\ell}\rangle = (2L^{\ell})\Delta t$, if we rescale the time by introducing $\tau = L^2 t$, then all jump moments higher than the second disappear in the limit $L \to 0$, and Eq. (36) becomes

$$\frac{\partial P}{\partial t} = \frac{\partial^2 P}{\partial x^2}\ . \tag{41}$$

   This is the familiar diffusion equation obtained from a continuum approximation to the discrete random walk.
2. *The diffusion limit of the Moran model*. For the Moran model with no mutation, we have from Eqs. (26) and (40) that the odd moments again vanish. If we describe the process by $x(t) = n(t)/N$, the fraction of the genes that are of type A at time t, then the even jump moments are given by

$$\begin{aligned} & \left\langle (x(t+\Delta t)-x)^{\ell}\right\rangle_{x(t)=x} \\ & \qquad = \frac{1}{N^{\ell}}2x\,(1-x)\,\Delta t + o\,(\Delta t)\ , \end{aligned}$$

   and so introducing a rescaled time $\tau = 2t/N^2$, and letting $N \to \infty$ we obtain the Fokker–Planck equation

$$\frac{\partial P}{\partial t} = \frac{1}{2}\frac{\partial^2}{\partial x^2}\left[x(1-x)P\right]\ . \tag{42}$$

The factor of 2 in the rescaling of the time is included so that the diffusive form of the Moran model agrees with that found in the Wright–Fisher model [6].

Now suppose mutations are included. The transition rates are given by Eq. (27) and lead to jump moments $\langle (x(t+\Delta t)-x)^{\ell}\rangle \sim N^{-\ell}$. So the first and second jump moments are not of the same order, and the introduction of a rescaled time $\tau = t/N$, and subsequently letting $N \to \infty$, gives a Fokker–Planck equation of the form (37), but with $B = 0$ and $A(x) = v - (u+v)x$. This corresponds to a *deterministic* process with $\mathrm{d}x/\mathrm{d}t = v - (u+v)x$ [22]. The fact that the system tends to a macroscopic equation when $N \to \infty$ has to be taken into account when determining the nature of the fluctuations for large N. We will discuss this further in Sect. "System Size Expansion".

On the other hand, suppose that the mutation rates scale with N according to $u = 2\tilde{u}/N$ and $v = 2\tilde{v}/N$, where $\tilde{u}$ and $\tilde{v}$ have a finite limit as $N \to \infty$, and where the 2 has again been chosen to agree with the Wright–Fisher model. Now both the first and second jump moments are of order N^{-2}, with the higher moments falling off faster with N. Therefore once again introducing the rescaled time $\tau = 2t/N^2$ and letting $N \to \infty$, we obtain the Fokker–Planck equation

$$\frac{\partial P}{\partial t} = -\frac{\partial}{\partial x}\left[\{\tilde{v} - (\tilde{u}+\tilde{v})x\}P\right] + \frac{1}{2}\frac{\partial^2}{\partial x^2}\left[x(1-x)P\right] . \tag{43}$$

So depending on the precise scaling with N, the Moran model gives different limits as $N \to \infty$ [24]. In the first case, the mutational effects are strong enough that a macroscopic description exists, with fluctuations about the macroscopic state, as discussed in Sect. "System Size Expansion". In the second case, the mutational effects are weaker, and there is no macroscopic equation describing the system; the large N limit is a nonlinear Fokker–Planck equation of the diffusive type.

The Fokker–Planck equation (37) for stationary processes, where A and B are functions of x only, can be solved by separation of variables, with solutions of the form $p(x)\mathrm{e}^{-\lambda t}$, where λ is a constant. The equation for $p(x)$ is then a second order differential equation which, when boundary conditions are given, is of the Sturm–Liouville type. To specify the boundary conditions we once again introduce the probability current, this time through the continuity equation,

$$\frac{\partial P(x,t)}{\partial t} + \frac{\partial J(x,t)}{\partial x} = 0 , \tag{44}$$

where the probability current $J(x,t)$ is given by

$$J(x,t) = A(x,t)P(x,t) - \frac{1}{2}\frac{\partial}{\partial x}\left[B(x,t)P(x,t)\right] . \tag{45}$$

Let us suppose that the system is defined on the interval $[a,b]$. Then if the boundaries are reflecting, there is no net flow of probability across $x = a$ and $x = b$. This implies that $J(a,t) = 0$ and $J(b,t) = 0$. If we integrate the equation of continuity (44) from $x = a$ to $x = b$, and apply these boundary conditions, we see that $\int_a^b P(x,t)\mathrm{d}x$ is independent of time. Therefore, if the pdf is initially normalized, it remains normalized. This is in contrast with the case of absorbing boundary conditions, defined by $P(a,t) = 0$ and $P(b,t) = 0$. If the boundary conditions are at infinity we require that $\lim_{x\to\pm\infty} P(x,t) = 0$, so that if P is well-behaved it is normalizable, and also that $\partial P/\partial x$ is well-behaved in this limit: $\lim_{x\to\pm\infty} \partial P/\partial x = 0$. If A or B do not diverge as $x \to \pm\infty$ this implies that $\lim_{x\to\pm\infty} J(x,t) = 0$. Other types of boundary conditions are possible, and we do not attempt a complete classification here [16,46].

If A and B are independent of time, then from Eq. (44), the stationary state of the system must be given by $\mathrm{d}J(x)/\mathrm{d}x = 0$, that is, J is a constant. For reflecting boundary conditions this constant is zero, and so from Eq. (45) the stationary pdf, $P_{\mathrm{st}}(x)$ must satisfy

$$0 = A(x)P_{\mathrm{st}}(x) - \frac{1}{2}\frac{\partial}{\partial x}\left[B(x)P_{\mathrm{st}}(x)\right] . \tag{46}$$

This may be integrated to give

$$P_{\mathrm{st}}(x) = \frac{C}{B(x)}\exp\left\{2\int^x \mathrm{d}x' \quad \frac{A(x')}{B(x')}\right\} , \tag{47}$$

where C is a constant which has to be chosen so that $P_{\mathrm{st}}(x)$ is normalized.

The Fokker–Planck equation, with A independent of t and B constant, can be transformed into the Schrödinger-like problem

$$-B\frac{\partial \psi}{\partial t} = -\frac{B^2}{2}\frac{\partial^2 \psi}{\partial x^2} + U(x)\psi , \tag{48}$$

by the transformation

$$P(x,t) = \left[P_{\mathrm{st}}(x)\right]^{1/2}\psi(x,t) , \tag{49}$$

where

$$U(x) = \frac{1}{2}\left[A(x)\right]^2 + \frac{B}{2}\frac{\mathrm{d}A}{\mathrm{d}x} . \tag{50}$$

So a one-dimensional stationary stochastic process, under certain conditions (such as constant second jump moment) is equivalent to quantum mechanics in imaginary time, with B taking over the role of Planck's constant.

As an example we consider the *Ornstein–Uhlenbeck process* defined by

$$\frac{\partial P}{\partial t} = \frac{\partial}{\partial x}[axP] + D\frac{\partial^2 P}{\partial x^2}, \quad x \in (-\infty, \infty), \quad a > 0. \quad (51)$$

In this case, the potential (50) is given by $U(x) = [a^2x^2 - 2aD]/2$, and so the problem is equivalent to the one-dimensional simple harmonic oscillator in quantum mechanics, but with an energy shift. As in that problem [47], the eigenfunctions are Hermite polynomials. Specifically, the right-eigenfunctions are

$$p_m(x) = P_{\text{st}}(x)\frac{1}{[2^m m!]^{1/2}} H_m(\alpha x), \quad (52)$$

where H_m are the Hermite polynomials [1] and $\alpha = (a/2D)^{1/2}$. The eigenvalue corresponding to the eigenfunction (52) is $\lambda_m = am$, $m = 0, 1, \ldots$ and the left-eigenfunctions are $q_m(x) = [P_{\text{st}}(x)]^{-1} p_m(x)$. From these explicit solutions we may calculate other quantities of interest, such as correlation functions. We note that the eigenvalues are all non-negative and that the stationary state corresponds to $\lambda = 0$. The left-eigenfunction for the stationary state is equal to 1. These latter results hold true for a wide-class of such problems.

Stochastic Differential Equations

So far we have described stochastic processes in terms of equations which give the time evolution of pdfs. In this section, we will describe equations for the stochastic variables themselves. The most well known instance of such an equation is the Langevin equation for the velocity of a Brownian particle, and so we begin with this particular example.

Suppose that a small macroscopic particle of mass m (such as a pollen grain) is immersed in a liquid at a temperature T. In addition to any macroscopic motion that the particle may have, its velocity fluctuates due to the random collisions of the particle with the molecules of the liquid. For simplicity, we confine ourselves to one-dimensional motion – along the x-axis. Then the equation of motion of the particle may be written in the form

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2} = -\alpha\frac{\mathrm{d}x}{\mathrm{d}t} - \frac{\mathrm{d}V}{\mathrm{d}x} + \mathcal{F}(t). \quad (53)$$

The first term on the right-hand side is due to the viscosity of the fluid and α is the friction constant. The second term, where $V(x)$ is a potential, represents the interaction of the particle with any external forces, such as gravity. The final term is the random force due to collisions with the molecules of the liquid. Clearly to complete the specification of the dynamics of the particle we need to give (i) the initial position and velocity of the particle, and (ii) the statistics of the random force $\mathcal{F}(t)$.

To make progress with these points, we imagine a large number of realizations of the dynamics, in which the particle starts with the same initial position, x_0, and velocity, v_0, but where the initial positions and velocities of the molecules in the liquid will be different. Taking the average over a large number of such realizations will give the average position $\langle x(t)\rangle$ and velocity $\langle v(t)\rangle$ at time t, conditional on $x(0) = x_0$ and $v(0) = v_0$. The statistics of the fluctuating force $\mathcal{F}(t)$ are assumed to be such that

(a) $\langle \mathcal{F}(t)\rangle = 0$, since we do not expect one direction to be favored over the other.

(b) $\langle \mathcal{F}(t)\mathcal{F}(t')\rangle = 2D\delta(t - t')$, since we expect that after a few molecular collisions the value that $\mathcal{F}$ takes on will be independent of its former value. That is, the force $\mathcal{F}$ becomes uncorrelated over times of the order of a few collision times between molecules. This is tiny on observational time scales, and so taking the correlation function to be a delta-function is an excellent approximation. The weight of the delta-function is denoted by $2D$, where at this stage D is undetermined.

(c) $\mathcal{F}(t)$ is taken to be Gaussianly distributed on grounds of simplicity, but also because by the central limit theorem it is assumed that the net effect of the large number of molecules which collide with the pollen grain will lead to a distribution which is Gaussian.

Since a Gaussian distribution is specified by its first two moments, conditions (a), (b) and (c) completely define the statistics of $\mathcal{F}(t)$.

Finally, Eq. (53) as it stands does not define a Markov process. This is most easily seen if we write down a discrete time version of the equation. The second derivative means that $x(t + \delta t)$ not only depends on $x(t)$, but also on $x(t - \delta t)$. Therefore only first order derivatives should be included in such equations if the process is to be Markov. This is easily achieved by promoting $v(t)$ to be a second stochastic variable in addition to $x(t)$. Then Eq. (53) may be equivalent written as

$$\begin{aligned} \frac{\mathrm{d}x}{\mathrm{d}t} &= v\,, \\ m\frac{\mathrm{d}v}{\mathrm{d}t} &= -\alpha v - \frac{\mathrm{d}V}{\mathrm{d}x} + \mathcal{F}(t)\,, \end{aligned} \quad (54)$$

which does define a Markov process. Although, as we remarked in the Introduction, we deal almost exclusively with Markov processes in this article, the situation we have just discussed is a good illustration of one way of dealing with processes which are presented as being non-Markovian. The method simply consists of adding a sufficient number of supplementary variables to the definition of the state variables of the process until it becomes Markovian. There is no guarantee that this will be possible or require only a small number of additional variables to be promoted in this way, but it is the most straightforward and direct way of rendering non-Markovian processes tractable.

To begin the analysis of Eq. (54) we assume that there are no external forces and so the term $\mathrm{d}V/\mathrm{d}x$ is equal to zero. We may then write Eq. (54) as the Langevin equation

$$\frac{\mathrm{d}v}{\mathrm{d}t} = -\gamma v + F(t)\,; \quad v(0) = v_0\,, \tag{55}$$

where $\gamma = \alpha/m$ and $F(t) = \mathcal{F}(t)/m$. This implies that

$$\langle F(t)\rangle = 0 \ \text{ and } \ \langle F(t)F(t')\rangle = \frac{2D}{m^2}\delta(t-t')\,. \tag{56}$$

Note that since $F(t)$ is a random variable, solving the Langevin equation will give $v(t)$ as a random variable (having a known distribution). It is therefore a *stochastic differential equation*. The function F is frequently called "the noise term" or simply "the noise". It is *white noise* since the Fourier transform of a delta-function is a constant – all frequencies are present in equal amounts.

Multiplying the Langevin equation (55) by the integrating factor $\mathrm{e}^{\gamma t}$ gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[v(t)\mathrm{e}^{\gamma t}\right] = F(t)\mathrm{e}^{\gamma t} \Rightarrow v(t) = v_0\mathrm{e}^{-\gamma t} + \mathrm{e}^{-\gamma t}\int_0^t \mathrm{d}t'\,F(t')\mathrm{e}^{\gamma t'}\,. \tag{57}$$

By taking the average of the expression for $v(t)$ we find $\langle v(t)\rangle = v_0\mathrm{e}^{-\gamma t}$. More interestingly, if we square the expression for $v(t)$ and take the average, then we find

$$\langle v^2(t)\rangle = v_0^2\mathrm{e}^{-2\gamma t} + \frac{D}{\alpha m}\left[1-\mathrm{e}^{-2\gamma t}\right]\,, \tag{58}$$

which implies that

$$\lim_{t\to\infty}\langle v^2(t)\rangle = \frac{D}{\alpha m}\,. \tag{59}$$

On the other hand, as $t\to\infty$, the Brownian particle will be in thermal equilibrium:

$$\lim_{t\to\infty}\langle v^2(t)\rangle = v_{\mathrm{eq}}^2 \quad \text{and} \quad \frac{1}{2}mv_{\mathrm{eq}}^2 = \frac{1}{2}kT\,,$$

where T is the temperature of the liquid and k is Boltzmann's constant. This implies that

$$\frac{1}{2}m\left(\frac{D}{\alpha m}\right) = \frac{1}{2}kT \ \Rightarrow \ D = \alpha kT\,. \tag{60}$$

The molecules of the liquid are acting as a heat bath for the system – which in this case is a single Brownian particle. The equation $D = \alpha kT$ is a simple example of a fluctuation-dissipation theorem, and determines D in terms of the friction constant, α, and of the temperature of the liquid, T.

Although we have presented a somewhat heuristic rationale for Eq. (54), it may be derived in a more controlled way. A particularly clear derivation has been given by Zwanzig [60], where the starting point is a Hamiltonian which contains three terms: for the system, the heat bath and the interaction between the system and the heat bath. Taking the heat bath to be made up of coupled harmonic oscillators and the interaction term between the system and heat bath to be linear, it is possible to integrate out the bath degrees of freedom exactly, and be left only with the equations of motion of the system degrees of freedom plus the initial conditions of the bath degrees of freedom. Assuming that the bath is initially in thermal equilibrium, so that these initial values are distributed according to a Boltzmann distribution, adds extra "noise" terms to the equations of motion which, with a few more plausible assumptions, make them of the Langevin type.

Examples of Langevin–like Equations

1. *Overdamped Brownian motion*. Frequently the viscous damping force $-\alpha v$ is much larger than the inertial term $m\mathrm{d}^2x/\mathrm{d}t^2$ in Eq. (53), and so to a good approximation the left-hand side of Eq. (53) can be neglected. Scaling time by α, we arrive at the Langevin equation for the motion of an overdamped Brownian particle:

$$\frac{\mathrm{d}x}{\mathrm{d}t} = -V'(x) + \mathcal{F}(t)\,; \quad x(0) = x_0\,, \tag{61}$$

where $'$ denotes differentiation with respect to x and where, due to the rescaling of time by α,

$$\langle\mathcal{F}(t)\rangle = 0; \quad \langle\mathcal{F}(t)\mathcal{F}(t')\rangle = 2\tilde{D}\delta(t-t'); \quad \tilde{D} = \frac{D}{\alpha}\,. \tag{62}$$

A particularly well-known case is when the Brownian particle is moving in the harmonic potential $V(x) = ax^2/2$. Then

$$\frac{\mathrm{d}x}{\mathrm{d}t} = -ax + \mathcal{F}(t)\,; \quad x(0) = x_0\,. \tag{63}$$

Since Eq. (63) relating $x(t)$ to $\mathcal{F}(t)$ is linear, and since the distribution of $\mathcal{F}(t)$ is Gaussian, then $x(t)$ is also distributed according to a Gaussian distribution. Comparing with Eqs. (55) and (56), which also define a linear system, we find that $\langle x(t)\rangle = x_0\mathrm{e}^{-at}$ and, from

Eq. (58), $\langle x^2(t)\rangle = x_0^2 \mathrm{e}^{-2at} + (\tilde{D}/a)\left[1-\mathrm{e}^{-2at}\right]$. This gives

$$P(x,t|x_0,0) = \sqrt{\frac{a}{2\pi\tilde{D}\left[1-\mathrm{e}^{-2at}\right]}}\exp\left\{-\frac{a\left(x-x_0\mathrm{e}^{-at}\right)^2}{2\tilde{D}\left[1-\mathrm{e}^{-2at}\right]}\right\} . \quad (64)$$

It is straightforward to check that this conditional pdf satisfies the Fokker–Planck equation (51) for the Ornstein–Uhlenbeck process. Below we will show this more directly, by starting from the Langevin equation (61) and deriving Eq. (51) if $V(x)$ is quadratic.

Another case of interest is when $V(x)$ is a double-well potential, $V(x) = -ax^2/2 + bx^4/4$. If the particle is initially located near the bottom of one of the potential wells, it will take on average a time of the order of $\mathrm{e}^{\Delta V/D}$ to hop over the barrier and into the well on the other side. Here ΔV is the height of the barrier that it has to hop over [29].

2. *Environmental noise in population biology*. One of the simplest models of two species with population sizes N_1 and N_2 which are competing for a common resource, is the two coupled deterministic ordinary differential equations $\dot{N}_i = r_i N_i$, $i = 1,2$. The growth rates, r_i, depend on the population sizes in such a way that as the population sizes increase, the r_i decrease to reflect the increased competition for resources. This could be modeled, for instance, by taking $r_i = a_i - b_{ii}N_i - b_{ij}N_j$ with $i,j = 1,2$ and $i \neq j$. In reality, external factors such as climate, terrain, the presence of other species, and indeed any factor which has an uncertain influence on these two species, will also affect the growth rate. This can be modeled by adding an external random term to the r_i which represents this *environmental stochasticity* [33]. Then the equations become

$$\begin{aligned}\frac{\mathrm{d}N_1}{\mathrm{d}t} &= a_1N_1 - b_{11}N_1^2 - b_{12}N_1N_2 + N_1\zeta_1(t)\\ \frac{\mathrm{d}N_2}{\mathrm{d}t} &= a_2N_2 - b_{22}N_2^2 - b_{21}N_2N_1 + N_2\zeta_2(t) .\end{aligned} \quad (65)$$

Since the noise terms, $\zeta_i(t)$ are designed to reflect the large number of coupled variables omitted from the description of the model, it is natural, by virtue of the central limit theorem, to assume that they are Gaussianly distributed. It also seems reasonable to assume that any temporal correlation between these external influences is on scales very much shorter than those of interest to us here, and that the noises have zero mean. We therefore assume that

$$\langle\zeta_i(t)\rangle = 0 ; \quad \langle\zeta_i(t)\zeta_j(t')\rangle = 2D_i\delta_{ij}\delta(t-t') , \quad (66)$$

where the D_i describe the strength of the stochastic effects. The deterministic equations (that is, Eq. (65) without the noise terms) have a fixed point at the origin, one on each of the N_1 and N_2 axes, and may have another at non-zero N_1 and N_2. For some values of the parameters this latter fixed point may be a saddle, with those on the axes being stable and the origin unstable. In this situation the eventual fate of the species depends significantly on the noise: if the combination of the nonlinear dynamics and the noise drives the system to the vicinity of the fixed point on the N_1 axis, then species 2 will become extinct, and vice-versa.

Langevin equations with Gaussian white noise are equivalent to Fokker–Planck equations. This can be most easily seen by calculating the jump moments (39) from the Langevin equation. For instance, if we begin from the Langevin equation for an overdamped Brownian particle (61),

$$\begin{aligned}\Delta x(t) \equiv x(t+\Delta t) - x(t) &= \int_t^{t+\Delta t} \mathrm{d}t'\, \dot{x}(t')\\ &= -\int_t^{t+\Delta t} \mathrm{d}t'\, V'(x(t')) + \eta(t) ,\end{aligned} \quad (67)$$

where $\eta(t) = \int_t^{t+\Delta t} \mathrm{d}t'\, \mathcal{F}(t')$. From Eq. (62) it is straightforward to calculate the moments of $\eta(t)$: $\langle\eta(t)\rangle = 0$,

$$\langle\eta^2(t)\rangle = \int_t^{t+\Delta t} \mathrm{d}t' \int_t^{t+\Delta t} \mathrm{d}t'' \langle\mathcal{F}(t')\mathcal{F}(t'')\rangle = 2\tilde{D}\Delta t \quad (68)$$

and, since $\eta(t)$ is Gaussian, $\langle\eta^n(t)\rangle$ is zero if n is odd, and at least of order $(\Delta t)^2$ for $n \geq 4$. This implies that

$$\begin{aligned}M_1(x,\Delta t) &= -V'(x)\Delta t + \mathcal{O}\left(\Delta t\right)^2 ,\\ M_2(x,\Delta t) &= 2\tilde{D}\Delta t + \mathcal{O}\left(\Delta t\right)^2 ,\end{aligned} \quad (69)$$

with all moments of order $(\Delta t)^2$ or higher for $\ell > 2$. The notation $\mathcal{O}\left(\Delta t\right)^2$ means that the magnitude of this quantity is less than a constant times $(\Delta t)^2$, for sufficiently small nonzero $(\Delta t)^2$. This is a weaker, but more specific, statement than saying it is $o\left(\Delta t\right)$. Using Eqs. (35) and (36), the Fokker–Planck equation which is equivalent to the

Langevin equation (61) is found to be

$$\frac{\partial P}{\partial t} = \frac{\partial}{\partial x}\left[V'(x)P\right] + \tilde{D}\frac{\partial^2 P}{\partial x^2} . \tag{70}$$

From Eq. (47), the stationary pdf is $P_{\text{st}}(x) = C\exp\{-V(x)/\tilde{D}\} = C\exp\{-V(x)/kT\}$, as expected.

Although in this article we have largely restricted our attention to stochastic processes involving one variable, the construction of a Fokker–Planck equation from the Langevin equation goes through in a similar way for an n-dimensional process $\mathbf{x} = (x_1, \dots, x_n)$. In this case the jump moments are

$$\left\langle \Delta x_{i_1}(t)\Delta x_{i_2}(t)\dots\Delta x_{i_\ell}(t)\right\rangle_{\mathbf{x}(t)=\mathbf{x}} = D_{i_1\dots i_\ell}(\mathbf{x},t)\Delta t + o(\Delta t) , \tag{71}$$

where $\Delta x_{i_\alpha} = x_{i_\alpha}(t+\Delta t) - x_{i_\alpha}$. The Kramers–Moyal expansion is then

$$\frac{\partial P}{\partial t} = \sum_{\ell=1}^{\infty}\frac{(-1)^\ell}{\ell!}\frac{\partial^\ell}{\partial x_{i_1}\dots\partial x_{i_\ell}}\left\{D_{i_1\dots i_\ell}(\mathbf{x},t)P\right\} . \tag{72}$$

The Langevin equation for Brownian motion (54), without going to the overdamped limit, serves as a simple illustration of this generalization. Here $\Delta x(t) = v\Delta t$ and $\Delta v(t) = -\gamma v\,\Delta t - m^{-1}V'(x)\,\Delta t + m^{-1}\eta(t)$. This results in the Fokker–Planck equation

$$\frac{\partial P}{\partial t} = -\frac{\partial}{\partial x}\left[vP\right] + \frac{\partial}{\partial v}\left[\left\{\gamma v + m^{-1}V'(x)\right\}P\right] + \frac{\gamma kT}{m}\frac{\partial^2 P}{\partial v^2} . \tag{73}$$

This is Kramer's equation. It has a stationary pdf $P_{\text{st}}(x,v) = C\exp\{-E/kT\}$, where $E = mv^2/2 + V(x)$.

We end this section by finding the Fokker–Planck equation which is equivalent to the general set of Langevin equations of the form

$$\dot{x}_i = A_i(\mathbf{x},t) + \sum_{\alpha=1}^{m} g_{i\alpha}(\mathbf{x},t)\,\zeta_\alpha(t); \quad i = 1,\dots,n, \tag{74}$$

where $\zeta_\alpha(t)$, $\alpha = 1,\dots,m$, is a Gaussian white noise with zero mean and with

$$\langle\zeta_\alpha(t)\zeta_\beta(t')\rangle = \delta_{\alpha\beta}\delta(t-t') . \tag{75}$$

Proceeding as in Eq. (67), but noting the dependence of the function $g_{i\alpha}$ on the stochastic variable, yields

$$\begin{aligned} M_i(\mathbf{x},t,\Delta t) &= \left[A_i(\mathbf{x},t) + \theta(0)\sum_{j=1}^{n}\sum_{\alpha=1}^{m} g_{j\alpha}(\mathbf{x},t)\frac{\partial}{\partial x_j}g_{i\alpha}(\mathbf{x},t)\right]\Delta t + \mathcal{O}(\Delta t)^2 , \\ M_{ij}(\mathbf{x},t,\Delta t) &= \sum_{\alpha=1}^{m}\left[g_{i\alpha}(\mathbf{x},t)g_{j\alpha}(\mathbf{x},t)\right]\Delta t + \mathcal{O}(\Delta t)^2 , \end{aligned} \tag{76}$$

with all jump moments higher than the second being of order $(\Delta t)^2$ or higher. The quantity $\theta(0)$ is the value of the Heaviside theta function, $\theta(x)$, at $x = 0$ and is indeterminate. This indicates that the Langevin description does not correspond to a unique Fokker–Planck equation. This situation occurs whenever the white noise in a Langevin equation is multiplied by a function which depends on the state variable, as in Eq. (74). For systems such as this acted upon by *multiplicative noise* the Langevin description has to be supplemented by a rule which says whether the state variable in the multiplying function ($g_{i\alpha}$ in Eq. (74)) is that before or after the noise pulse acts [52]. If it is taken to be the value immediately after the noise pulse acts then $\theta(0) = 0$ (Itô rule), whereas if it is taken to be the average of the values before and after, then $\theta(0) = 1/2$ (Stratonovich rule). The Fokker–Planck equation is now found from Eq. (72) to be

$$\frac{\partial P}{\partial t} = -\sum_{i=1}^{n}\frac{\partial}{\partial x_i}\left[A_i(\mathbf{x},t)P(\mathbf{x},t)\right] + \frac{1}{2}\sum_{i,j=1}^{n}\sum_{\alpha=1}^{m}\frac{\partial^2}{\partial x_i\partial x_j}\left[g_{i\alpha}(\mathbf{x},t)g_{j\alpha}(\mathbf{x},t)P(\mathbf{x},t)\right] , \tag{77}$$

in the Itô case and

$$\frac{\partial P}{\partial t} = -\sum_{i=1}^{n}\frac{\partial}{\partial x_i}\left[A_i(\mathbf{x},t)P(\mathbf{x},t)\right] + \frac{1}{2}\sum_{i,j=1}^{n}\sum_{\alpha=1}^{m}\frac{\partial}{\partial x_i}\left[g_{i\alpha}(\mathbf{x},t)\frac{\partial}{\partial x_j}\left\{g_{j\alpha}(\mathbf{x},t)P(\mathbf{x},t)\right\}\right], \tag{78}$$

in the Stratonovich case.

Path Integrals

While most early work on stochastic processes was concerned with linear systems, naturally attention soon moved on to the many interesting systems which could be modeled as nonlinear stochastic processes. These systems are much more difficult to analyze. For example, a nonlinear Langevin equation cannot be solved directly, and so the averaging procedure cannot be carried out in the same explicit way as described in Sect. "Stochastic Differential Equations". There is however one method which is applicable to many nonlinear stochastic differential equations of interest: the solution of these equations can be formally written down as a path-integral, and from this correlation functions and other quantities of physical interest can be obtained. This also has the advantage that all the formalism and approximation schemes developed to study functional integrals over the years can be called into play.

Path-integrals are intimately related to Brownian motion and the earliest work on the subject by Wiener [56, 57], emphasized this. If the problem of interest is formulated as a set of Langevin equations, the derivation of the path-integral representation is particularly straightforward, if rather heuristic. For clarity we begin with the simplest case: an overdamped system with a single degree of freedom, x, acted upon by white noise. The Langevin equation is given by Eq. (61) and the noise is defined by Eq. (62). Since the noise is assumed to be Gaussian, Eq. (62) is a complete specification. An equivalent way of giving it is through the pdf [12]:

$$P[\mathcal{F}]\,\mathcal{D}\mathcal{F} \propto \exp\left(-\frac{1}{4\tilde{D}}\int \mathrm{d}t \mathcal{F}^2(t)\right)\,\mathcal{D}\mathcal{F}\,, \tag{79}$$

where $\mathcal{D}\mathcal{F}$ is the functional measure. The idea is now to regard the Langevin equation (61) as defining a mapping $\mathcal{F} \mapsto x$. The pdf for the x variable is then given by

$$\begin{aligned} P[x] &= P[\mathcal{F}]|_{\mathcal{F}=\dot{x}+V'(x)}\,J[x] \\ &\propto \exp\left(-\frac{1}{4\tilde{D}}\int \mathrm{d}t\,[\dot{x}+V'(x)]^2\right)\,J[x]\,, \end{aligned} \tag{80}$$

where

$$J[x] = \det\left[\frac{\delta\mathcal{F}}{\delta x}\right]\,, \tag{81}$$

is the Jacobian of the transformation. An explicit expression for the Jacobian may be obtained either by direct calculation of a discretized form of the Langevin equation [21] or through use of the identity relating the determinant of a matrix to the exponential of the trace of the logarithm of that matrix [59]. One finds that $J[x] \propto \exp\{\theta(0)\int \mathrm{d}t\,V''(x)\}$. The quantity $\theta(0)$ is once again the indeterminate value of the Heaviside theta function $\theta(x)$ at $x = 0$. Its appearance is a reflection of the fact that, due to the Brownian-like nature of the paths in the functional integral, the nature of the discretization appears explicitly through this factor [48]. If we consistently use the mid-point rule throughout, then we may take $\theta(0) = 1/2$, which gives

$$\begin{aligned} P[x] &\propto \exp\left(-\frac{1}{4\tilde{D}}\int \mathrm{d}t\,[\dot{x}+V'(x)]^2 + \frac{1}{2}\int \mathrm{d}t\,V''(x)\right) \\ &= \exp\left(-S[x]/\tilde{D}\right)\,. \end{aligned} \tag{82}$$

All quantities of interest can now be found from expression (82). For example, the conditional probability distribution, $P(x,t|x_0,t_0)$ is given by

$$\langle\delta(x-x(t))\rangle_{x(t_0)=x_0} = \int_{x(t_0)=x_0} \mathcal{D}x\delta(x-x(t))\,P[x]\,. \tag{83}$$

The expression (82) has much in common with Feynman's formulation of quantum mechanics as a path-integral [11]. In fact another way to obtain the result is to exploit the transformation (49) to write the Fokker–Planck equation (70) as a Schrödinger equation in imaginary time $\tau = it$, with a potential $U(x) = (1/2)[V'(x)]^2 - \tilde{D}V''(x)$, following Eq. (50). The action in the quantum-mechanical path-integral is

$$\begin{aligned} &\frac{i}{\hbar}\int \mathrm{d}t\left[\frac{1}{2}\dot{x}^2 - U(x)\right] \longrightarrow \\ &\frac{1}{2\tilde{D}}\int \mathrm{d}\tau\left[-\frac{1}{2}\dot{x}^2 - \frac{1}{2}\left[V'(x)\right]^2 + \tilde{D}V''(x)\right]\,, \end{aligned} \tag{84}$$

which is Eq. (82) since $\int_{t_0}^{t}\mathrm{d}t\,\dot{x}V'(x) = \int_{x_0}^{x}\mathrm{d}x\,V'(x) = V(x) - V(x_0)$ does not depend on the path, only on the end-points. The functional $S[x]$ is analogous to the action in classical mechanics, and is frequently referred to as such. It is also sometimes referred to as the generalized Onsager–Machlup functional, in recognition of the original work carried out by Onsager and Machlup [40], in the case of a linear Langevin equation, in 1953.

The above discussion can be generalized in many ways. For example, if the Langevin equation for an n-dimensional process takes the form

$$\dot{x}_i = A_i(\mathbf{x}) + \zeta_i(t)\,, \quad \langle\zeta_i(t)\zeta_j(t')\rangle = 2D_{ij}\delta(t-t')\,, \tag{85}$$

where $\zeta_i(t)$ is a Gaussian noise with zero mean and D_{ij} is independent of $\mathbf{x}$, then the general Onsager–Machlup functional is [21]

$$S[x]=\int \mathrm{d}t\left[\frac{1}{4}\sum_{i,j}\{\dot{x}_i-A_i(\mathbf{x})\}\,D^{-1}_{ij}\,\{\dot{x}_j-A_j(\mathbf{x})\}\right.$$
$$\left.+\frac{1}{2}\sum_i\frac{\partial A_i}{\partial x_i}\right]\,, \qquad (86)$$

if the matrix D_{ij} is non-singular. The generalization to the situation where the noise is multiplicative is more complicated, and is analogous to the path-integral formulation of quantum mechanics in curved space [20].

System Size Expansion

In Example 2 of Sect. "The Fokker–Planck Equation" we explicitly showed how the master equation may have different limits when the size of the system, N, becomes large. In one case both the first and second jump moments were of the same order (and much larger than the higher jump moments) and so a nonlinear Fokker–Planck equation of the diffusion type was obtained in the limit $N \to \infty$. In another case, the first jump moment scaled in a different way to the second moment, and so the $N \to \infty$ limit gave a deterministic macroscopic equation of the form $\dot{x}=f(x)$, with finite N effects presumably consisting of $1/\sqrt{N}$ fluctuations about the macroscopic state, $x(t)$. It is the second scenario that we will explore in this section. It can be formalized by writing

$$\frac{n}{N}=x(t)+\frac{\xi}{\sqrt{N}}\,, \qquad (87)$$

and substituting this into the master equation, then equating terms of the same order in $1/\sqrt{N}$. The leading order equation obtained in this way will be the macroscopic equation, and the function $f(x)$ will emerge from the analysis. The next-to-leading order equation turns out to be a *linear* Fokker–Planck equation in the variable ξ. Higher order terms may also be included. This formalism was first developed by van Kampen [51] and is usually referred to as van Kampen's system-size expansion. We will describe it in the specific case of a one-step process for a single stochastic variable in order to bring out the essential features of the method.

When using this formalism it is useful to rewrite the master equation (23) using step operators which act on an arbitrary function of n according to $\mathcal{E}f(n)=f(n+1)$ and $\mathcal{E}^{-1}f(n)=f(n-1)$. This gives

$$\frac{\mathrm{d}P(n,t)}{\mathrm{d}t}=(\mathcal{E}-1)\left[T(n-1|n)P(n,t)\right]$$
$$+\left(\mathcal{E}^{-1}-1\right)\left[T(n+1|n)P(n,t)\right]\,. \qquad (88)$$

We begin by using Eq. (87) to write the pdf which appears in the master Equation (88) as

$$P(Nx(t)+\sqrt{N}\xi,t)=\Pi(\xi,t)$$
$$\Rightarrow\quad \dot{P}=\frac{\partial\Pi}{\partial t}-N^{1/2}\frac{\mathrm{d}x}{\mathrm{d}t}\frac{\partial\Pi}{\partial\xi}\,. \qquad (89)$$

This gives an expression for the left-hand side of the master equation, $\dot{P}$. To get an expression for the right-hand side,

(a) the step operators are expanded in powers of $1/\sqrt{N}$ [53]:

$$\mathcal{E}^{\pm 1}=1\pm\frac{1}{\sqrt{N}}\frac{\partial}{\partial\xi}+\frac{1}{2!}\frac{1}{N}\frac{\partial^2}{\partial\xi^2}+\mathcal{O}\left(\frac{1}{N^{3/2}}\right)\,, \qquad (90)$$

(b) $T(n\pm 1|n)$ is expressed in terms of ξ and N,
(c) $P(n,t)$ is replaced by $\Pi(\xi,t)$.

Steps (a), (b) and (c) gives the right-hand side of the master equation as a power-series in $1/\sqrt{N}$. Equating the left-hand and right-hand sides order by order in $1/\sqrt{N}$ (this may require a rescaling of the time, t, by a power of $\sqrt{N}$), gives to leading order (the $\partial\Pi/\partial\xi$ cancels) an equation of the form $\mathrm{d}x/\mathrm{d}t=f(x)$. This may be solved subject to the condition $x(0)=x_0=n_0/N$, if we take the initial condition on the master equation to be $P(n,0)=\delta_{n,n_0}$. We denote the solution of this macroscopic equation by $x_{\mathrm{M}}(t)$.

To next order in $1/\sqrt{N}$, the Fokker–Planck equation

$$\frac{\partial\Pi}{\partial t}=-f'(x)\frac{\partial}{\partial\xi}\left[\xi\Pi\right]+\frac{1}{2}g(x)\frac{\partial^2\Pi}{\partial\xi^2}\,, \qquad (91)$$

describing a linear stochastic process is found. The functions $f'(x)$ and $g(x)$ are to be evaluated when $x=x_{\mathrm{M}}(t)$, and so are simply functions of time. If the macroscopic system tends to a fixed point: $x_{\mathrm{M}}(t)\to x^*$, as $t\to\infty$, then $f'(x)$ and $g(x)$ may be replaced by constants in order to study the fluctuations about this stationary state.

To illustrate the method we use Example 3, Sect. "The Master Equation". Equating both sides of the master equation in this case one finds

$$-N^{1/2}\frac{\mathrm{d}x}{\mathrm{d}t}\frac{\partial\Pi}{\partial\xi}+\frac{\partial\Pi}{\partial t}=\frac{1}{\sqrt{N}}\left[f_-(x)-f_+(x)\right]\frac{\partial\Pi}{\partial\xi}$$
$$+\frac{1}{2}\frac{1}{N}\left[f_-(x)+f_+(x)\right]\frac{\partial^2\Pi}{\partial\xi^2}$$
$$+\frac{1}{N}\left[f_-'(x)-f_+'(x)\right]\frac{\partial}{\partial\xi}\left[\xi P\right]+\dots\,, \qquad (92)$$

where the functions $f_-(x)$ and $f_+(x)$ are given by:

$$f_-(x)=cx^2+\mathrm{d}x\,,\qquad f_+(x)=2bx(1-x)\,. \qquad (93)$$

For the left- and right-hand sides to balance in Eq. (92), a rescaled time $\tau = t/N$ needs to be introduced. Then to leading order one finds $\mathrm{d}x/\mathrm{d}\tau = f(x)$, where $f(x) = f_+(x) - f_-(x)$. At next to leading order Eq. (91) is found with $g(x) = f_+(x) + f_-(x)$. The explicit form of the macroscopic equation is

$$\frac{\mathrm{d}x}{\mathrm{d}\tau} = x\,(r - ax)\ , \tag{94}$$

where $r = 2b - d$ and $a = 2b + c$. Equation (94) is the logistic equation, which is the usual phenomenological way to model intraspecies competition.

Since the Fokker–Planck equation (91) describes a linear process, its solution is a Gaussian. This means that the probability distribution $\Pi(\xi, t)$ is completely specified by the first two moments $\langle \xi(t) \rangle$ and $\langle \xi^2(t) \rangle$. Multiplying Eq. (91) by ξ and ξ^2 and integrating over all ξ one finds

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\langle \xi(t)\rangle &= f'(x_{\mathrm{M}}(t))\langle \xi(t)\rangle\ , \\ \frac{\mathrm{d}}{\mathrm{d}t}\langle \xi^2(t)\rangle &= 2f'(x_{\mathrm{M}}(t))\langle \xi^2(t)\rangle + g(x_{\mathrm{M}}(t))\ . \end{aligned} \tag{95}$$

We have chosen the initial condition to be $x_0 = n_0/N$, which implies that $\xi(0) = 0$. The first equation in (95) then implies that $\langle \xi(t) \rangle = 0$ for all t. Multiplying the second equation by $f^{-2}(x_{\mathrm{M}}(t))$ one finds that

$$\langle \xi^2(t)\rangle = f^2(x_{\mathrm{M}}(t)) \int_0^t \mathrm{d}t'\, \frac{g(x_{\mathrm{M}}(t'))}{f^2(x_{\mathrm{M}}(t'))}\ , \tag{96}$$

and so the determination of $\langle \xi^2(t) \rangle$ is reduced to quadrature. The method can be applied to systems with more than one stochastic variable and those which are not one-step processes. Details are given in van Kampen's book [53].

Future Directions

This article has focused largely on classical topics in the theory of stochastic processes, since these form the foundations on which the subject is built. Much of the current work, and one would expect future work, will be numerical in character. Some of this will begin from a basic Markovian description in the form of reactions among chemical species – even if the system is not chemical in nature (Example 3 of Sect. "The Master Equation" is an example). A straightforward algorithm developed by Gillespie [17,18], and since then extended and improved [3,19], provides an efficient way of simulating such systems. It thus provides a valuable method of investigating systems which may be formulated as complicated multivariable master equations, which complements the methods we have discussed here. However, many current studies do not begin from a system which can be described in this way, and there is every indication that this will be more true in the future. For instance, in agent based models the stochastic element may be due to mutations in characteristics, traits or behavior, which may be difficult or impossible to formulate mathematically. Such agent based models are certainly individually based, but each individual may have different attributes and generally behave in such a complex way that only numerical simulations can be used to explore the behavior of the system as a whole. Although these complex systems may be used to model more realistic situations, the well-known problems associated with the large number of parameters typically required to describe such systems, will mean that simplified versions will need to be analyzed in order to understand them at a deeper level. These simpler models are likely to include those where the agents of a particular species are essentially identical. In this article we have discussed how the classical equations of the theory of stochastic processes, such as the Fokker–Planck equation, can be obtained from such models. They will therefore form a bridge between the agent-based approaches which are expected to become more prevalent in the future, and the analytic approaches which lie at the heart of the theory of stochastic processes.

Article Outline

Glossary

Implied volatility The value of asset return volatility which equates a model-implied derivative price to the observed market price. Most notably, the term is used to identify the volatility implied by the Black and Scholes [63] option pricing formula.

Quadratic return variation The ex-post sample-path return variation over a fixed time interval.

Realized volatility The sum of finely sampled squared asset return realizations over a fixed time interval. It is an estimate of the quadratic return variation over such time interval.

Stochastic volatility A process in which the return variation dynamics include an unobservable shock which cannot be predicted using current available information.

Definition of the Subject

Given the importance of return volatility on a number of practical financial management decisions, the efforts to provide good real-time estimates and forecasts of current and future volatility have been extensive. The main framework used in this context involves stochastic volatility models. In a broad sense, this model class includes GARCH, but we focus on a narrower set of specifications in which volatility follows its own random process, as is common in models originating within financial economics. The distinguishing feature of these specifications is that volatility, being inherently unobservable and subject to independent random shocks, is not measurable with respect to observable information. In what follows, we refer to these models as *genuine* stochastic volatility models.

Much modern asset pricing theory is built on continuous-time models. The natural concept of volatility within this setting is that of genuine stochastic volatility. For example, stochastic volatility (jump-)diffusions have provided a useful tool for a wide range of applications, including the pricing of options and other derivatives, the modeling of the term structure of risk-free interest rates, and the pricing of foreign currencies and defaultable bonds. The increased use of intraday transaction data for construction of so-called realized volatility measures provides additional impetus for considering genuine stochastic volatility models. As we demonstrate below, the realized volatility approach is closely associated with the continuous-time stochastic volatility framework of financial economics.

There are some unique challenges in dealing with genuine stochastic volatility models. For example, volatility is truly latent and this feature complicates estimation and inference. Further, the presence of an additional state variable – volatility – renders the model less tractable from an analytic perspective. We review how such challenges have been addressed through development of new estimation methods and imposition of model restrictions allowing for closed-form solutions while remaining consistent with the dominant empirical features of the data.

Introduction

The label Stochastic Volatility is applied in two distinct ways in the literature. For one, it is used to signify that the (absolute) size of the innovations of a time series displays random fluctuations over time. Descriptive models of financial time series almost invariably embed this feature nowadays as asset return series tend to display alternating quiet and turbulent periods of varying length and intensity. To distinguish this feature from models that operate with an a priori known or deterministic path for the volatility process, the random evolution of the conditional return variance is termed stochastic volatility. The simplest case of deterministic volatility is the constant variance assumption invoked in, e. g., the Black and Scholes [63] framework. Another example is modeling the variance purely as a given function of calendar time, allowing only for effects such as time-of-year (seasonals), day-of-week (institutional and announcement driven) or time-of-day (diurnal effects due to, e. g., market microstructure features). Any model not falling within this class is then a stochastic volatility model. For example, in the one-factor continuous-time Cox, Ingersoll, and Ross [113] (CIR) model the (stochastic) level of the short term interest rate governs the dynamics of the (instantaneous) drift and diffusion term of all zero-coupon yields. Likewise, in GARCH models the past return innovations govern the one-period ahead conditional mean and variance. In both models, the volatility is known, or deterministic, at a given point in time, but the random evolution of the processes renders volatility stochastic for any horizon beyond the present period.

The second notion of stochastic volatility, which we adopt henceforth, refers to models in which the return variation dynamics is subject to an unobserved random shock so that the volatility is inherently latent. That is, the current volatility state is not known for sure, conditional on the true data generating process and the past history of all available discretely sampled data. Since the CIR and GARCH models described above render the current (conditional) volatility known, they are not stochastic volatility models in this sense. In order to make the distinction clear cut, we follow Andersen [10] and label this second, more restrictive, set *genuine* stochastic volatility (SV) models.

There are two main advantages to focusing on SV models. First, much asset pricing theory is built on continuous-time models. Within this class, SV models tend to fit more naturally with a wide array of applications, including the pricing of currencies, options, and other derivatives, as well as the modeling of the term structure of interest rates. Second, the increasing use of high-frequency intraday data for construction of so-called realized volatility measures is also starting to push the GARCH models out of the limelight as the realized volatility approach is naturally linked to the continuous-time SV framework of financial economics.

One drawback is that volatility is not measurable with respect to observable (past) information in the SV setting. As such, an estimate of the current volatility state must be filtered out from a noisy environment and the estimate will change as future observations become available. Hence, in-sample estimation typically involves smoothing techniques, not just filtering. In contrast, the conditional variance in GARCH is observable given past information, which renders (quasi-)maximum likelihood techniques for inference quite straightforward while smoothing techniques have no role. As such, GARCH models are easier to estimate and practitioners often rely on them for time-series forecasts of volatility. However, the development of powerful method of simulated moments, Markov Chain Monte Carlo (MCMC) and other simulation based procedures for estimation and forecasting of SV models may well render them competitive with ARCH over time on that dimension.

Direct indications of the relations between SV and GARCH models are evident in the sequence of papers by Dan Nelson and Dean Foster exploring the SV diffusion limits of ARCH models as the case of continuous sampling is approached, see, e. g., Nelson and Foster [219]. Moreover, as explained in further detail in the estimation section below, it can be useful to summarize the dynamic features of asset returns by tractable pseudo-likelihood scores obtained from GARCH-style models when performing simulation based inference for SV models. As such, the SV and GARCH frameworks are closely related and should be viewed as complements. Despite these connections we focus, for the sake of brevity, almost exclusively on SV models and refer the interested reader to the GARCH chapter for further information.

The literature on SV models is vast and rapidly growing, and excellent surveys are available, e. g., Ghysels et al. [158] and Shephard [239,240]. Consequently, we focus on providing an overview of the main approaches with illustrations of the scope for applications of these models to practical finance problems.

Model Specification

The original econometric studies of SV models were invariably cast in discrete time and they were quite similar in structure to ARCH models, although endowed with a more explicit structural interpretation. Recent work in the area has been mostly directly towards a continuous time setting and motivated by the typical specifications in financial economics. This section briefly reviews the two alternative approaches to specification of SV models.

Discrete-Time SV Models and the Mixture-of-Distributions Hypothesis

Asset pricing theory contends that financial asset prices reflect the discounted value of future expected cash flows, implying that all news relevant for either discount rates or cash flows should induce a shift in market prices. Since economic news items appear almost continuously in real time, this perspective rationalizes the ever-changing nature of prices observed in financial markets. The process linking news arrivals to price changes may be complex, but if it is stationary in the statistical sense it will nonetheless produce a robust theoretical association between news arrivals, market activity and return volatility. In fact, if the number of news arrival is very large, standard central limit theory will tend to imply that asset returns are approximately normally distributed *conditional* on the news count. More generally, variables such as the trading volume, the number of transactions or the number of price quotes are also naturally related to the intensity of the information flow. This line of reasoning has motivated specifications such as

$$y_t|s_t \rightsquigarrow N(\mu_y s_t \ , \ \sigma_y^2 s_t) \ , \tag{1}$$

where y_t is an "activity" variable related to the information flow, s_t is a positive intensity process reflecting the rate of news arrivals, μ_y represents the mean response to an information event, and σ_y is a pure scaling parameter.

This is a normal mixture model, where the s_t process governs or "mixes" the scale of the distribution across the periods. If s_t is constant, this is simply an i.i.d. Gaussian process for returns and possible other related variables. However, this is clearly at odds with the empirical evidence for, e. g., return volatility and trading volume. Therefore, s_t is typically stipulated to follow a separate stochastic process with random innovations. Hence, each period the return series is subject to two separate shocks, namely the usual idiosyncratic error term associated with the (normal) return distribution, but also a shock to the variance or volatility process, s_t. This endows the return process with genuine stochastic volatility, reflecting the random intensity of news arrivals. Moreover, it is typically assumed that only returns, transactions and quotes are observable, but not the actual value of s_t itself, implying that σ_y cannot be separately identified. Hence, we simply fix this parameter at unity.

The time variation in the information flow series induces a fat-tailed unconditional distribution, consistent with stylized facts for financial return and, e. g., trading volume series. Intuitively, days with a lot of news display more rapid price fluctuations and trading activity than days with a low news count. In addition, if the s_t process is positively correlated, then shocks to the conditional mean and variance processes for y_t will be persistent. This is consistent with the observed clustering in financial markets, where return volatility and trading activity are contemporaneously correlated and each display pronounced positive serial dependence.

The inherent randomness and unobserved nature of the news arrival process, even during period t, renders the true mean and variance series latent. This property is the major difference with the GARCH model class, in which the one-step-ahead conditional mean and variance are a known function of observed variables at time $t-1$. As such, for genuine SV models, we must distinguish the full, but infeasible, information set ($s_t \in \mathcal{F}_t$) and the observable information set ($s_t \notin \mathcal{I}_t$). This basic latency of the mixing variable (state vector) of the SV model complicates inference and forecasting procedures as discussed below.

For short horizon returns, μ_y is nearly negligible and can reasonably be ignored or simply fixed at a small constant value, and the series can then be demeaned. This simplification produces the following return (innovation) model,

$$r_t = \sqrt{s_t}\, z_t \ , \tag{2}$$

where z_t is an i.i.d. standard normal variable, implying a simple normal-mixture representation,

$$r_t|s_t \rightsquigarrow N(0, s_t) \ . \tag{3}$$

Univariate return models of the form (3) as well as multivariate systems including a return variable along with other related market activity variables, such as the transactions count, the quote intensity or the aggregate trading volume, stem from the Mixture-of-Distributions Hypothesis (MDH).

Actual implementation of the MDH hinges on a particular representation of the information-arrival process s_t. Clark [102] uses trading volume as a proxy for the activity variable, a choice motivated by the high contemporaneous correlation between return volatility and volume. Tauchen and Pitts [247] follow a structural approach to characterize the joint distribution of the daily return and volume relation governed by the underlying latent information flow s_t. However, both these models assume temporal independence of the information flow, thus failing to capture the clustering in these series. Partly in response, Gallant et al. [153] examine the joint conditional return-volume distribution without imposing any structural MDH restrictions. Nonetheless, many of the original discrete-time SV specifications are compatible with the MDH framework, including Taylor [249][1], who proposes an autoregressive parametrization of the latent log-volatility (or information flow) variable

$$\log(s_{t+1}) = \eta_0 + \eta_1 \log(s_t) + u_t,\ u_t \rightsquigarrow \text{i.i.d}(0, \sigma_u^2)\,, \tag{4}$$

[1] Discrete-time SV models go father back in time, at least to the easly paper by Rosenberg [232] recently reprinted in Shephard [240].

where the error term, u_t, may be correlated with the disturbance term, z_t, in the return Eq. (2) so that $\rho = \text{corr}(u_t, z_t) \neq 0$. If $\rho < 0$, downward movements in asset prices result in higher future volatility as also predicted by the so-called 'leverage effect' in the exponential GARCH, or EGARCH, form of Nelson [218] and the asymmetric GARCH model of Glosten et al. [160].

Early tests of the MDH include Lamoureux and Lastrapes [194] and Richardson and Smith [231]. Subsequently, Andersen [11] studies a modified version of the MDH that provides a much improved fit to the data. Further refinements of the MDH specification have been pursued by, e. g., Liesenfeld [198,199] and Bollerslev and Jubinsky [67]. Among the first empirical studies of the related approach of stochastic time changes are Ané and Geman [29], who focus on stock returns, and Conley et al. [109], who focus on the short-term risk-free interest rate.

Continuous-Time Stochastic Volatility Models

Asset returns typically contain a predictable component, which compensates the investor for the risk of holding the security, and an unobservable shock term, which cannot be predicted using current available information. The conditional asset return variance pertains to the variability of the unobservable shock term. As such, over a non-infinitesimal horizon it is necessary to first specify the conditional mean return (e. g., through an asset pricing model) in order to identify the conditional return variation. In contrast, over an infinitesimal time interval this is not necessary because the requirement that market prices do not admit arbitrage opportunities implies that return innovations are an order of magnitude larger than the mean return. This result has important implications for the approach we use to model and measure volatility in continuous time.

Consider an asset with log-price process $\{p(t) \ , \ t \in [0, T]\}$ defined on a probability space $(\Omega, \mathcal{F}, P)$. Following Andersen et al. [19] we define the continuously compounded asset return over a time interval from $t-h$ to t, $0 \leq h \leq t \leq T$, to be

$$r(t,h) = p(t) - p(t-h) \,. \tag{5}$$

A special case of (5) is the cumulative return up to time t, which we denote $r(t) \equiv r(t,t) = p(t) - p(0)$, $0 \leq t \leq T$. Assume the asset trades in a frictionless market void of arbitrage opportunities and the number of potential discontinuities (jumps) in the price process per unit time is finite. Then the log-price process p is a semi-martingale (e. g., Back [33]) and therefore the cumulative return $r(t)$ admits the decomposition (e. g., Protter [229])

$$r(t) = \mu(t) + M^{\mathrm{C}}(t) + M^{\mathrm{J}}(t) \,, \tag{6}$$

where $\mu(t)$ is a predictable and finite variation process, $M^{\mathrm{C}}(t)$ a continuous-path infinite-variation martingale, and $M^{\mathrm{J}}(t)$ is a compensated finite activity jump martingale. Over a discrete time interval the decomposition (6) becomes

$$r(t,h) = \mu(t,h) + M^{\mathrm{C}}(t,h) + M^{\mathrm{J}}(t,h) \,, \tag{7}$$

where $\mu(t,h) = \mu(t) - \mu(t-h)$, $M^{\mathrm{C}}(t,h) = M^{\mathrm{C}}(t) - M^{\mathrm{C}}(t-h)$, and $M^{\mathrm{J}}(t,h) = M^{\mathrm{J}}(t) - M^{\mathrm{J}}(t-h)$.

Denote now with $[r,r]$ the quadratic variation of the semi-martingale process r, where (Protter [229])

$$[r,r]_t = r(t)^2 - 2\int r(s-)\mathrm{d}r(s) \,, \tag{8}$$

and $r(t-) = \lim_{s \uparrow t} r(s)$. If the finite variation process μ is continuous, then its quadratic variation is identically zero and the predictable component μ in decomposition (7) does not affect the quadratic variation of the return r. Thus, we obtain an expression for the quadratic return variation over the time interval from $t-h$ to t, $0 \leq h \leq t \leq T$ (e. g., Andersen et al. [21] and Barndorff-Nielsen and Shephard [51,52]):

$$\begin{aligned} \mathrm{QV}(t,h) &= [r,r]_t - [r,r]_{t-h} \\ &= [M^{\mathrm{C}}, M^{\mathrm{C}}]_t - [M^{\mathrm{C}}, M^{\mathrm{C}}]_{t-h} \\ &\quad + \sum_{t-h<s\leq t} \Delta M^2(s) \\ &= [M^{\mathrm{C}}, M^{\mathrm{C}}]_t - [M^{\mathrm{C}}, M^{\mathrm{C}}]_{t-h} \\ &\quad + \sum_{t-h<s\leq t} \Delta r^2(s) \,. \end{aligned} \tag{9}$$

Most continuous-time models for asset returns can be cast within the general setting of Eq. (7), and Eq. (9) provides a framework to study the model-implied return variance. For instance, the Black and Scholes [63] model is a special case of the setting described by Eq. (7) in which the conditional mean process μ is constant, the continuous martingale M^C is a standard Brownian motion process, and the jump martingale M^J is identically zero:

$$\mathrm{d}p(t) = \mu \mathrm{d}t + \sigma \mathrm{d}W(t) \,. \tag{10}$$

In this case, the quadratic return variation over the time interval from $t-h$ to t, $0 \leq h \leq t \leq T$, simplifies to

$$\mathrm{QV}(t,h) = \int_{t-h}^{t} \sigma^2 \mathrm{d}s = \sigma^2 h \,, \tag{11}$$

that is, return volatility is constant over any time interval of length h.

A second notable example is the jump-diffusion model of Merton [214],

$$\mathrm{d}p(t) = (\mu - \lambda\overline{\xi})\mathrm{d}t + \sigma \mathrm{d}W(t) + \xi(t)\mathrm{d}q_t \,, \tag{12}$$

where q is a Poisson process uncorrelated with W and governed by the constant jump intensity λ, i. e., $\mathrm{Prob}(\mathrm{d}q_t = 1) = \lambda \mathrm{d}t$. The scaling factor $\xi(t)$ denotes the magnitude of the jump in the return process if a jump occurs at time t. It is assumed to be normally distributed,

$$\xi(t) \rightsquigarrow N(\overline{\xi}, \sigma_{\xi}^2) \,. \tag{13}$$

In this case, the quadratic return variation process over the time interval from $t-h$ to t, $0 \le h \le t \le T$ becomes

$$\begin{aligned} \mathrm{QV}(t,h) &= \int_{t-h}^{t} \sigma^2 \mathrm{d}s + \sum_{t-h \le s \le t} J(s)^2 \\ &= \sigma^2 h + \sum_{t-h \le s \le t} J(s)^2 \,, \end{aligned} \tag{14}$$

where $J(t) \equiv \xi(t)\mathrm{d}q(t)$ is non-zero only if a jump actually occurs.

Finally, a broad class of stochastic volatility models is defined by

$$\mathrm{d}p(t) = \mu(t)\mathrm{d}t + \sigma(t)\mathrm{d}W(t) + \xi(t)\mathrm{d}q_t \,, \tag{15}$$

where q is a constant-intensity Poisson process with log-normal jump amplitude (13). Equation (15) is also a special case of (7) and the associated quadratic return variation over the time interval from $t-h$ to t, $0 \le h \le t \le T$, is

$$\begin{aligned} \mathrm{QV}(t,h) &= \int_{t-h}^{t} \sigma(s)^2 \mathrm{d}s + \sum_{t-h \le s \le t} J(s)^2 \\ &\equiv IV(t,h) + \sum_{t-h \le s \le t} J(s)^2 \,. \end{aligned} \tag{16}$$

As in the general case of Eq. (9), Eq. (16) identifies the contribution of diffusive volatility, termed 'integrated variance' (IV), and cumulative squared jumps to the total quadratic variation.

Early applications typically ignored jumps and focused exclusively on the integrated variance component. For instance, IV plays a key role in Hull and White's [174] SV option pricing model, which we discuss in Sect. "Options" below along with other option pricing applications. For illustration, we focus here on the SV model specification by Wiggins [256]:

$$\mathrm{d}p(t) = \mu \mathrm{d}t + \sigma(t)\mathrm{d}W_p(t) \tag{17}$$

$$\mathrm{d}\sigma(t) = f(\sigma(t))\mathrm{d}t + \eta\sigma(t)\mathrm{d}W_\sigma(t) \,, \tag{18}$$

where the innovations to the return $\mathrm{d}p$ and volatility σ, W_p and W_σ, are standard Brownian motions. If we define $y = \log(\sigma)$ and apply Itô's formula we obtain

$$\begin{aligned} \mathrm{d}y(t) &= \mathrm{d}\log(\sigma(t)) \\ &= \left[-\frac{1}{2}\eta^2 + \frac{f(\sigma(t))}{\sigma(t)} \right] \mathrm{d}t + \eta \mathrm{d}W_\sigma(t) \,. \end{aligned} \tag{19}$$

Wiggins approximates the drift term $f(\sigma(t)) \approx \{\alpha + \kappa[\log(\overline{\sigma}) - \log(\sigma(t))]\}\sigma(t)$. Substitution in Eq. (19) yields

$$\mathrm{d}\log(\sigma(t)) = [\overline{\alpha} - \kappa \log(\sigma(t))]\mathrm{d}t + \eta \mathrm{d}W_\sigma(t) \,, \tag{20}$$

where $\overline{\alpha} = \alpha + \kappa\log(\overline{\sigma}) - \frac{1}{2}\eta^2$. As such, the logarithmic standard deviation process in Wiggins has diffusion dynamics similar in spirit to Taylor's discrete time AR(1) model for the logarithmic information process, Eq. (4). As in Taylor's model, negative correlation between return and volatility innovations, $\rho = \mathrm{corr}(W_p, W_\sigma) < 0$, generates an asymmetric response of volatility to return shocks similar to the leverage effect in discrete-time EGARCH models.

More recently, several authors have imposed restrictions on the continuous-time SV jump-diffusion (15) that render the model more tractable while remaining consistent with the empirical features of the data. We return to these models in Sect. "Options" below.

Realized Volatility

Model-free measures of return variation constructed only from concurrent return realizations have been considered at least since Merton [215]. French et al. [148] construct monthly historical volatility estimates from daily return observations. More recently, the increased availability of transaction data has made it possible to refine early measures of historical volatility into the notion of 'realized volatility', which is endowed with a formal theoretical justification as an estimator of the quadratic return variation as first noted in Andersen and Bollerslev [18]. The realized volatility of an asset return r over the time interval from $t-h$ to t is

$$RV(t,h;n) = \sum_{i=1}^{n} r\left(t - h + \frac{ih}{n}, \frac{h}{n}\right)^2 \,. \tag{21}$$

Semi-martingale theory ensures that the realized volatility measure RV converges to the return quadratic variation QV, previously defined in Eq. (9), when the sampling frequency n increases. We point the interested reader to, e. g., Andersen et al. [19] to find formal arguments in support of this claim. Here we convey intuition for this result by considering the special case in which the asset return follows a continuous-time diffusion without jumps,

$$\mathrm{d}p(t) = \mu(t)\mathrm{d}t + \sigma(t)\mathrm{d}W(t)\,. \tag{22}$$

As in Eq. (21), consider a partition of the $[t-h, t]$ interval with mesh h/n. A discretization of the diffusion (22) over a sub-interval from $(t-h+(i-1)h/n)$ to $(t-h+ih/n)\,,\ i = 1,\dots,n$, yields

$$\begin{aligned} r\left(t-h+\frac{ih}{n},\frac{h}{n}\right) &\approx \mu\left(t-h+\frac{(i-1)h}{n}\right)\frac{h}{n} \\ &+ \sigma\left(t-h+\frac{(i-1)h}{n}\right)\Delta W\left(t-h+\frac{ih}{n}\right)\,, \end{aligned} \tag{23}$$

where $\Delta W(t-h+ih/n) = W(t-h+ih/n) - W(t-h+(i-1)h/n)$.

Suppressing time indices, the squared return r^2 over the time interval of length h/n is therefore:

$$r^2 = \mu^2\left(\frac{h}{n}\right)^2 + 2\mu\sigma\Delta W\left(\frac{h}{n}\right) + \sigma^2(\Delta W)^2\,. \tag{24}$$

As $n \to \infty$ the first two terms vanish at a rate higher than the last one. In particular, to a first order approximation the squared return equals the squared return innovation and therefore the squared return conditional mean and variance are

$$\mathrm{E}\left[r^2|\mathcal{F}_t\right] \approx \sigma^2\frac{h}{n} \tag{25}$$

$$\mathrm{Var}\left[r^2|\mathcal{F}_t\right] \approx 2\sigma^4\left(\frac{h}{n}\right)^2\,. \tag{26}$$

The no-arbitrage condition implies that return innovations are serially uncorrelated. Thus, summing over $i = 1,\dots,n$ we obtain

$$\begin{aligned} &\mathrm{E}\left[RV(t,h,n)|\mathcal{F}_t\right] \\ &\quad = \sum_{i=1}^{n}\mathrm{E}\left[r\left(t-h+\frac{ih}{n},\frac{h}{n}\right)^2|\mathcal{F}_t\right] \\ &\quad \approx \sum_{i=1}^{n}\sigma\left(t-h+\frac{(i-1)h}{n}\right)^2\frac{h}{n} \\ &\quad \approx \int_{t-h}^{t}\sigma(s)^2\mathrm{d}s \end{aligned} \tag{27}$$

$$\begin{aligned} &\mathrm{Var}\left[RV(t,h,n)|\mathcal{F}_t\right] \\ &\quad = \sum_{i=1}^{n}\mathrm{Var}\left[r\left(t-h+\frac{ih}{n},\frac{h}{n}\right)^2|\mathcal{F}_t\right] \\ &\quad \approx \sum_{i=1}^{n}2\sigma\left(t-h+\frac{(i-1)h}{n}\right)^4\left(\frac{h}{n}\right)^2 \\ &\quad \approx 2\left(\frac{h}{n}\right)\int_{t-h}^{t}\sigma(s)^4\mathrm{d}s\,. \end{aligned} \tag{28}$$

Equation (27) illustrates that realized volatility is an unbiased estimator of the return quadratic variation, while Eq. (28) shows that the estimator is consistent as its variance shrinks to zero when we increase the sampling frequency n and keep the time interval h fixed. Taken together, these results suggest that RV is a powerful and model-free measure of the return quadratic variation. Effectively, RV gives practical empirical content to the latent volatility state variable underlying the models previously discussed in Sect. “Continuous-Time Stochastic Volatility Models”.

Two issues complicate the practical application of the convergence results illustrated in Eqs. (27) and (28). First, a continuum of instantaneous return observations must be used for the conditional variance in Eq. (28) to vanish. In practice, only a discrete price record is observed, and thus an inevitable discretization error is present. Barndorff-Nielsen and Shephard [52] develop an asymptotic theory to assess the effect of this error on the RV estimate (see also [209]). Second, market microstructure effects (e. g., price discreteness, bid-ask spread positioning due to dealer inventory control, and bid-ask bounce) contaminate the return observations, especially at the ultra-high frequency. These effects tend to generate spurious correlations in the return series which can be partially eliminated by filtering the data prior to forming the RV estimates. However, this strategy is not a panacea and much current work studies the optimal sampling scheme and the construction of improved realized volatility in the presence of microstructure noise. This growing literature is surveyed by Hansen and Lunde [165], Bandi and Russell [46], McAleer and Medeiros [205], and Andersen and Benzoni [14]. Recent notable contributions to this literature include Bandi and Russell [45], Barndorff-Nielsen et al. [49], Diebold and Strasser [121], and Zhang, Mykland, and Aï t-Sahalia [262]. Related, there is the issue of how to construct RV measures when the market is rather illiquid. One approach is to use a lower sampling frequency and focus on longer-horizon RV measure. Alternatively the literature has explored volatility measures that are more robust to situations in which the noise-to-signal ratio is high, e. g., Alizadeh et al. [8], Brandt and Diebold [72], Brandt and Jones [73], Gallant et al. [151], Garman and Klass [157], Parkinson [221], Schwert [237], and Yang and Zhang [259] consider the high-low price range measure. Dobrev [122] generalizes the range estimator to high-frequency data and shows its link with RV measures.

Equations (27) and (28) also underscore an important difference between RV and other volatility measures. RV is an ex-post model-free estimate of the quadratic variation process. This is in contrast to ex-ante measures which attempt to forecast future quadratic variation using information up to current time. The latter class includes parametric GARCH-type volatility forecasts as well as forecasts built from stochastic volatility models through, e. g., the Kalman filter (e. g., [167,168]), the particle filter (e. g., [186,187]) or the reprojection method (e. g., [152,155]).

More recently, other studies have pursued more direct time-series modeling of volatility to obtain alternative ex-ante forecasts. For instance, Andersen et al. [21] follow an ARMA-style approach, extended to allow for long memory features, to model the logarithmic foreign exchange rate realized volatility. They find the fit to dominate that of traditional GARCH-type models estimated from daily data. In a related development, Andersen, Bollerslev, and Meddahi [24,25] exploit the general class of Eigenfunction Stochastic Volatility (ESV) models introduced by Meddahi [208] to provide optimal analytic forecast formulas for realized volatility as a function of past realized volatility. Other scholars have pursued more general model specifications to improve forecasting performance. Ghysels et al. [159] consider Mixed Data Sampling (MIDAS) regressions that use a combination of volatility measures estimates at different frequencies and horizons. Related, Engle and Gallo [137] exploit the information in different volatility measures, captured by a multivariate extension of the multiplicative error model suggested by Engle [136], to predict multi-step volatility. Finally, Andersen et al. [20] build on the Heterogeneous AutoRegressive (HAR) model by Barndorff-Nielsen and Shephard [50] and Corsi [110] and propose a HAR-RV component-based regression to forecast the h-steps ahead quadratic variation:

$$\begin{aligned}\mathrm{RV}(t+h,h) = \beta_0 + \beta_D \mathrm{RV}(t,1) + \beta_W \mathrm{RV}(t,5)\\ + \beta_M \mathrm{RV}(t,21) + \varepsilon(t+h)\,. \qquad (29)\end{aligned}$$

Here the lagged volatility components $\mathrm{RV}(t,1)$, $\mathrm{RV}(t,5)$, and $\mathrm{RV}(t,21)$ combine to provide a parsimonious approximation to the long-memory type behavior of the realized volatility series, which has been documented in several studies (e. g., Andersen et al. [19]). Simple OLS estimation yields consistent estimates for the coefficients in the regression (29), which can be used to forecast volatility out of sample.

As mentioned previously, the convergence results illustrated in Eqs. (27) and (28) stem from the theory of semi-martingales under conditions more general than those underlying the continuous-time diffusion in Eq. (22). For instance, these results are robust to the presence of discontinuities in the return path as in the jump-diffusion SV model (15). In this case the realized volatility measure (21) still converges to the return quadratic variation, which is now the sum of the diffusive integrated volatility IV and the cumulative squared jump component:

$$\mathrm{QV}(t,h) = \mathrm{IV}(t,h) + \sum_{t-h\le s\le t} J(s)^2\,. \qquad (30)$$

The decomposition in Eq. (30) motivates the quest for separate estimates of the two quadratic variation components, IV and squared jumps. This is a fruitful exercise in forecasting applications, since separate estimation of the two components increases predictive accuracy (e. g., [20]). Further, this decomposition is relevant for derivatives pricing, e. g., options are highly sensitive to jumps as well as large moves in volatility (e. g., [141,220]).

A consistent estimate of integrated volatility is the k-skip bipower variation, BV (e. g., Barndorff-Nielsen and Shephard [53]),

$$\begin{aligned}\mathrm{BV}(t,h;k,n) = \frac{\pi}{2}\sum_{i=k+1}^{n}\left| r\left(t-h+\frac{ih}{n},\frac{h}{n}\right)\right|\\ \times\left| r\left(t-h+\frac{(i-k)h}{n},\frac{h}{n}\right)\right|. \qquad (31)\end{aligned}$$

Liu and Maheu [202] and Forsberg and Ghysels [147] show that realized power variation, which is robust to the presence of jumps, can improve volatility forecasts. A well-known special case of (31) is the ‘realized bipower variation’, which has $k = 1$ and is denoted $\mathrm{BV}(t,h;n) \equiv \mathrm{BV}(t,h;1,n)$. We can combine bipower variation with the realized volatility RV to obtain a consistent estimate of the squared jump component, i. e.,

$$\begin{aligned}\mathrm{RV}(t,h;n) - \mathrm{BV}(t,h;n) \underset{n\to\infty}{\longrightarrow} \mathrm{QV}(t,h) - \mathrm{IV}(t,h)\\ = \sum_{t-h\le s\le t} J(s)^2\,. \qquad (32)\end{aligned}$$

The result in Eq. (32) are useful to design tests for the presence of jumps in volatility, e. g., Andersen et al. [20], Barndorff-Nielsen and Shephard [53,54], Huang and

Tauchen [172], and Mizrach [217]. More recently, alternative approaches to test for jumps have been developed by Aït-Sahalia and Jacod [6], Andersen et al. [23], Lee and Mykland [195], and Zhang [261].

Applications

The power of the continuous-time paradigm has been evident ever since the work by Merton [212] on intertemporal portfolio choice, Black and Scholes [63] on option pricing, and Vasicek [255] on bond valuation. However, the idea of casting these problems in a continuous-time diffusion context goes back all the way to the work in 1900 by Bachelier [32].

Merton [213] develops a continuous-time general-equilibrium intertemporal asset pricing model which is later extended by Cox et al. [112] to a production economy. Because of its flexibility and analytical tractability, the Cox et al. [112] framework has become a key tool used in several financial applications, including the valuation of options and other derivative securities, the modeling of the term structure of risk-free interest rates, the pricing of foreign currencies and defaultable bonds.

Volatility has played a central role in these applications. For instance, an option's payoff is non-linear in the price of the underlying asset and this feature renders the option value highly sensitive to the volatility of underlying returns. Further, derivatives markets have grown rapidly in size and complexity and financial institutions have been facing the challenge to manage intricate portfolios exposed to multiple risk sources. Risk management of these sophisticated positions hinges on volatility modeling. More recently, the markets have responded to the increasing hedging demands of investors by offering a menu of new products including, e. g., volatility swaps and derivatives on implied volatility indices like the VIX. These innovations have spurred an even more pressing need to accurately measure and forecast volatility in financial markets.

Research has responded to these market developments. We next provide a brief illustrative overview of the recent literature dealing with option pricing and term structure modeling, with an emphasis on the role that volatility modeling has played in these two key applications.

Options

Rubinstein [233] and Bates [55], among others, note that prior to the 1987 market crash the Black and Scholes [63] (BS) formula priced option contracts quite accurately whereas after the crash it has been systematically underpricing out-of-the-money equity-index put contracts. This feature is evident from Fig. 1, which is constructed from options on the S&P 500 futures. It shows the implied volatility function for near-maturity contracts traded both before and after October 19, 1987 ('Black Monday'). The mild u-shaped pattern prevailing in the pre-crash implied volatilities is labeled a 'volatility smile,' in contrast to the asymmetric post-1987 'volatility smirk'. Importantly, while the steepness and level of the implied volatility curve fluctuate day to day depending on market conditions, the curve has been asymmetric and upward sloping ever since 1987, so the smirk remains in place to the current date, e. g., Benzoni et al. [60]. In contrast, before the crash the implied volatility curve was invariably flat or mildly u-shaped as documented in, e. g., [57]. Finally, we note that the post-1987 asymmetric smirk for index options contrasts sharply with the pattern for individual equity options, which possess flat or mildly u-shaped implied volatility curves (e. g., [37,65]).

Given the failures of the BS formula, much research has gone into relaxing the underlying assumptions. A natural starting point is to allow volatility to evolve randomly, inspiring numerous studies that examine the option pricing implications of SV models. The list of early contributions includes [174,188,211,238,244,245,256]. Here we focus in particular on the Hull and White [174] model,

$$\mathrm{d}p(t) = \mu_p \mathrm{d}t + \sqrt{V(t)}\mathrm{d}W_p(t) \tag{33}$$

$$\frac{\mathrm{d}V(t)}{V(t)} = \mu_V \mathrm{d}t + \sigma_V \mathrm{d}W_V(t) \,, \tag{34}$$

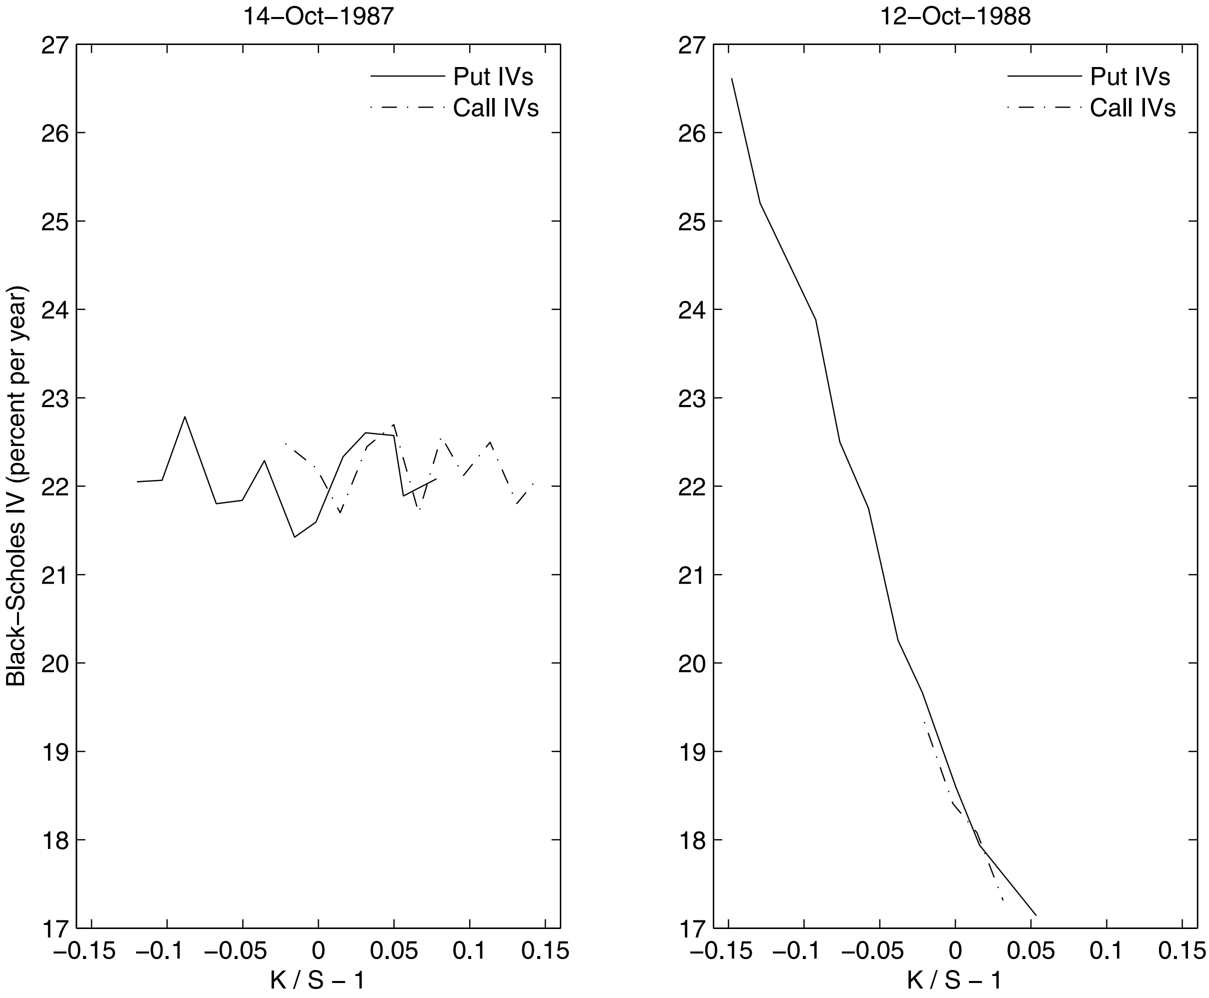
where W_p and W_V are standard Brownian motions. In general, shocks to returns and volatility may be (negatively) correlated, however for tractability Hull and White assume $\rho = \mathrm{corr}(\mathrm{d}W_p, \mathrm{d}W_V) = 0$. Under this assumption they show that, in a risk-neutral world, the premium C^{HW} on a European call option is the Black and Scholes price C^{BS} evaluated at the average integrated variance $\overline{V}$,

$$\overline{V} = \frac{1}{T-t}\int_t^T V(s)\mathrm{d}s \,, \tag{35}$$

integrated over the distribution $h(\overline{V}|V(t))$ of $\overline{V}$:

$$C^{\mathrm{HW}}(p(t), V(t)) = \int C^{\mathrm{BS}}(\overline{V})h(\overline{V}|V(t))\mathrm{d}\overline{V} \,. \tag{36}$$

The early efforts to identify a more realistic probabilistic model for the underlying return were slowed by the analytical and computational complexity of the option pricing problem. Unlike the BS setting, the early SV specifications do not admit closed-form solutions. Thus, the evaluation of the option price requires time-consuming computations through, e. g., simulation methods or nu-



Stochastic Volatility, Figure 1

Pre- and post-1987 crash implied volatilities. The plots depict Black-Scholes implied volatilities computed from near-maturity options on the S&P 500 futures on October 14, 1987 (the week before the 1987 market crash) and a year later

merical solution of the pricing partial differential equation by finite difference methods. Further, the presence of a latent factor, volatility, and the lack of closed-form expressions for the likelihood function complicate the estimation problem.

Consequently, much effort has gone into developing restrictions for the distribution of the underlying return process that allow for (semi) closed-form solutions and are consistent with the empirical properties of the data. The 'affine' class of continuous-time models has proven particularly useful in providing a flexible, yet analytically tractable, setting. Roughly speaking, the defining feature of affine jump-diffusions is that the drift term, the conditional covariance term, and the jump intensity are all a linear-plus-constant (affine) function of the state vector. The Vasicek [255] bond valuation model and the Cox et al. [112] intertemporal asset pricing model provide powerful examples of the advantages of the affine paradigm.

To illustrate the progress in option pricing applications built on affine models, consider the return dynamics

$$\mathrm{d}p(t) = \mu \mathrm{d}t + \sqrt{V(t)}\mathrm{d}W_p(t) + \xi_p(t)\mathrm{d}q(t) \qquad (37)$$

$$\mathrm{d}V(t) = \kappa(\overline{V} - V(t))\mathrm{d}t + \sigma_V \sqrt{V(t)}\mathrm{d}W_V(t) + \xi_V(t)\mathrm{d}q(t)\,, \qquad (38)$$

where W_p and W_V are standard Brownian motions with non-zero correlation $\rho = \mathrm{corr}(\mathrm{d}W_p, \mathrm{d}W_V)$, q is a Poisson process, uncorrelated with W_p and W_V, with jump intensity

$$\lambda(t) = \lambda_0 + \lambda_1 V(t)\,, \tag{39}$$

that is, $\mathrm{Prob}(\mathrm{d}q_t = 1) = \lambda(t)\mathrm{d}t$. The jump amplitudes variables ξ_p and ξ_V have distributions

$$\xi_V(t) \rightsquigarrow \exp(\overline{\xi}_V) \tag{40}$$

$$\xi_p(t)|\xi_V(t) \rightsquigarrow N\left(\overline{\xi}_p + \rho_\xi \xi_V(t), \sigma_p^2\right)\,. \tag{41}$$

Here volatility is not only stochastic but also subject to jumps which occur simultaneously with jumps in the underlying return process. The Black and Scholes model is a special case of (37)–(41) for constant volatility, $V(t) = \sigma^2, 0 \leq t \leq T$, and no jumps, $\lambda(t) = 0, 0 \leq t \leq T$. The Merton [214] model arises from (37)–(41) if volatility is constant but we allow for jumps in returns.

More recently, Heston [170] has considered a special case of (37)–(41) with stochastic volatility but without jumps. Using transform methods he derives a European option pricing formula which may be evaluated readily through simple numerical integration. His SV model has GARCH-type features, in that the variance is persistent and mean reverts at a rate κ to the long-run mean $\overline{V}$. Compared to Hull and White's [174] setting, Heston's model allows for shocks to returns and volatility to be negatively correlated, i. e., $\rho < 0$, which creates a leverage-type effect and skews the return distribution. This feature is consistent with the properties of equity index returns. Further, a fatter left tail in the return distribution results in a higher cost for crash insurance and therefore makes out-of-the-money put options more expensive. This is qualitatively consistent with the patterns in implied volatilities observed after the 1987 market crash and discussed above.

Bates [56] has subsequently extended Heston's approach to allow for jumps in returns and using similar transform methods he has obtained a semi-closed form solution for the option price. The addition of jumps provides a more realistic description of equity returns and has important option pricing implications. With diffusive shocks (e. g., stochastic volatility) alone a large drop in the value of the underlying asset over a short time span is very unlikely whereas a market crash is always possible as long as large negative jumps can occur. This feature increases the value of a short-dated put option, which offers downside protection to a long position in the underlying asset.

Finally, Duffie et al. [130] have introduced a general model with jumps to volatility which embeds the dynamics (37)–(41). In model (37)–(41), the likelihood of a jump to occur increases when volatility is high ($\lambda_1 > 0$) and a jump in returns is accompanied by an outburst of volatility. This is consistent with what is typically observed during times of market stress. As in the Heston case, variance is persistent with a mean reversion coefficient κ towards its *diffusive* long-run mean $\overline{V}$, while the total long-run variance mean is the sum of the diffusive and jump components. In the special case of constant jump intensity, i. e., $\lambda_1 = 0$, the total long-run mean is $\overline{V} + \overline{\xi}_V \lambda_0/\kappa$. The jump term $(\xi_V(t)\mathrm{d}q(t))$ fattens the right tail of the variance distribution, which induces leptokurtosis in the return distribution. Two effects generate asymmetrically distributed returns. The first channel is the diffusive leverage effect, i. e., $\rho < 0$, the second is the correlation between the volatility and the jump amplitude of returns generated through the coefficient ρ_ξ. Taken together, these effects increase model-implied option prices and help produce a realistic volatility smirk.

Several empirical studies rely on models of the form (37)–(41) in option-pricing applications. For instance, Bates [56] uses Deutsche Mark options to estimate a model with stochastic volatility and constant-intensity jumps to returns, while Bates [57] fits a jump-diffusion model with two SV factors to options on S&P 500 futures. In the latter case, the two SV factors combine to help capture features of the long-run memory in volatility while retaining the analytical tractability of the affine setting (see, e. g., [101] for another model with similar features). Alternative approaches to model long memory in continuous-time SV models rely on the fractional Brownian motion process, e. g., Comte and Renault [108] and Comte et al. [107], while Breidt et al. [76], Harvey [166] and Deo et al. [118] consider discrete-time SV models (see [175] for a review). Bakshi et al. [34,37] estimate a model similar to the one introduced by Bates [56] using S&P 500 options.

Other scholars rely on underlying asset return data alone for estimation. For instance, Andersen et al. [15] and Chernov et al. [95] use equity-index returns to estimate jump-diffusion SV models within and outside the affine (37)–(41) class. Eraker et al. [142] extend this analysis and fit a model that includes constant-intensity jumps to returns and volatility.

Finally, another stream of work examines the empirical implications of SV jump-diffusions using a joint sample of S&P 500 options and index returns. For example, Benzoni [59], Chernov and Ghysels [93], and Jones [190] estimate different flavors of the SV model without jumps. Pan [220] fits a model that has jumps in returns with time-varying intensity, while Eraker [141] extends Pan's work by adding jumps in volatility.

Overall, this literature has established that the SV jump-diffusion model dramatically improves the fit of underlying index returns and options prices compared to the

Black and Scholes model. Stochastic volatility alone has a first-order effect and jumps further enhance model performance by generating fatter tails in the return distribution and reducing the pricing error for short-dated options. The benefits of the SV setting are also significant in hedging applications.

Another aspect related to the specification of SV models concerns the pricing of volatility and jump risks. Stochastic volatility and jumps are sources of uncertainty. It is an empirical issue to determine whether investors demand to be compensated for bearing such risks and, if so, what the magnitude of the risk premium is. To examine this issue it is useful to write model (37)–(41) in so-called risk-neutral form. It is common to assume that the volatility risk premium is proportional to the instantaneous variance, $\eta(t) = \eta_V V(t)$. Further, the adjustment for jump risk is accomplished by assuming that the amplitude $\tilde{\xi}_p(t)$ of jumps to returns has mean $\bar{\tilde{\xi}}_p = \bar{\xi}_p + \eta_p$. These specifications are consistent with an arbitrage-free economy. More general specifications can also be supported in a general equilibrium setting, e. g., a risk adjustment may apply to the jump intensity $\lambda(t)$. However, the coefficients associated to these risk adjustments are difficult to estimate and to facilitate identification they typically are fixed at zero. Incorporating such risk premia in model (37)–(41) yields the following risk-neutral return dynamics (e. g., Pan [220] and Eraker [141]):

$$\mathrm{d}p(t) = (r - \mu^*)\mathrm{d}t + \sqrt{V(t)}\mathrm{d}\widetilde{W}_p(t) + \tilde{\xi}_p(t)\mathrm{d}q(t) \quad (42)$$

$$\begin{aligned}\mathrm{d}V(t) = {}& [\kappa(\overline{V} - V(t)) + \eta_V V(t)]\mathrm{d}t \\ & + \sigma_V \sqrt{V(t)}\mathrm{d}\widetilde{W}_V(t) + \xi_V(t)\mathrm{d}q(t)\,, \end{aligned} \quad (43)$$

where r is the risk-free rate, μ^* a jump compensator term, $\widetilde{W}_p$ and $\widetilde{W}_V$ are standard Brownian motions under this so-called $\mathcal{Q}$ measure, and the risk-adjusted jump amplitude variable $\tilde{\xi}_p$ is assumed to follow the distribution,

$$\tilde{\xi}_p(t)|\xi_V(t) \rightsquigarrow N\left(\bar{\tilde{\xi}}_p + \rho_\xi \xi_V(t), \sigma_p^2\right) . \quad (44)$$

Several studies estimate the risk-adjustment coefficients η_V and η_p for different specifications of model (37)–(44); see, e. g., Benzoni [59], Broadie et al. [78], Chernov and Ghysels [93], Eraker [141], Jones [190], and Pan [220]. It is found that investors demand compensation for volatility and jump risks and these risk premia are important for the pricing of index options. This evidence is reinforced by other studies examining the pricing of volatility risk using less structured but equally compelling procedures. For instance, Coval and Shumway [111] find that the returns on zero-beta index option straddles (i. e., combinations of calls and puts that have offsetting covariances with the index) are significantly lower than the risk-free return. This evidence suggests that in addition to market risk at least a second factor (likely, volatility) is priced in the index option market. Similar conclusions are obtained by Bakshi and Kapadia [36], Buraschi and Jackwerth [79], and Broadie et al. [78].

Risk-Free Bonds and Their Derivatives

The market for (essentially) risk-free Treasury bonds is liquid across a wide maturity spectrum. No-arbitrage restrictions constrain the allowable dynamics in the cross-section of bond yields. Much work has gone into the development of tractable dynamic term structure models capable of capturing the salient time-series properties of interest rates while respecting such cross-sectional no-arbitrage conditions. The class of so-called 'affine' dynamic term structure models provides a flexible and arbitrage-free, yet analytically tractable, setting for capturing the dynamics of the term structure of interest rates. Following Duffie and Kan [129], Dai and Singleton [114,115], and Piazzesi [226], the short term interest rate, $y_0(t)$, is an affine (i. e., linear-plus-constant) function of a vector of state variables, $X(t) = \{x_i(t),\ i = 1, \ldots, N\}$:

$$y_0(t) = \delta_0 + \sum_{i=1}^{N} \delta_i x_i(t) = \delta_0 + \delta_X' X(t)\,, \quad (45)$$

where the state-vector X has risk-neutral dynamics

$$\mathrm{d}X(t) = \tilde{\mathcal{K}}(\tilde{\Theta} - X(t))\mathrm{d}t + \Sigma\sqrt{S(t)}\mathrm{d}\widetilde{W}(t)\,. \quad (46)$$

In Eq. (46), $\widetilde{W}$ is an N-dimensional Brownian motion under the so-called $\mathcal{Q}$-measure, $\tilde{\mathcal{K}}$ and $\tilde{\Theta}$ are $N \times N$ matrices, and $S(t)$ is a diagonal matrix with the ith diagonal element given by $[S(t)]_{ii} = \alpha_i + \beta_i' X(t)$. Within this setting, the time-t price of a zero-coupon bond with time-to-maturity τ is given by

$$P(t, \tau) = \mathrm{e}^{A(\tau) - B(\tau)' X(t)}\,, \quad (47)$$

where the functions $A(\tau)$ and $B(\tau)$ solve a system of ordinary differential equations (ODEs); see, e. g., Duffie and Kan [129]. Semi-closed form solutions are also available for bond derivatives, e. g., bond options as well as caps and floors (e. g., Duffie et al. [130]).

In empirical applications it is important to also establish the evolution of the state vector X under the physical probability measure $\mathcal{P}$, which is linked to the $\mathcal{Q}$-dynamics (46) through a market price of risk, $\Lambda(t)$. Following Dai and Singleton [114] the market price of risk is often given by

$$\Lambda(t) = \sqrt{S(t)}\lambda\,, \tag{48}$$

where λ is an $N \times 1$ vector of constants. More recently, Duffee [127] proposed a broader 'essentially affine' class, which retains the tractability of standard models but, in contrast to the specification in Eq. (48), allows compensation for interest rate risk to vary independently of interest rate volatility. This additional flexibility proves useful in forecasting future yields. Subsequent generalization are in Duarte [124] and Cheridito et al. [92].

Litterman and Scheinkman [201] demonstrate that virtually all variation in US Treasury rates is captured by three factors, interpreted as changes in 'level', 'steepness', and 'curvature'. Consistent with this evidence, much of the term-structure literature has focused on three-factor models. One problem with these models, however, is that the factors are latent variables void of immediate economic interpretation. As such, it is challenging to impose appropriate identifying conditions for the model coefficients and in particular to find the ideal representation for the 'most flexible' model, i. e., the model with the highest number of identifiable coefficients. Dai and Singleton [114] conduct an extensive specification analysis of multi-factor affine term structure models. They classify these models into subfamilies according to the number of (independent linear combination of) state variables that determine the conditional variance matrix of the state vector. Within each subfamily, they proceed to identify the models that lead to well-defined bond prices (a condition they label 'admissibility') and among the admissible specifications they identify a 'maximal' model that nests econometrically all others in the subfamily. Joslin [191] builds on Dai and Singleton's [114] work by pursuing identification through a normalization of the drift term in the state vector dynamics (instead of the diffusion term, as in Dai and Singleton [114]). Duffie and Kan [129] follow an alternative approach to obtain an identifiable model by rotating from a set of latent state variables to a set of observable zero-coupon yields. Collin-Dufresne et al. [104] build on the insights of both Dai and Singleton [114] and Duffie and Kan [129]. They perform a rotation of the state vector into a vector that contains the first few components in the Taylor series expansion of the yield curve around a maturity of zero and their quadratic variation. One advantage is that the elements of the rotated state vector have an intuitive and unique economic interpretation (such as level, slope, and curvature of the yield curve) and therefore the model coefficients in this representation are identifiable. Further, it is easy to construct a model-independent proxy for the rotated state vector, which facilitates model estimation as well as interpretation of the estimated coefficients across models and sample periods.

This discussion underscores an important feature of affine term structure models. The dependence of the conditional factor variance $S(t)$ on one or more of the elements in X introduces stochastic volatility in the yields. However, when a square-root factor is present parametric restrictions (admissibility conditions) need to be imposed so that the conditional variance $S(t)$ is positive over the range of X. These restrictions affect the correlations among the factors which, in turn, tend to worsen the cross-sectional fit of the model. Specifically, CIR models in which $S(t)$ depends on all the elements of X require the conditional correlation among the factors to be zero, while the admissibility conditions imposed on the matrix $\mathcal{K}$ renders the unconditional correlations non-negative. These restrictions are not supported by the data. In contrast, constant-volatility Gaussian models with no square-root factors do not restrict the signs and magnitude of the conditional and unconditional correlations among the factors but they do, of course, not accommodate the pronounced and persistent volatility fluctuations observed in bond yields. The class of models introduced by Dai and Singleton [114] falls between these two extremes. By including both Gaussian and square-root factors they allow for time-varying conditional volatilities of the state variables and yet they do not constrain the signs of some of their correlations. This flexibility helps to address the trade off between generating realistic correlations among the factors while capturing the time-series properties of the yields' volatility.

A related aspect of (unconstrained) affine models concerns the dual role that square-root factors play in driving the time-series properties of yields' volatility and the term structure of yields. Specifically, the time-t yield $y_\tau(t)$ on a zero-coupon bond with time-to-maturity τ is given by

$$P(t,\tau) = \mathrm{e}^{-\tau y_\tau(t)}\,. \tag{49}$$

Thus, we have

$$y_\tau(t) = -\frac{A(\tau)}{\tau} + \frac{B(\tau)'}{\tau}X(t)\,. \tag{50}$$

It is typically assumed that the B matrix has full rank and therefore Eq. (50) provides a direct link between the state-vector $X(t)$ and the term-structure of bond yields. Further, Itô's Lemma implies that the yield y_τ also follows a diffusion process:

$$\mathrm{d}y_\tau(t) = \mu_{y_\tau}(X(t),t)\mathrm{d}t + \frac{B(\tau)'}{\tau}\Sigma\sqrt{S(t)}\mathrm{d}\widetilde{W}(t)\,. \tag{51}$$

Consequently, the (instantaneous) quadratic variation of the yield given as the squared yield volatility coefficient for y_τ is

$$V_{y_\tau}(t) = \frac{B(\tau)'}{\tau} \Sigma S(t) \Sigma' \frac{B(\tau)}{\tau} . \tag{52}$$

The elements of the $S(t)$ matrix are affine in the state vector $X(t)$, i. e., $[S(t)]_{ii} = \alpha_i + \beta_i' X(t)$. Further, invoking the full rank condition on $B(\tau)$, Eq. (50) implies that each state variable in the vector $X(t)$ is an affine function of the bond yields $Y(t) = \{y_{\tau_j}(t), \; j = 1, \ldots, J\}$. Thus, for any τ there is a set of constants $a_{\tau,j}, \; j = 0, \ldots, J$, so that

$$V_{y_\tau}(t) = a_{\tau,0} + \sum_{j=1}^{J} a_{\tau,j} y_{\tau_j}(t) . \tag{53}$$

Hence, the current quadratic yield variation for bonds at any maturity is a linear combination of the term structure of yields. As such, the market is complete, i. e., volatility is perfectly spanned by a portfolio of bonds.

Collin-Dufresne and Goldstein [103] note that this spanning condition is unnecessarily restrictive and propose conditions which ensures that volatility no longer directly enters the main bond pricing Eq. (47). This restriction, which they term 'unspanned stochastic volatility' (USV), effectively breaks the link between the yields' quadratic variation and the level of the term structure by imposing a reduced rank condition on the $B(\tau)$ matrix. Further, since their model is a special (nested) case of the affine class it retains the analytical tractability of the affine model class. Recently Joslin [191] has derived more general conditions for affine term structure models to exhibit USV. His restrictions also produce a market incompleteness (i. e., volatility cannot be hedged using a portfolio of bonds) but do not constrain the degree of mean reversion of the other state variables so that his specification allows for more flexibility in capturing the persistence in interest rate series. (See also the USV conditions in the work by Trolle and Schwartz [253]).

There is conflicting evidence on the volatility spanning condition in fixed income markets. Collin-Dufresne and Goldstein [103] find that swap rates have limited explanatory power for returns on at-the-money 'straddles', i. e., portfolios mainly exposed to volatility risk. Similar findings are in Heidari and Wu [169], who show that the common factors in LIBOR and swap rates explain only a limited part of the variation in the swaption implied volatilities. Moreover, Li and Zhao [197] conclude that some of the most sophisticated multi-factor dynamic term structure models have serious difficulties in hedging caps and cap straddles, even though they capture bond yields well. In contrast, Fan et al. [143] argue that swaptions and even swaption straddles can be well hedged with LIBOR bonds alone, supporting the notion that bond markets are complete.

More recently other studies have examined several versions of the USV restriction, again coming to different conclusions. A direct comparison of these results, however, is complicated by differences in the model specification, the estimation method, and the data and sample period used in the estimation. Collin-Dufresne et al. [105] consider swap rates data and fit the model using a Bayesian Markov Chain Monte Carlo method. They find that a standard three-factor model generates a time series for the variance state variable that is essentially unrelated to GARCH estimates of the quadratic variation of the spot rate process or to implied variances from options, while a four-factor USV model generates both realistic volatility estimates and a good cross-sectional fit. In contrast, Jacobs and Karoui [178] consider a longer data set of US Treasury yields and pursue quasi-maximum likelihood estimation. They find the correlation between model-implied and GARCH volatility estimates to be high. However, when estimating the model with a shorter sample of swap rates, they find such correlations to be small or negative. Thompson [250] explicitly tests the Collin-Dufresne and Goldstein [103] USV restriction and rejects it using swap rates data. Bikbov and Chernov [62], Han [164], Jarrow et al. [183], Joslin [192], and Trolle and Schwartz [254] rely on data sets of derivatives prices and underlying interest rates to better identify the volatility dynamics.

Andersen and Benzoni [12] directly relate model-free realized volatility measures (constructed from high-frequency US Treasury data) to the cross-section of contemporaneous bond yields. They find that the explanatory power of such regressions is very limited, which indicates that volatility is not spanned by a portfolio of bonds. The evidence in Andersen and Benzoni [12] is consistent with the USV models of Collin-Dufresne et al. [105] and Joslin [191], as well as with a model that embeds weak dependence between the yields and volatility as in Joslin [192]. Moreover, Duarte [125] argues that the effects of mortgage-backed security hedging activity affects both the interest rate volatility implied by options and the actual interest rate volatility. This evidence suggests that variables that are not in the span of the term structure of yields and forward rates contribute to explain volatility in fixed income markets. Also related, Wright and Zhou [258] find that adding a measure of market jump volatility risk to a regression of excess bond returns on the term structure of forward rates nearly doubles the R^2 of the regression.

Taken together, these findings suggest more generally that genuine SV models are critical for appropriately capturing the dynamic evolution of the term structure.

Estimation Methods

There are a very large number of alternative approaches to estimation and inference for parametric SV models and we abstain from a thorough review. Instead, we point to the basic challenges that exist for different types of specifications, how some of these were addressed in the early literature and finally provide examples of methods that have been used extensively in recent years. Our exposition continues to focus on applications to equity returns, interest rates, and associated derivatives.

Many of the original SV models were cast in discrete time, inspired by the popular GARCH paradigm. In that case, the distinct challenge for SV models is the presence of a strongly persistent latent state variable. However, more theoretically oriented models, focusing on derivatives applications, were often formulated in continuous time. Hence, it is natural that the econometrically-oriented literature has moved in this direction in recent years as well. This development provides an added complication as the continuous-time parameters must be estimated from discrete return data and without direct observations on volatility. For illustration, consider a fully parametric continuous-time SV model for the asset return r with conditional variance V and coefficient vector Ψ. Most methods to estimate Ψ rely on the conditional density f for the data generating process,

$$f(r(t), V(t)|\mathcal{I}(t-1), \Psi) = f_{r|V}(r(t)|V(t), \mathcal{I}(t-1), \Psi) \times f_V(V(t)|\mathcal{I}(t-1), \Psi) , \quad (54)$$

where $\mathcal{I}(t-1)$ is the available information set at time $t-1$. The main complications are readily identified. First, analytic expressions for the discrete-time transition (conditional) density, f, or the discrete-time moments implied by the data generating process operating in continuous time, are often unavailable. Second, volatility is latent in SV models, so that even if a closed-form expression for f is known, direct evaluation of the above expression is infeasible due to the absence of explicit volatility measures. The marginal likelihood with respect to the observable return process alone is obtained by integrating over all possible paths for the volatility process, but this integral has a dimension corresponding to sample size, rendering the approach infeasible in general.

Similar issues are present when estimating continuous-time dynamic term structure models. Following Piazzesi [227], a change of variable gives the conditional density for a zero-coupon yield y on a bond with time to maturity τ:

$$f(y_\tau(t)|\mathcal{I}(t-1), \Psi) = f_X(g(y_\tau(t), \Psi)|\mathcal{I}(t-1), \Psi) \times |\nabla_y g(y_\tau(t), \Psi)| . \quad (55)$$

Here the latent state vector X has conditional density f_X, the function $g(\cdot, \Psi)$ maps the observable yield y into X, $X(t) = g(y_\tau(t), \Psi)$, and $\nabla_y g(y_\tau(t), \Psi)$ is the Jacobian determinant of the transformation. Unfortunately, analytic expressions for the conditional density f_X are known only in some special cases. Further, the mapping $X(t) = g(y_\tau(t), \Psi)$ holds only if the model provides an exact fit to the yields, while in practice different sources of error (e. g., model mis-specification, microstructure effects, measurement errors) inject a considerable degree of noise into this otherwise deterministic linkage (for correct model specification) between the state vector and the yields. As such, a good measure of X might not be available to evaluate the conditional density (55).

Estimation via Discrete-Time Model Specification or Approximation

The first empirical studies have estimated discrete-time SV models via a (Generalized) Method of Moments procedure by matching a number of theoretical and sample moments, e. g., Chan et al. [89], Ho et al. [171], Longstaff and Schwartz [204], and Melino and Turnbull [211]. These models were either explicitly cast in discrete time or were seen as approximate versions of the continuous-time process of interest. Similarly, several authors estimate diffusive affine dynamic term structure models by approximating the continuous-time dynamics with a discrete-time process. If the error terms are stipulated to be normally distributed, the transition density of the discretized process is multivariate normal and computation of unconditional moments then only requires knowledge of the first two moments of the state vector. This result facilitates quasi-maximum likelihood estimation. In evaluating the likelihood function, some studies suggest using closed-form expressions for the first two moments of the continuous-time process instead of the moments of the discretized process (e. g., Fisher and Gilles [145] and Duffee [127]), thus avoiding the associated discretization bias. This approach typically requires some knowledge of the state of the system which may be obtained, imperfectly, through matching the system, given the estimated parameter vector, to a set of observed zero-coupon yields to infer the state vector X. A modern alternative is to use the so-called particle filter as an efficient filtering procedure for the unobserved state variables given the estimated parameter vector. We provide more detailed accounts of both of these procedures later in this section.

Finally, a number of authors develop a simulated maximum likelihood method that exploit the specific structure of the discrete-time SV model. Early examples are Danielsson and Richard [117] and Danielsson [116] who exploit the Accelerated Gaussian Importance Sampler for efficient Monte Carlo evaluation of the likelihood. Subsequent improvements were provided by Fridman and Harris [149] and Liesenfeld and Richard [200], with the latter relying on Efficient Importance Sampling (EIS). In a second step, EIS can also be used for filtering the latent volatility state vector. In general, these inference techniques provide quite impressive efficiency but the methodology is not always easy to generalize beyond the structure of the basic discrete-time SV asset return model. We discuss the general inference problem for continuous-time SV models for which the lack of a closed-form expression for the transition density is an additional complicating factor in a later section.

Filtering the Latent State Variable Directly During Estimation

Some early studies focused on direct ways to extract estimates of the latent volatility state variable in discrete-time SV asset return models. The initial approach was based on quasi-maximum likelihood (QML) methods exploiting the Kalman filter. This method requires a transformation of the SV model to a linear state-space form. For instance, Harvey and Shephard [168] consider a version of the Taylor's [249] discrete-time SV model,

$$p(t) = p(t-1) + \beta + \sqrt{V(t)}\varepsilon(t) \tag{56}$$

$$\log(V(t)) = \alpha + \phi \log(V(t-1)) + \eta(t)\,, \tag{57}$$

where p is the logarithmic price, ε is a zero-mean error term with unit variance, and η is an independently-distributed error term with zero mean and variance σ_η^2.

Define $y(t) = p(t) - p(t-1) - \beta$, square the observations in Eq. (56), and take logarithms to obtain the *measurement equation*,

$$\ell(t) = \omega + h(t) + \xi(t)\,, \tag{58}$$

where $\ell(t) \equiv \log y(t)^2$, $h(t) \equiv \log(V(t))$. Further, ξ is a zero-mean disturbance term given by $\xi(t) = \log(\varepsilon(t)^2) - \mathrm{E}[\log(\varepsilon(t)^2)]$, $\omega = \log(\sigma^2) + \mathrm{E}[\log(\varepsilon(t)^2)]$, and σ is a scale constant which subsumes the effect of the drift term α in Eq. (57). The autoregression (57) yields the *transition equation*,

$$h(t) = \phi h(t-1) + \eta(t)\,, \tag{59}$$

Taken together, Eqs. (58) and (59) are the linear state-space transformation of the SV model (56)–(57). If the joint distribution of ε and η is symmetric, i. e., $f(\varepsilon, \eta) = f(-\varepsilon, -\eta)$, then the disturbance terms in the state-space form are uncorrelated even if η and ε are not. A possible dependence between ε and η allows the model to pick up some of the asymmetric behavior often observed in stock returns. Projection of $[h(t) - \mathrm{E}_{t-1} h(t)]$ over $[\,\ell(t) - \mathrm{E}_{t-1}\,\ell(t)\,]$ yields the Kalman filter estimate of the latent (logarithmic) variance process:

$$\begin{aligned} \mathrm{E}_t\, h(t) = \mathrm{E}_{t-1}\, h(t) & \\ &+ \frac{\mathrm{E}\{[h(t) - \mathrm{E}_{t-1}\, h(t)] \times [\ell(t) - \mathrm{E}_{t-1}\,\ell(t)]\}}{\mathrm{E}\{[\ell(t) - \mathrm{E}_{t-1}\,\ell(t)]^2\}} \\ &\times [\ell(t) - \mathrm{E}_{t-1}\,\ell(t)]\,, \end{aligned} \tag{60}$$

where the conditional expectations $\mathrm{E}_{t-1}\,\ell(t)$ and $\mathrm{E}_{t-1}\, h(t)$ are given by:

$$\mathrm{E}_{t-1}\,\ell(t) = \omega + \mathrm{E}_{t-1}\, h(t) \tag{61}$$

$$\mathrm{E}_{t-1}\, h(t) = \phi\, \mathrm{E}_{t-1}\, h(t-1)\,. \tag{62}$$

To start the recursion (60)–(62), the initial value $\mathrm{E}_0\, h(0)$ is fixed at the long-run mean $\log(\overline{V})$.

Harvey and Shephard [168] estimate the model coefficients via quasi-maximum likelihood, i. e. by treating the errors ξ and η as though they were normal and maximizing the prediction-error decomposition form of the likelihood function obtained via the Kalman filter. Inference is valid as long as the standard errors are appropriately adjusted. In their application they rely on daily returns on the value-weighted US market index over 1967–1987 and daily returns for 30 individual stocks over 1974–1983. Harvey et al. [167] pursue a similar approach to fit a multivariate SV model to a sample of four exchange rate series from 1981 to 1985. One major drawback of the Kalman filter approach is that the finite sample properties can be quite poor because the error term, ξ, is highly non-Gaussian, see, e. g., Andersen, Chung, and Sørensen [27]. The method may be extended to accommodate various generalizations including long memory persistence in volatility as detailed in Ghysels, Harvey, and Renault [158].

A related literature, often exploited in multivariate settings, specifies latent GARCH-style dynamics for a state vector which governs the systematic evolution of a higher dimensional set of asset returns. An early representative of these specifications is in Diebold and Nerlove [120], who exploit the Kalman filter for estimation, while Fiorentina et al. [144] provide a likelihood-based estimation procedure using MCMC techniques. We later review the MCMC approach and the associated filtering application, e. g, the 'particle filter', in some detail.

The state-space form is also useful to characterize the dynamics of interest rates. Following, e. g., Piazzesi [226], for a discrete-time dynamic term structure model the measurement and transition equations are

$$y_\tau(t) = -\frac{A(\tau)}{\tau} + \frac{B(\tau)'}{\tau} X(t) + \xi_\tau(t) \tag{63}$$

$$X(t) = \mu + \Phi X(t-1) + \Sigma \sqrt{S(t)}\, \varepsilon(t)\,, \tag{64}$$

where $S(t)$ is a matrix whose elements are affine functions of the state vector X, and A and B solve a system of difference equations. When all the yields are observed with error (i. e., $\xi_\tau \neq 0 \forall \tau,\ 0 \leq \tau \leq T$), QML estimation of the system (63)–(64) via the extended Kalman filter method yields an estimate of the coefficient vector. Applications of this approach for the US term structure data include Campbell and Viceira [81], Gong and Remolona [161], and Pennacchi [225]. The extended Kalman filter involves a linear approximation of the relation between the observed data and the state variables, and the associated approximation error will produce biased estimates. Christoffersen et al. [99] raise this concern and recommend the use of the so-called unscented Kalman filter for estimation of systems in which the relation between data and state variables is highly non-linear, e. g., options data.

Methods Accommodating the Lack of a Closed-Form Transition Density

We have so far mostly discussed estimation techniques for models with either a known transition density or one that is approximated by a discrete-time system. However, the majority of empirically-relevant continuous-time models do not possess explicit transition densities and alternative approaches are necessary. This problem leads us naturally towards the large statistics and econometric literature on estimation of diffusions from discretely-observed data. The vast majority of these studies assume that all relevant variables are observed so the latent volatility or yield curve state variables, integral to SV models, are not accounted for. Nonetheless, it may be feasible to extract the requisite estimates of the state variable by alternate means, thus restoring the feasibility, albeit not efficiency, of the basic approach. Since the literature is large and not directly geared towards genuine SV models, we focus on methods that have seen use in applications involving latent state variables.

A popular approach is to invert the map between the state vector and a subset of the observables assuming that the model prices specific securities exactly. In applications to equity markets this is done, e. g., by assuming that one option contract is priced without error, which implies a specific value (estimate) of the variance process given the model parameters Ψ. For instance, Pan [220] follows this approach in her study of S&P 500 options and returns, which we review in more detail in Sect. "Estimation from Option Data". In applications to fixed income markets it is likewise stipulated that certain bonds are priced without error, i. e., in Eq. (63) the error term $\xi_{\tau_i}(t)$ is fixed at zero for a set of maturities $\tau_1, \ldots, \tau_N$, where N matches the dimension of the state vector X. This approach yields an estimate for the latent variables through the inverse-map $X(t) = g(y_\tau(t), \Psi)$.

One criticism of the state vector inversion procedure is that it requires ad hoc assumptions regarding the choice of the securities that are error-free (those used to compute model-implied measures of the state vector) vis-a-vis those observed with error (used either for estimation or to assess model performance in an 'out-of-sample' cross-sectional check). In fact, the extracted state vector can be quite sensitive to the choice of derivatives (or yields) used. Nevertheless, this approach has intuitive appeal. Model-implied measures of the state vector, in combination with a closed-form expression for the conditional density (55), allow for efficient estimation of the coefficient vector Ψ via maximum likelihood. Analytic expressions for f_X in Eq. (55) exist in a limited number of cases. For instance, if X is Gaussian then f_X is multivariate normal, while if X follows a square-root process then f_X can be expressed in terms of the modified Bessel function (e. g., [113]). Different flavors of these continuous-time models are estimated in, e. g., [91,106,132,182,223]. In more general cases, including affine processes that combine Gaussian and square-root state variables, closed-form expressions for f_X are no longer available. In the rest of this section we briefly review different methods to overcome this problem. The interested reader may consult, e. g., [226] for more details.

Lo [203] warns that the common approach of estimating parameters of an Itô process by applying maximum likelihood to a discretization of the stochastic differential equation yields inconsistent estimators. In contrast, he characterizes the likelihood function as a solution to a partial differential equation. The method is very general, e. g., it applies not only to continuous-time diffusions but also to jump processes. In practice, however, analytic solutions to the partial differential equations (via, e. g., Fourier transforms) are available only for a small class of models so computationally-intensive methods (e. g., finite differencing or simulations) are generally required to solve the problem. This is a severe limitation in the case of multivariate systems like SV models.

For general Markov processes, where the above solution is infeasible, a variety of procedures have been advocated in recent years. Three excellent surveys provide different perspectives on the issue. Aït-Sahalia, Hansen, and Scheinkman [5] discuss operator methods and mention the potential of applying a time deformation technique to account for genuine SV features of the process, as in Conley, Hansen, Luttmer, and Scheinkman [109]. In addition, the Aït-Sahalia [3,4] closed-form polynomial expansions for discretely-sampled diffusions are reviewed along with the Schaumburg [235] extension to a general class of Markov processes with Lévy-type generators. Meanwhile, Bibby, Jacobsen, and Sørensen [61] survey the extensive statistics literature on estimating functions for diffusion-type models and Bandi and Phillips [42] explicitly consider dealing with nonstationary processes (see also the work of Bandi [39], Bandi and Nguyen [41], and Bandi and Phillips [43,44]).

The characteristic function based inference technique has been particularly widely adopted due to the natural fit with the exponentially affine model class which provides essentially closed-form solutions for many pricing applications. Consequently, we dedicate a separate section to this approach.

Characteristic Functions Singleton [242] proposes to exploit the information contained in the conditional characteristic function of the state vector X,

$$\phi(iu, X(t), \Psi) = \mathrm{E}\left[\mathrm{e}^{iu' X(t+1)} \middle| X(t)\right] , \qquad (65)$$

to pursue maximum likelihood estimation of affine term structure models. In Equation (65) we highlight the dependence of the characteristic function on the unknown parameter vector Ψ. When X is an affine (jump-)diffusion process, ϕ has the exponential affine form,

$$\phi(iu, X(t), \Psi) = \mathrm{e}^{\alpha_t(u) + \beta_t(u)' X(t)} , \qquad (66)$$

where the functions α and β solve a system of ODEs. As such, the transition density f_X is known explicitly up to an inverse-Fourier transformation of the characteristic function (65),

$$f_X(X(t+1) \big| X(t); \Psi) = \frac{1}{\pi^N} \int_{\mathbb{R}^N_+} \mathrm{Re}\left[\mathrm{e}^{-iu' X(t+1)} \phi(iu, X(t), \Psi)\right] \mathrm{d}u \, . \qquad (67)$$

Singleton shows that Gauss–Legendre quadrature with a relatively small number of quadrature points allows to accurately evaluate the integral in Eq. (67) when X is univariate. As such, the method readily delivers efficient estimates of the parameter vector, Ψ, subject to an auxiliary assumption, namely that the state vector may be extracted by assuming that a pre-specified set of security prices is observed without error while the remainder have non-trivial error terms.

When X is multivariate the Fourier inversion in Eq. (67) is computationally more demanding. Thus, when estimating multi-dimensional systems Singleton suggests focusing on the conditional density function of the individual elements of X, but conditioned on the full state vector,

$$f_{X_j}(X_j(t+1) | X(t); \Psi) = \frac{1}{2\pi} \int_{\mathbb{R}} \mathrm{e}^{-i\omega \mathbf{I}_j' X(t+1)} \phi(i\omega \mathbf{I}_j, X(t), \Psi) \mathrm{d}\omega \, , \qquad (68)$$

where the vector $\mathbf{I}_j$ has 1 in the jth element and zero elsewhere so that the jth element of X is $X_j(t+1) = \mathbf{I}_j' X(t+1)$. Maximization of the likelihood function obtained from f_{X_j}, for a fixed j, will often suffice to obtain a consistent estimate of Ψ. Exploiting more than one of the conditional densities (68) will result in more efficient Ψ estimate. For instance, the scores of multiple univariate log-likelihood functions, stacked in a vector, yield moment conditions that allow for generalized method of moment (GMM) estimation of the system. Alternatively, Joslin [192] proposes a change-of-measure transformation which reduces the oscillatory behavior of the integrand in Eq. (67). When using this transformation, Gauss-Hermite quadrature more readily provides a solution to the integral in (67) even if the state vector X is multi-dimensional, thus facilitating full ML estimation of the system.

Related, several studies have pursued GMM estimation of affine processes using characteristic functions. Definition (65) yields the moment condition

$$\mathrm{E}\left[(\phi(iu, X(t), \Psi) - \mathrm{e}^{iu' X(t+1)}) z(u, X(t))\right] = 0 \, , \qquad (69)$$

where X is an N-dimensional (jump-)diffusion, $u \in \mathbb{R}^N$, and z is an instrument function. When X is affine, the characteristic function takes the exponential form (66). Different choices of u and z yield a set of moment conditions that can be used for GMM estimation and inference. Singleton [242] derives the optimal instrument in terms of delivering efficient estimates. Carrasco et al. [86] approximate the optimal instrument with a set of basis functions that do not require the knowledge of the conditional likelihood function, thus avoiding one of the assumptions invoked by Singleton. Further, they build on Carrasco and Florens [87] to implement estimation using a continuum of moment conditions, which yields maximum-likelihood efficiency. Other applications of GMM-characteristic function methods to affine (jump-) diffusions for equity index returns are in Chacko and Viceira [88] and Jiang and Knight [184].

In some cases the lack of closed-form expressions for the moment condition in Eq. (69) can hinder GMM estimation. In these cases the expectation in Eq. (69) can be evaluated by Monte Carlo integration. This is accomplished by simulating a long sample from the discretized process for a given value of the coefficient vector Ψ. The parameter Ψ is then estimated via the simulated method of moments (SMM) of McFadden [206] and Duffie and Singleton [131]. Singleton [242] proposes SMM characteristic function estimators that exploit the special structure of affine term structure models.

Efficient Estimation of General Continuous-Time Processes

A number of recent approaches offer excellent flexibility in terms of avoiding approximations to the continuous-time model-implied transition density while still facilitating efficient estimation of the evolution of the latent state vector for the system.

Maximum Likelihood with Characteristic Functions
Bates [58] develops a filtration-based maximum likelihood estimation method for affine processes. His approach relies on Bayes' rule to recursively update the joint characteristic function of latent variables and data conditional on past data. He then obtains the transition density by Fourier inversion of the updated characteristic function.

Denote with $y(t)$ and $X(t)$ the time-t values of the observable variable and the state vector, respectively, and let $Y(t) \equiv \{y(1), \dots, y(t)\}$ be the data observed up to time t. Consider the case in which the characteristic function of $z(t+1) \equiv (y(t+1), X(t+1))$ conditional on $z(t) \equiv (y(t), X(t))$, is an exponential affine function of $X(t)$:

$$\begin{aligned}\phi(is, iu, z(t), \Psi) &= \mathrm{E}\left[\mathrm{e}^{is' y(t+1)+iu' X(t+1)} \middle| z(t)\right] \\ &= \mathrm{e}^{\alpha(is,iu,y(t))+\beta(is,iu,y(t))' X(t)} . \quad (70)\end{aligned}$$

Next, determine the value of the characteristic function conditional on the observed data $Y(t)$:

$$\begin{aligned}&\phi(is, iu, Y(t), \Psi) \\ &\quad = \mathrm{E}\left[\mathrm{E}\left[\mathrm{e}^{is' y(t+1)+iu' X(t+1)} \middle| z(t)\right] \middle| Y(t)\right] \\ &\quad = \mathrm{E}\left[\mathrm{e}^{\alpha(is,iu,y(t))+\beta(is,iu,y(t))' X(t)} \middle| Y(t)\right] \\ &\quad = \mathrm{e}^{\alpha(is,iu,y(t))} \psi(\beta(is, iu, y(t)), Y(t), \Psi) , \quad (71)\end{aligned}$$

where $\psi(iu, Y(t), \Psi) \equiv \mathrm{E}\left[\mathrm{e}^{iu' X(t)} \middle| Y(t)\right]$ denotes the (marginal) characteristic function for the state vector conditional on the observed data. Fourier inversion then yields the conditional density for the observation $y(t+1)$ conditional on $Y(t)$:

$$\begin{aligned}&f_y(y(t+1)|Y(t); \Psi) \\ &\quad = \frac{1}{2\pi} \int_{\mathbb{R}} \mathrm{e}^{-is' y(t+1)} \phi(is, 0, Y(t), \Psi) \mathrm{d}s . \quad (72)\end{aligned}$$

The next step updates the characteristic function ψ (Bartlett [48]):

$$\begin{aligned}\psi(iu, Y(t+1), \Psi) &= \frac{1}{2\pi f_y(y(t+1)|Y(t); \Psi)} \\ &\quad \cdot \int_{\mathbb{R}} \mathrm{e}^{-is' y(t+1)} \phi(is, iu, Y(t), \Psi) \mathrm{d}s . \quad (73)\end{aligned}$$

To start the recursion, Bates initializes ψ at the unconditional characteristic function of the latent variable X. The log-likelihood function is then given by

$$\begin{aligned}\log \mathcal{L}(Y(T); \Psi) &= \log(f_y(y(1); \Psi)) \\ &\quad + \sum_{t=2}^{T} \log(f_y(y(t)|Y(t-1); \Psi)) . \quad (74)\end{aligned}$$

A nice feature is that the method provides a natural solution to the filtering problem. The filtered estimate of the latent state X and its variance are computed from the first and second derivatives of the moment generating function $\psi(u, Y(t); \Psi)$ in Eq. (73), evaluated at $u = 0$:

$$\begin{aligned}\mathrm{E}[X(t+1)|Y(t+1); \Psi] &= \frac{1}{2\pi f_y(y(t+1)|Y(t); \Psi)} \\ &\quad \times \int_{\mathbb{R}} \mathrm{e}^{-is' y(t+1)} \phi_u(is, 0, Y(t); \Psi) \mathrm{d}s \quad (75)\end{aligned}$$

$$\operatorname{Var}[X(t+1)|Y(t+1);\Psi] = \frac{1}{2\pi f_y(y(t+1)|Y(t);\Psi)} \times \int_{\mathbb{R}} \mathrm{e}^{-is'y(t+1)} \phi_{uu}(is, 0, Y(t);\Psi)\mathrm{d}s - \{\mathrm{E}[X(t+1)|Y(t+1)]\}^2 \,. \quad (76)$$

A drawback is that at each step t of the iteration the method requires storage of the entire characteristic function $\psi(iu, Y(t);\Psi)$. To deal with this issue Bates recommends to approximate the true ψ with the characteristic function of a variable with a two-parameter distribution. The choice of the distribution depends on the X-dynamics while the two parameters of the distribution are determined by the conditional mean $\mathrm{E}[X(t+1)|Y(t+1);\Psi]$ and variance $\operatorname{Var}[X(t+1)|Y(t+1);\Psi]$ given in Equations (75)–(76).

In his application Bates finds that the method is successful in estimating different flavors of the SV jump-diffusion for a univariate series of daily 1953–1996 S&P 500 returns. In particular, he shows that the method obtains estimates that are equally, if not more, efficient compared to the efficient method of moments and Markov Chain Monte Carlo methods described below. Extensions of the method to multivariate processes are theoretically possible, but they require numerical integration of multi-dimensional functions, which is computationally demanding.

Simulated Maximum Likelihood In Sect. "Filtering the Latent State Variable Directly During Estimation" we discussed methods for simulated ML estimation and inference in discrete-time SV models. Pedersen [224] and Santa-Clara [234] independently develop a simulated maximum likelihood (SML) method to estimate continuous-time diffusion models. They divide each interval in between two consecutive data points X_{t+1} and X_t into M sub-intervals of length $\Delta = 1/M$ and they discretize the X process using the Euler scheme,

$$X_{t+(i+1)\Delta} = X_{t+i\Delta} + \mu(X_{t+i\Delta})\Delta + \Sigma(X_{t+i\Delta})\sqrt{\Delta}\varepsilon_{t+(i+1)\Delta} \,, \quad i = 0, \ldots, M-1 \,, \quad (77)$$

where μ and Σ are the drift and diffusion terms of the X process and ε is multivariate normal with mean zero and identity variance matrix. The transition density of the discretized process is multivariate normal with mean μ and variance matrix $\Sigma\Sigma'$. As Δ goes to zero, this density converges to that of the continuous-time process X. As such, the transition density from X_t to X_{t+1} is given by

$$f_X(X_{t+1}|X_t;\Psi) = \int f_X(X_{t+1}|X_{t+1-\Delta};\Psi) \times f_X(X_{t+1-\Delta}|X_t;\Psi)\mathrm{d}X_{t+1-\Delta} \,. \quad (78)$$

For sufficiently small values of Δ the first term in the integrand, $f_X(X_{t+1}|X_{t+1-\Delta};\Psi)$, is approximated by the transition density of the discretized process, while the second term, $f_X(X_{t+1-\Delta}|X_t;\Psi)$, is a multi-step-ahead transition density that can be computed from the recursion from X_t to $X_{t+1-\Delta}$. Writing the right-hand side of Eq. (78) as a conditional expectation yields

$$f_X(X_{t+1}|X_t;\Psi) = E_{X_{t+1-\Delta}|X_t}\left[f_X(X_{t+1}|X_{t+1-\Delta};\Psi)\right] . \quad (79)$$

The expectation in Eq. (79) can be computed by Monte Carlo integration over a large number of paths for the process X, simulated via the Euler scheme (77). As Δ vanishes, the Euler scheme is consistent. Thus, when the size of the simulated sample increases the sample average of the function f_X, evaluated at the random draws of $X_{t+1-\Delta}$, converges to the true transition density. Application of the principles in Bladt and Sørensen [64] may well be useful in enhancing the efficiency of the simulation scheme and hence the actual efficiency of the inference procedure in practice.

Brandt and Santa-Clara [75] apply the SML method to estimate a continuous-time model of the joint dynamics of interest rates in two countries and the exchange rate between the two currencies. Piazzesi [227] extends the SML approach for jump-diffusion processes with time-varying jump intensity. She considers a high-frequency policy rule based on yield curve information and an arbitrage-free bond market and estimates the model using 1994–1998 data on the Federal Reserve target rate, the six-month LIBOR rate, and swap yields.

An important issue is how to initialize any unobserved component of the state vector, $X(t)$, such as the volatility state at each observation to provide a starting point for the next Monte Carlo integration step. This may be remedied through application of the particle filter, as mentioned earlier and discussed below in connection with MCMC estimation. Another possibility is, as also indicated previously, to extract the state variable through inversion from derivatives prices or yields assumed observed without pricing errors.

Indirect Inference There are also other method-of-moments strategies to estimate finitely-sampled continuous-time processes of a general type. One prominent approach approximates the unknown transition density for the continuous-time process with the density of a semi-nonparametric (SNP) auxiliary model. Then one can use the score function of the auxiliary model to form moment conditions for the parameter vector $\varPsi$ of the continuous-time model. This approach yields the efficient method of moments estimator (EMM) of Gallant and Tauchen [154], Gallant et al. [150], and Gallant and Long [152], and the indirect inference estimator of Gouriéroux et al. [162] and Smith [243].

To fix ideas, suppose that the conditional density for a continuous-time return process r (the 'structural' model) is unknown. We intend to approximate the unknown density with a discrete-time model (the 'auxiliary' model) that is tractable and yet sufficiently flexible to accommodate the systematic features of the actual data sample well. A parsimonious auxiliary density for r embeds ARMA and EGARCH leading terms to capture the conditional mean and variance dynamics. There may be residual excess skewness and kurtosis that elude the ARMA and EGARCH forms. As such, the auxiliary density is rescaled using a nonparametric polynomial expansion of order K, which yields

$$g_K(r(t)|x(t);\xi) = \left(\nu + (1-\nu) \times \frac{[P_K(z(t),x(t))]^2}{\int_{\mathbb{R}}[P_K(z(t),x(t))]^2\phi(u)\mathrm{d}u}\right)\frac{\phi(z(t))}{\sqrt{h(t)}}\,, \tag{80}$$

where ν is a small constant, $\phi(.)$ is the standard normal density, $x(t)$ contains lagged return observations, and

$$z(t) = \frac{r(t)-\mu(t)}{\sqrt{h(t)}}\,, \tag{81}$$

$$\mu(t) = \phi_0 + ch(t) + \sum_{i=1}^{s}\phi_i r(t-1) + \sum_{i=1}^{u}\delta_i\varepsilon(t-1)\,, \tag{82}$$

$$\begin{aligned}\log h(t) &= \omega + \sum_{i=1}^{p}\beta_i \log h(t-1) \\ &\quad + (1+\alpha_1 L + \cdots + \alpha_q L^q) \\ &\quad \times \left[\theta_1 z(t-1) + \theta_2(b(z(t-1)) - \sqrt{2/\pi})\right],\end{aligned} \tag{83}$$

$$P_K(z,x) = \sum_{i=0}^{K_z} a_i(x) z^i = \sum_{i=0}^{K_z}\left(\sum_{|j|=0}^{K_x} a_{ij}x^j\right) z^i\,, \quad a_{00} = 1\,. \tag{84}$$

Here j is a multi-index vector, $x^j \equiv (x_1^{j_1},\dots,x_M^{j_M})$, and $|j| \equiv \sum_{m=1}^{M} j_m$. The term $b(z)$ is a smooth (twice-differentiable) function that closely approximates the absolute value operator in the EGARCH variance equation.

In practice, the representation of P_K is given by Hermite orthogonal polynomials. When the order K of the expansion increases, the auxiliary density will approximate the data arbitrarily well. If the structural model is indeed the true data generating process, then the auxiliary density will converge to that of the structural model. For a given K, the QML estimator $\hat{\xi}$ for the auxiliary model coefficient satisfies the score condition

$$\frac{1}{T}\sum_{t=1}^{T}\frac{\partial \log g_K(r(t)|x(t);\hat{\xi})}{\partial\xi} = 0\,. \tag{85}$$

Suppose now that the structural model is correct and $\varPsi_0$ is the true value of its coefficient vector. Consider a series $\{r(t;\varPsi), x(t;\varPsi)\}$, $t = 1,\dots,\mathcal{T}(T)$, simulated from the structural model. Then we expect that the score condition (85) holds when evaluated by averaging over the simulated returns rather than over the actual data:

$$m_{\mathcal{T}(T)}(\varPsi_0,\hat{\xi}) = \frac{1}{\mathcal{T}(T)}\sum_{t=1}^{\mathcal{T}(T)}\frac{\partial \log g_K(r(t,\varPsi_0)|x(t,\varPsi_0);\hat{\xi})}{\partial\xi} \approx 0\,. \tag{86}$$

When T and $\mathcal{T}(T)$ tend to infinity, condition (86) holds exactly.

Gallant and Tauchen [154] propose the EMM estimator $\hat{\varPsi}$ defined via

$$\hat{\varPsi} = \arg\min_{\varPsi} m_{\mathcal{T}(T)}(\varPsi,\hat{\xi})'\,\hat{W}_T m_{\mathcal{T}(T)}(\varPsi,\hat{\xi})\,, \tag{87}$$

where the weighting matrix $\hat{W}_T$ is a consistent estimate of the inverse asymptotic covariance matrix of the auxiliary score function, e. g., the inverse outer product of the SNP gradient:

$$\hat{W}_T^{-1} = \frac{1}{T}\sum_{t=1}^{T}\left[\frac{\partial \log g_K(r(t)|x(t);\hat{\xi})}{\partial\xi}\right] \times \left[\frac{\partial \log g_K(r(t)|x(t);\hat{\xi})}{\partial\xi}\right]'\,. \tag{88}$$

An important advantages of the technique is that EMM estimates achieve the same degree of efficiency as the ML procedure, when the score of the auxiliary model asymptotically spans the score of the true model. It also delivers powerful specification diagnostics that provide guidance in the model selection. Gallant and Tauchen [154] show that the EMM estimator is asymptotically normal. Further, under the assumption that the structural model is correctly specified, they derive a χ^2 statistic for the test of over-identifying restrictions. Gallant et al. [150] normalize the vector $m_{\mathcal{T}(T)}(\hat{\Psi}, \hat{\xi})$ by its standard error to obtain a vector of score t-ratios. The significance of the individual score elements is often informative of the source of model mis-specification, with the usual caveat that failure to capture one characteristic of the data may result in the significance of a moment condition that pertains to a coefficient not directly related to that characteristic (due to correlation in the moment conditions). Finally, EMM provides a straightforward solution to the problem of filtering and forecasting the latent return variance process V, i. e., determining the conditional densities $f(V(t)|x(t), \Psi)$ and $f(V(t+j)|x(t), \Psi)$, $j \geq 0$. This is accomplished through the *reprojection* method discussed in, e. g., Gallant and Long [152] and Gallant and Tauchen [155]. In applications to dynamic term structure models, the same method yields filtered and forecasted values for the latent state variables.

The reprojection method assumes that the coefficient vector Ψ is known. In practice, Ψ is fixed at the EMM estimate $\hat{\Psi}$. Then one simulates a sample of returns and latent variables from the structural model and fits the auxiliary model on the simulated data. This is equivalent to the first step of the EMM procedure except that, in the reprojection step, we fit the auxiliary model assuming the structural model is correct, rather than using actual data. The conditional density of the auxiliary model, estimated under the null, approximates the unknown density of the structural model:

$$g_K(r(t+j)|x(t); \tilde{\xi}) \approx f(r(t+j)|x(t); \hat{\Psi}), \quad j \geq 0\,, \quad (89)$$

where $\tilde{\xi}$ is the QML estimate of the auxiliary model coefficients obtained by fitting the model on simulated data. This approach yields filtered estimates and forecasts for the conditional mean and variance of the return via

$$\mathrm{E}\left[r(t+j)|x(t); \hat{\Psi}\right] = \int y g_K(y|x(t); \tilde{\xi})\mathrm{d}y\,, \quad (90)$$

$$\mathrm{Var}\left[r(t+j)|x(t); \hat{\Psi}\right] = \int \left(y - \mathrm{E}\left[r(t+j)|x(t); \hat{\Psi}\right]\right)^2 \times g_K(y|x(t); \tilde{\xi})\mathrm{d}y\,. \quad (91)$$

An alternative approach consists in fitting an auxiliary model for the latent variable (e. g., the return conditional variance) as a function of current and lagged returns. It is straightforward to estimate such model using data on the latent variable and the associated returns simulated from the structural model with the EMM coefficient $\hat{\Psi}$. Also in this case the auxiliary model density approximates the true one, i. e.,

$$g_K^V(V(t+j)|x(t); \tilde{\xi}) \approx f^V(V(t+j)|x(t); \hat{\psi})\,, \quad j \geq 0. \quad (92)$$

This approach yields a forecast for the conditional variance process,

$$\mathrm{E}\left[V(t+j)|x(t); \hat{\Psi}\right] = \int v g_K^V(v|x(t); \tilde{\xi})\mathrm{d}v\,. \quad (93)$$

In sum, reprojection is a simulation approach to implement a non-linear Kalman-filter-type technique, which yields effective forecasts for the unobservable state vector.

The indirect inference estimator by Gouriéroux et al. [162] and Smith [243] is closely related to the EMM estimator. Indirect inference exploits that the following two quantities should be close when the structural model is correct and the data are simulated at the true parameter Ψ_0: (i) the QML estimator $\hat{\xi}$ for the auxiliary model computed from actual data; (ii) the QML estimator $\hat{\xi}(\Psi)$ for the auxiliary model fitted on simulations from the structural model. Minimizing the distance between $\hat{\xi}$ and $\hat{\xi}(\Psi)$ in an appropriate metric yields the indirect inference estimator for Ψ. Similar to EMM, asymptotic normality holds and a χ^2 test for over-identifying restrictions is available. However, the indirect inference approach is computationally more demanding, because finding the value of Ψ that minimizes the distance function requires re-estimating the auxiliary model on a different simulated sample for each iteration of the optimization routine. EMM does not have this drawback, since the EMM objective function is evaluated at the same fitted score at each iteration. Nonetheless, there may well be circumstances where particular auxiliary models are of primary economic interest and estimation based on the corresponding moment conditions may serve as a useful diagnostic tool for model performance in such directions.

Several studies have used EMM to fit continuous-time SV jump-diffusion models for equity index returns, e. g., Andersen et al. [15], Benzoni [59], Chernov and Ghysels [93], and Chernov et al. [94,95]. Andersen and Lund [28] and Andersen et al. [16] use EMM to estimate SV jump-diffusion models for the short-term interest rate. Ahn et al. [1,2], Brandt and Chapman [71], and Dai and Singleton [114] fit different flavors of multi-factor dynamic term structure models. Andersen et al. [27] document the small-sample properties of the efficient method of moments estimator for stationary processes, while Duffee and Stanton [128] study its properties for near unit-root processes. A. Ronald Gallant and George E. Tauchen at Duke University have prepared well-documented general-purpose EMM and SNP packages, available for download at the web address ftp.econ.duke.edu in the directories pub/get/emm and pub/get/snp. In applications it is often useful to customize the SNP density to allow for a more parsimonious fit of the data under investigation. For instance, Andersen et al. [15,16], Andersen and Lund [28], and Benzoni [59] rely on the SNP density (80)–(84).

Markov Chain Monte Carlo The MCMC method provides a Bayesian solution to the inference problem for a dynamic asset pricing model. The approach treats the model coefficient Ψ as well as the vector of latent state variables X as random variables and computes the posterior distribution $f(\Psi, X|Y)$, conditional on certain observable variables Y, predicted by the model. The setting is sufficiently general to deal with a wide range of situations. For instance, X and Y can be the (latent) volatility and (observable) return processes as is the case of an SV model for asset returns. Or X and Y can be the latent state vector and observable yields in a dynamic term structure model.

The posterior distribution $f(\Psi, X|Y)$ is the main tool to draw inference not only on the coefficient Ψ but also on the latent vector X. Since $f(\Psi, X|Y)$ is unknown in closed-form in relevant applications, MCMC relies on a simulation (a Markov Chain) from the conditional density $f(\Psi, X|Y)$ to compute mode, mean, and standard deviations for the model coefficients and state variables via the Monte Carlo method.

The posterior $f(\Psi, X|Y)$ is analytically untractable and extremely high-dimensional, so that simulation directly from $f(\Psi, X|Y)$ is typically infeasible. The MCMC approach hinges on the Clifford–Hammersley theorem, which determines conditions under which the posterior $f(\Psi, X|Y)$ is uniquely determined by the marginal posterior distributions $f(\Psi|X, Y)$ and $f(X|\Psi, Y)$. In turn, the posteriors $f(\Psi|X, Y)$ and $f(X|\Psi, Y)$ are determined by a set or univariate posterior distributions. Specifically, denote with $\Psi(i)$ the ith element of the coefficient Ψ, $i = 1, \ldots, K$, and with $\Psi(-i)$ the vector consisting of all elements in Ψ except for the ith one. Similarly denote with $X(t)$ the tth row of the state vector, $t = 1, \ldots, T$, and with $X(-t)$ the rest of the vector. Then the Clifford–Hammersley theorem allows to characterize the posterior $f(\Psi, X|Y)$ via $K + T$ univariate posteriors,

$$f(\Psi(i)|\Psi(-i), X, Y) \, , \quad i = 1, \ldots, K \tag{94}$$

$$f(X(t)|X(-t), \Psi, Y) \, , \quad t = 1, \ldots, T \, . \tag{95}$$

The construction of the Markov Chain relies on the so-called Gibbs sampler. The first step of the algorithm consists in choosing initial values for the coefficient and the state, Ψ_0 and X_0. When (one of or both) the multi-dimensional posteriors are tractable, the Gibbs sampler generates values Ψ_1 and X_1 directly from $f(\Psi|X, Y)$ and $f(X|\Psi, Y)$. Alternatively, each element of Ψ_1 and X_1 is drawn from the univariate posteriors (94)–(95). Some of these posteriors may also be analytically intractable or efficient algorithms to draw from these posteriors may not exist. In such cases the Metropolis-Hastings algorithm ensures that the simulated sample is consistent with the posterior target distribution. Metropolis-Hastings sampling consists of an accept-reject procedure of the draws from a 'proposal' or 'candidate' tractable density, which is used to approximate the unknown posterior (see, e. g., Johannes and Polson [187]).

Subsequent iterations of Gibbs sampling, possibly in combination with the Metropolis-Hastings sampling, yield a series of 'sweeps' $\{\Psi_s, X_s\}$, $s = 1, \ldots, S$, with limiting distribution $f(\Psi, X|Y)$. A long number of sweeps may be necessary to 'span' the whole posterior distribution and obtain convergence due to the serial dependence of subsequent draws of coefficients and state variables. When the algorithm has converged, additional simulations provide a sample from the joint posterior distribution.

The MCMC approach has several advantages. First, the inference automatically accounts for parameter uncertainty. Further, the Markov Chain provides a direct and elegant solution to the *smoothing* problem, i. e., the problem of determining the posterior distribution for the state vector X conditional on the entire data sample, $f(X(t)|Y(1), \ldots, Y(T), \Psi)$, $t = 1, \ldots, T$. The limitation on the approach is largely that efficient sampling schemes for the posterior distribution must be constructed for each specific problem at hand which by nature is case specific and potentially cumbersome or inefficient. Nonetheless, following the development of more general simulation algorithms, the method has proven flexible for efficient estimation of a broad class of important models.

One drawback is that MCMC does not deliver an immediate solution to the *filtering* problem, i. e., determining $f(X(t)|Y(1), \ldots, Y(t), \Psi)$, and the *forecasting* problem, i. e., determining $f(X(t+j)|Y(1), \ldots, Y(t), \Psi)$, $j > 0$. However, recent research is overcoming this limitation through the use of the 'particle filter'. Bayes rule implies

$$f(X(t+1)|Y(1),\dots,Y(t+1),\Psi) \propto f(Y(t+1)| X(t+1),\Psi) f(X(t+1)|Y(1),\dots,Y(t),\Psi)\,, \quad (96)$$

where the symbol $\propto$ denotes 'proportional to'. The first density on the right-hand side of Eq. (96) is determined by the SV model and it is often known in closed form. In contrast, the second density at the far-right end of the equation is given by an integral that involves the unknown filtering density at the prior period, $f(X(t)|Y(1),\dots,Y(t),\Psi)$:

$$f(X(t{+}1)|Y(1),\dots,Y(t),\Psi) = \int f(X(t{+}1)|X(t),\Psi) \times f(X(t)|Y(1),\dots,Y(t),\Psi)\mathrm{d}X(t)\,. \quad (97)$$

The particle method relies on simulations to construct a finite set of weights $w^i(t)$ and particles $X^i(t)$, $i = 1,\dots,N$, that approximate the unknown density with a finite sum,

$$f(X(t)|Y(1),\dots,Y(t),\Psi) \approx \sum_{i=1}^{N} w^i(t)\delta_{X^i(t)}\,, \quad (98)$$

where the Dirac function $\delta_{X^i(t)}$ assigns mass one to the particle $X^i(t)$. Once the set of weights and particles are determined, it is possible to re-sample from the discretized distribution. This step yields a simulated sample $\{X^s(t)\}_{s=1}^{S}$ which can be used to evaluate the density in Eq. (97) via Monte Carlo integration:

$$f(X(t+1)|Y(1),\dots,Y(t),\Psi) \approx \frac{1}{S}\sum_{s=1}^{S} f(X(t+1)|X^s(t),\Psi)\,. \quad (99)$$

Equation (99) solves the forecasting problem while combining formulas (96) and (99) solves the filtering problem. The challenge in practical application of the particle filter is to identify an accurate and efficient algorithm to construct the set of particles and weights. We point the interested reader to Kim et al. [193], Pitt and Shephard [228] and Johannes and Polson [187] for a discussion on how to approach this problem.

The usefulness of the MCMC method to solve the inference problem for SV models has been evident since the early work by Jacquier et al. [180], who develop an MCMC algorithm for the logarithmic SV model. Jacquier et al. [181] provide extensions to correlated and non-normal error distributions. Kim et al. [193], Pitt and Shephard [228] and Chib et al. [96] develop simulation-based methods to solve the filtering problem, while Chib et al. [97] use the MCMC approach to estimate a multivariate SV model. Elerian et al. [135] and Eraker [140] discuss how to extend the MCMC inference method to a continuous-time setting. Eraker [140] uses the MCMC approach to estimate an SV diffusion process for interest rates, while Jones [189] estimates a continuous-time model for the spot rate with non-linear drift function. Eraker et al. [142] estimate an SV jump-diffusion process using data on S&P 500 return while Eraker [141] estimates a similar model using joint data on options and underlying S&P 500 returns. Li et al. [196] allow for Lévy-type jumps in their model. Collin-Dufresne et al. [104] use the MCMC approach to estimate multi-factor affine dynamic term structure model using swap rates data. Johannes and Polson [186] give a comprehensive survey of the still ongoing research on the use of the MCMC approach in the general nonlinear jump-diffusion SV setting.

Estimation from Option Data

Options' payoffs are non-linear functions of the underlying security price. This feature renders options highly sensitive to jumps in the underlying price and to return volatility, which makes option data particularly useful to identify return dynamics. As such, several studies have taken advantage of the information contained in option prices, possibly in combination with underlying return data, to estimate SV models with or without discontinuities in returns and volatility.

Applications to derivatives data typically require a model for the pricing errors. A common approach is to posit that the market price of an option, O^*, normalized by the underlying observed security price S^*, is the sum of the normalized model-implied option price, O/S^*, and a disturbance term ε (e. g., Renault [230]):

$$\frac{O^*}{S^*} = \frac{O(S^*,V,K,\tau,\Psi)}{S^*} + \varepsilon\,, \quad (100)$$

where V is the latent volatility state, K is the option strike price, τ is time to maturity, and Ψ is the vector with the model coefficients. A pricing error ε could arise for several reasons, including measurement error (e. g., price discreteness), asynchroneity between the derivatives and underlying price observations, microstructure effects, and perhaps most importantly specification error. The structure imposed on ε depends on the choice of a specific 'loss function' used for estimation (e. g., Christoffersen and Jacobs [98]). Several studies have estimated the coefficient vector Ψ by minimizing the sum of the squared option pricing errors normalized by the underlying price S^*, as in Eq. (100). Others have focused on either squared dollar pricing errors, or squared errors normalized by the options market price (instead of S^*). The latter approach has the advantage that a $1 error on an expensive in-the-money option carries less weight than the same error on a cheaper out-of-the-money contract. The drawback is that giving a lot of weight to the pricing errors on short-maturity deep-out-of-the-money options could bias the estimation results. Finally, the common practice of expressing option prices in terms of their Black-Scholes implied volatilities has inspired other scholars to minimize the deviations between Black-Scholes implied volatilities inferred from model and market prices (e. g., Mizrach [216]). An alternative course is to form a moment-based loss function and follow a GMM- or SMM-type approach to estimate Ψ. To this end moment conditions stem from distributional assumptions on the pricing error ε (e. g., $\mathrm{E}[\varepsilon] = 0$) or from the scores of a reduced-form model that approximates the data.

In estimating the model, some researchers have opted to use a panel of options consisting of contracts with multiple strikes and maturities across dates in the sample period. This choice brings a wealth of information on the cross-sectional and term-structure properties of the implied volatility smirk into the analysis. Others rely on only one option price observation per time period, which shifts the focus to the time-series dimension of the data. Some studies re-estimate the model on a daily basis rather than seeking a single point estimate for the coefficient Ψ across the entire sample period. This ad hoc approach produces smaller in-sample pricing errors, which can be useful to practitioners, but at the cost of concealing specification flaws by over-fitting the model, which tends to hurt out-of-sample performance. The different approaches are in part dictated by the intended use of the estimated system as practitioners often are concerned with market making and short-term hedging while academics tend to value stable relations that may form the basis for consistent modeling of the dominant features of the system over time.

Early contributions focus on loss functions based on the sum of squared option pricing errors and rely entirely on option data for estimation. This approach typically yields an estimate of the model coefficient Ψ that embeds an adjustment for risk, i. e., return and volatility dynamics are identified under the risk-neutral rather than the physical probability measure. For instance, Bates [56] considers an SV jump-diffusion model for Deutsche Mark foreign currency options and estimates its coefficient vector Ψ via nonlinear generalized least squares of the normalized pricing errors with daily option data from January 1984 to June 1991. A similar approach is followed by Bates [57] who fits an SV model with two latent volatility factors and jumps using daily data on options on the S&P 500 futures from January 1988 to December 1993. Bakshi et al. [34] focus on the pricing and hedging of daily S&P 500 index options from June 1988 to May 1991. In their application they re-calibrate the model on a daily basis by minimizing the sum of the squared dollar pricing errors across options with different maturities and strikes. Huang and Wu [173] explore the pricing implications of the time-changed Lévy process by Carr and Wu [84] for daily S&P 500 index options from April 1999 to May 2000. Their Lévy return process allows for discontinuities that exhibit higher jump frequencies compared to the finite-intensity Poisson jump processes in Equations (37)–(41). Further, their model allows for a random time change, i. e., a monotonic transformation of the time variable which generates SV in the diffusion and jump components of returns. In contrast, Bakshi et al. [35] fit an SV jump-diffusion model by SMM using daily data on long-maturity S&P 500 options (LEAPS).

More recent studies have relied on joint data on S&P 500 option prices and underlying index returns, spanning different periods, to estimate the model. This approach forces the same model to price securities in two different markets and relies on information from the derivatives and underlying securities to better pin down model coefficients and risk premia. For instance, Eraker [141] and Jones [190] fit different flavors of the SV model (with and without jumps, respectively) by MCMC. Pan [220] follows a GMM approach to estimate an SV jump-diffusion model using weekly data. She relies on a single at-the-money option price observation each week, which identifies the level of the latent volatility state variable (i. e., at each date she fixes the error term ε at zero and solves Eq. (100) for V). Aït-Sahalia and Kimmel [7] apply Aït-Sahalia's [4] method to approximate the likelihood function for a joint sample of options and underlying prices. Chernov and Ghysels [93] and Benzoni [59] obtain moment conditions from the scores of a SNP auxiliary model. Similarly, other recent studies have found it useful to use joint derivatives and interest rate data to fit dynamic term structure models, e. g., Almeida et al. [9], and Bikbov and Chernov [62].

Finally, a different literature has studied the option pricing implications of a model in which asset return volatility is a deterministic function of the asset price and time, e. g., Derman and Kani [119], Dupire [134], Rubinstein [233], and Jackwerth and Rubinstein [177]. Since volatility is not stochastic in this setting, we do not review these models here and point the interested reader to, e. g., [133] for an empirical analysis of their performance.

Future Directions

In spite of much progress in our understanding of volatility new challenges lie ahead. In recent years a wide array of volatility-sensitive products has been introduced. The market for these derivatives has rapidly grown in size and complexity. Research faces the challenge to price and hedge these new products. Moreover, the recent developments in model-free volatility modeling have effectively given empirical content to the latent volatility variable, which opens the way for a new class of estimation methods and specification tests for SV systems. Related, improved volatility measures enable us to shed new light on the properties and implications of the volatility risk premium. Finally, more work is needed to better understand the linkage between fluctuations in economic fundamentals and low- and high-frequency volatility movements. We conclude this chapter by briefly reviewing some open issues in these four areas of research.

Volatility and Financial Markets Innovation

Volatility is a fundamental input to any financial and real investment decision. Markets have responded to investors' needs by offering an array of volatility-linked instruments. In 1993 the Chicago Board Option Exchange (CBOE) has introduced the VIX index, which measures the market expectations of near-term volatility conveyed by equity-index options. The index was originally computed using the Black-Scholes implied volatilities of eight different S&P 100 option (OEX) series so that, at any given time, it represented the implied volatility of a hypothetical at-the-money OEX option with exactly 30 days to expiration (see [257]). On September 22, 2003, the CBOE began disseminating price level information using a revised 'model-free' method for the VIX index. The new VIX is given by the price of a portfolio of S&P 500 index options and incorporates information from the volatility smirk by using a wider range of strike prices rather than just at-the-money series (see [77]). On March 26, 2004, trading in futures on the VIX Index started on the CBOE Futures Exchange (CFE) while on February 24, 2006, options on the VIX began trading on the Chicago Board Options Exchange. These developments have opened the way for investors to trade on option-implied measures of market volatility. The popularity of the VIX prompted the CBOE to introduce similar indices for other markets, e. g., the VXN NASDAQ 100 Volatility Index.

Along the way, a new over-the-counter market for volatility derivatives has also rapidly grown in size and liquidity. Volatility derivatives are contracts whose payments are expressed as functions of realized variance. Popular examples are variance swaps, which at maturity pay the difference between realized variance and a fixed strike price. According to estimates by BNP Paribas reported by the Risk [176] magazine, the daily trading volume for variance swaps on indices reached $4–5 million in vega notional (measured in dollars per volatility point) in 2006, which corresponds to payments in excess of $1 billion per percentage point of volatility on an annual basis (Carr and Lee [82]). Using variance swaps hedge fund managers and proprietary traders can easily place huge bets on market volatility.

Finally, in recent years credit derivatives markets have evolved in complexity and grown in size. Among the most popular credit derivatives are the credit default swaps (CDS), which provide insurance against the risk of default by a particular company. The buyer of a single-name CDS acquires the right to sell bonds issued by the company at face value when a credit event occurs. Multiple-name contracts can be purchased simultaneously through credit indices. For instance, the CDX indices track the credit spreads for different portfolios of North American companies while the iTraxx Europe indices track the spreads for portfolios of European companies. At the end of 2006 the notional amount of outstanding over-the-counter single- and multi-name CDS contracts stood at $19 and $10 trillion, respectively, according to the September 2007 Bank for International Settlements Quarterly Review.

These market developments have raised new interesting issues for research to tackle. The VIX computations based on the new model-free definition of implied volatility used by the CBOE requires the use of options with strike prices that cover the entire support of the return distribution. In practice, liquid options satisfying this requirement often do not exist and the CBOE implementation introduces random noise and systematic error into the index (Jiang and Tian [185]). Related, the VIX implementation entails a truncation, i. e., the CBOE discards illiquid option prices with strikes lying in the tails of the return distribution. As such, the notion of the VIX is more directly linked to that of corridor volatility [26]. In sum, robust implementation of a model free measure of implied volatility is still an open area of research. Future developments in this direction will also have important repercussions on the hedging practices for implied-volatility derivatives.

Pricing and hedging of variance derivatives is another active area of research. Variance swaps admit a simple replication strategy via static positions in call and put options on the underlying asset, similar to model-free implied volatility measures (e. g., [77,83]). In contrast, it is still an open area of research to determine the replication strategy for derivatives whose payoffs are non-linear function of realized variance, e. g., volatility swaps, which pay the square-root of realized variance, or call and put options on realized variance. [82] is an interesting paper in this direction.

Limited liability gives shareholders the option to default on the firm's debt obligation. As such, a debt claim has features similar to a short position in a put option. The pricing of corporate debt is therefore sensitive to the volatility of the firms' assets: higher volatility increases the probability of default and therefore reduces the price of debt and increases credit spreads. The insights and techniques developed in the SV literature could prove useful in credit risk modeling and applications (e. g., [179,248,260]).

The Use of Realized Volatility for Estimation of SV Models

Another promising line of research aims at extracting the information in RV measures for the estimation of dynamic asset pricing models. Early work along these lines includes Barndorff-Nielson and Shephard [51], who decompose RV into actual volatility and realized volatility error. They consider a state-space representation for the decomposition and apply the Kalmann filter to estimate different flavors of the SV model. Moreover, Bollerslev and Zhou [68] and Garcia et al. [156], build on the insights of Meddahi [210] to estimate SV diffusion models using conditional moments of integrated volatility. More recently, Todorov [252] generalizes the analysis for the presence of jumps.

Related, recent studies have started to use RV measures to test the implications of models previously estimated with lower-frequency data. Since RV gives empirical content to the latent quadratic variation process, this approach allows for a direct test of the model-implied restrictions on the latent volatility factor. Recent work along these lines includes Andersen and Benzoni [12], who use model-free RV measures to show that the volatility spanning condition embedded in some affine term structure models is violated in the US Treasury market. Christoffersen et al. [100] note that the Heston square-root SV model implies that the dynamics for the standard deviation process are conditionally Gaussian. They reject this condition by examining the distribution of the changes in the square-root RV measure for S&P 500 returns.

Volatility Risk Premium

More work is needed to better understand the link between asset return volatility and model risk premia. Also in this case, RV measures are a fruitful source of information to shed new light on the issue. Among the recent studies that pursue this venue is Bollerslev et al. [66], who exploit the moments of RV and option-implied volatility to gauge a measure of the volatility risk premium. Todorov [251] explores the variance risk premium dynamics using high-frequency S&P 500 index futures data and data on the VIX index. He finds the variance risk premium to vary significantly over time and to increase during periods of high volatility and immediately after big jumps in underlying returns. Carr and Wu [85] provide a broader analysis of the variance risk premium for five equity indices and 35 individual stocks. They find the premium to be large and negative for the indices while it is much smaller for the individual stocks. Further, they also find the premium to increase (in absolute value) with the level of volatility. Additional work on the volatility risk premium embedded in individual stock options is in Bakshi and Kapadia [36], Driessen et al. [123], and Duarte and Jones [126]. Other studies have examined the linkage between volatility risk premia and equity returns (e. g., [69]) and hedge-fund performance (e. g., [70]). New research is also examining the pricing of aggregate volatility risk in the cross-section of stock returns. For instance, Ang et al. [30] find that average returns are lower on stocks that have high sensitivities to innovations in aggregate volatility and high idiosyncratic volatility (see also the related work by Chen [90] Ang et al. [32], Bandi et al, Guo et al. [42]). This evidence is consistent with the findings of the empirical option pricing literature, which suggests that there is a negative risk premium for volatility risk. Intuitively, periods of high market volatility are associated to worsened investment opportunities and tend to coincide with negative stock market returns (the so-called leverage effect). As such, investors are willing to pay higher prices (i. e., accept lower expected returns) to hold stocks that do well in high-volatility conditions.

Determinants of Volatility

Finally, an important area of future research concerns the linkage between asset return volatility and economic uncertainty. Recent studies have proposed general equilibrium models that produce low-frequency fluctuations in conditional volatility, e. g., Campbell and Cochrane [80], Bansal and Yaron [47], McQueen and Vorkink [207], and Tauchen [246]. Related, Engle and Rangel [139] and Engle et al. [138] link macroeconomic variables and long-run volatility movements. It is still an open issue, however, to determine the process through which news about economic fundamentals are embedded into prices to generate high-frequency volatility fluctuations. Early research by Schwert [236] and Shiller [241] has concluded that the amplitude of the fluctuations in aggregate stock volatility is difficult to explain using simple models of stock valuation. Further, Schwert [236] notes that while aggregate leverage is significantly correlated with volatility, it explains a relatively small part of the movements in stock volatility. Moreover, he finds little evidence that macroeconomic volatility (measured by inflation and industrial production volatility) helps predict future asset return volatility. Model-free realized volatility measures are a useful tool to further investigate this issue. Recent work in this direction includes Andersen et al. [22] and Andersen and Bollerslev [17], who explore the linkage between news arrivals and exchange rates volatility, and Andersen and Benzoni [13], who investigate the determinants of bond yields volatility in the US Treasury market. Related, Balduzzi et al. [38] and Fleming and Remolona [146] study the reaction of trading volume, bid-ask spread, and price volatility to macroeconomic surprises in the US Treasury market, while Brandt and Kavajecz [74] and Pasquariello and Vega [222] focus instead on the price discovery process and explore the implications of order flow imbalances (excess buying or selling pressure) on day-to-day variation in yields.

Article Outline

Glossary

Adjacency matrix The *adjacency matrix* of a graph with N sites is an $N \times N$ matrix $[a_{ij}]$ with entries $a_{ij} = 1$ if i and j are linked, and $a_{ij} = 0$ otherwise. The adjacency matrix is symmetric ($a_{ij} = a_{ji}$) if the links in the graph are undirected.

Coupler link rules *Coupler rules* are local rules that act on pairs of *next-nearest sites* of a graph at time t to decide whether they should be linked at $t + 1$. The decision rules fall into one of three basic classes – totalistic (T), outer-totalistic (OT) or restricted-totalistic (RT) – but can be as varied as those for conventional cellular automata.

Decoupler link rules *Decoupler rules* are local rules that act on pairs of *linked sites* of a graph at time t to decide whether they should be unlinked at $t + 1$. As for coupler rules, the decision rules fall into one of three basic classes – totalistic (T), outer-totalistic (OT) or restricted-totalistic (RT) – but can be as varied as those for conventional cellular automata.

Degree The *degree* of a node (or site, *i*) of a graph is equal to the number of distinct nodes to which *i* is linked, and where the links are assumed to possess no directional information. In general graphs, the *in*-degree (= number of incoming links towards *i*) is distinguished from the *out*-degree (= number of outgoing links originating at *i*).

Effective dimension A quantity used to approximate the *dimensionality* of a graph. It is defined as the ratio between the average number of next-nearest neighbors to the average degree, both averaged over all nodes of the graph. The effective dimension equals the Euclidean dimension *d*, in cases where the graph is the familiar *d*-dimensional hypercubic lattice.

Graph A *graph* is a finite, nonempty set of nodes (referred to as "sites" throughout this article), together with (a possibly empty) set of edges (or links). The links may be either *directed* (in which case the edge from a site *i*, say, is directed away from *i* toward another site *j*, and is considered distinct from another directed edge originating at *j* and pointed toward *i*) or *undirected* (in which case if a link exists between sites *i* and *j* it carries no directional information).

Graph grammar *Graph grammars* (sometimes also referred to as *graph rewriting systems*) apply formal language theory to networks. Each language specifies the space of "valid structures", and the production (or "rewrite") rules by which given graphs may be transformed into other valid graphs.

Graph metric function The *graph metric function* defines the distance between any two nodes, *i* and *j*. It is equal to the length of the shortest path between *i* and *j*. If no path exists (such as when *i* and *j* are on two disconnected components of the same graph), the distance is assumed to be equal to ∞.

Graph-rewriting automata *Graph-rewriting automata* are generalized CA-like systems in which both (the number of) nodes and links are allowed to change.

Next-nearest neighbor Two sites *i* and *j* are *next-nearest neighbors* in a graph if (1) they are not directly linked (so that $a_{ij} = 0$; see *adjacency matrix*), and (2) there exists at least one other site *k* such that $k \notin \{i, j\}$, and *i* and *j* are both lined to *k*.

Random dynamics approximation The long-term behavior of structurally dynamic cellular automata may be approximated in certain cases (in which the structure and value configurations are both sufficiently random and uncorrelated) by a *random dynamics approximation*: values of sites are replaced by the probability p_σ of a site having value σ (and is assumed to be equal for all sites), and links between sites are replaced by the probability p_ℓ of being linked (and also assumed to be the same for all pairs of sites). The approximation often yields qualitatively correct predictions about how the real system evolves under a specific set of rules; for example, to predict whether one expects unbounded growth or that the lattice will eventually settle onto a low periodic state or simply decay.

Restricted totalistic rules *Restricted totalistic rules* are a generalized class of link rules (operating on pairs of sites, *i* and *j*), analogous to "outer totalistic" rules (that operate on site values) used in conventional CA. The local neighborhood around *i* and *j* is first partitioned into three sets: (1) the two sites, *i* and *j*; (2) sites connected to either *i* or *j*, but not both; and (3) sites connected to both *i* and *j*. The *restricted totalistic rule* is then completely defined by associating a specific action with each possible 3-tuple of site-value sums (where the individual components represent a unique sum in each of the three neighborhoods).

Structurally dynamic cellular automata *Structurally dynamic cellular automata* are generalizations of conventional cellular automata models in which the underlying lattice structure is dynamically coupled to the local site-value configurations.

SDCA model hierarchy The *SDCA model hierarchy* is a set of eight related structurally dynamic cellular automata models, defined explicitly for studying their formal computational capabilities. The hierarchy is ordered (from lowest to highest level) according to their relative computational strength. For example, the SDCA model at the top of the hierarchy is capable of simulating a conventional CA with a speedup factor of two.

Definition of the Subject

Structurally dynamic cellular automata (abbreviated, SDCA) are a generalized class of CA in which the topological structure of the (usually quiescent) underlying lattice is dynamically coupled to the local site value configuration. The coupling is defined to treat *geometry* and *value configurations* on an approximately equal footing: the lattice structure is altered locally as a function of individual site neighborhood value-states and geometries, while the underlying local topology supports site-value evolution precisely as in conventional nearest-neighbor CA models defined on random lattices.

SDCA provide a dynamical framework for a CA-like analysis of the generation, transmission and interaction of topological disturbances in a lattice. Moreover, they provide a natural testbed for studying self organized geometry; by which we mean true structural evolution, and not merely space-time patterns of value configurations that may be *interpreted* geometrically (but are really just "bits" of information overlayed on top of an otherwise static background lattice).

Introduction

SDCA were formally introduced in 1986 as part of a physics doctoral dissertation by Ilachinski [31], and developed further by Ilachinski and Halpern [29,30], Halpern [21,23], Halpern and Caltagirone [22], Majercik [39], and Alonso-Sanz and Martín [6,7,8]; in their original incarnation [28], and at least two subsequent papers [22,61], SDCA were called *topological automata*. Pedagogical discussions appear in Adamatzky [1] and Ilachinski [32]. Extensions of the basic SDCA model (all discussed in this article) include the addition of probabilistic rules, memory and reversibility.

Applications include the simulation of crystal growth [36], the study of pattern formation of random cellular structures [66], modeling synaptic plasticity in neural network models [19], phase transitions in chemical systems [62], chemical self-assembly [26], and gene-regulatory networks [22]. Majercik [39] has studied SDCA as generalized models of computation, and describes a CA-universal SDCA that can simulate any conventional CA of the same dimension.

More recently, O'Sullivan [56] and Saidani [63,64] have used graph-based CA models similar to SDCA to study urban dynamics and emergent behaviors of self-reconfigurable robots, respectively. Tomita et al. [67,68,69,70,71] have introduced *graph-rewriting automata* in which both links and (the number of) nodes are allowed to change; and show that these systems are capable of both self-replication and Turing universality (among with many other emergent behaviors). Since SDCA provide the basic formalism for describing locally induced topological changes within arbitrary graphs, they are a potentially powerful general tool for studying complex adaptive networks, such as communication and social networks [6]. The *concept* behind SDCA has also been used as a foundation for philosophical musings about computationally emergent artificiality [49].

More ambitious applications of SDCA encroach on fundamental physics. Because SDCA are inherently self-modifying systems – in which physical events are not just dynamically coupled to, but are an integral part of the spatio-temporal arena on which their transformations are defined – they are a potentially powerful methodological and ontological tool for exploring discrete pre-geometric theories of space-time [42]. Just as "value structure" solitons are ubiquitous in conventional CA models [32,74], "link structure" solitons might emerge in SDCA; physical particles would, in such a scheme, be viewed as geometrodynamic disturbances propagating within a dynamic lattice. Three SDCA-like theories of pregeometry have recently been proposed in which space-time is a self-organized emergent construct: Hillman [27], Nowotny and Requardt [55] and Wolfram [75].

Finally, we briefly comment on ostensible overlaps between SDCA and four other related fields of study: (1) *Lindenmeyer* (or L-) *systems*, (2) *graph grammars*, (3) *random graphs* (abbreviated, RG), and (4) *dynamic network analysis* (abbreviated, DNA). L-systems [57] are generalized CA systems in which the number of sites can grow with time, and consist of recursive rules for rewriting strings of symbols. If interpreted graphically, abstract symbol strings can be used to model growth processes of plants and evolving morphology of physical organisms. Graph grammars [20,35] apply formal language theory to networks, and consist of production rules that define the set of "valid structures" in a given graph language. The study of RG [15] was introduced by Erdos and Renyi in the late 1950s [16], and is a mathematical framework for exploring the general topological structures of computational systems and the behavior of certain random dynamical systems. Like SDCA, RG describes evolving graphs, but the dynamics are global and random. DNA [41,50] is an emerging field that fuses traditional social network theory with statistical analysis and modeling; part of its charter is to explore general properties of network generation and evolution.

While, conceptually speaking, there is a prima facie relationship between SDCA and all four fields of study, the elucidation of a more precise nature of the relationship between SDCA and these other systems awaits a future study. (The relationship appears particularly strong between SDCA and a generalized L-system called the *graph development system* (abbreviated, GDS), introduced by Doi [14], but not developed further since its original conception. Using incidence matrices to represent arbitrary topologies, GDS is essentially a grammar by which submatrices of the whole matrix are rewritten to describe topological changes. SDCA also formally falls under the broader rubrics of DNA and RG; however, there is no explicit reference to SDCA in the current literature of either field.)

The Basic Model

Conventional CA are defined on fixed, and typically regular, lattices (one-dimensional lines, two-dimensional Euclidean or hexagonal grids, etc.), the sites of which are populated with discrete-valued dynamic elements ($\equiv \sigma_i \in \{0, 1, \dots, k\}$, where i labels a particular site on the lattice) that evolve according to local transition functions, $f: \sigma_i \rightarrow \sigma_i'$. We emphasize that the dynamics of conventional CA are confined to the temporal evolution of the σ_is.

SDCA generalize conventional CA in two ways: (1) they relax the assumption that the underlying lattice is uniform, allowing the local site ↔ site connectivity pattern to vary throughout the lattice; and (2) they allow *both* the set $\{\sigma_i\}$ *and* the lattice to evolve according to local transition rules. The most obvious – also the most dramatic – conceptual change this entails over the dynamics of conventional CA, is that the meaning of "local" itself changes as a function of how the SDCA system evolves: previously far separated sites may become neighbors; and sites that are local at time t may become far separated at some later time, t'.

To properly define SDCA, we first generalize regular lattices to mathematical graphs $\equiv G$ () possessing arbitrary topology. Assuming G has N lattice sites, and that G is (for now) an *undirected* graph (meaning that none of G's links carry directional information), G is completely defined by the N-by-N *adjacency* matrix, ℓ_{ij}:

$$\ell_{ij} = \begin{cases} 1 & \text{if } i \text{ and } j \text{ are linked;} \\ 0 & \text{otherwise.} \end{cases} \qquad (1)$$

Using the graph metric function,

$$D_{ij} = \underset{\text{Paths}, P_{ij}}{\text{Minimum}} \left[\text{\#links}, l_{rs} \,|\, \{r, s\} \in P_{ij} \right], \qquad (2)$$

we can write a general r-neighborhood CA *value*-transition rule 'f' (which will from now on refer generically to as a σ-rule) in the form

$$\sigma_i^{t+1} = f\left[\{\sigma_j^t\} | j \in S_r^G(i) \right], \qquad (3)$$

where $S_r^G(i) = \{j | D_{ij} \leq r\}$ is the radius-r *graph sphere* about the site i. In words, the value of σ_i^{t+1} is some function, f, of the values σ_j^t in radius r graph sphere around the site i. With this distance measure, G becomes a *discrete metric space*. If G is a one-dimensional line, and $r = 1$, then $S_r^G(i) = \{i-1, i, i+1\}$; i. e., it is equal to the conventional three site local neighborhood of elementary CA.

We now formally extend a conventional CA's dynamic arena – limited to the values $\sigma_i^t \in \{0, 1, \dots, k-1\}$, $i = 1, \dots, N$ – to one that includes the components of the underlying lattice's adjacency matrix:

$$\begin{cases} \sigma^{t+1} = F_\sigma[\{\sigma^t\}, \{\ell^t\}] \\ \ell^{t+1} = F_\ell[\{\sigma^t\}, \{\ell^t\}] \end{cases}, \qquad (4)$$

where F_σ and F_ℓ are some functions (to be defined explicitly below) that explicitly couple the changing *value* states and *geometries*. The complete system at time t is specified by the state-vector

$$|G\rangle_t = |\sigma_1^t, \dots, \sigma_N^t;\ \{\ell_{ij}^t\}\rangle\,. \qquad (5)$$

The time-evolution of $|G\rangle$ proceeds according to the following transition rules: (i) σ-rules of the general form given above and familiar from *CA* simulations and (ii) ℓ-rules, which are divided into site *couplers*, linking previously unconnected vertices and site *decouplers*, which disconnect linked points. Because the topology can be altered only by either a deletion of *existing links* or an addition of links between pairs of vertices 'i' and 'j' with $D_{ij} = 2$, the dynamics is *strictly local*.

To be more precise, we first restrict the general σ-rule F_1 to (maximally symmetric) *totalistic* (**T**) and *outer-totalistic* (**OT**) type. Since the underlying lattice is a fully dynamic object, $|G\rangle$ will, in general, tend towards having a complex local geometry with an unspecified local *directionality*. The most general rules which can therefore be applied are those which are completely invariant under all rotation and reflection symmetry transformations on local neighborhoods. **T** (**OT**) σ-rules are then specified by listing particular *sums* $\{\alpha\}$ (*outer-sums* $\{\alpha_0\}, \{\alpha_1\}$ corresponding to center site values '0' and '1' respectively) for which the value of the center site becomes '1'. Formally,

$$\sigma_i^{t+1} = \phi_{\{\alpha\}} \left(\sum_j \ell_{ij}^t \sigma_j^t, \sigma_i^t \right), \qquad (6)$$

where

$$\phi_{\{\alpha\}}(x, a) = \begin{cases} \sum_\alpha \delta(x + a, \alpha) & \longleftrightarrow \mathbf{T} \\ a \sum_{\alpha_1} \delta(x, \alpha_1) + (1 - a) \sum_{\alpha_0} \delta(x, \alpha_0) & \longleftrightarrow \mathbf{OT}\,, \end{cases} \qquad (7)$$

and $\delta(x, y)$ is the *Kronecker* delta. Note that $\sum_j \ell_{ij}^t \sigma_j^t$ sums the values of all sites 'j' linked to 'i' at time 't'. The action on the state $|G\rangle$ is represented by

$$\widehat{\phi}^i_{\{\alpha\}} |\sigma\rangle_t = \left| \sigma_1^t, \dots, \sigma_i^{t+1} = \phi_{\{\alpha\}} \left(\sum \ell_{ij}^t \sigma_j^t, \sigma_i^t \right), \dots, \sigma_N^t \right\rangle, \qquad (8)$$

where we distinguish the *operator* $\widehat{\phi}^i$ acting on the global value state from the actual local transition *function* ϕ which transforms each site value.

Link Rules

Local geometry altering rules are constructed by direct analogy: for any two selected sites i and j we restrict attention to site values of vertices contained within a 1-*sphere* of either site; that is, to all $k \in S_1(i,j) = S_1(i) \cup S_1(j)$. Link operators, whose action on the state is represented by:

$$\begin{aligned} \textit{decouplers:}\quad & \widehat{\psi}^{ij}_{\{\beta\}} \left|\ell^t_{ij}\right\rangle = \left|\ell^t_{11}, \ldots, \ell^{t+1}_{ij} = \psi^{ij}, \ldots, \ell^t_{NN}\right\rangle \\ \textit{couplers:}\quad & \widehat{\omega}^{ij}_{\{\varepsilon\}} \left|\ell^t_{ij}\right\rangle = \left|\ell^t_{11}, \ldots, \ell^{t+1}_{ij} = \omega^{ij}, \ldots, \ell^t_{NN}\right\rangle , \end{aligned} \tag{9}$$

either *link* or *unlink* two sites '*i*' and '*j*' depending on whether the actual sum of values in $S_1(i,j)$ matches any of those given in the $\{\beta\}$ or $\{\varepsilon\}$ lists, which completely define *decouplers* and *couplers*, respectively.

In order to construct classes of rules analogous to the two types of σ-rules defined above, we partition the local neighborhood into 3 disjoint sets (see Fig. 1): $S_1(i,j) = V_{ij} \cup A_{ij} \cup B_{ij}$, where

$$\begin{cases} \vee_{ij} = \{i,j\}, \\ A_{ij} = \{k | k \in C_1(i) \cap C_1(j)\}, \text{ where } C_1(i) = S_1(i) - \{i\}, \\ B_{ij} = S_1(i) \cup S_1(j) - \vee_{ij} - A_{ij} . \end{cases} \tag{10}$$

The action of link operators is then conveniently expressed as a function of the sums within the individual partitions. Defining $\nu_{ij} = \sigma_i + \sigma_j$, $a_{ij} = \sum_{k \in A_{ij}} \sigma_k$, and $b_{ij} = \sum_{k \in B_{ij}} \sigma_k$, we get *decouplers*, $\psi^{ij}_{\{\beta\}} = \psi^{ij}_{\{\beta\}}(\nu_{ij}, a_{ij}, b_{ij})$, where

$$\psi^{ij}_{\{\beta\}}(x,y,z) = \begin{cases} \{1 - \sum_k \delta(x+y+z, \beta_k)\}\ell_{ij} & \leftrightarrow \mathbf{T} \\ \{1 - \sum_k \delta(x, \beta_{1,k})\delta(y+z, \beta_{2,k})\}\ell_{ij} & \leftrightarrow \mathbf{OT} \\ \{1 - \sum_k \delta(x, \beta_{1,k})\delta(y, \beta_{2,k})\delta(z, \beta_{3,k})\}\ell_{ij} & \leftrightarrow \mathbf{RT} , \end{cases} \tag{11}$$

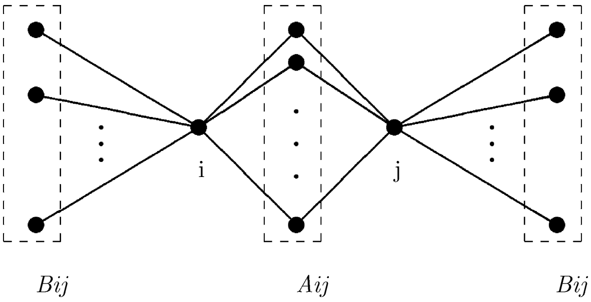
and *couplers*, $\omega^{ij}_{\{\varepsilon\}} = \omega^{ij}_{\{\varepsilon\}}(\nu_{ij}, a_{ij}, b_{ij})$, where

$$\omega^{ij}_{\{\varepsilon\}}(x,y,z) = \begin{cases} \delta(D_{ij}, 2) \sum_k \delta(x+y+z, \varepsilon_k) & \leftrightarrow \mathbf{T} \\ \delta(D_{ij}, 2) \sum_k \delta(x, \varepsilon_{1,k})\delta(y+z, \varepsilon_{2,k}) & \leftrightarrow \mathbf{OT} \\ \delta(D_{ij}, 2) \sum_k \delta(x, \varepsilon_{1,k})\delta(y, \varepsilon_{2,k})\delta(z, \varepsilon_{3,k}) & \leftrightarrow \mathbf{RT} . \end{cases} \tag{12}$$

In the above expressions, **RT** stands for *restricted totalistic* rules which maximally subdivide the local neighborhood. The inclusion of an ℓ_{ij} in the expressions for ψ assures that only those sites already *linked* can be decoupled and the $\delta(D_{ij}, 2)$ in the equations defining ω are put in to make sure that only sites separated by distance = 2 may be dynamically coupled.

The three type-specific *sums* appearing above are indexed with the following conventions:

- **T** rules are defined by the '*k*' overall sums of values in $S_1(i,j)$ for which the particular action is to be taken. For example, define 'ψ' by *unlinking* '*i*' and '*j*' if the total sum = 1 (= β_1), 3 (= β_2) or 5 (= β_3). Equation (11) then states that $\ell^{n+1}_{ij} = 0$ if and only if $\ell^n_{ij} = 1$ and $\nu^n_{ij} + a^n_{ij} + b^n_{ij} \in \{1,3,5\}$.
- **OT** rules are specified by giving '*k*' 2-tuples $(\beta_{1,k}, \beta_{2,k})$, and $(\varepsilon_{1,k}, \varepsilon_{2,k})$, where $\{1,k\}$ labels the sum '$\sigma_i + \sigma_j$' and $\{2,k\}$ labels the corresponding *outer sum* $= \sum_{s \in S_1(i,j) - \{i,j\}} \sigma_s$. For example, *link* '*i*' and '*j*' if $\sigma_i + \sigma_j = 0$ and outer sum = $\{3,4\}$, so that 'ω' is defined by listing the two 2-tuples $(\varepsilon_{1,1}0, \varepsilon_{2,1} = 3)$ and $(\varepsilon_{1,2} = 0, \varepsilon_{2,2} = 4)$.
- **RT** rules are completely specified by giving the '*k*' 3-tuples of values $(x\sigma_i + \sigma_j, y = \text{sum in } A, z = \text{sum in } B)$, for which the link operation between '*i*' and '*j*' is to be performed. For example, define 'ψ' by *unlinking* '*i*' and '*j*' for the following values of partitioned sums: (0, 0, 1), (0, 0, 2), (0, 1, 1), (1, 1, 1); we then have that $(\beta_{1,1} = 0, \beta_{2,1} = 0, \beta_{3,1} = 1)$, $(\beta_{1,2} = 0, \beta_{2,2} =$



Structurally Dynamic Cellular Automata, Figure 1
Neighborhood partitioning. In the same way as *outer* sites can be considered separately for σ-transitions, we may, for topology transitions, distinguish between those sites belonging to *both* i and j (∈ A_{ij}) and those belonging to *one* of the two sites but not both (∈ B_{ij}). In this way we obtain the analogous *totalistic* (T), *outer-totalistic* (OT), and an additional type called *restricted totalistic* (RT)

$0, \beta_{3,2} = 2)$, $(\beta_{1,3} = 0, \beta_{2,3} = 1, \beta_{3,3} = 1)$, and $(\beta_{1,4} = 0, \beta_{2,4} = 1, \beta_{3,4} = 1)$.

Global transition operators are obtained by applying individual σ- and ℓ- operators to all *sites* and *site-pairs* in the graph G:

$$\begin{cases} \widehat{\Phi}_{\{\alpha\}}\,|\sigma\rangle = \prod_i \widehat{\phi}^{\,i}_{\{\alpha\}}\,|\sigma\rangle \ , \\ \widehat{\Psi}_{\{\beta\}}\,|\ell\rangle = \prod_{n\langle ij\rangle} \widehat{\psi}^{\,ij}_{\{\beta\}}\,|\ell\rangle \ , \\ \widehat{\Omega}_{\{\varepsilon\}}\,|\ell\rangle = \prod_{nn\langle ij\rangle} \widehat{\omega}^{\,ij}_{\{\varepsilon\}}\,|\ell\rangle \ , \end{cases} \tag{13}$$

where the products for $\widehat{\Psi}$ and $\widehat{\Omega}$ need to be taken only over *nearest* and *next nearest* pairs respectively. Given the full *value-topology* transition rule Γ, defined by

$$|G\rangle_{t+1} = (\widehat{\Omega}\widehat{\Psi}\widehat{\Phi})|G\rangle_t = \Gamma|G\rangle_t \ , \tag{14}$$

the fundamental problem is to understand the generic behavior of accessible graphs-G emerging from all possible initial structures and value configurations. We emphasize that the lattice *fully* participates in the dynamics and that, in general, no embedding is implied – it is the abstract *connectivity* itself whose evolution we are attempting to trace.

An Example

The application of the rather cumbersome expressions defining transition rules is in practice extremely straightforward, as we demonstrate with the following example: Consider a graph G defined as a (5×5) lattice with some distribution of values $\sigma = 1$ at time '$t = 1$' (see Fig. 2). We are interested in one *global* update of the system $|G\rangle_{t=1} \xrightarrow{\Gamma} |G\rangle_{t=2}$ with rules specified by

$$\begin{array}{l} \text{(value)} \\[1em] \text{(topology)} \\ \end{array} \left\{ \begin{array}{l} \Phi_{\{\alpha\}} : \{\alpha\}_{\mathbf{T}} = \{\alpha_1 = 1, \alpha_2 = 3, \alpha_3 = 5\} \ , \\ \Psi_{\{\beta\}} : \{\beta\}_{\mathbf{OT}} = \left\{ \begin{array}{l} (\beta_{1,1} = 1, \beta_{2,1} = 3) \\ (\beta_{1,2} = 1, \beta_{2,2} = 4) \end{array} \right\} , \\ \Omega_{\{\varepsilon\}} : \{\varepsilon\}_{\mathbf{OT}} = \{\varepsilon_{1,1} = 1, \varepsilon_{2,1} = 3\} \ . \end{array} \right. \tag{15}$$

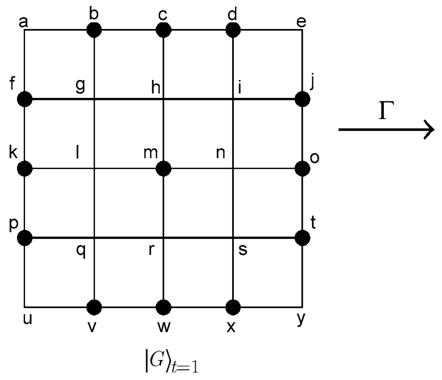
We evolve the system by systematically sweeping through all *sites*, *linked* pairs, and *next-nearest neighbors*:

1. *All Sites:* … setting $\sigma_i = 1$ only at those 'i' for which the sum of the values at 'i' and its neighbors is equal to '2' at $t = 1$. By "neighbors" of any point 'i' we will always mean the set of vertices linked to 'i': (a, b), (h, m) and (x, y), for example, are all neighbors at $t = 1$. Writing out a few value-changing terms explicitly, we find that

$$\begin{aligned} \sigma_c^{t=2} &= \phi\left(\sigma_b^{t=1} + \sigma_c^{t=1} + \sigma_d^{t=1} + \sigma_h^{t=1}\right) \\ &= \phi(3) = 1, \quad \text{and} \\ \sigma_b^{t=2} &= \phi\left(\sigma_a^{t=1} + \sigma_b^{t=1} + \sigma_c^{t=1} + \sigma_g^{t=1}\right) \\ &= \phi(2) = 0. \end{aligned} \tag{16}$$

2. *All linked pairs of sites 'i' and 'j':* … removing those links only if the 2-tuple $(\alpha, \beta) \in \{(1, 3), (1, 4)$, where $\alpha = \sigma_i + \sigma_j$ and 'β' is the sum of values of the neighbors of 'i' and 'j' at $t = 1$. For the points 'c' and 'h', for example, we have $(\alpha, \beta) = (1, 3)$, so that the link ℓ_{ch} is no longer present in $|G\rangle_{t=2}$:

$$\begin{aligned} \ell_{ch}^{t=2} = \psi\Big(&\sigma_c^{t=1} + \sigma_h^{t=1}, \sigma_b^{t=1} + \sigma_d^{t=1} + \sigma_g^{t=1} \\ &+ \sigma_i^{t=1} + \sigma_m^{t=1}\Big)\, \ell_{ch}^{t=1} \\ = \psi&(1, 3)(1) = 0 \,. \end{aligned} \tag{17}$$



Structurally Dynamic Cellular Automata, Figure 2

Sample dynamic update of a (5 × 5) lattice from $t = 1$ to $t = 2$, obeying a T-type σ-rule with $\sigma \to \sigma'$ for local sums = 1, 3, 5 (i. e. $\alpha \in \{1, 3, 5\}$), and OT-type ℓ-rules: (i) *link* for $\{\varepsilon_{1,1} = 1, \varepsilon_{2,1} = 3\}$ and (ii) *unlink* for $\{\beta_{1,1} = 1, \beta_{2,1} = 3\}$ and $\{\beta_{1,2} = 1, \beta_{2,2} = 4\}$. *Solid* sites indicate that $\sigma = 1$

3. *All next-nearest neighbors 'i' and 'j': …* linking them only if the 2-tuple $(\alpha, \beta) = \{(1, 3)\}$. By "next-nearest neighbor" we mean those pairs which are themselves unlinked but which share at least one other linked neighbor: (a, g), (h, r) and (w, y), for example, are all next-nearest neighbors at $t = 1$. For 'c' and 'g' we find

$$\begin{aligned}\ell_{cg}^{t=2} &= \omega\Big(\sigma_c^{t=1} + \sigma_g^{t=1}, \sigma_b^{t=1} + \sigma_d^{t=1} + \sigma_f^{t=1} \\ &\qquad + \sigma_h^{t=1} + \sigma_l^{t=1}\Big)\,\delta(D_{cg}, 2) \\ &= \omega(1, 3)(1) = 1\,. \end{aligned} \tag{18}$$

Notice that although $\ell_{dn}^{t=1} = 0 \to \ell_{dn}^{t=2} = 1$, it is hidden by overlap with the remaining links $\ell_{di}^{t=2} = 1$ and $\ell_{in}^{t=2} = 1$. For this reason, not all link changes can always be observed directly in the following figures.

Other sites and links are updated in precisely the same manner. Had the link-rules been of **T**-type, only one sum would have to be considered: the sum of the values of the points in question along with their neighbors' values. Had they been, instead, of **RT**-type, three sums would have to be considered: the sum of the values of the sites in question, the sum of the values of their common neighbors (neighborhood A in Fig. 1) and the sum of the values of the points that are neighbors of one of the considered points, but not of the other (neighborhood B in Fig. 1). The final state $|G\rangle_{t=2}$ emerges after the above process has been applied concurrently to all pairs, neighbors and next-nearest neighbors in $|G\rangle_{t=1}$.

Comments

We conclude this section by making a few important general comments:

Comment 1. As defined above, Γ consists of three operators acting simultaneously on the state $|G\rangle$. More generally, one may prescribe any of 10 possible time-orderings to the operators Ω, Ψ and Φ. That is, specify certain intermediate state dependencies, so that, for example $\Gamma_1|G\rangle \equiv (\Omega\Psi)(\Phi|G\rangle)$ would in general be expected to yield results different from, say, $\Gamma_2|G\rangle \equiv \Omega(\Phi(\Psi|G\rangle))$. While we will be solely concerned with the synchronous time ordering defined above, we do not expect the qualitative results to depend critically on this choice.

Comment 2. A given rule Γ is completely defined by the set of sums $\{\alpha\}$, $\{\beta\}$ and $\{\varepsilon\}$. Alternatively, we can conveniently summarize a chosen transition rule by its vector-code $\vec{C} = (c[\phi], c[\psi], c[\omega])_{a,b}$, where

$$\begin{aligned} c[\phi] &= \begin{cases} \sum_\alpha 2^\alpha & \leftrightarrow \mathbf{T} \\ \sum_{\alpha_0} 2^{2\alpha_0} + \sum_{\alpha_1} 2^{(2\alpha_1+1)} & \leftrightarrow \mathbf{OT} \end{cases} \\ c[\psi] &= \begin{cases} \sum_k 2^{\beta_k} & \leftrightarrow \mathbf{T} \\ \sum_k 2^{3\beta_{2,k}+\beta_{1,k}} & \leftrightarrow \mathbf{OT} \\ \sum_k 2^{3(\beta_{2,k}+a\beta_{3,k})+\beta_{1,k}} & \leftrightarrow \mathbf{RT} \end{cases} \\ c[\omega] &= \begin{cases} \sum_k 2^{\varepsilon_k} & \leftrightarrow \mathbf{T} \\ \sum_k 2^{3\varepsilon_{2,k}+\varepsilon_{1,k}} & \leftrightarrow \mathbf{OT} \\ \sum_k 2^{3(\varepsilon_{2,k}+b\varepsilon_{3,k})+\varepsilon_{1,k}} & \leftrightarrow \mathbf{RT} \end{cases} \end{aligned} \tag{19}$$

where $a = \max\{\beta_{2,k}\} + 1$, $b = \max\{\varepsilon_{2,k}\} + 1$, and must be specified only for **RT**-type topology rules. The Γ appearing in the above example, therefore, can be summarized by $c[\phi] = 42$, $c[\psi] = 2^{3(3)+1} = 1024$ and $c[\omega] = 2^{3(4)+1} + 2^{3(3)+1} = 9216$. Note that '$\Psi$' and '$\Omega$' are chosen always to be of the same type.

Comment 3. Computer simulations of these systems require that some measures be taken to prevent possible memory overflows, such as would happen in cases either of pure coupling, where links are continually added and none deleted, or in isolated regions of a graph where for a few sites more neighbors are added than are allowed by memory. We thus introduce *working* link transition rules

$$\tilde{\psi}^{ij} \equiv \begin{cases} \psi^{ij} & \longleftrightarrow d_i' \text{ or } d_j' > \delta \equiv d_{\min} \\ 1 & \longleftrightarrow \text{else}\,, \end{cases} \tag{20}$$

$$\tilde{\omega}^{ij} \equiv \begin{cases} \omega^{ij} & \longleftrightarrow d_i' \text{ or } d_j' < \Delta \equiv d_{\max} \\ 0 & \longleftrightarrow \text{else}\,, \end{cases} \tag{21}$$

where $d_i =$ degree(i) (i. e. number of neighbors of i). In words: make a sweep of the lattice, temporarily storing the candidates to *add* and *delete* for each point. If, for any point i, the updated degree is greater than δ then proceed with deleting the stored deletion-candidates, otherwise do not delete; similarly, provided that the updated degree is less than Δ proceed with addition. Thus, it is sufficient that *one* of two points allow a dynamic link change between them for that change to be enacted. In the following, the complete constrained dynamics will be quoted as $\vec{C}_{(a,b)}^{[\delta,\Delta]}$. If constraints play no role in the actual evolution of specific examples, they will be left out of the definition.

Comment 4. Because each dynamic update involves three separate types of processing, the number of possible rules is extraordinarily large (see Table 1). Unlike pure σ-transitions, however, the fraction of the total number which yield interesting behavior (i. e. neither immediately explosive, where the number of links increases with-

Structurally Dynamic Cellular Automata, Table 1

Numbers of possible rules for each of the three types of transition rules. $d =$ *maximum allowable degree* and $a =$ *maximum sum to be used from partition* A_{ij}*. Example:* for $d = 5$, we have $N_\phi = 4096$, $N_\psi = 2^{24} \sim 2 \times 10^7$ and $N_\omega = 2^{21} \sim 2 \times 10^6$. We thus have $N_T = N_\phi N_\psi N_\omega \sim 10^{17}$ possible type OT Γ s

Rule type	ϕ	ψ	ω
T	2^{d+1}	2^{2d}	2^{2d-1}
OT	2^{2d+2}	$2^{6(d-1)}$	$2^{3(2d-3)}$
RT	—	$2^{3(a+1)(2d-1)}$	$2^{3(a+1)(2d+1)}$

out bound, nor immediately degenerative, where an initial graph rapidly dwindles to a few isolated links) appears to be manageably smaller.

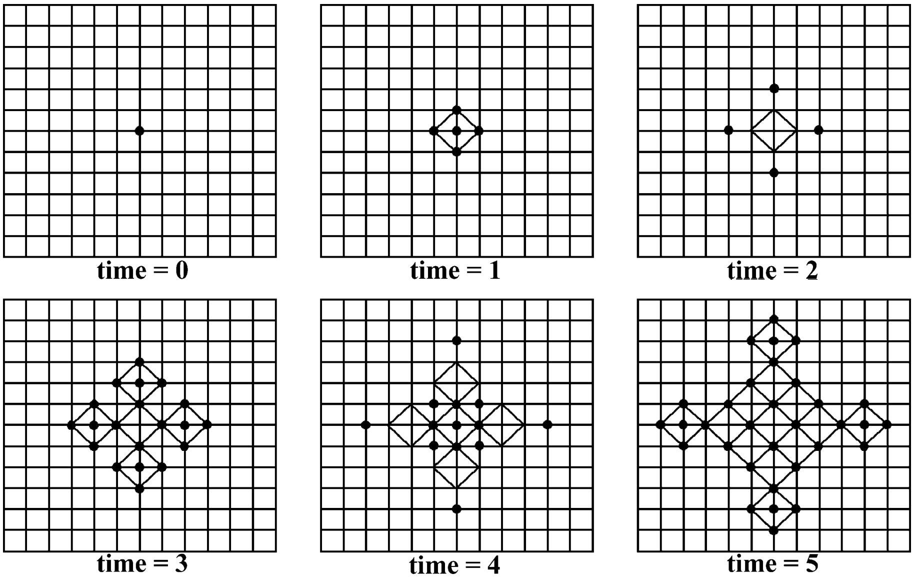
Comment 5. Although it is the intrinsic geometrical patterning whose generic behavioral properties we are trying to deduce, one may approach SDCA from an alternative point of view: maintain the emphasis on unraveling the value configurational behavior, and interpret the presence of $[\Psi, \Omega]$ as background operators inducing nonlocal spatial connectivities. Whereas the systems defined above are completely abstract entities, in that locality is strictly defined by the link structure, the alternative scheme would be to embed the discrete networks in some specified manifold, and to study the effects of dynamically allocated nonlocal communication channels.

Emerging Patterns and Behaviors

Consider patterns that emerge from simple value seeds starting from ordered two dimensional Euclidean lattices. A single non-zero site may represent a small local disturbance that then propagates outward, restructuring the lattice. With appropriately chosen Γs one can induce a rich spectrum of different time evolutions only slightly perturbed by very few concurrent link changes to ones in which the initial geometry becomes radically altered. (The graphical representation of evolving one dimensional systems, in which link additions must be shown as *arcs* to avoid overlap with existing links, is needlessly confusing and is not considered.)

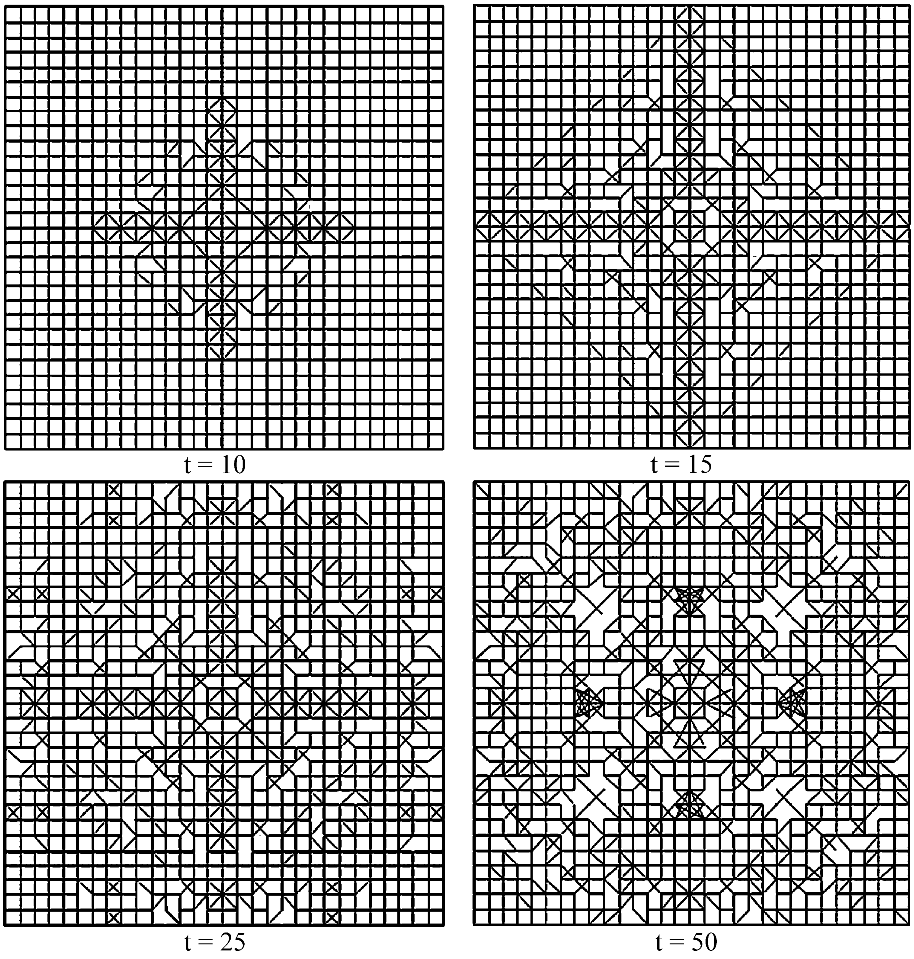
Figure 3 shows the first five iterations of a system starting from a four neighbor lattice with a single non-zero site at its center, the link structure is given explicitly and the solid circles represent sites with $\sigma = 1$. Notice how the link additions *follow* the emerging corrugated boundary surface of the value configuration. Remember that link additions are more than passive markers indicating particular correlations between local value configurations and structure; their presence directly influences all subsequent value development in their immediate vicinity.

Figure 4 (in which site values are suppressed for clarity) shows the continued development of this system. Though boundary effects begin to appear by $t = 25$, the



Structurally Dynamic Cellular Automata, Figure 3

First five iterations of an SDCA system starting from a 4-neighbor Euclidean lattice seeded with a single non-zero site at the center. The global transition rule Γ consists of T σ-rule and RT ℓ-rules: $\vec{C} = (26, 69648, 32904)_{[3,3]}$ (see text for rule definitions and code). Solid sites have $\sigma = 1$



Structurally Dynamic Cellular Automata, Figure 4
Several further time frames in the structural evolution of the same system shown in the preceding figure. The values have been suppressed for clarity. The boundaries of the original lattice do not extend beyond the region shown so that the development is strictly confined to a 31 × 31 graph

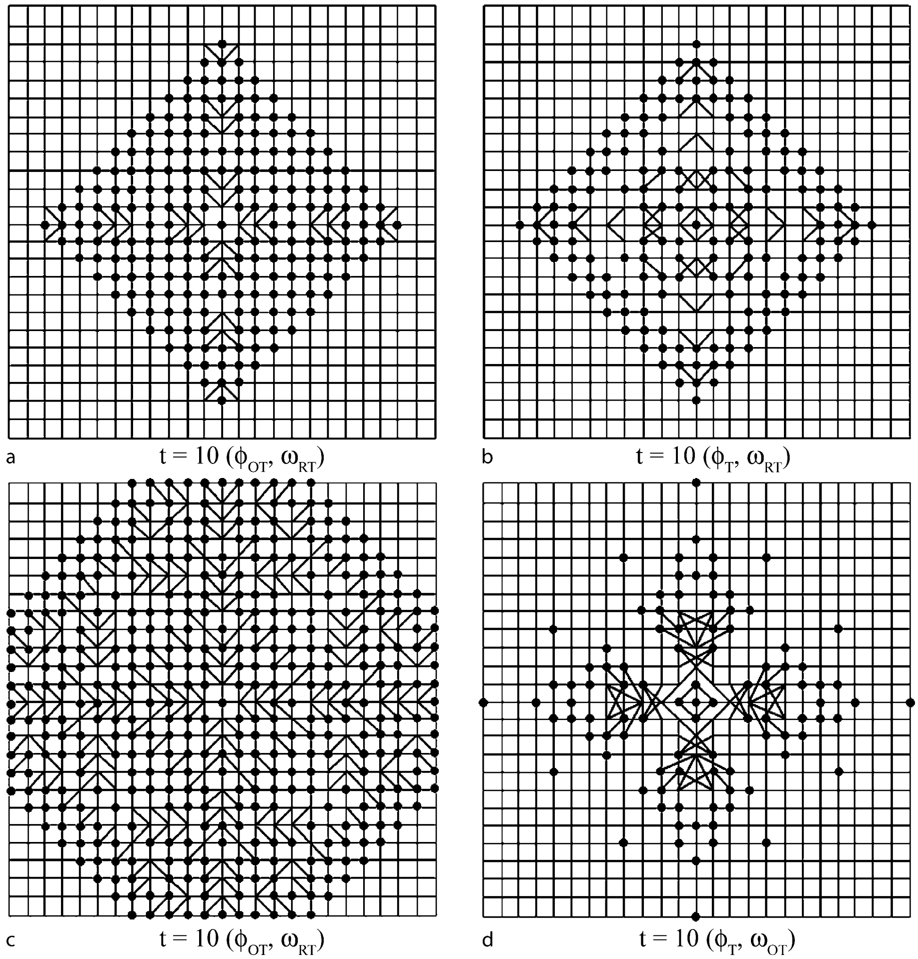
characteristic manner in which this particular Γ restructures the initial graph is clear:

- There is a high degree of geometrical organization (the symmetry of the initial state is trivially preserved by the totally symmetric Γ).
- The lattice remains connected.
- The distribution of link changes made throughout the lattice remains fairly uniform (i. e. there is an approximate uniformity in the probability of appearance of particular local value states which induce a structural change.
- Link-lengths do not get arbitrarily large.

The last point implies that for a system embedded in the plane, communication channels remain approximately local. The global pattern emerges as a consequence of local ordering. On the other hand, Γs for which link-lengths get arbitrarily large are also easy to find.

Some other varieties of behavior are shown in Figs. 5 and 6. Figures 5a and b are representative of the class of ℓ-rules that only mildly perturb the underlying lattice (and for which σ states do not differ much from their conventional CA cousins). Other rules, of course, may have a stronger effect on the lattice, giving rise to associated σ states bearing little or no resemblance to their conventional CA counterparts.

Figure 5c shows an example of a link rule that *accelerates* the outward propagation of the value configuration. Compare the diameter of this pattern to that in the earlier figures, both shown at equal times. The outwardly oriented



a
t = 10 (ϕ_{OT}, ω_{RT})
b
t = 10 (ϕ_{T}, ω_{RT})
c
t = 10 (ϕ_{OT}, ω_{RT})
d
t = 10 (ϕ_{T}, ω_{OT})

Structurally Dynamic Cellular Automata, Figure 5

Snapshot views of four typical developing states starting from a single non-zero site at the center of a 4-neighbor graph. Γs are as follows: a OT $c[\phi] = 1022$ and RT coupler $c[\omega] = 16$, $b = 1$; b T $c[\phi] = 22$ and RT coupler $c[\omega] = 32$, $b = 2$; c OT $c[\phi] = 1022$ and RT coupler $c[\omega] = 8$, $b = 1$; d T σ- and OT ℓ-rules $\vec{C} = (682, 19634061312, 133120)_{[2,8]}$

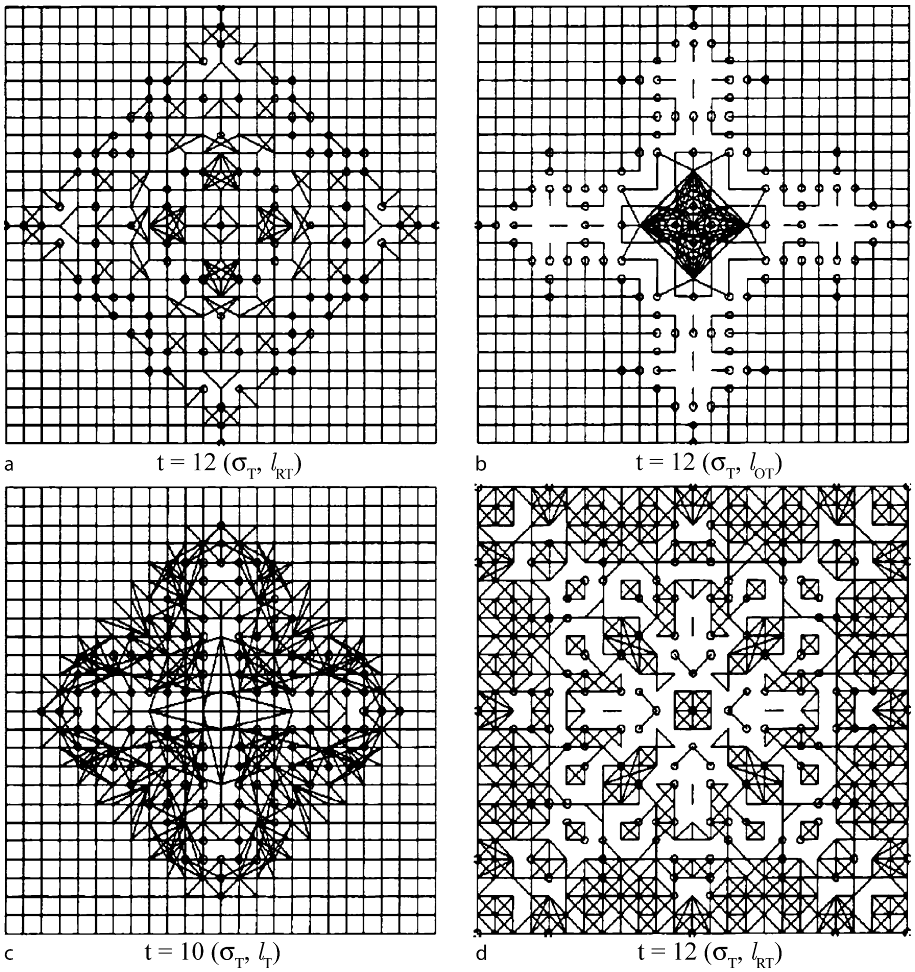
links that emerge from sites along the boundary surface become conduits by which non-zero values rapidly propagate. Had the underlying lattice topology been suppressed in this figure, and attention focused exclusively on the developing σ state, we could have interpreted the result as showing an effective increase in information propagation speed due to non-local connectivities (see comment 5 of the previous section).

Figure 5d, on the other hand, gives an example in which the link dynamics *lags behind* the σ development. The boundary proceeds outward essentially unaffected by changes in geometry, which are themselves confined to the interior parts of the lattice (at least at this early stage of this system's development).

Figure 6 shows snapshot views of a few system undergoing a slightly more complex evolution. Figure 6b, for example, shows a rule in which the outward σ propagation rapidly deletes most links from the original lattice but leaves a complex (though structurally stable) geometry at the origin of the initial disturbance. Figure 6c, on the other hand, shows a typical state of a system whose global connectivity becomes progressively more complicated.

A typical evolution starting from an initial state in which all sites are randomly assigned $\sigma = 1$ with probability $p = 1/2$ is shown in Fig. 7. Notice the rapid development of complex local connectivity patterns, the appearance of which points to a geometrical self-organization.

In general, structural behaviors emerging from random σ-states under typical Γs can be grouped into four basic classes (not to be confused with Wolfram's classification of elementary CA [74]):



a
$t = 12\ (\sigma_T, l_{RT})$
b
$t = 12\ (\sigma_T, l_{OT})$
c
$t = 10\ (\sigma_T, l_T)$
d
$t = 12\ (\sigma_T, l_{RT})$

Structurally Dynamic Cellular Automata, Figure 6

Four more examples of states emerging from simple seeds. Figure a, b, c start from 4-neighbor graphs and d from an 8-neighbor graph (≡ 4-neighbor with diagonals). Γs are as follows: a T σ- and RT ℓ-rules $\vec{C} = (42, 69648, 32904)_{[3,3]}$; b T σ- and OT ℓ-rules $\vec{C} = (42, 589952, 8192)_{[2,8]}$; c T σ- and ℓ-rules $\vec{C} = (42, 128, 4)_{[0,10]}$; d T $c[\phi] = 682$ and RT ℓ-rules defined explicitly by $\Psi_{(104),(114),(124),(103),(113),(123)}$ and $\Omega_{(111),(215)}$

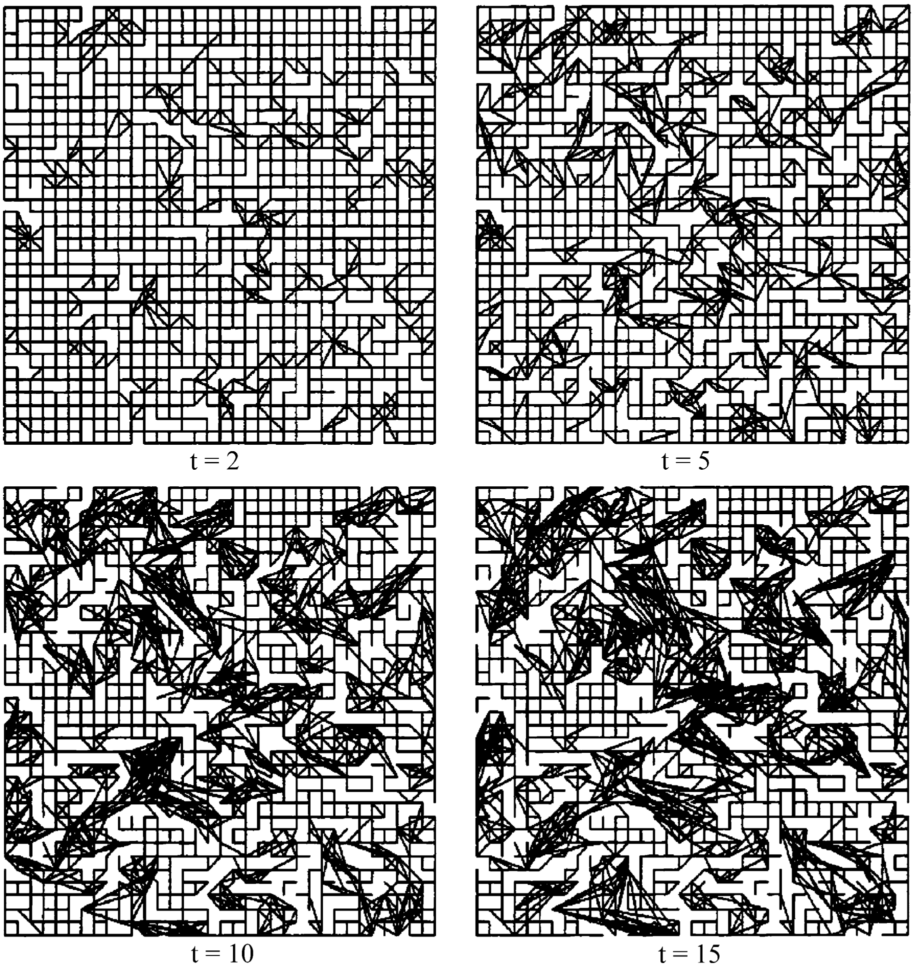
- *Class-1*, in which initial graphs decay into structurally much simpler final states: most links are destroyed, and graphs ℓ^t_{ij}, for sufficiently large t, consist essentially of a large number of small local subgraphs.
- *Class-2*, whose final states are characterized by periodic but globally connected geometries. SDCA typically arise in this class either because of a specific class-2 Φs remaining unchanged by the coupling to the lattice or class-3 Φs coupling with $\{\Psi, \Omega\}$ in such a way as to induce a lattice structure that supports a periodic state.
- *Class-3*, consisting of SDCA that tend to grow in size and complexity, at least as measured by two basic metrics: the *average degree*, $\langle\text{deg}\rangle \equiv (1/N) \cdot \sum_i \left[|S_1(i)| - 1\right]$, and *effective dimensionality*, $D_{\text{effec}} \equiv \langle N_{\text{nn}}\rangle / \langle\text{deg}\rangle$, where $\langle N_{\text{nn}}\rangle$ is the average number of next-nearest neighbors. The values of both $\langle\text{deg}\rangle$ and D_{effec} increase without bound for class-3 SDCA (unless an arbitrary upper constraint Δ is imposed on Γ).

Because the σ-density responds to the changing local neighborhood structure, it is possible that what at first appears to be an explosive growth in fact eventually leads to a more sedate, if not static, behavior at some larger $\langle\text{deg}\rangle \gg \Delta$. Φs that yield $\langle\sigma\rangle_t \sim$ *constant* over a range of $\langle\text{deg}\rangle$ (such as the *sum modulo*-2 rule; see below), when coupled with link rules that themselves become progressively less active with increasing $\langle\text{deg}\rangle$, may induce evolutions leading to only mild changes within specific ranges of the local structural parameters.

- *Class-4*, which is a provisional class (pending stronger evidence) that denotes a set of rules that yield open-ended σ- and ℓ changes, but during which the value of D_{effec} remains roughly constant. Ψs and Ωs belonging to this class effectively induce a *structural equilibrium*: despite the fact that large numbers of link changes continue to be made, so that the detailed structure of the evolving graph continually changes, the average ratio of the number of next-nearest to nearest neighbors stays approximately constant over long periods of time. While there is evidence to suggest this class is *real*, simulations have unfortunately been run for too short a time and on graphs containing too few sites to permit making any conclusive statements regarding the veracity of this class. Nonetheless, it is tempting to speculate that, for arbitrary values of D^*, there exists at least one set of SDCA rules for which $D_{\text{effec}} \approx D^*$ (within a desired $\epsilon > 0$) as the size of the graph $N \to \infty$. (*Pseudo* class-4 behavior, of course, can always be artificially induced either by imposing severe $[\delta, \Delta = \delta]$ constraints, or, as must typically be done for category-3 Γs, by deliberately impeding growth with some threshold Δ.)

Statistical Measures

As evidenced by Fig. 7, it is already nontrivial to meaningfully visualize the short-time evolution of (initially) *regu-*



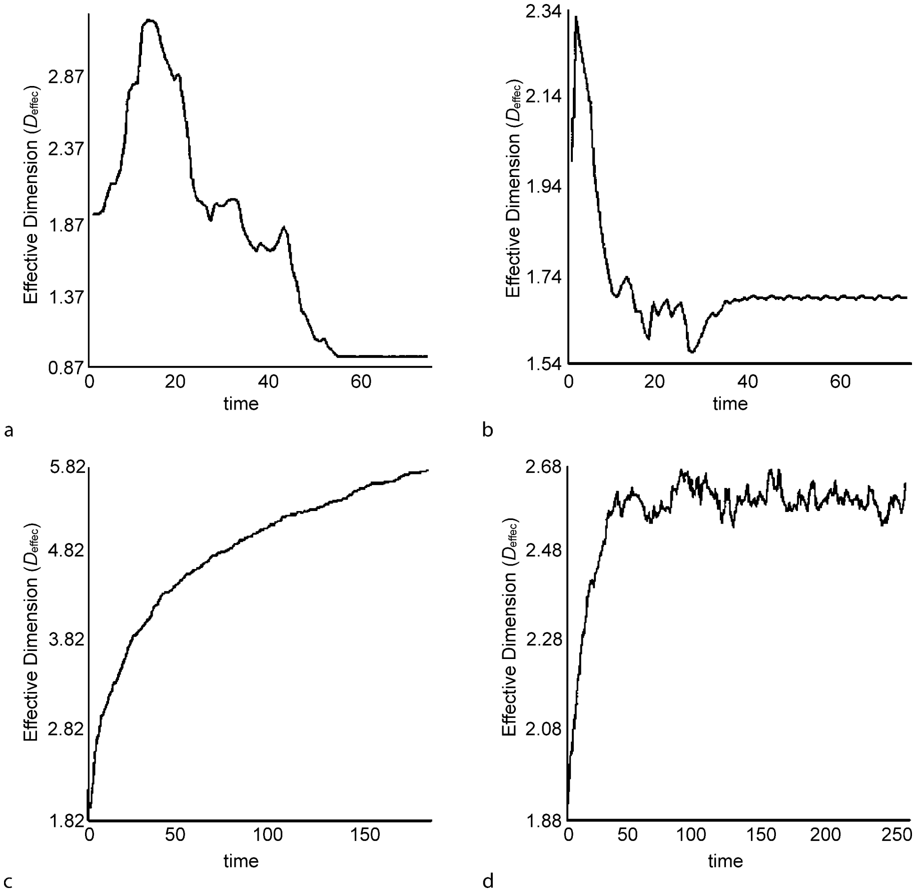
Structurally Dynamic Cellular Automata, Figure 7
Evolution of a 35 × 35 lattice, with randomly seeded sites. The development proceeds according to T σ- and OT ℓ-rules defined by code $\vec{C} = (84, 36864, 2048)$. The constraints are $[\delta = 0, \Delta = 10]$. The appearance of localized substructures is evidence of a geometrical self-organization

lar lattices that start with random initial value state. Visualizing the long-term dynamics of systems that start from a completely random state is even more difficult (although graph visualization algorithms may help). However, even in cases for which a direct visual inspection of the dynamics reveals little, one can always indirectly keep abreast of a given system's properties by monitoring its core structural and behavioral measures (a more detailed account is given in [31]).

Site value measures include the average density of sites with value $\sigma = 1$, $\langle \sigma \rangle_t \sim (1/N) \sum_{i=1}^{N} \sigma_i^t$; the local value correlation, $C^t \equiv \langle \sigma_i^t \cdot \sigma_j^t \rangle - (\rho^t)^2$, where $\langle \sigma_i^t \cdot \sigma_j^t \rangle$ is averaged over all pairs i and j with $\ell_{ij} = 1$; the fraction of sites whose value *changes* during one step of the evolution, $\Delta_t \equiv (1/N) \sum_{i=1}^{N} \{\sigma_i^{t-1} \oplus_2 \sigma_i^t\}$, where $\oplus_2$ is a sum *modulo*-2.

Geometry measures include the *average degree*, $\langle \text{deg} \rangle$; the *average number of next-nearest neighbors*, $\langle N_{\text{nn}} \rangle_t \equiv (1/N) \sum_i [|S_2(i)| - |S_1(i)| - 1]$; and D_{effec}. A measure of how the actual size of local neighborhoods changes with time may be obtained by embedding graphs into the two-dimensional plane and calculating the average pathlength at time t. Of course, global features that describe all complex networks – such as *connectivity*, *density*, *clustering*, and *path lengths* (2,6), are applicable to SDCA as well.

Link changes may be monitored by keeping track of (1) the total number of *link changes* (allowed under prescribed constraint conditions), $\Delta_t^{(l)} \equiv (1/2) \sum_{i=1}^{N} \cdot \sum_{j=1}^{N} \{l_{ij}^t \oplus_2 l_{ij}^{t-1}\}$; (2) the *constraint influence*, $f_l \equiv \Delta_t^{(l)} / N_t^{(l)}$, where $N_t^{(l)}$ is the total number of link changes that would have occurred in the absence of constraints ($f_l = 1$ indicates that the evolution is *pure*,



Structurally Dynamic Cellular Automata, Figure 8

Time development of the effective dimensionality D_{effec} for each of the four categories of behavior (see text): a T type Γ defined by $\vec{C} = (42, 128, 4)$; b T σ- and OT ℓ-rules $\vec{C} = (64, 9216, 1024)$; c T σ- and OT ℓ-rules $\vec{C} = (682, 512, 512)_{[0,10]}$; d T σ- and RT ℓ-rules defined explicitly by $\vec{\beta} \in \{(011), (110), (121), (233), (243)\}$ and $\vec{\epsilon} \in \{(120), (010), (021), (224)\}$

meaning it is unaffected by constraints; $f_l \sim$ *small* suggests that the imposed constraint window $[\delta, \Delta]$ has resulted in observed structures that are *impure*); (3) the link *creation-* and link *deletion-ratios*, $f_C \equiv N_C/\Delta_t^{(l)}$ and $f_D \equiv N_D/\Delta_t^{(l)}$, where N_C and N_D are the numbers of link created and destroyed, respectively; (4) the *activity levels*, $\gamma_C^t \equiv N_C/N_{\text{nn}}^{t-1}$ and $\gamma_D^t \equiv N_D/N_{\text{l}}^{t-1}$ (where N_l^{t-1} is the number of links at time $t-1$), which give the number of dynamic alterations relative to the corresponding spaces from which the candidates for alteration are selected; and (5) the *link evolution index*, $\gamma_L^n \equiv \left(1/N_l^{t=0}\right) \sum_i \sum_j \{l_{ij}^{t=0} \oplus_2 l_{ij}^n\}$, which gives the fraction of the initial lattice remaining after n iterations.

Figure 8 shows time series plots of D_{effec} for rules in each of the four behavioral classes defined above. The initial structure in each case is 35 × 35 4-neighbor Euclidean lattice, so that $D_{\text{effec}}^{t=0} \sim 2$. Figure 8a gives an example of class-1 behavior, in which a short period of initial growth is followed by a decay into mostly disconnected clusters. The final state is characterized by $\langle \text{deg} \rangle < 1$, and is stable. Figure 8b shows a system that starts from the same initial state as in Fig. 8a but whose Γ leads to a periodic geometry. Just the right number of links have been deleted to permit regions with isolated activity to emerge.

Figure 8c shows class-3 behavior in which D_{effec} steadily increases. The apparent leveling off seen toward the end of the run is due both to a decreased overall activity level and the increasingly effect of the $\Delta = 10$ constraint. The system in Fig. 8d exhibits class-4 behavior, characterized by a ongoing structural development within a relatively narrow interval of values of D_{effec}. Note that the structural changes here are essentially *pure*, and are not merely artifacts of any imposed constraints. Ilachinski (3) explores a wide range of emergent behaviors across all four classes, and examines the qualitative relationship between emergent behavior and initial σ- and ℓ-seeding.

Phase Plots

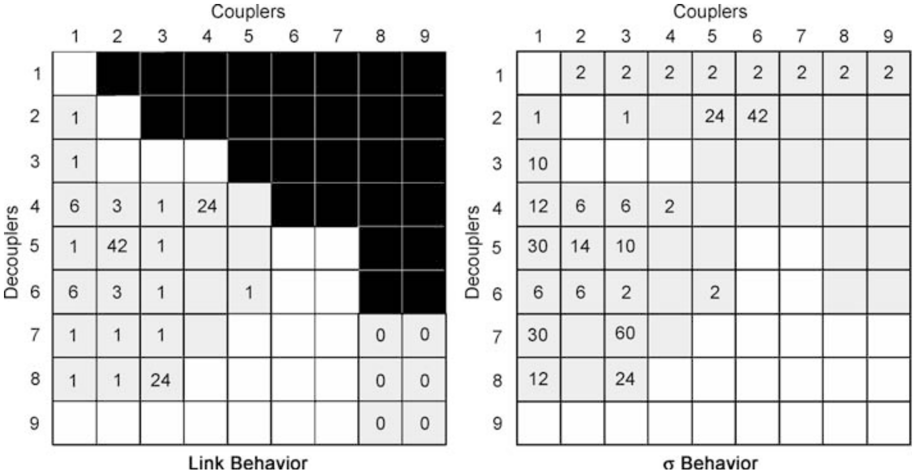
While it is of obvious interest to systematically explore every possible combination of β's and ϵ's that define ℓ-rules, Table 1 unfortunately suggests that the resulting rule space is simply too large. Nonetheless, we can learn much even by focusing our attention on a small subset of the complete rule space, keeping Φ, the initial σ-seeding, and all other factors constant. Specifically, consider the subset of all possible ℓ-rules that consists of **OT** link rules consisting of a single *coupler*, ω, and a single *decoupler*, ψ. Moreover, let $\phi \equiv \oplus_2$ (i. e., sum *modulo*-2 rule), demand that only pairs of $\sigma = 0$ sites be considered for a link change, and consider ℓ-rules belonging to the following set:

$$\begin{array}{lll} \textit{decouplers:} & \{\beta_{1,1} = 0, \beta_{2,1} = \mu\}, & 1 \leq \mu \leq 0, \\ \textit{couplers:} & \{\epsilon_{1,1} = 0, \epsilon_{2,1} = \nu\}, & 1 \leq \nu \leq 0. \end{array} \tag{22}$$

Figure 9 summarizes the behavior of a four neighbor, 25 × 25 lattice with periodic boundary conditions, starting from an initial σ-seed consisting of a single nonzero site. Four basic kinds of structural behaviors emerge:

1. *Static state:* this trivially occurs when the link rules are unable to take effect; namely, when $\mu \geq 7$ and $\nu \geq 8$.
2. *Rapid growth:* for an entire range of μ and ν, the average number of neighbors for each site of the lattice increases rapidly for 20–30 iterations.
   This number would likely continue to increase, were it not for the constraint conditions ($\equiv [0, 10]$). The "final state" is neither stable nor periodic. One sometimes also sees *delayed growth* in this class of behavior, in which case the link structure is initially relatively quiescent (and the behavior of the system as a whole mimics that of a conventional CA). As coupler rules are triggered by specific σ states, the average degree of the lattice rapidly increases (at least until the constraint conditions take effect).
3. *Spontaneous decay:* when decouplers are stronger than couplers, the average degree typically decreases. If this occurs too rapidly, the structure surrounding the single nonzero valued site may become isolated from other parts of the lattice. If a few non-zero values do not leak out into the outlying regions, link changes remain confined to the central subgraph, leading to either rapid stability or periodicity.
4. *Initial growth, followed by periodicity:* this is the least common behavior, and requires a delicate balance between coupler and decoupler rules.

It is interesting to compare these results with those obtained from a random σ seed. In this case, the sharp divisions between characteristic behaviors disappear, and there is a pronounced increase in the number of links for all μ and ν. However, the inclusion of an additional decoupler, may induce decay and periodicity. For example, consider the same initial lattice and Φ as used in Fig. 9, fix two **OT** ℓ-rules $\Psi_{(0,5)}$ and $\Omega_{(0,1)}$, and add the decoupler $\Psi_{(0,\mu)}$: $\{\beta_{1,1} = 0, \beta_{2,1} = \mu\}$, $1 \leq \mu \leq 9$. Surveying the emergent behaviors for this range of μ's, one now finds decaying lattices for $\mu \geq 2$. In each case, the initial graph succumbs to periodicity following a transient of between 50 and 100 iterations. The evolving lattice is also more prone to break up into small disconnected subgraphs.



Structurally Dynamic Cellular Automata, Figure 9

Phase plot **that summarizes behavior of a four neighbor, 25 × 25 lattice with periodic boundary conditions, starting from an initial σ-seed consisting of a single nonzero site. Γ is defined by the sum *modulo*-2 σ-rule and ℓ-rules of the form: *decouplers*–$\{\beta_{1,1} = 0, \beta_{2,1} = \mu\}$, *couplers*–$\{\epsilon_{1,1} = 0, \epsilon_{2,1} = \nu\}$. *Grey areas* in both plots denote *periodic states*. *White areas* denote *growth* in the plot for link behavior, and a *nonperiodic* state for σ-behavior. The *black* area that appears in the link-bevavior plot denotes *decay*. Numbers that appear in *individual boxes* denote period lengths**

Although, just as in conventional CA, small changes to ℓ-rules can lead to large differences in emergent behavior, they generally appear to do so in a more predictable and patterned manner. Of course, particular classes of Γ may induce more complex phase plots; for example, isolated pockets of anomalous (and rapidly shifting) behavior may appear within larger surrounding regions undergoing otherwise mutually consistent and slowly changing dynamics. A better sense of the space of possible emergent behaviors, along with a deeper understanding of the relationship between Φ and ℓ-rules, awaits a future study.

SDCA as Models of Computation

The basic SDCA model, as outlined above (which we will denote as SDCA$_0$ to avoid possible confusion with the hierarchy of related SDCA models introduced in this section), was modified and generalized by Majercik [39] into a form more suitable for addressing its formal *computational capabilities* rather than as an exploratory toolkit for describing physical processes (which is the primary reason for which SDCA$_0$ were first conceived). Motivated primarily by finding models of human brain function (for which one intuitively expects nonlocal neural connections to play a fundamental role in the rewiring of neural tissue), Majercik shows that suitably generalized SDCA are not only capable of universal computation, but actually represent a more efficient class of computational models than conventional CA. Majercik also reports an SDCA that can solve the *firing squad* problem in $O(\log t)$ time (i. e., exponentially faster than the $O(t)$ in conventional CA), and a class of CA-*universal* SDCA models that can simulate any conventional CA with a speedup factor of two. (The *firing squad* problem [46] consists of finding a rule for which all sites in a CA evolve into a special state after the exactly the same number of steps.)

Majercik proceeds by first identifying five properties of SDCA$_0$ that, while reasonable from a physical modeling standpoint, make it difficult to rigorously formulate and prove theorems:

1. *Finiteness:* The requirement that SDCA$_0$ be strictly finite, both in time and space, is obviously necessary for computer experiments, but is unnecessarily restrictive for general theorem proving. Likewise, the assumption that the sets α, β and ϵ must be finite is questioned.
2. *Bidirectionality:* While SDCA$_0$ are defined with symmetric links, an obvious generalization that makes the basic model more readily applicable to neural dynamics (among other kinds of physical and biological systems) is to allow for unidirectional links.
3. *Link-rule Asymmetry:* While SDCA$_0$'s link decoupler function (Eq. (11)) contains the factor ℓ_{ij} to explicitly prevent the system from inadvertently linking two unlinked sites, SDCA$_0$ does not include an analogous term for the coupler function (that is, a term to prevent an evolving system from inadvertently unlinking two linked sites).

4. *Inconsistency:* While σ-rules effectively ignore site positions, all three types of link rules assume that the various neighborhoods surroundings individual sites (A_{ij}, B_{ij}, and $C_{ij} \equiv \{k | D_{ik} = 1 \oplus D_{jk} = 1\}$, where '$\oplus$' denotes *exclusive or*) are all *recognized as such* by the dynamics. That is, the link rules effectively " know" the positions of a site's neighbors, while σ-rules possess no such information.
5. *Small Rule Set:* The class of σ- and ℓ-rules used by SDCA_0 may be generalized to include a far broader class of transition functions.

On the basis of these observations, Majercik [39] introduces a set of three core models to define a hierarchy of eight alternative SDCA computational systems, $\{\text{SDCA}^{(1)}, \text{SDCA}^{(2)}, \ldots, \text{SDCA}^{(8)}\}$. The three core models are (1) the *relative location* model ($= M_{\text{R}}$), (2) the *labeled links* model ($= M_{\text{L}}$), and (3) the *symmetric links* model ($= M_{\text{S}}$). They differ only in the degree to which their σ- and ℓ-transition functions depend on *specific* sites. For example, M_{R}'s transition functions depend on the state and exact relative position of each neighbor (and therefore "knows" the exact source of any state in a local neighborhood). In M_{L}, links are labeled and the transition functions know both neighbor states and the label of the links to given neighbors, but the exact neighbor locations remain unspecified. Finally, in M_{S}, it is assumed that no information about the source of the neighborhood states exists, and transition functions only know the number of neighbors in a particular state.

Each of the three core models may be defined in two versions: an *unbounded links* (abbreviated, UL) version, in which the number of neighbors a given site can have is unbounded, and a *bounded links* (abbreviated, BL) version, in which an explicit upper limit is imposed. In addition, there is also one *finite labels* version of M_{L}. Majercik imposes certain mild conditions on the local transition functions; for example, that local neighborhoods always remain strictly finite, σ-rules leave quiescent neighborhoods alone, and that links between sites with quiescent neighborhood remain unaltered.

***Relative Location* SDCA model** In the *Relative Location* model, the transition functions all have access to the exact relative *location* and *state* of each neighbor site. Define a *neighbor* of site i, $n_i \in S \times Z^d$, as a pair that specifies the state (by a single label) and relative location of the neighboring site (as a d-tuple of coordinates). Let $W = S \times Z^d$ be the set of all possible neighbors, and $\mathcal{F}_W$ (called the *neighborhood function*) be the set of all possible finite, nonempty, partial functions that map Z^d to W. The local state transition function $\sigma : \mathcal{F} \to W$ maps neighborhood functions to the state set of SDCA. The local link transition function $\lambda : \mathcal{F} \times \mathcal{F} \times \{0, 1, 2\} \to \{0, 1\}$ maps pairs of neighborhood functions (that define the neighborhoods of two sites, i and j and a number that specifies the status of the link between i and j: value *zero* meaning that i and j are neither direct neighbors nor next-nearest neighbors; value *one* meaning that i and j are immediate neighbors; and value *two* meaning i and j are next-nearest neighbors) to one of two link states: *zero*, meaning no link between i and j, and *one*, meaning a link exists.

***Labeled Links* SDCA model** The *Labeled Links* model removes from M_{R}'s transition functions any dependency on the exact relative location of a site's neighbors, but allows the links to still be *labeled* so that the transitions functions can distinguish one link from another. This ability to "label" links paves the way for us to define SDCA with unidirectional links, since the labels can be used to distinguish between the *input* and *output* links to a site. Consider, for example, the UL-version of M_{L}. Labeling the links by natural numbers, $\mathcal{N}$, we define a neighbor of site i, as a pair (q, n), where $q \in S$ labels the state of the neighboring site, and $n \in \mathcal{N}$ labels the link between i and its neighbor. Site i is defined as the direct neighbor linked via the 0th link, and the set of all possible neighbors, $W = S \times \mathcal{N}$. As for M_{R}, $\mathcal{F}_W$ is the set of neighborhood functions that map Z^d to W, the local state transition function $\sigma : \mathcal{F} \to S$ maps neighborhood functions to states in S, and the local link transition function $\lambda : \mathcal{F} \times \mathcal{F} \times \{0, 1, 2\} \to \{0, 1\}$ maps pairs of neighborhood functions and a number to either the values *zero* (unlinked) or *one* (linked).

***Symmetric Links* SDCA model** The *Symmetric Links* model imposes the strictest constraint of all by doing away with all means by which the local transition functions may distinguish different neighborhood orientations. Consider the unbounded link version of M_{S}. Assume the SDCA has a total of n states, and let $S = \{1, 2, \ldots, n\}$. Let $\vec{n}_i \in N^n$ be an n-dimensional vector such that $(n_i)_k$ is equal to the number of site i's neighbors in state k. Then the local state transition function $\sigma : N^n \to S$ maps vectors in N^n to states in S, and the local link transition function $\lambda : N^n \times \{0, 1, 2\} \to \{0, 1\}$ maps a vector in N^n and a link status label to either the values *zero* (unlinked) or *one* (linked). M_{S} can also be modified slightly to allow the local transition functions to retain knowledge of the state of site i: simply let $\sigma : S \times N^n \to S$ map the pair consisting of the *state* of site i and a vector that defines the distribution of states among i's immediate neighbors (excluding i). The local link function likewise assumes a similar form $\lambda\colon S^2 \times N^n \times \{0,1,2\} \rightarrow \{0,1\}$, where the first component of the 3-tuple input to *lambda* is a pair that defines the states of the two sites to which the link function is being applied.

SDCA as CA Simulators

What does it mean to say that one dynamical system *simulates* another? Heuristically, it means that, for certain initial states, one system behaves just like another [32,74]. Suppose we have two CA systems – CA and CA′ – defined by rules ϕ and ϕ', and initial states $\vec{\sigma} \in \Sigma$ and $\vec{\sigma}' \in \Sigma$, respectively. Then, loosely speaking, T iterations of CA are said to be "simulated" by nT $(n \geq 1)$ iterations of CA′, provided there exists some invertible function, $f\colon \Sigma \rightarrow \Sigma$, by which $\vec{\sigma}'$ is replaced by $f(\vec{\sigma})$. Simulation is a transitive relationship: if system B simulates system A, and another system C simulates B, then C also simulates A.

For example, a single site with a particular value in CA may be simulated by a fixed *block of sites* in CA′. After n steps, the blocks in CA′ evolve to exactly the same final state as the single time-step evolution of individual sites in CA. As a concrete example, consider the elementary (one-dimensional, binary valued, conventional CA) rules ϕ_{18} and ϕ_{90}:

	111	110	101	100	011	010	001	000
	↓	↓	↓	↓	↓	↓	↓	↓
ϕ_{18}:	0	0	0	1	0	0	1	0
ϕ_{90}:	0	1	0	1	1	0	1	0

Provided that *two time steps* under ϕ_{18} are carried out for every time step of rule ϕ_{90}, it is easy to show that under the block transforms $0 \rightarrow f(0) = 00$ and $1 \rightarrow f(1) = 10$, the evolution of arbitrary starting configurations under ϕ_{90} is reproduced – or *simulated* – by ϕ_{18}. For example, the global state $\vec{\sigma} =$ '0011000' – which evolves into $\phi_{90}(\vec{\sigma}) =$ '0111100' under ϕ_{90} – yields the same state (after it is block-transformed) that results from two iterations of ϕ_{18} applied to ϕ_{90}'s block-transformed initial state, $f(\vec{\sigma}) =$ '00001010000000':

$$\phi_{18}[\phi_{18}[f(\vec{\sigma})]] = 00101010100000 = f[\phi_{90}(\vec{\sigma})]. \quad (23)$$

Now consider the specific case of SDCA simulating a conventional CA (we follow Majercik [39]). First, because SDCA cannot be expected to preserve the local topology of a simulated CA, it is necessary to define separate *encoding* $(= e)$ and *decoding* $(= d)$ functions – $e\colon \Sigma_{\mathrm{CA}} \rightarrow \Sigma_{\mathrm{SDCA}}$ transforms the initial configuration of the CA systems to configurations in the SDCA system being used to simulate it (where Σ_{CA} and Σ_{SDCA} are the configurations spaces of CA and SDCA, respectively); and $d\colon \Sigma_{\mathrm{SDCA}} \rightarrow \Sigma_{\mathrm{CA}}$ effectively performs the inverse transformation. Encoding (and decoding) functions are called *structurally defined* if they are recursive and use a finite amount of information to encode (or decode) a given configuration; and are otherwise expected to transform quiescent states to quiescent states. Majercik further assumes that (1) e has access to the rule table of the conventional CA system being simulated; (2) d does not have access to the rule tables of either system; and (3) e and d must together satisfy the relation: $e \times d = \mathrm{Identity}(\Sigma_{\mathrm{CA}})$.

Denoting the global transition functions of the CA and SDCA systems by Φ_{CA} and Φ_{SDCA}, respectively, Φ_{SDCA} is said to *simulate* Φ_{CA} if there exist $m \geq 1, n \geq 1$ and structurally-defined functions $e\colon \Sigma_{\mathrm{CA}} \rightarrow \Sigma_{\mathrm{SDCA}}$ and $d\colon \Sigma_{\mathrm{SDCA}} \rightarrow \Sigma_{\mathrm{CA}}$, such that for any configuration $\vec{\sigma} \in \Sigma_{CA}$ and any $k \geq 1$,

$$\Phi^{kn}_{\mathrm{CA}}(\vec{\sigma}) = d\left[\Phi^{km}_{\mathrm{SDCA}}\left[e\left(\vec{\sigma}\right)\right]\right]. \quad (24)$$

If $m > n$ then Φ_{SDCA} simulates Φ_{CA} with a *slowdown* factor of m/n. If $m < n$ then Φ_{SDCA} simulates Φ_{CA} with a *speedup* factor of n/m.

SDCA Hierarchy of Models

Majercik [39] uses the three generalized models introduced above $(M_{\mathrm{R}}, M_{\mathrm{L}}$, and $M_{\mathrm{R}})$ to define a hierarchy of eight SDCA models of computation. At the top of his hierarchy (arranged from top-to-bottom in roughly, but not completely, decreasing order of computational strength; see discussion that follows) are the UL and BL versions of M_{R}: $\mathrm{SDCA}^{(8)}$ and $\mathrm{SDCA}^{(7)}$, respectively; followed by $\mathrm{SDCA}^{(6)} =$ UL version of M_{L}; $\mathrm{SDCA}^{(5)} =$ BL version of M_{L}; $\mathrm{SDCA}^{(4)} =$ a *finite labels* version of M_{L}; $\mathrm{SDCA}^{(3)} =$ UL version of M_{S}; $\mathrm{SDCA}^{(2)} =$ BL version of M_{S}; and, sitting on the lowest level (computationally speaking), is $\mathrm{SDCA}^{(1)} = \mathrm{SDCA}_0$.

A little thought suffices to establish certain relationships among the various classes. Give two classes, C_1 and C_2, let $C_1 \leq_{\mathrm{s}} C_2$ denote the fact that if, given any SDCA $S_1 \in C_1$ there exists an SDCA $S_2 \in C_2$ that simulates S_1. Then, for example, since any BL SDCA can be simulated by an unbounded links version of the same system, and a finite links version of M_{L} can be simulated by a bounded links version, we know immediately that $\mathrm{SDCA}^{(7)} \leq_{\mathrm{s}} \mathrm{SDCA}^{(8)}$, $\mathrm{SDCA}^{(4)} \leq_{\mathrm{s}} \mathrm{SDCA}^{(5)} \leq_{\mathrm{s}} \mathrm{SDCA}^{(6)}$, and $\mathrm{SDCA}^{(2)} \leq_{\mathrm{s}} \mathrm{SDCA}^{(3)}$. Similar reasoning [39] leads to the general relationship:

$$\begin{cases} \mathrm{SDCA}^{(3)} \leq_{\mathrm{s}} \mathrm{SDCA}^{(8)} \leq_{\mathrm{s}} \mathrm{SDCA}^{(6)}\,, & \text{and} \\ \mathrm{SDCA}^{(2)} \leq_{\mathrm{s}} \mathrm{SDCA}^{(7)} \leq_{\mathrm{s}} \mathrm{SDCA}^{(5)}\,. \end{cases} \quad (25)$$

Finally, since the unbounded links version of M_R has all the information necessary to construct the neighborhood partitions used by SDCA$_0$, and since SDCA$^{(8)}$ $\leq_\mathrm{s}$ SDCA$^{(6)}$, we see that SDCA$_0$ $\leq_\mathrm{s}$ SDCA$^{(6)}$ and SDCA$_0$ $\leq_\mathrm{s}$ SDCA$^{(8)}$.

Majercik's two main results, which we state without proof, are:

> *Majercik Theorem 1:* Given an arbitrary 1-dimensional conventional CA with radius $r = 1$, there exists an unbounded links version of M_R (= SDCA$^{(8)}$ of the SDCA hierarchy) that can simulate it with a speedup factor of two.

> *Majercik Theorem 2:* There exists a 1-dimensional finite links version of M_L (= SDCA$^{(4)}$) that can simulate an arbitrary k-state 1-dimensional conventional CA with radius $r = 1$ with a slowdown factor $O\left(k^{2r}\sqrt{2r\log k}\right)$.

Detailed proofs of these two theorems appear in [39] (where they are called *Theorems 4.4* and *4.5*, respectively). In chapter 5 of his thesis [39], Majercik presents an explicit construction of a CA-universal SDCA$^{(4)}$ computational model, and compares it to Albert and Culik's [3] construction of a 1-dimensional CA-universal conventional CA that simulates any 1-dimensional, k-state, radius r CA with an $O\left(k^{8r}\right)$ slowdown. Although Majercik's CA-universal SDCA uses more states than Albert and Culik's universal CA, it is also markedly faster.

The reason why the SDCA is faster is at least intuitively clear. An SDCA's dynamic links effectively endow an otherwise conventional CA with a random access memory. Since SDCA can establish links between any two sites a distance d apart in $O(\log d)$ time, *any* site potentially has access to the state of any other site. While it may be argued that sites in conventional CA can also access the states of other cells, they *cannot do so permanently*. Once information is accessed once and used, the connection is lost, and must subsequently be re-established. Moreover, the links in SDCA can potentially connect sites that are arbitrarily far apart; so that, once a small number of links are dynamically created, they continue to provide long-range communication channels throughout the network. Since the propagation of information in a conventional CA is necessarily limited in being able to flow one site at a time, the overall computational speed is obviously limited.

However, it is worth pointing out that while the computational strength of Majercik's CA-universal SDCA model undoubtedly derives from its ability to forge long-range communication links, the results as quoted from [39] do not tap into what is potentially SDCA's greatest strength; namely, the ability to *adaptively create links, even as a given computation unfolds*. In Majercik's model, the links are dynamically coupled to an actual computation only insofar as they are initially fixed as a function of the initial state. While the local structure certainly *evolves* (as it does in all SDCA systems, as the computation itself unfolds), it does so purely as a consequence of the SDCA rules, and not adaptively to the evolution.

Majercik concludes his thesis by speculating on how an *adaptive* variant of his CA-universal SDCA may be used to explore certain aspects of evolutionary learning. (Working from a different set of assumptions, Halpern [23,24] applies evolutionary programming techniques to SDCA$_0$ to explore what happens when the structure is allowed to play an *explicit* dynamic role in the computation; see next section.) The question of whether there exist SDCA-universal SDCA models – that are able to simulate certain classes of the SDCA hierarchy, for example – remains open.

SDCA & Genetic Algorithms

Genetic algorithms (abbreviated, GA) are a class of heuristic search algorithms and computational models of adaptation and evolution based on natural selection. In nature, the search for beneficial adaptations to a continually changing environment (i. e., evolution) is fostered by the cumulative evolutionary knowledge that each species possesses of its forebears. This knowledge, which is encoded in the chromosomes of each member of a species, is passed on from one generation to the next by a mating process in which the chromosomes of "parents" produce "offspring" chromosomes. A comprehensive review of GA is given by Mitchell [45].

While GAs may be effectively used to search for "interesting" topological structures (but for which the structures themselves do not play any dynamic role; see, for example, Lehmann [37]), Halpern [23] is the first to explore a novel hybrid algorithm between GA and SDCA, in which SDCA rules are used to *evolve a GA*. Weinert et al. [72] explore a related "structurally dynamic" GA model, in which links between adjacent individuals of a population are dynamically chosen according to deterministic or probabilistic rules. In this section, we follow Halpern [23,24].

Formally, GAs are defined by (1) an ensemble of "candidate solution" vectors, $\{\vec{s}_i\}$: $\vec{s}_i \in M_\mathcal{P} \subseteq R^n$, where M is the set of all possible solutions to a given "problem" $\mathcal{P}$ (the $\vec{s}_i$ are usually, but not always, defined as a string of binary numbers [45]), and (2) a "fitness function", $f(\vec{s})$, that represents how well a given $\vec{s}$ "solves" $\mathcal{P}$. The goal of the GA is to find the global optimal solution,

$\vec{s}^*$ such that (from the point of view of *maximizing* fitness, $f(\vec{s}) \leq f(\vec{s}^*) \equiv f^*, \forall \vec{s} \in M$. Optimization proceeds through the combined processes of *selection*, *breeding*, *mutation*, and *crossover replacement* [45]; to which – in the hybrid SDCA↔GA algorithm, Halpern adds the new feature of *self-selective neighborhood structure*.

It should be immediately noted that this is not an ad-hoc addition. Muhlenbein [47] points out that if each generation of a GA searches over the entire possible solution space, the algorithm may – depending on the fitness function – converge prematurely to a sub-optimal solution. To reduce the likelihood of this happening, Muhlenbein introduces a spatial population structure; restricting fitness and mating to neighborhoods called *demes*. Demes are geographically separate subpopulations in which candidate solutions evolve along disparate trajectories; though occasional mixing still occurs through the process of migration.

In Halpern's variant [23], an otherwise conventional GA is placed within the structure of SDCA$_0$ (i. e., the basic model defined by Eqs. (11)–(14)). Heuristically, this allows each candidate solution to "choose a community" with which to mate, during each generation. The choice of neighborhoods thus becomes an integral component of the GA, and is determined dynamically by the evolving solutions.

Halpern's algorithm proceeds as follows [24]: *(Step 1)* an initially random lattice (defined by adjacency matrix $l_{ij}^{(t=0)}$) is seeded with single-chromosome candidate solutions of fixed length, one per site; *(Step 2)* a fitness function, $f_i = \sum_{i=1}^{N} \delta_{ij}$, is defined to assign a numerical measure of "optimality" to each site (N is the number of sites, and δ_{ij} is the value – equal to 0 or 1 – of the jth gene of the ith chromosome; *(Step 3)* each site i ranks each of its nearest and *next*-nearest neighbors according to f_i; *(Step 4)* each site disconnects with a fraction, f_D, of its least-fit neighbors, and connects with a fraction, f_C, of its fittest next-nearest neighbors; *(Step 5)* each site randomly mates with one of its nearest neighbors (i. e., the usual processes of mutation and crossover operations are applied [45]); *(Step 6)* the least fit members of the population are replaced by the offsprings from *Step* 5; and *(Step 7)* loop through steps *5–7*, until some suitable "optimality" threshold (or some other convergence criterion) is satisfied.

Halpern [23,24] reports a wide range of resulting behaviors, collectively suggesting a clear relationship between the parameters defining the GA optimization and lattice connectivity. Of particular interest are the dynamic conditions for which the fitness-based creation and deletion of links increases the rate of growth of overall fitness. The fastest convergence occurs when lattice connectivity first increases, then decreases, then eventually levels off. In the first stage, the fittest possible communities are first established; in the second stage, connections with poorer candidate solution are deleted; finally, in the third stage, the system essentially "fine-tunes" its optimal solutions. Halpern [24] finds two different evolutionary paths toward high connectivity: (1) monotonic growth over time (for low mutation rates, p_μ), and (2) a *phase transition* between low and high degrees of connectivity (for some p_μ^*). Using SDCA↔GA hybrid model parameters $N = 100$ and $f_D = f_C = 0.1$, $p_\mu^* \approx 0.05$, for which Halpern [24] finds a sharp increase in the number of links per site between generations 350 and 450.

Despite the novelty of the approach, and the promising link between optimization rates and dynamic structure established in [23], concrete applications of the algorithm – except for Weinert et al. [72] work on a related hybrid GA algorithm – have yet to be developed. One suggestion, from Halpern [24], is to use the SDCA↔GA hybrid model for finding "optimal" connectivity patterns in parallel computers. The search algorithm may be used to directly model how component processors are connected, and decide to keep or sever existing links, or establish new ones, adaptively as a function of local fitness criteria.

Generalized SDCA Models

Despite SDCA being obviously more "complex" than conventional CA (and certainly more complex to formally define, if only because one must specify *both* σ *and* ℓ rules), the SDCA model nonetheless has more in common with *elementary* CA than with any of its brethren's more "complicated" variants. By "elementary" CA we mean the simplest one-dimensional CA with $\sigma \in \{0, 1\}$ and local neighborhoods consisting only of left and right (i. e., *nearest*) neighbors. Just as there are many generalizations of elementary CA – for example, increasing the state space to include σ's that take on one of N values, larger-sized neighborhoods, and memory, among many other possibilities – so too there are natural extensions of basic SDCA. In this section we discuss three generalizations: (1) rules that are *reversible in time*, (2) rules that retain a *memory of past states*, and (3) *probabilistic* rules.

Reversible SDCA

The first generalization of the basic SDCA model, explored extensively by Alonso-Sanz [7], is to apply the *Fredkin reversible-rule construction* to ℓ rules to render them reversible in time. Consider a conventional CA system that is first-order in time, $\sigma_i^{t+1} = \phi[\sigma_j^t \in \mathcal{N}_i]$, where $\mathcal{N}_i$ is the neighborhood around site i and, generally, $\sigma_i \in \mathcal{Z}_k$. The *Fredkin* construction converts this system into an explicitly invertible one that is *second-order* in time by subtracting the value of the center site at time $t-1$:

$$\sigma_i^{t+1} = \phi\left[\sigma_j^t \in \mathcal{N}_i\right] \ominus_k \sigma_i^{t-1}, \tag{26}$$

where '$\ominus_k$' is subtraction *modulo-k*. Since Eq. (26) can be trivially solved for σ_i^{t-1} $\left(=\phi[\sigma_j^t \in \mathcal{N}_i] \ominus_k \sigma_i^{t+1}\right)$, we see that any *pair of consecutive configurations uniquely specifies the backwards trajectory of the system*. Moreover, this is true for arbitrary (and, in particular, *irreversible*) functions ϕ.

Now, exactly the same procedure may be applied to link functions:

$$\begin{cases} l_{ij}^{t+1} = \psi\left(\{\sigma_k^t\}, \{l_{ij}^t\}\right) \ominus_2 l_{ij}^{t-1}, \\ l_{ij}^{t+1} = \omega\left(\{\sigma_k^t\}, \{l_{ij}^t\}\right) \ominus_2 l_{ij}^{t-1}, \end{cases} \tag{27}$$

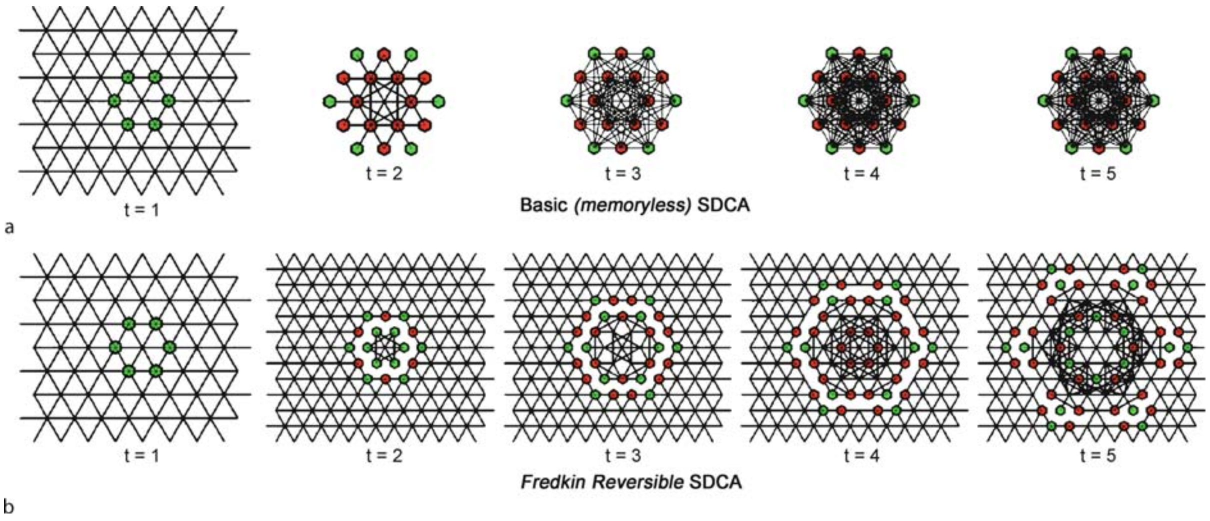
where $\ominus_2$ is subtraction *modulo*-2 (since links are obviously binary valued).

Following Alonso-Sanz [7,8], we consider these two specific SDCA link rules (which will also be used in a later example):

$$\begin{cases} \psi\left(\sigma_i^t, \sigma_j^t, l_{ij}^t\right) = 0 \text{ iff } l_{ij}^t = 1 \text{ and } \sigma_i^t + \sigma_j^t = 0\,, \\ \omega\left(\sigma_i^t, \sigma_j^t, l_{ij}^t\right) = 1 \text{ iff } l_{ij}^t = 0, \sigma_i^t > 0, \sigma_j^t > 0, \text{ and } D_{ij} = 2. \end{cases} \tag{28}$$

Figure 10 compares the evolution of the *Fredkin reversible* version of these rules to their memoryless counterpart. Both evolutions start on a two dimensional hexagonal lattice, and values evolve according to the three-state (i. e., $\sigma \in \{0,1,2\}$), next-nearest neighborhood **T** *beehive* rule. The *beehive* rule is defined explicitly by assigning one of three values $(0, 1,$ or $2)$, to each possible 3-tuple, (N_0, N_1, N_2), that gives the number of local sites with N_0 0s, N_1 1s, and N_2 2s [7]: $(0,0,6) \to 0$, $(0,1,5) \to 1$, $(0,2,4) \to 2$, $(0,3,3) \to 1$, $(0,4,2) \to 2$, $(0,5,1) \to 0$, $(0,6,0) \to 0$, $(1,0,5) \to 0$, $(1,1,4) \to 2$, $(1,2,3) \to 2$, $(1,3,2) \to 2$, $(1,4,1) \to 1$, $(1,5,0) \to 1$, $(2,0,4) \to 0$, $(2,1,3) \to 0$, $(2,2,2) \to 2$, $(2,3,1) \to 2$, $(2,4,0) \to 0$, $(3,0,3) \to 0$, $(3,1,2) \to 2$, $(3,2,1) \to 2$, $(3,3,0) \to 0$, $(4,0,2) \to 0$, $(4,1,1) \to 0$, $(4,2,0) \to 2$, $(5,0,1) \to 2$, $(5,1,0) \to 0$, $(6,0,0) \to 0$.

The top row of Fig. 10 shows the first four steps ($t = 1, 2, 3,$ and 4) in the memoryless evolution of the initial "ring" of sites that appears at $t = 1$. The link rules used for this run are those defined in Eq. (28). Since the decoupler removes links between pairs of sites whose values are equal to zero, most of the lattice disappears after a single time step, and both value and link activity is confined to a small region. After two more steps of changes, the system quickly attains a fixed point: $\{\sigma^t, \ell_{ij}^t\} = \{\sigma^{t=4}, \ell_{ij}^{t=4}\}$ for all $t \geq 5$. While the frequency of states is not constrained to total six for a dynamic lattice, the *beehive* rule is unchanged; if the sum of frequencies at a given site exceeds six, the site value remains the same.



Structurally Dynamic Cellular Automata, Figure 10
Comparison between first few time steps of a a *memoryless* SDCA, evolving according to link rules defined in Eq. (28), and b the *Fredkin reversible* versions of these rules (obtained by applying Eq. (27) to Eq. (28)). In both cases, σ's evolve according to the *beehive* rule defined in the text. (Reproduced with permission from [7])

The bottom row shows the evolution of the *Fredkin reversible* versions of the rules defined in Eq. (28) (to simplify the visualization, links along the border sites are not shown). In contrast to the basic SDCA version, the initial lattice in this case *does not* decay. Since, according to Eq. (27) (which assumes that $\ell_{ij}^{t=0} = \ell_{ij}^{t=1}$), the initial hexagonal lattice is subtracted from the evolved structure at $t = 1$(*modulo*-2), the original graph is effectively restored, and the outlying regions appear undisturbed.

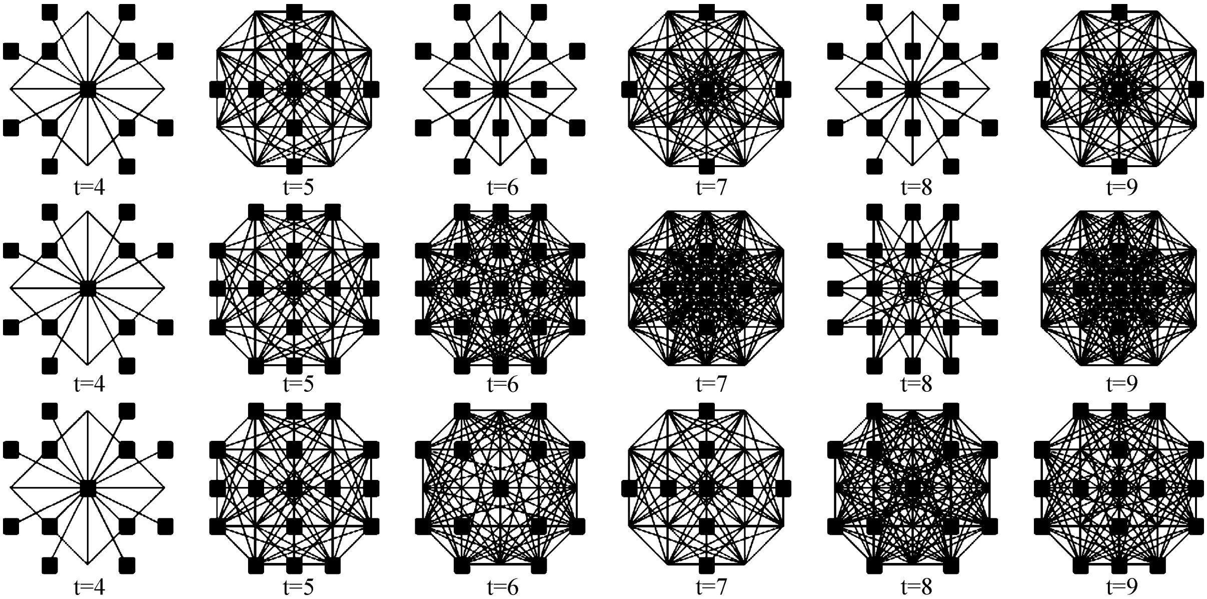
SDCA with Memory

A second generalization to the basic SDCA model, introduced and studied by Alonso-Sanz and Martín [6,7,8], is to endow both σ-rules and ℓ-rules with *memory*. The rules for conventional memoryless CA and SDCA, depend only on neighborhood configurations that appear on the immediately preceding time step. Therefore, rules may be said to possess a "memory" of depth m if they depend explicitly on values (in the case of CA), or on both values and link states (in the case of SDCA), that existed on m previous time steps. We note, in passing, that since the *Fredkin construction* couples states at times $t+1$, t and $t-1$, reversibility may be considered a specific form of memory that extends backwards a single step.

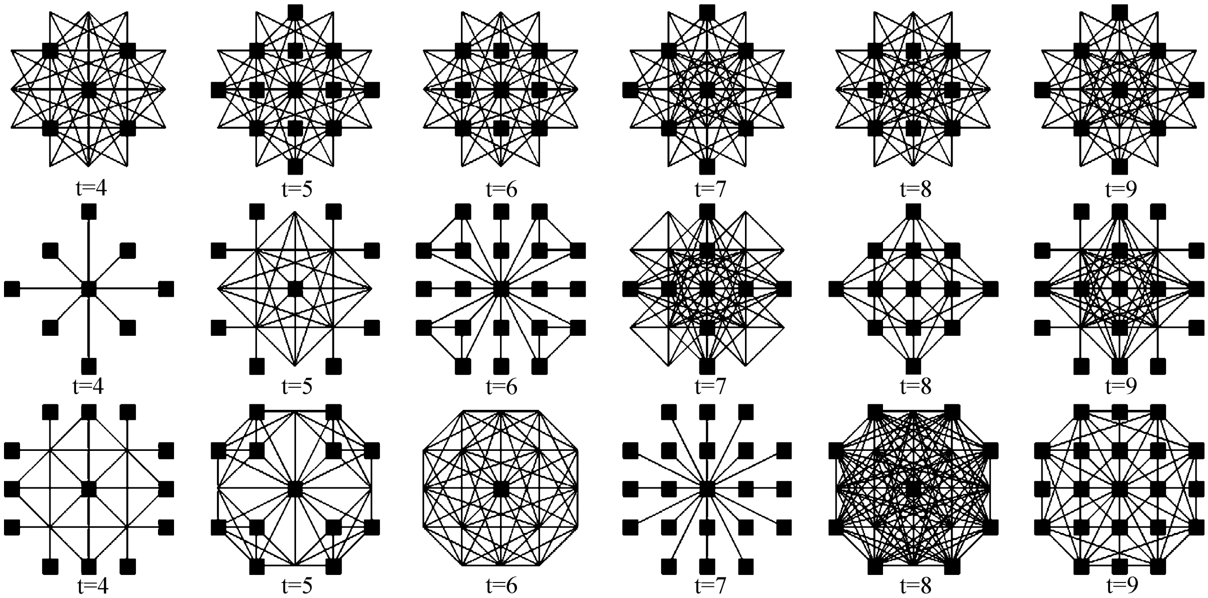
Of course, there is no unique prescription for introducing a dependency on past values; and a variety of alternative memory mechanisms have been proposed in the literature (for example, see page 43 in [32] and page 118 in [74]). We focus our discussion on the approach proposed by Alonso-Sanz (14), and for the moment confine our attention to value rules, $\phi: \sigma \to \sigma'$. Alonso-Sanz's approach is to preserve the form of the transition rule, but have it act on an effective site value that is a weighted function of its m prior values.

This is done by introducing a memory-endowed value rule, ϕ_m, that – in contrast to its memoryless version, ϕ – is not, in general, a function of a given site's current value, σ_i, *alone*, but is instead a function of the transformed value, $s = \mathcal{M}_\phi(\sigma; m, \alpha)$, obtained from σ_i's past m values: $\phi_m: s \to \sigma'$, where $0 \le \alpha \le 1$ is a numerical *memory factor*. The value transforming memory function, $\mathcal{M}$, assumes the following specific form (to avoid confusion, note that in Eqs. (29) and (30), σ_i^x means *the value of* σ_i *at time* $t = x$, and α^x means *the numerical quantity* α *raised to the power* x):

$$s_i^t = M_\phi\left(\sigma_i^t; m, \alpha\right) = \begin{cases} 1 & \text{if } \left(\hat{\sigma}_i^t\right)_m > 1/2, \\ \sigma_i^t & \text{if } \left(\hat{\sigma}_i^t\right)_m = 1/2, \\ 0 & \text{if } \left(\hat{\sigma}_i^t\right)_m < 1/2, \end{cases} \qquad (29)$$



Structurally Dynamic Cellular Automata, Figure 11
Sample runs of a SDCA with memory for memory weighting $\alpha = 0.6$. The SDCA is initialized as a Euclidean four-neighbor lattice, and evolves according to the *parity* T σ-rule and the two ℓ rules defined in Eq. (28). The first row of evolving patterns applies memory only to *values*; the second row applies memory only to *links*, and the third row shows the evolution when memory is applied to both. (Reproduced by permission from [8])



Structurally Dynamic Cellular Automata, Figure 12
Sample runs of the same SDCA shown in Fig. 11, but with memory weighting $\alpha = 1.0$. (Reproduced by permission from [8])

where

$$\left(\hat{\sigma}_i^t\right)_m = \frac{\sigma_i^t + \sum_{\Delta t=1}^m \alpha^{\Delta t} \cdot \sigma_i^{t-\Delta t}}{1 + \sum_{\Delta t=1}^m \alpha^{\Delta t}} \,. \tag{30}$$

At any given time, t, the depth m can never exceed $t-1$. Our discussion follows Alonso-Sanz [8], and sets $m(t) \equiv t-1$ for all t; i. e., we assume that $\mathcal{M}_\phi(\sigma; m, \alpha)$ yields a weighted mean value of *all* the previous values of a given site. In practice, memory becomes active only after a certain number of initialization steps, here taken to be three; with seeded values $s_i^1 = \sigma_i^1$ and $s_i^2 = \sigma_i^2$.

Memory can be added to link rules in a similar manner. The form of the link rules (ψ and ω) remains the same, but rather than acting on a graph that is defined by its adjacency matrix, ℓ_{ij}^t, ψ and ω instead act on the memory-transformed values, $L = \mathcal{M}_{(\psi,\omega)}(\ell; m, \alpha)$:

$$L_{ij}^t = M_{(\psi,\omega)}\left(l_{ij}^t; m, \alpha\right) = \begin{cases} 1 & \text{if } \left(\hat{l}_{ij}^t\right)_m > 1/2, \\ l_{ij}^t & \text{if } \left(\hat{l}_{ij}^t\right)_m = 1/2, \\ 0 & \text{if } \left(\hat{l}_{ij}^t\right)_m < 1/2, \end{cases} \tag{31}$$

where

$$\left(\hat{l}_{ij}^t\right)_m = \frac{l_{ij}^t + \sum_{\Delta t=1}^m \alpha^{\Delta t} \cdot l_{ij}^{t-\Delta t}}{1 + \sum_{\Delta t=1}^m \alpha^{\Delta t}} \,. \tag{32}$$

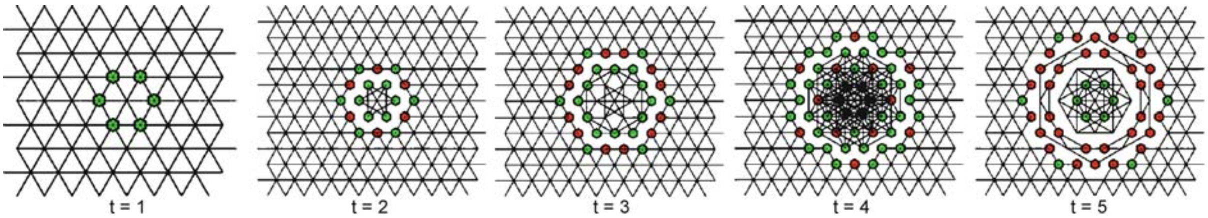
As for memory-endowed σ-rules, the memory for link rules is activated only on the third iteration step, and the system is initialized by setting $L_i^1 = \sigma_i^1$ and $L_i^2 = \sigma_i^2$.

Figures 11 and 12 show the effects of applying partial memory weighting ($\alpha = 0.6$) and full memory ($\alpha = 0.6$), respectively, to a SDCA that starts with a Euclidean four-neighbor lattice, and evolves according to the *parity* **T** σ-rule (that assigns a value *zero* to a site if the sum of the values in its neighborhood is *even*, and assigns the value *one* if the sum is *odd*) and the ℓ rules defined above in Eq. (28). The first row of evolving patterns (for each α) applies memory only to *values*; the second applies memory only to *links*, and the third appliers memory to both. Figure 13 shows the reversible *beehive* SDCA shown in Fig. 10, but with full memory ($\alpha = 1.0$).

Probabilistic SDCA

Another natural extension of the basic SDCA model is to replace the set of explicit σ- and/or ℓ-rules with probabilities. In this way one can study the evolution of a system that undergoes random but σ-dependent lattice changes. For example, this may be useful for studying genetic networks in which new links are forged (with a given probability) only if both genes are active, and existing connections are broken if both sites are inactive.

Following Halpern and Caltagirone [22], consider the *parity* **T** σ-rule and the following probabilistic versions of



Structurally Dynamic Cellular Automata, Figure 13
Sample runs of a reversible *beehive* SDCA with full memory ($\alpha = 1.0$); compare to Fig. 10. (Reproduced by permission from [8])

decoupler (ψ_p) and coupler rules (ω_p):

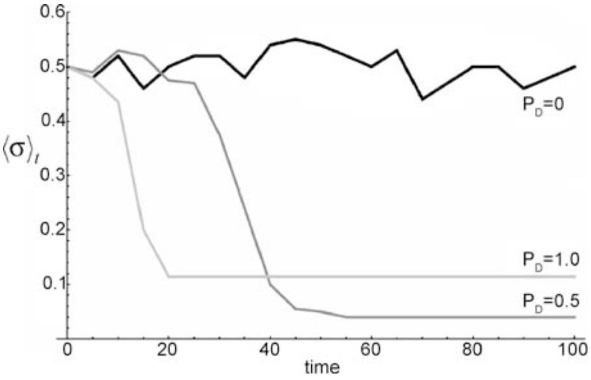
$$(decoupler): \begin{cases} l_{ij}^{t+1} = \psi_p\left(l_{ij}^t;\sigma_i^t,\sigma_j^t,p_D\right), \\ \psi_p \equiv 1-\delta\left(\sigma_i^t+\sigma_j^t,0\right)\cdot\delta\left(p_D>r\right), \end{cases}$$

$$(coupler): \begin{cases} l_{ij}^{t+1} = \omega_p\left(l_{ij}^t;\sigma_i^t,\sigma_j^t,p_D\right), \\ \omega_p \equiv \delta\left(D_{ij},2\right)\cdot\delta\left(\sigma_i^t+\sigma_j^t,2\right)\cdot\delta\left(p_C>r\right), \end{cases} \tag{33}$$

where P_D and P_C are the *decoupler* and *coupler* probabilities, respectively, and r is a random number between 0 and 1.

Thus, ψ_p unlinks two previously linked sites with probability P_D *if and only if* the sum of their site values is *zero*; and ω_p links two previously unlinked sites with probability P_C *if and only if* they are next-nearest neighbors and the sum of their site values is *two*.

Figure 14 shows time series plots of $\langle\sigma\rangle$ as a function of time for three different cases: (1) $P_D = 0$ (no decoupling at all), (2) $P_D = 1/2$, and (3) $P_D = 1$ (decoupler rule applied 100% of the time (consistent with *non*-probabilistic SDCA rules). We see that changing P_D induces qualitatively different σ behavior, that ranges from small fluctuations around $\langle\sigma\rangle \sim 0.5$ (for $P_D = 0$), to decay to small static values ($\langle\sigma\rangle = 0.05$ for $P_D = 1/2$, and $\langle\sigma\rangle = 0.12$ for $P_D = 1$).



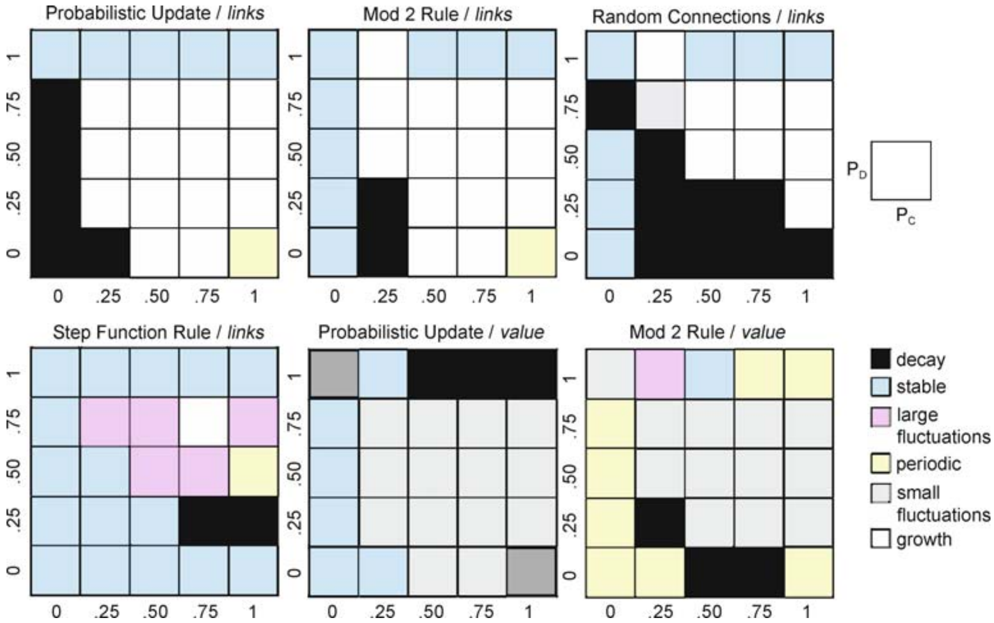
Structurally Dynamic Cellular Automata, Figure 14
Time series of average σ value, $\langle\sigma\rangle_t$, for the Halpern-Caltagirone rules (defined in Eq. (33)) and for three values of *decoupler* probability: $P_D = 0$, $P_D = 1/2$, and $P_D = 1$. (Reproduced with permission from [22])

Halpern and Caltagirone [22] have studied a wide range of probabilistic SDCA, using random initial σ configurations, *step-function*, *parity*, and Conway's *life* σ-rules, Cartesian and random initial lattice structures, and various probabilities $0 \leq P_D \leq 1$ and $0 \leq P_C \leq 1$. Some of their results are reproduced (with permission) in the *behavioral phase* plots shown in Fig. 15. (The *step-function* rule is defined by $\sigma_i^{t+1} = 0$ if and only if $\sum_j \ell_{ij}^t \sigma_i^t > 2$ and $\sigma_i^{t+1} = 1$ if and only if $\sum_j \ell_{ij}^t \sigma_i^t \leq 2$; Conway's *life* rule assigns $\sigma^{t+1} = 1$ to a site if and only if $\sigma^{(t)} = 0$ and the sum of values in its neighborhood at time t is equal to 3 or $\sigma^t = 1$ and the sum of values is equal to 2 or 3; otherwise $\sigma^{t+1} = 0$.)

Figure 15 shows a wide range of possible behaviors. Consider, for example, the number of *links per site* for the case where the lattice is updated with probabilistic ℓ-rules and the σ's are all random (shown at the top left of the figure). Four distinct classes of behavior appear, with *growth* dominant for most values of P_D and P_C.

Pure decoupling (or pure coupling) leads to complete decay (or growth to a stable state); a mixed state of coupling/decoupling generally yields slow growth. Periodic behavior occurs only for $P_D \sim P_C \sim 1$. Compare this behavior with the cases where the σ-rule is either the *parity* value rule (shown in the middle of the top row of Fig. 15) or the *step-function* rule (shown at left bottom of the figure). While the *parity* rule also displays four similar phases (growth to stability, decay to stability, incomplete growth, and incomplete decay), decaying structures eventually reach a stable (not null) final state. The *step-function* rule shows an even greater variety of possible behaviors, and appears more sensitive to small changes in link probabilities.

The probabilistic SDCA system discussed in this section adds a stochastic element *specifically to SDCA*. Of course, there are other ways of injecting stochasticity into a CA with dynamic topology. For example, Makowiec [40] combines the deterministic evolution of a conventional



Structurally Dynamic Cellular Automata, Figure 15

Behavioral phase **plots summarizing the long term evolution for several different σ and ℓ-rules defined in Eq. (33). The *x* and *y* axes for each plot depict values ($\in \{0, .25, .5, .75, 1\}$) of P_C and P_D, respectively. There are six classes of behavior: *growth*, *decay*, *stability*, large and small *fluctuations* (around a stable lattice), and *periodicity*. The initial graph is a Cartesian four-neighbor lattice in each case except for the *top-right* plot (labeled *Random connections/links*) for which the initial graph is random. (Reproduced with permission from [22])**

CA with an asynchronous stochastic evolution of its underlying lattice (patterned after the Barabasi–Albert [9] model of degree distributions in small-world networks), to explore the influence of dynamic topology on the zero-temperature limit of ferromagnetic transitions.

Random Dynamics Approximation

For cases in which the structure and value configurations are both sufficiently random and uncorrelated, a *random dynamics approximation* (abbreviated, RDA) may suffice to qualitatively predict how the system will tend to evolve under a specific rule set; for example, to predict whether a given rule is more (or less) likely to yield unbounded growth, to eventually settle into a low periodic state, or to simply decay. The idea is to approximate the real SDCA as a *mean-field*; that is, assume all local value and structural correlations are close to zero (and can thus be ignored), and replace all specific site values and local link geometries with average, or effective, values.

More precisely, assuming that (1) the probability $p_n^{(\sigma_i)}$ of a site '*i*' having value $\sigma = 1$ at time $t = n$ is the same for all sites – so that $p_n^{(\sigma_i)} = p_n^{(\sigma)}$ for all *i* – and (2) that the probability $p_n^{(l_{ij})}$ of two sites '*i*' and '*j*' being linked at $t = n$ is the same for all pairs of sites – so that $p_n^{(l_{ij})} = p_n^{(l)}$ for all *i* and *j* – the RDA evolution equations may be written formally as follows:

$$\begin{cases} p_{n+1}^{(\sigma)} = F_{\mathrm{RDA}}[p_n^{(\sigma)}, p_n^{(l)}; \Gamma_{\mathrm{SDCA}}], \\ p_{n+1}^{(l)} = G_{\mathrm{RDA}}[p_n^{(\sigma)}, p_n^{(l)}; \Gamma_{\mathrm{SDCA}}], \end{cases} \tag{34}$$

where SDCA's rule Γ_{SDCA} (defined in Eq. (14)) is included, formally, to remind us that the functional forms assumed by F_{RDA} and G_{RDA} will be different for different Γ_{SDCA}s.

The first function, F_{RDA}, is the easier of the two to calculate. For any given site with degree *d* we simply count the total number of ways to distribute the local σ-values among the *d* possible neighboring sites to obtain the desired sums that define a given rule. In this way we find the average expected σ density at $t = n + 1$, assuming all sites in the lattice have the same degree *d* at time $t = n$:

$$p_{n+1}^{(\sigma)}(d, p_n^{(\sigma)}) = \begin{cases} \sum_{\{\alpha\}} \binom{d+1}{\alpha} \left[p_n^{(\sigma)}\right]^{\alpha} \left(1 - p_n^{(\sigma)}\right)^{d+1-\alpha} & \leftrightarrow \mathbf{T} \\ \sum_{\{\alpha_0\}} \binom{d}{\alpha_0} \left[p_n^{(\sigma)}\right]^{\alpha_0+1} \left(1 - p_n^{(\sigma)}\right)^{d-\alpha_0} & \\ \quad + \sum_{\{\alpha_1\}} \binom{d+1}{\alpha_1} \left[p_n^{(\sigma)}\right]^{\alpha_1} \left(1 - p_n^{(\sigma)}\right)^{d+1-\alpha_1} & \leftrightarrow \mathbf{OT} \end{cases} \tag{35}$$

We then get $F_{\mathrm{RDA}} \to p_{n+1}^{(\sigma)} = \sum_d P(d; p_n^{(l)}) \cdot p_n^{(\sigma)}(d, p_n^{(\sigma)})$ as an average over all possible degrees, where $P(d; p_n^{(l)})$ is the probability that any site has exactly d neighbors. Since this means that, out of a total of $N-1$ possible neighbors, a given site must have exactly d links, and not be connected to any of the remaining $(N-1-d)$ sites, we have by inspection:

$$P\left(d; p_n^{(l)}\right) = \begin{pmatrix} N-1 \\ d \end{pmatrix} \left[p_n^{(l)}\right]^d \left(1 - p_n^{(l)}\right)^{N-1-d} . \quad (36)$$

To calculate the second function in Eq. (34) ($= G_{\mathrm{RDA}}$), we first define the local transition functions

$$\begin{cases} p_n^a\,(d_1, d_2, \lambda) \\ = \mathrm{Prob}\left(l = 1 \to l' = 0 \mid d_i = d_1, d_j = d_2, \left|A_{ij}\right| = \lambda\right), \\ p_n^b\,(d_1, d_2, \lambda) \\ = \mathrm{Prob}\left(D = 2 \to l' = 1 \mid d_i = d_1, d_j = d_2, \left|A_{ij}\right| = \lambda\right), \end{cases} \quad (37)$$

which give the probabilities that any two sites – i and j – will be *disconnected* (p_n^a) or *connected* (p_n^b) if they have prescribed degrees $d_i = d_1$ and $d_j = d_2$, and are each linked to the *same* λ sites in the shared neighbor set, A_{ij} (see Fig. 1). In the case of type-**T** σ- and ℓ-rules, p_n^a and p_n^b are given explicitly by (**OT** versions of σ- and ℓ-rules, and **RT** versions of ℓ-rules are defined by similar, but slightly more complicated, expressions):

$$\begin{cases} p_n^a\,(d_1, d_2, \lambda) = \sum_k \begin{pmatrix} d_1 + d_2 - \lambda \\ \beta_k \end{pmatrix} \left[p_n^{(\sigma)}\right]^{\beta_k} \\ \qquad \cdot \left(1 - p_n^{(\sigma)}\right)^{d_1 + d_2 - \lambda - \beta_k}, \\ p_n^b\,(d_1, d_2, \lambda) = \sum_k \begin{pmatrix} d_1 + d_2 + 2 - \lambda \\ \varepsilon_k \end{pmatrix} \left[p_n^{(\sigma)}\right]^{\varepsilon_k} \\ \qquad \cdot \left(1 - p_n^{(\sigma)}\right)^{d_1 + d_2 + 2 - \lambda - \varepsilon_k}, \end{cases} \quad (38)$$

where β_k and ϵ_k refer to the sums that appear in Eqs. (11) and (12). The total probability that any two sites will be disconnected ($l = 1 \to l' = 0$) or connected ($D = 2 \to l' = 1$) – P_n^a and P_n^b, respectively – may then be obtained by summing over all possible local topologies:

$$\begin{cases} P_n^a \equiv \left\langle \mathrm{Prob}\left(l = 1 \to l' = 0\right) \right\rangle \\ \quad = \sum_{d_1} \sum_{d_2} \sum_{\lambda} P_1\,(d_1, d_2, \lambda) \cdot p_n^a\,(d_1, d_2, \lambda), \\ P_n^b \equiv \left\langle \mathrm{Prob}\left(D = 2 \to l' = 1\right) \right\rangle \\ \quad = \sum_{d_1} \sum_{d_2} \sum_{\lambda} P_2\,(d_1, d_2, \lambda) \cdot p_n^b\,(d_1, d_2, \lambda), \end{cases} \quad (39)$$

where

$$\begin{cases} P_1\,(d_1, d_2, \lambda) = \mathrm{Prob}(\text{sites } i, j \mid l_{ij} = 1 \text{ have } d_i = d_1, \\ \qquad\qquad d_j = d_2, \left|A_{ij}\right| = \lambda), \\ P_2\,(d_1, d_2, \lambda) = \mathrm{Prob}(\text{sites } i, j \mid l_{ij} = 0 \text{ have } d_i = d_1, \\ \qquad\qquad d_j = d_2, \left|A_{ij}\right| = \lambda). \end{cases} \quad (40)$$

To find P_1 we need to count, from among the remaining $N-2$ sites, the number of ways of selecting disjoint sets S_1, containing $d_1 - 1 - \lambda$ sites linked only to i; S_2, consisting of $d_2 - 1 - \lambda$ sites connected only to j; and S_3, with λ sites linked to *both* i and j. But this is simply a multinomial coefficient, so we can write:

$$P_1\,(d_1, d_2, \lambda) = \frac{(N-2)_{d_1 + d_2 - \lambda - 2}}{(d_1 - 1 - \lambda)!\,(d_2 - 1 - \lambda)!\lambda!} \cdot \left[p^{(l)}\right]^{d_1 + d_2 - 2} \left(1 - p^{(l)}\right)^{2(N-1) - d_1 - d_2}, \quad (41)$$

where $(n)_k \equiv n(n-1)\cdots(n-k+1)$. Similarly, for P_2, we need to count the number of ways of choosing $d_1 - \lambda$ sites from i, $d_2 - \lambda$ sites from j, and λ sites from both:

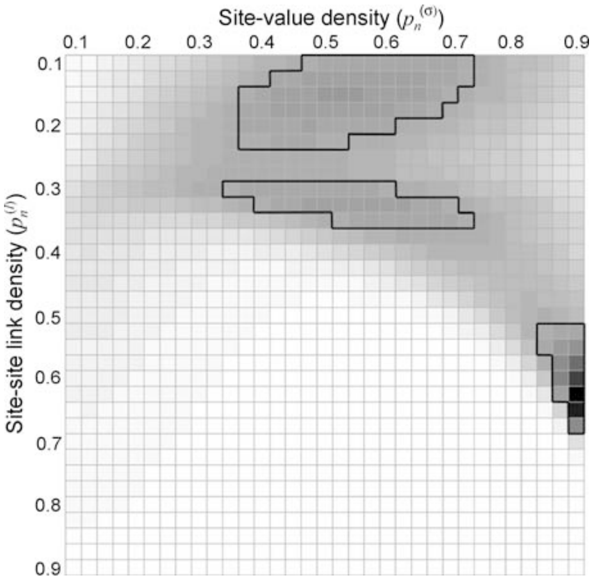
$$P_2\,(d_1, d_2, \lambda) = \frac{(N-3)_{d_1 + d_2 - \lambda - 2}}{(d_1 - \lambda)!\,(d_2 - \lambda)!\lambda!} \cdot \left[p^{(l)}\right]^{d_1 + d_2} \left(1 - p^{(l)}\right)^{2(N + \lambda - 3) - d_1 - d_2}. \quad (42)$$

The second (link-update) function of the pair of functions in Eq. (34) is thus given by

$$G_{\mathrm{RDA}} \to p_{n+1}^{(l)} = p_n^{(l)} \cdot \left(1 - P_n^a\right) + \left(1 - p_n^{(l)}\right) \cdot P_{D=2} \cdot P_n^a, \quad (43)$$

where, assuming that two sites, i and j, are not themselves connected, $P_{D=2}$ = probability that there exists at least one site k, such that $D_{ik} = D_{jk} = 1$, which implies that $P_{D=2} = 1 - \mathrm{Prob}\,(\text{there is no such } k) = 1 - (1 - [p_n^{(l)}]^2)^{N-2}$; and P_1 and P_2 are defined in Eqs. (41) and (42).

A *structural equilibrium* is established when $p_{n+1}^{(l)} \approx p_n^{(l)}$, which happens when the average number of new connections is equal to the average number of link deletions: $P_n^b \cdot \langle N_{\mathrm{nn}} \rangle = P_n^a \cdot \langle \mathrm{deg} \rangle$, where $\langle \mathrm{deg} \rangle = p_n^{(l)}(N-1)$ is the average *degree*, and $\langle N_{\mathrm{nn}} \rangle$ is the average number of *next-nearest neighbors*. For SDCA rules that naturally tend to produce graphs with minimal site value and structural



Structurally Dynamic Cellular Automata, Figure 16
Density-plot of $\gamma_{\text{c::d}}$ for an OT *decoupler* rule: $\{(0,0),(1,1),(1,2),(2,2)\}$; an OT *coupler* rule: $\{(1,1)\}$; $0.1 \leq p_n^{(\sigma)} \leq 0.9$; and $0.1 \leq p_n^{(l)} \leq 0.9$; the rectangular area highlighted in black denotes the "equilibrium boundary" that separates regions of growth and decay

correlations, the predicted ratio of RDA link creations to deletions, $\gamma_{c:d} \equiv P_n^b \cdot \langle N_{\text{nn}} \rangle / P_n^a \cdot \langle \text{deg} \rangle$, may be used to predict qualitatively how the graphs will evolve. Since the average number of pairs of sites a distance $D = 2$ apart $= \binom{N}{2} \cdot P_{D=2} = \langle N_{\text{nn}} \rangle \cdot N/2$, we find that:

$$\gamma_{\text{c::d}} = \frac{P_n^b}{P_n^a} \cdot \frac{\left(1 - p_n^{(l)}\right)}{p_n^{(l)}} \cdot \left\{ 1 - \left(1 - \left[p_n^{(l)}\right]^2\right)^{N-2} \right\} . \quad (44)$$

$\gamma_{\text{c::d}}$ is also implicitly a function of site-value density, since $p_n^{(\sigma)}$ appears in both P_n^a and P_n^b, defined in Eq. (39).

Figure 16 shows a grayscale density-plot of $\gamma_{\text{c::d}}$ for an **OT** *decoupler* rule: $\{(0,0),(1,1),(1,2),(2,2)\}$; an **OT** *coupler* rule: $\{(1,1)\}$; $0.1 \leq p_n^{(\sigma)} \leq 0.9$; and $0.1 \leq p_n^{(l)} \leq 0.9$. Areas that are close to *white* represent combinations of $(p_n^{(\sigma)}, p_n^{(l)})$ for which $\gamma_{\text{c::d}} \ll 1$, and which therefore predict "decay"; areas that are close to *black* represent combinations of $(p_n^{(\sigma)}, p_n^{(l)})$ for which $\gamma_{\text{c::d}} \gg 1$, and predict "growth"; the rectangular area highlighted in black denotes the "equilibrium boundary" that separates regions of growth and decay.

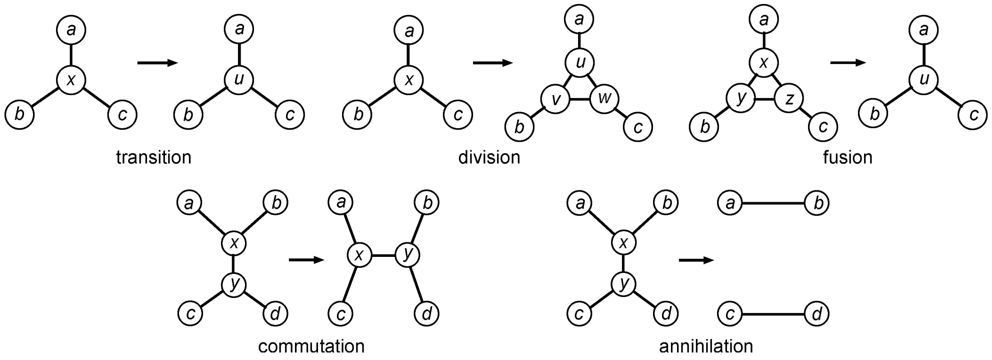
Related Graph Dynamical Systems

The original SDCA model [28] represents *one* (albeit not entirely arbitrary) approach to dynamically coupling site values ($\{\sigma_i\}$) and topology ($\{l_{ij}\}$), of the normally quiescent lattice. Since this model was primarily introduced as a general tool to explore self-organized emergent *geometries*, σ values are an integral dynamic component only because SDCA's original rules were conceived to generalize conventional CA rules, not replace them. Moreover, SDCA's link rules are, by design, close analogs of their conventional-CA brethren; this is the reason why SDCA's ψ and ω rules assume the familiar **T** and **OT** (and related **RT**) forms, as defined in Sect. "The Basic Model". Indeed, while the preceding sections of this article have introduced several generalizations – such as the addition of probabilistic rules, reversibility and memory – in each case, the basic *form* of the rules (as defined in Eqs. (11), (12), and (13)) has remained essentially the same. However, just as for conventional CA, an almost endless variety of different *kinds* of rules can in principle be defined; including rules that alter the geometry but are *not* functions of the σ states. In this section, we look at two illustrative examples of SDCA-like dynamical systems: one that uses coupled σ-ℓ rules, and another whose rules depend only on *topology*.

Graph Rewriting Automata

Tomita, Kurokawa, and Murata [67,68,69,70,71] have recently introduced *graph rewriting automata* (abbreviated, GRA), in which both links and (the number of) sites are allowed to change. Motivated by CA models of self-reproduction, Tomita et al suggest that fixed, two-dimensional lattices – used as static backdrops to most conventional models – are unnecessarily restrictive for describing self-reproductive processes. They cite, as an example, the inability of conventional CA to describe biological processes (such as embryonic development) that must unfold in a finite closed space; once the underlying space of the CA is defined at the start, however large (and sometimes deliberately assumed *infinite*), its size remains the same throughout the development. This not only makes it hard to model the typically growing need that developing organisms have for *space*, but makes it impractical even to provide some room for avoiding overlaps between the original and daughter patterns [67].

Motivated by these, and other issues related to computation, Tomita et al. [67,69] introduce GRA, which is a form of graph grammar [20]. At first glance, GRA appear superficially similar to SDCA, at least in the sense that they both dynamically couple site values with topology. However, the transition rules are very different, and – in GRA's case – two properties hold that are not true for SDCA systems: (1) *all sites have exactly three neighbors at all times* (which is the minimum number of neighbors that yield nontrivial graphs [67]), and (2) *multiple links*



Structurally Dynamic Cellular Automata, Figure 17
Graphical representations of the actions of the GRA rules defined in Eq. (45). (Reproduced from [69] with permission)

are allowed to exist between any two sites. The authors claim that the 3-neighbor restriction not only does *not* constrain the space of emergent geometries (an observation that is echoed by Wolfram [75]; see Subsect. "Network Automata" below) but has the added benefit of allowing the rules to be expressed in a regular form: each rule is defined by a rule *name* and, at most, six *symbols* for its argument:

$$
\begin{aligned}
&(\sigma \text{ rules}):\\
&\quad\Big\{ \textit{transition}\,(x,a,b,c) \;\to\; (u,a,b,c),\\
&(\text{site rules}):\\
&\quad\begin{cases} \textit{division}\,(x,a,b,c) & \to\; (u,v,w,a,b,c),\\ \textit{fusion}\,(x,y,z,a,b,c) & \to\; (u,a,b,c), \end{cases}\\
&(\text{link rules}):\\
&\quad\begin{cases} \textit{commutation}\,(x,y,a,b,c,d) & \to\; (x,y,a,b,c,d),\\ \textit{annihilation}\,(x,y,a,b,c,d) & \to\; (a,b,c,d), \end{cases}
\end{aligned}
\tag{45}
$$

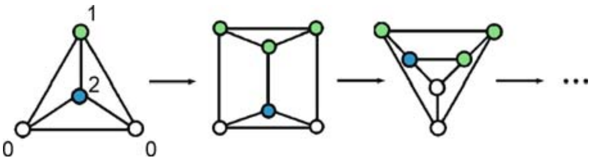
where x, y and z denote the σ values of the center sites *before* undergoing a structural change; u, v and w denote the σ values of the center sites *after* the structural change; and a, b, c, and d denote the states of the *neighboring sites*. The ordering is unimportant, so long as a given string can be obtained from another by cyclic permutation, otherwise the strings are different; i. e., (a,b,c) is both topologically and functionally equivalent to (b,c,a), but (c,b,a) is different. The action of σ, value, and links is graphically illustrated in Figure 17.

By convention, the GRA algorithm is applied in two steps: (1) site rules (*transition*, *division* and *fusion*) are executed first, and at all subsequent even time steps, followed by (2) link rules (*commutation* and *annihilation*), executed at odd steps.

In the event that multiple rules are simultaneously applicable – such as might happen, for example, if the rules include more than one division, or fusion, for the same lefthandside argument in their expressions (in Eq. (45)) – the order in which the rules are applied is determined by an a priori priority ranking. Also, since applying either *commutation* or *annihilation* rules to adjacent links yields inconsistency, whenever a local context arises in which this might happen, the application of these rules is temporarily suppressed. (This is done by sweeping through the link set *twice*: on the first pass, a temporary flag is set for each link that satisfies a rule condition; on the second pass, the link rule is applied *if and only if* the four neighboring links did not raise flags during the first pass.)

Figure 18 shows the first few steps in applying one *division* and two *commutation* rules to a simple initial graph. (Kohji Tomita provides several movies of GRA evolutions on his website: http://staff.aist.go.jp/k.tomita/ga/)

Tomita, Kurokawa, and Murata [67,68,69,70,71] report a variety of emergent behaviors, including (1) *arbitrary resolution* (because GRA rules effectively allow an arbitrary number of sites to "grow" out of any initial structure, these systems define their own "boundary conditions" and graphs with arbitrary resolution are possible); (2) *repetitive structures*, in which some geometrical subset of an initial graph is reproduced, indefinitely, and continu-



Structurally Dynamic Cellular Automata, Figure 18
Sample GRA evolution starting from the graph on the left. The rules are (see Eq. (45)): (1) *division*$(1,0,0,2) \to (1,1,1,0,0,2)$, (2) *commutation*$(1,2) \to (1,2)$, and (3) *commutation*$(0,0) \to (0,0)$. (Reproduced from [69] with permission)

ously grafted onto the original structure; and (3) *self-replication*, in which both site-value and structure is replicated after N steps. In [70], Tomita et al. describe how genetic algorithms [45] may be used for automating the search for self-replicating patterns.

In [67], Tomita et al. also present the design of a self-reproducing *Turing Machine*. *Turing machines* are abstract symbol manipulating devices that mimic the basic operations of a computer. Formally, they consist of a "tape" (of indefinite length, to record data), a "head" (that reads/writes symbols on the tape, and that can move left or right), and "state transition rules" (that tell the head which new symbols to write given the current state of the tape). The tape is analogous to "memory" in a modern computer; the head is analogous to the microprocessor. A Turing machine is called "universal" if it can simulate any other Turing machine.

Tomita et al.'s [67] *Turing machine* is modeled as a ladder structure: the upper sites constitute the "tape" mechanism; the lower sites form the "tape head" that reads the tape; both ends of the ladder are single sites that define "end of tape"; and the two ends are joined to form a loop. Although the tape is initially finite, the ladder can grow to arbitrary length, as required, by using appropriate GRA rules. Tomita et al. [67] self-replicating Turing GRA consists of 20 states and 257 (2-symbol) rules. They also introduce a design for a universal Turing machine [69] that consists of 30 states and 955 rules for reproduction, and 23 states and 745 rules for computation. While self-reproducing universal Turing machines can be described using conventional CA, their expression using GRA rules are considerably more compact.

Dynamic Graphs as Models of Self-Reconfigurable Robots

In the context of looking for self-reconfiguration algorithms that may be used to manufacture modular robots for industry, Saidani [63,64] has recently introduced a *dynamic graph calculus* that includes rules similar to those that define SDCA; but which depend only on the *topology* of (but not the σ-values living on) the lattice. Saidani and Piel [65] have also introduced an interactive programming environment for studying dynamic graph simulations called *Dynagraph*, and implemented in Smalltalk.

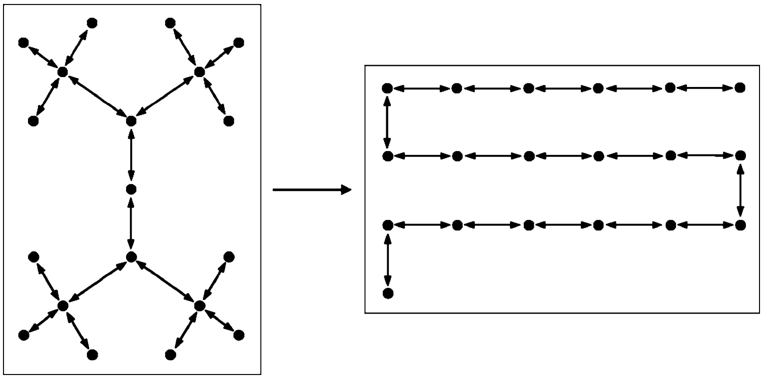
There are two basic approaches to designing modular robots: (1) to develop a set of elementary generic modules that can be rapidly assembled by humans to form robots that solve a specific problem, and (2) to design a set of (otherwise identical) primitive components that can adaptively reconfigure themselves. Focusing on the latter approach, Saidani [64] formally reinterprets modular "robots" to mean modular *networks*; and proceeds to model adaptive robotic self-reconfigurations as a class of recursive graph dynamical systems. In contrast to other related dynamic graph models [18,25], the "modules" (or subgraphs) of Saidani's model use local knowledge of their neighborhood topology to collectively evolve to some goal configuration. Although the dynamics transforms the global state, the evolution remains strictly decentralized, and individual modules do not know the (desired) final state.

Apart from restricting the dynamics to topology *alone* (indeed, none of the sites harbor information states of any kind), Saidani [63,64,65] further assumes that (1) connections between sites are *directional* (both *to*- and *from*-links may coexist between the same two modular components); (2) "active" sites reconfigure their local neighborhood by accepting, keeping, or removing their adjacent links according to rules that are functions of their current topology (defined as a given sites' current local neighborhood and the current neighborhood of its neighbors: a site only knows about its own *in*- and *out*-degree, which can obviously be computed from its local topology, and the *in*- and *out*-degrees of its nearest neighbors); (3) a site controls its *outgoing* links (and can connect or disconnect any outgoing links), but cannot sever incoming connections; (4) sites must maintain at least one link throughout an evolution (so that the graph remains connected); and (5) all sites are equipped with the same set of rules.

As in conventional CA and the basic SDCA model, the "reconfiguration" proceeds synchronously throughout the graph. The decision process includes an innate stochastic element: in the event that there is a rule that specifies that a site is to establish a link to a neighbor of one of its neighbors, but all neighboring sites have the same degree (which is the only dynamical discriminant), the neighbor with which a new link will be forged is selected at random.

As a concrete example, Saidani [64] presents a *tree-to-chain* algorithm that evolves an initial "tree" graph to a linear chain of linked sites (see Fig. 19). While we do not reproduce the full algorithm here, it is essentially a case-driven list of rules of the form *if condition* C_1 *(and condition* $C_2, \ldots$ *and condition* C_n*) then connect (or disconnect) site i to (from) the* n*th neighbor of i's neighbor*, ν. For example, an explicit "rule" might be: *if* $1 \le \deg^-(i) \le 2$ *and* $\deg^+(i) = 1$ *and* $|\tau(i)| = 2$ *then link i to a neighboring site j that has* $\deg^-(j) = 0$, where $\deg^-(i)$ and $\deg^+(i)$ are the *in*- and *out*-degrees of site *i*, and $\tau(i)$ is the total number of sites to which *i* is currently linked (with either incoming or outgoing links).

Conceptually, the details of Saidani's rules are less important than what the unfolding process represents as



Structurally Dynamic Cellular Automata, Figure 19
Schematic illustration of a *tree* topology reconfiguring itself into a linear *chain* using a set of case-based *"if–then"* topology rules defined in [64]; see text for details

a whole. An initial graph – which we recall is to be viewed as a distillation of a "modular robot" – is transformed, by the individual sites (or parts of the robot), into another *desired* structure; i. e., the graph is entirely *self-reconfigured*. Though the broader reverse-engineering problem (which includes asking such fundamental questions as *"How can a desired final state be mapped onto a specific cased-based list of graphical rules?"*) remains, as yet, unanswered, and the *Dynagraph* work environment [65] is currently limited to experimenting only with graphs that have less than 30 sites, the basic model already represents a viable new approach to using dynamic graphs to describe self-reconfigurable robots; and is potentially more far-reaching as a general model of topologically-reconfigurable dynamical systems.

SDCA as Models of Fundamental Physics

Pregeometric Theories of Emergent Space-Time

Although SDCA are a natural formal extension of conventional CA – and serve as general-purpose modeling tools – their conception was originally motivated by fundamental physics; specifically, by a search for models of self-organized emergent discrete space-time [42]. *"Space acts on matter, telling it how to move; … matter reacts back on space, telling it how to curve"*, which is the central lesson of Einstein's *geometrodynamics*, as explained by Misner, Thorne and Wheeler in their classic text on Gravitation [44]. Wheeler [73] has been a particularly eloquent spokesman for the need to search for what he calls a *pregeometry*, or a set of basic elements out of which what we normally think of geometry is built, but which are themselves devoid of a specific dimensionality: *"Space-time … often considered to be the ultimate continuum of physics, evidences nowhere more clearly than at big bang and at collapse that it cannot be a continuum. Obliterated in those events is not only matter, but the space and time that envelope that matter … we are led to ask out of what 'pregeometry' the geometry of space and spacetime are built"*. Wheeler has also proposed the idea that particles be viewed as geometric disturbances of spacetime, called *geometrodynamic excitons*.

A priori, SDCA appear tailor-made for describing pregeometric theories of space-time. Since in SDCA, lattice and local σ-values are explicitly coupled, and geometry and value configurations are treated on an approximately equal footing, SDCA is certainly at least formally consistent with Einstein's geometrodynamic credo. The structure is altered locally as a function of individual site neighborhood value-states and geometries, while local site-connectivity supports the site-value evolution in exactly the same way as in conventional CA models defined on random lattices. The microphysical view of physics that emerges from this construction is one in which a fundamentally discrete pregeometry continually evolves in time as an amorphous structure but with a globally well-defined dimensionality. Particles are constructs of that amorphous structure and can be viewed as locally persistent substructures – i. e. geometrical or topological solitons – with dimensions that differ from the surrounding value. Just as "value structure" solitons are ubiquitous in conventional CA models [32,74], "link structure" solitons might emerge in SDCA; physical particles would, in such a scheme, be viewed as geometrodynamic disturbances propagating within a dynamic lattice.

Of course, speculation regarding the ultimate constituents of matter and space-time date back at least as far as 500 BC when the philosopher Democritus mused on the idea that matter is made of indivisible units separated by void. Since then there have been countless attempts, with varying degrees of success, to fashion an entirely discrete theory of nature. We limit our discussion to a short survey of some recent work that centers on ideas that are either direct outgrowths of, or are otherwise conceptually related to, SDCA models. (A short history of pregeometric theories appears in chapter twelve of Ilachinski [32]).

One of the earliest proponents of pregeometry is Zuse [76], who speculated on what it would take for a CA-like universe to sustain "digital particles" on a cellular lattice. He focused on two main problems: (1) *How does the universe's observed isotropy arise from a CA's (Euclidean, hexagonal, etc.) anisotropy?*, and (2) *What is the information content of a physical particle?* As an answer to the first question, Zuse suggests …

"… *variable and growing automata. Irregularities of the grid structure are a function of moving patterns, which is represented by digital particles. Now, not only certain values are assigned to the single crosspoints of the grid in the concept of the cellular automaton which are interrelated and sequencing each other, but also the irregularities of the grid are itself functions of these values of the just existing interlinking network. One can imagine rather easily that in such a way the interdependence of mass, energy, and curvature of space may logically result from the behavior of the grid structure.*"

Jourjine [33] generalizes Euclidean lattice field theory on a d-dimensional lattice to a cell complex. Using homology theory to replace points by cells of various dimensions and fields by functions on cells, he develops a formalism that treats space-time as a dynamical variable and describes the change in the dimension of space-time as a phase transition.

Kaplunovsky and Weinstein [34] develop a field-theoretic formalism that treats the topology and dimension of the spacetime continuum as dynamically generated variables. Dimensionality is introduced out of the characteristic behavior of the energy spectrum of a system of a large number of coupled oscillators.

Dadic and Pisk [13] introduce a self-generating discrete-space model that is based on the local quantum-mechanics of graphs. Just as in SDCA, Dadic and Pisk's spatial structure is discrete but not static; it is fundamentally amorphous and evolves in time. Though the metric is essentially the same one used to define SDCA (i. e., D_{effec}), it is generalized to unlabeled graphs by referring to the topological description of the node positions rather than their arbitrary labels. Though their "graph dynamics" differs from what is used by SDCA (and uses a symmetrized Fock space that is local in terms of their graph metric, where "Fock space" is a Hilbert space used to describe quantum states with a variable, or unspecified, number of particles, and is made from the direct sum of tensor products of single-particle; or, in this case, single-*graph*, Hilbert spaces) it shares two important properties with SDCA: (1) interactions depend only on the local properties of the graph, and (2) interactions induce only minimal changes to the local metric function. An important consequence of their theory is that the dimension of a graph is a scale dependent quantity that is generated by the dynamics.

Combinatorial Space-Time Hillman [27] introduces a *combinatorial space-time*, which he defines as a class of dynamical systems in which finite pieces of spacetime contain finite amounts of information. Spacetime is modeled as a combinatorial object, constructed by dynamically coupling copies of finitely many types of certain allowed neighborhoods. There is no *a priori* metric, and no concept of continuity, which is expected to emerge on the macroscale.

The construction (and evolution) of spaces proceeds in three steps: (1) define a set X of combinatorial n-dimensional spaces (examples are conventional CA graphs, graphs with directional links, or some other kind of embedded symmetry); (2) define a set of local, invertible *primitive* maps $T\colon X \leftrightarrow Y$ between pairs of space sets, such that the maps do not all commute with one another (for example, a simple renaming of the sites or links gives an invertible, local map); (3) generate an arbitrary set of local invertible graph transformations by composing primitive maps with one another. Since the primitive maps are deliberately chosen so that they do not all commute, the act of composition yields infinitely many nontrivial transformations. The *orbits* $\{T^z(x) \mid z \in Z\}$ (for each space x in X) are $(n+1)$-dimensional combinatorial spacetimes; which include reversible CA and SDCA-like networks in which geometry evolves locally over time. Formally, Hillman uses matrices of nonnegative integers, directed graphs, and symmetric tensors to describe these systems, so that local equivalences between space sets are generated by simple matrix transformations. Concrete examples of dynamic combinatorial space-time graphs are given in [27].

Structurally Dynamic Disordered Cellular Networks As an explicit example of how dynamic graphs can be used to model pregeometry, consider *structurally dynamic disordered cellular networks* (abbreviated, SDDCN), recently introduced by Nowotny and Requardt [53,54,55,58,59,60]. SDDCN are a class of models closely related to SDCA but developed explicitly to describe a discrete, dynamic spacetime fundamental physics. The main difference between the two models is that whereas link connections in SDCA are strictly local, SDDCN are capable of generating both local and *translocal* links.

In contrast to more mainstream high-energy theories of fundamental physics (which are dominated by string theory and/or loop quantum gravity, both of which assume a certain level discretization at the Planck scale, but assume that a discrete space-time emerges from an underlying *continuum* physics), SDDCN takes a *bottom-up* approach. SDDCN assumes that there is underlying dynamic, discrete and highly erratic network substratum that consists of (on a given scale) irreducible mutually interacting agents exchanging information via primordial channels (links). The known continuum structures are expected to emerge on a macroscopic (or, mesoscopic) scale, via a sequence of coarse graining and/or renormalization steps.

Like SDCA, SDDCN are defined on arbitrary graphs, G, initially defined by a specified set of sites and links. Both sites and links are allowed to take on values. Site values, σ_i (which represent a primitive "charge"), are taken from some discrete set, $q \cdot \mathcal{Z}$, where q is a discrete *quantum of information*; link states assume the values $J_{ij} \in \{-1, 0, +1\}$, and represent an elementary coupling. The J_{ij} are equivalent to SDCA's l_{ij}, but take on *three* values rather than two. Heuristically, J_{ij} represent directed edges pointing either from site i to j (if $J_{ij} = 1$), or from j to i (if $J_{ij} = -1$); or, in the case of $J_{ij} = 0$, the absence of a link. At each time step (representing an elementary quantum of time), an elementary quantum q is transported along each existing directed link in the indicated direction. As for SDCA, SDDCN dynamically couples site values to links.

Nowotny and Requardt [53] introduce two network models: one in which connected sites that have very different internal states typically lead to large local fluctuations (= SDDCN$_1$), and another in which sites with similar internal states are connected (= SDDCN$_2$):

SDDCN$_1$

$$\leftrightarrow \begin{cases} \sigma_i^{t+1} = \sigma_i^t + \sum_j J_{ji}^t , & \\ J_{ij}^{t+1} = \mathrm{sign}\left(\Delta\sigma_{ij}\right) & \text{for} \begin{cases} \left|\Delta\sigma_{ij}\right| \geq \lambda_2 , \text{ or} \\ \left|\Delta\sigma_{ij}\right| \geq \lambda_1 \wedge J_{ij}^t \neq 0 , \end{cases} \\ J_{ij}^{t+1} = 0 , & \text{otherwise,} \end{cases}$$

SDDCN$_2$

$$\leftrightarrow \begin{cases} \sigma_i^{t+1} = \sigma_i^t + \sum_j J_{ji}^t , & \\ J_{ij}^{t+1} = \mathrm{sign}\left(\Delta\sigma_{ij}\right) & \text{for} \begin{cases} 0 < \left|\Delta\sigma_{ij}\right| < \lambda_1 , \text{ or} \\ 0 < \left|\Delta\sigma_{ij}\right| < \lambda_2 \wedge J_{ij}^t \neq 0 , \end{cases} \\ J_{ij}^{t+1} = J_{ij}^t , & \text{for } \Delta\sigma_{ij} = 0 , \\ J_{ij}^{t+1} = 0 , & \text{otherwise ,} \end{cases} \tag{46}$$

where $\Delta\sigma_{ij} = \sigma_i^t - \sigma_j^t$, and $\lambda_2 \geq \lambda_1 \geq 0$. Since SDDCN is intended to model pregeometric dynamics, Nowotny and Requardt [53] caution that the t parameter that appears in these equations must not to be confused with the "true time" that (they expect) emerges on coarser scales. In keeping with its physics-based motivation, SDDCN's dynamical laws depend only on the relative differences in site values, not on their absolute values. Indeed, charge is nowhere either created or destroyed, so that SDDCN conserves global "charge": $\sum_i \sigma_i^t =$ constant, where the arbitrary constant can be set to *zero*.

Both models start out initially on a simplex graph with $N \sim 200$ nodes, so that the maximum number of possible links is $N(N-1)/2$. The initial σ-seed consists of a uniform random distribution of values scattered over the interval $\{-k, -k+1, \ldots, k-1, k\}$, where $k \sim 100$. The initial values for link states, $J_{ij}^{t=0}$, are selected from $\{-1, 1\}$ with equal probability; i. e., the initial state is a maximally entangled nucleus of nodes and links. Nowotny and Requardt [55] state that "*… in a sense, this is a scenario which tries to imitate the big bang scenario. The hope is, that from this nucleus some large-scale patterns may ultimately emerge for large clock-time*". For most properties (other than the $\langle\sigma\rangle_t$ and $\sum_i |\sigma_i^{t+1} - \sigma_i^t|$, which are both equal to *zero* by construction), the average over the width of the initial vertex state distribution, taken over λ_1 and λ_2, specific realizations of initial conditions, and time, depend linearly on network size.

We summarize Nowotny's and Requardt's [53,55] findings, culled from extensive numerical experiments: (1) the appearance of very short limit cycles in SDDCN$_1$ (period 6 and multiples of 6, with the longest having period 36 on a network of size $N = 800$), (2) Much longer limit cycles and transients in SDDCN$_2$, both of which appear to grow approximately exponentially, (3) structurally, SDDCN$_1$ evolve from almost fully connected simplex networks to more sparse connectivities with increasing $\lambda_{1/2}$; there is a regime in which few vertices with very high degree coexist with many vertices with a low degree; for large (around $\lambda_1 \approx 60$; for large $\lambda_{1/2}$, the graph eventually breaks apart and all nodes become isolated; (4) for SDDCN$_2$, nodes typically have zero degree small $\lambda_{1/2}$, and links become increasingly dense as $\lambda_{1/2}$ increase; the degree distribution is generally broad and remains so for large $\lambda_{1/2}$ (the authors also note observing multiple local maxima of the distributions in a wide range of $\lambda_{1/2}$ values); (5) for SDDCN$_1$, there is an abrupt phase-transition in the temporal fluctuations of vertex degrees (defined as $\deg_i(t+1) - \deg_i(t)$) from a state in which there are essentially no fluctuations ("frozen network") to one with strong fluctuations ("liquid network"); (6) the distribution of site values is strongly bimodal for $62 \leq \lambda_1 \leq 85$ for SDDCN_1 (while SDDCN_1 distributions are not bimodal, the width of the site value distributions for different values of λ_1 appears modulated.

From a fundamental physics perspective, the most interesting class of behaviors of SDDCN involves emergent dimensionality. Nowotny and Requardt [55] argue that since the continuum is a self-organized dynamic structure that emerges in the limit of large N and t, the most useful measure of "dimension" cannot be purely local (as in the case of *effective dimensionality*, D_{effec}, used for describing SDCA systems). Rather, it must be an intrinsically *global property*; one that is independent of any arbitrary embedding dimension, and one that can take on relatively stable values in the *whole* (to characterize effective system-wide characteristics), while simultaneously being relatively impervious to otherwise rapidly changing structural changing taking place on the microscale. Toward this end, Nowotny and Requardt [53] define the upper (and lower) scaling dimensions, $D_S^U(i)$ (and $D_S^L(i)$), with respect to site i:

$$\begin{aligned} D_S^U(i) &= \limsup_{r\to\infty} \frac{\ln \beta(i,r)}{\ln r}, \\ D_S^L(i) &= \liminf_{r\to\infty} \frac{\ln \beta(i,r)}{\ln r}, \end{aligned} \tag{47}$$

and the upper (and lower) connectivity dimensions, $D_C^U(i)$ (and $D_C^L(i)$), with respect to site i:

$$\begin{aligned} D_C^U(i) &= \limsup_{r\to\infty} \frac{\ln \partial\beta(i,r)}{\ln r}, \\ D_C^L(i) &= \liminf_{r\to\infty} \frac{\ln \partial\beta(i,r)}{\ln r}, \end{aligned} \tag{48}$$

where $\beta(i,r) = \#\,\text{sites} j \mid D_{ij} \leq r$, and $\partial\beta(i,r)$ is the number of sites on the *surface* of the r-sphere. When the upper and lower limits coincide, we have the *scaling dimension* $(= D_S)$ and the *connectivity dimension* $(= D_C)$, respectively. D_S is related to well known dimensional concepts in fractal geometry; D_C is a more physical measure that describes how the graph is connected, and thus how sites may potentially influence one another [55]. Preliminary research [53] suggests that under certain conditions, behavior resembling a structural phase transition to states with stable internal (and/or connectivity) dimensions is possible.

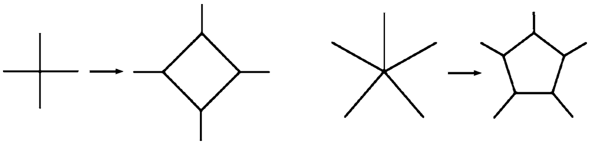
Network Automata

Stephen Wolfram devotes chapter nine of his Opus – *A new kind of science* (abbreviated, NKS) [75] – to applying CA to fundamental physics; and speculates on ways in which space may be described using a dynamic network. The central, overarching theme of NKS is that "simple" programs often suffice to capture complex behaviors.

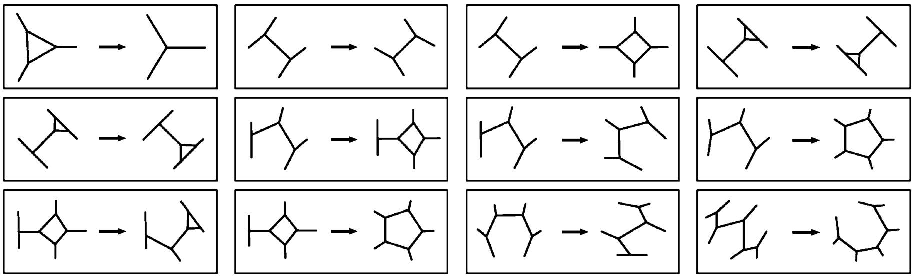
The bold claim made in chapter nine of NKS is that, on an even more fundamental level, what underlies *all the laws of physics*, as we currently understand them, is a simple CA-like program, from which, ultimately, all the phenomenologically observed complexity in the universe naturally emerges. As for the specific forms such a "program" may take, Wolfram's intellectual point of departure echoes that of other proponents of a discrete dynamic pregeometric theory:

"... cellular automata ... cells are always arranged in a rigid array in space. I strongly suspect that in the underlying rule for our universe there will be no such built-in structure. Rather ... my guess is that at the lowest level there will just be certain patterns of connectivity that tend to exist, and that space as we know it will then emerge from these patterns as a kind of large-scale limit".

Wolfram introduces his *network automata* (abbreviated, NA) with these basic assumptions (see additional notes in NKS [75] on the evolution of networks: pp. 1037–1040): (1) features of our universe emerge solely from properties of space, (2) the underlying model (and/or "rules") must contain only a minimal underlying geometric structure, (3) the individual sites of emergent graphs must not be assigned any intrinsic position, (4) sites are limited to possessing purely *topological* information (that defines the set of sites to which a given site is connected), (5) incoming and outgoing connections need not be distinguished, and (6) all sites have exactly the same total number of links to other sites (which is assumed equal to *three*). This last assumption – which is essentially the same one made by Nowotny and Requardt [53] as the basis of their SDDCN model; see Subsect. "Structurally Dynamic Disordered Cellular Networks" above – does not lead to any loss of generality. With two connections, only very trivial graphs are possible; and it is easy to show that any site with more than three links can always be redefined, locally, as a collection of sites with exactly three links each (see Fig. 20).



Structurally Dynamic Cellular Automata, Figure 20
Illustration of how sites that have more than three links can always be redefined as a set of sites with exactly three links each



Structurally Dynamic Cellular Automata, Figure 21
Examples of planarity-preserving network substitution rules. (Reproduced from [75] with permission)

Wolfram [75] gives several concrete examples of evolving graphs (as models of pregeometry), the dynamics of which are prescribed by a set of *substitution* rules rules; i. e., explicit lists of the topological configurations (of sites and links) that are used to replace (at time $t+1$) specific local configurations (as they appear at time t). However, in contrast to SDCA rules, Wolfram's substitution rules are strictly *topological*; no site-value information is used. Also, the number of sites in the graph can change as the graph evolves; where, in SDCA, the number remains constant.

Figure 21 shows examples of rules in which specific clusters of sites are replaced with other clusters of sites. While the rules shown in the figure share the property that they all preserve planarity, there is no particular reason for imposing such a restriction; in fact, rules that generate non-planarity are just as easy to define. Wolfram speculates (pp. 526–530 in [75]) that "particle states" may be defined as mobile *non*-planar subgraphs that persist on an otherwise planar, but *randomly* fluctuating topology. Reversible versions of these rules may also be constructed, by associating a "backward" version with each "forward" transformation.

Some care must be taken while both *defining* and *applying* these rules consistently. For example, if a cluster of sites contains a certain number of links at t, one is not permitted to define a rule that replaces that cluster with another one that has a different number of connections. Another restriction is that rules must be independent of orientation; that is, if a candidate rule requires identifying the specific links (of, say, an otherwise topologically symmetric n-link local subgraph) before activating a desired substitution, that rule is likewise forbidden. However, even with these restrictions, a large number of rules are still possible. For example, 419 distinct rules may be defined for clusters with no more than five sites.

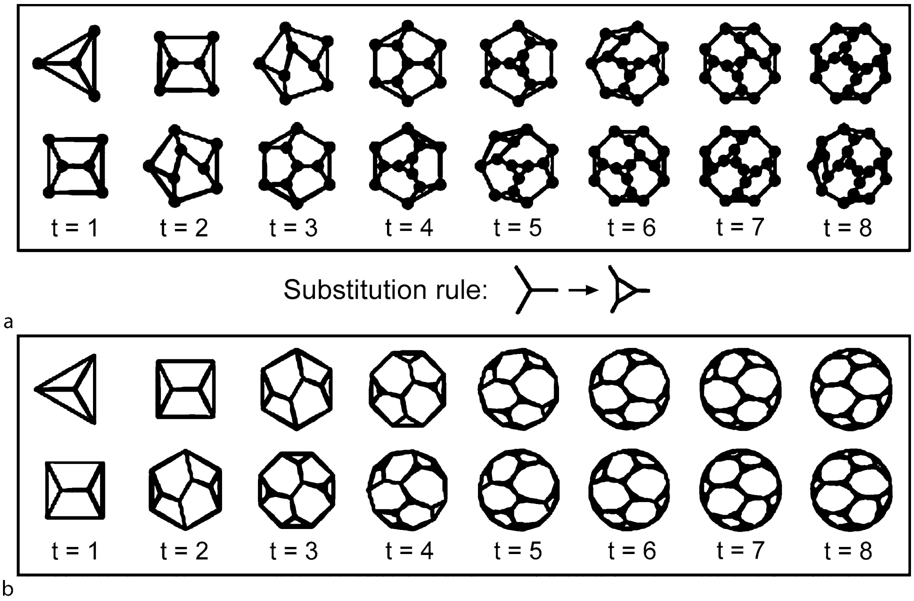
In applying network rules, one cannot simply simultaneously replace all pertinent subgraphs with their replacements, since, in general, two or more subgraphs with the same topology may overlap somewhere within the network. Since there is no *priori*, or universally consistent, way of ordering the subgraphs, *meta*-rules must be imposed to eliminate any possible ambiguities. For example, one method (*m1*) is to restrict replacements to a single subgraph per time step, selecting the subgraph whose replacement entails the minimal change to all recently updated sites. Another method (*m2*) is to allow all possible nonoverlapping replacements, while ignoring those that overlap. Wolfram reports that, although the second method obviously produces larger graphs in fewer steps, the two methods generally produce qualitatively similar structures.

Figure 22 traces the first few steps in the evolution of a simple graph under the action of a single substitution rule (defined at the center of the figure). Figures 22a and 22b show the results of applying this rule using methods *m1* and *m2*, respectively. In each case, the top row shows the form of the network before the substitution takes place at that step, and the bottom row shows the network that results from the substitution. The subgraph (or subgraphs, in Fig. 22a) involved in the replacement is highlighted at both top and bottom.

Wolfram also suggests that analogs of *mobile automata* [43] can be defined for evolving networks. By tagging a site i, say, with a "charge", $\sigma_i \equiv 1$, substitution rules may be defined to replace clusters of sites around the charged site. The effect is that the charge itself appears to move, as its effective (relative) position within the network changes as the geometric dynamics unfolds. (However, Wolfram also notes – on page 1040 in [75] – that *"despite looking at several hundred cases I have not been able to find network mobile automata with especially complicated behavior"*).

Future Directions and Speculations

Although SDCA were first introduced over two decades ago [28], much of their behavior remains unexplored. Of course, this is due largely to the difficulty of studying dy-



Structurally Dynamic Cellular Automata, Figure 22
Examples of network evolutions using the substitution rule shown at center. See text for explanation. (Reproduced from [75] with permission)

namical systems that harbor an a priori vastly larger coupled value-geometry space than the "merely" spatially-confined behavioral space of conventional CA. Only relatively recently have desktop computers become sufficiently powerful, and visualization programs adept enough at rendering multidimensional graphs [12], to make a serious study of SDCA behaviors possible. For example, the general-purpose math programs *Mathematica* (http://www.wri.com) and *Maple* (http://www.maplesoft.com) both provide powerful built-in graph-rendering algorithms to help visualize complex graphs. Standalone public-domain packages are also available; for example, AGNA [2], NetDraw [11], and Pajek [52]. In this final section, we list several open questions and briefly speculate on possible future directions.

Because of the relative paucity of studies dedicated purely to exploring the space of emergent structures (such as Wolfram's [74] pioneering studies of conventional CA), many (even very fundamental) questions remain open: *What kinds of geometries can arise?, Which subspace of the space of all possible graphs corresponds to those that are actually attainable using SDCA (and SDCA-like) rules?, What are the conditions for which certain geometries do, and do not, form?, What combinations of* σ*- and* ℓ*-rules give rise to specific kinds of graphs?*

Other open problems include: (1) determining whether the (provisionally defined) set of class-4 rules, for which effective dimension appears to remain constant, is *genuine*, rather than being either a long-term transient or an unintentional artifact of imposed run-time constraints; and, if this class is "real", we obviously need to ask, *How large is it?*, and *Under what conditions does it arise?*; (2) developing SDCA as formal mathematical models, perhaps as members of a broader class of graph grammars [20,35]; and (3) finding purely geometric analogs of the solitons known to exist in conventional CA models [32,74].

This article has introduced several generalizations of the basic SDCA model, including *memory* effects (Subsect. "SDCA With Memory"), *reversibility* (Subsect. "Reversible SDCA"), *probabilistic transitions* (Subsect. "Probabilistic SDCA"), and a class of SDCA-like dynamical systems that evolve according to rules that depend only on *topology* (Subsects. "Dynamic Graphs as Models of Self-Reconfigurable Robots" and "Network Automata"). However, other possibilities abound: (1) σ site-variables may take on a larger range of values, $\sigma \in \{0, 1, \ldots, k-1\}$; (2) link variables, ℓ_{ij}, may similarly take on a larger range of values, $\ell_{ij} \in \{0, \pm 1, \pm 2, \ldots, \pm m\}$ (where, say, ± determines "directionality", and absolute value, $|\ell_{ij}|$, represents either channel capacity for information flow or some other innate property); and (3) both sites and links may take on richer, and more explicitly "active", roles of *agent-actors* [17].

Apart from these formal extensions, some obvious future applications include modeling communication and social network dynamics, studying the dynamics of plasticity in artificial neural networks, designing adaptive self-reconfiguring parallel-computer networks (as well as "amorphous" computer chips), studying behaviors of gene-regulatory networks, and providing the conceptual core for fundamental pregeometric physical theories of discrete, emergent space-times.

Article Outline

Glossary

Submarine landslide A gravitational mass failure feature on the seafloor.

Slow earthquake A discrete slip event that produces millimeter to meter-scale displacements identical to those produced during earthquakes but without the associated seismic shaking.

GPS The Global Positioning System consists of a constellation of at least 24 medium earth orbiting satellites transmitting two or more microwave frequencies for use in precise positioning.

Seafloor geodesy The application of geodetic methods (studies of the change in the shape of the earth's surface) applied to a submarine environment.

Definition of the Subject

The term 'submarine landslide' encompasses a multitude of gravitational mass failure features at areal scales from square meters to thousands of square kilometers. Here, we concentrate on the large end of that spectrum, namely the submarine landslides that, when they move either in contained slip events or catastrophically, can generate surface displacements equivalent to $> M6$ earthquakes and/or hazardous tsunami.

The term 'slow earthquake' describes a discrete slip event that produces millimeter to meter-scale displacements identical to those produced during earthquakes but without the associated seismic shaking. Slow earthquakes, primarily associated with tectonic fault zones, have been recognized and studied with increasing frequency in the past decade largely due to the decreasing cost and proliferation of Global Positioning System (GPS) geodetic networks capable of detecting the ground motion [1,2,3]. Recently, one such GPS network on the south flank of Kilauea volcano, has recorded multiple slow earthquakes on the subaerial portion of a large landslide system that occurs primarily in the submarine environment [4,5,6]. Because the bathymetric charts surrounding the Hawaiian islands are littered with the remnants of massive, catastrophically emplaced submarine landslides (Fig. 1) it is natural to wonder if a slow-slipping submarine landslide is a precursory stage of one that will ultimately fail catastrophically.

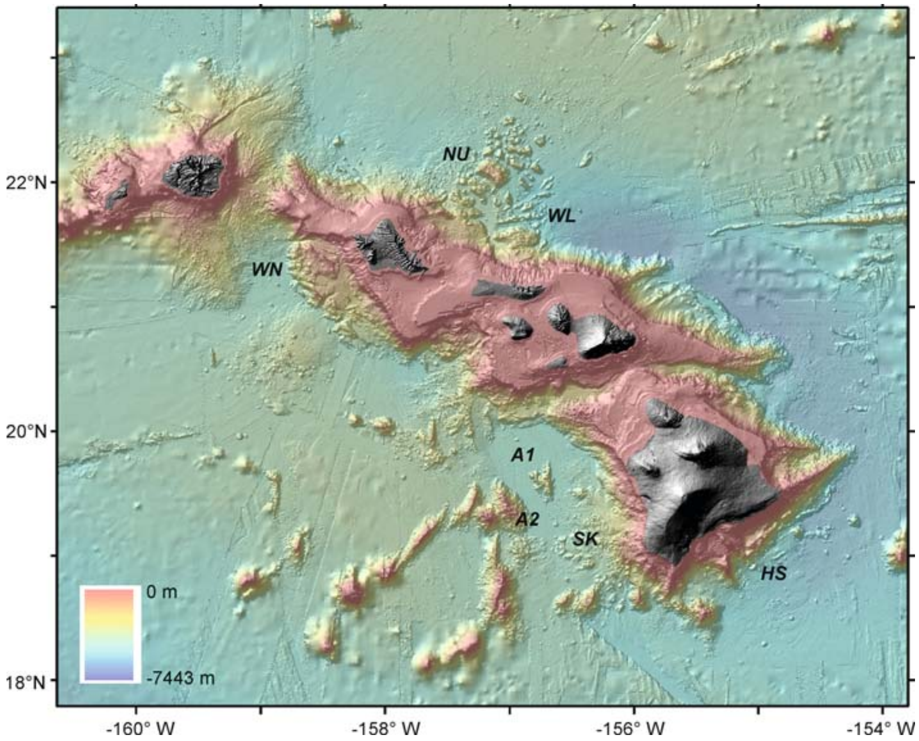
We see two principal reasons why monitoring submarine landslides and slow earthquakes associated with them is important. First, because catastrophic failure of submarine landslides can cause tsunami they represent significant hazards to coastal zones. Understanding and monitoring how slow slip may lead to accelerated slip and catastrophic failure is, therefore, very important in terms of hazard mitigation. Second, submarine landslide systems can be some of the most active as well as spatially confined deforming areas on earth and so they represent excellent targets of study for furthering our understanding of the general fault failure process. For instance a pertinent question for which we do not yet have an answer is: are fault frictional properties homogeneous enough that the occurrence of slow earthquakes on a detachment fault plane underlying a landslide could relieve stress on the fault or do the slow earthquakes in one region load a neighboring seismogenic patch bringing it closer to a large sudden failure (i. e. an earthquake)?

While installation and operation of GPS networks on land is now relatively routine and somewhat inexpensive, the in situ monitoring of submarine landslide motion represents a significant technical challenge with accordingly higher costs. Submarine geodesy e. g. [7], however, is a nascent and rapidly evolving field with relative and absolute positioning techniques being intensely studied and developed. The near future is sure to see many advances in our monitoring and understanding of submarine landslides and slow earthquakes due to the application of submarine geodetic techniques.

Introduction

Submarine Landslides

The last 30 years have seen a dramatic increase in the recognition of submarine landslides world-wide, due largely to the increased prevalence and capability of swath and side-looking sonar mapping systems and systematic submarine mapping programs. For instance, the side-scan sonar mapping of the Hawaiian exclusive economic zone in the 1980s resulted in the discovery that massive submarine landslides are spatially distributed along the entire Hawaiian Ridge [8] (Fig. 1). These features are some of the largest landslides on the planet, with more than 70 attaining lengths greater than 20 km and some having lengths greater than 200 km and total volumes exceeding 5000 km^3. Since then, submarine landslides associated with other volcanic islands e. g. [9,10,11], mid-ocean ridges [12], and continental margins [13] have also



Submarine Landslides and Slow Earthquakes: Monitoring Motion with GPS and Seafloor Geodesy, Figure 1
Topographic and bathymetric map of the Hawaiian Islands (data from http://geopubs.wr.usgs.gov/i-map/i2809/). Studied submarine landslides are indicated: HS, Hilina Slump; SK, South Kona; A1, Alika 1; A2, Alika 2; WL, Wailau; NU, Nu'uanu; WN, Wai'anae

been studied. Of these, the slopes flanking volcanic islands, especially when they are in their steeper-sloped shield-building stage [14,15], tend to be particularly susceptible to landslide instability and so they have been the focus of much recent research in the Canary Islands [16,17] and especially in the Hawaiian Islands [18,19,20,21,22,23]. For instance, most of the Hawaiian submarine landslides are thought to be inactive, except for those on the flanks of the Big Island e. g. [21].

The morphology of submarine landslide features is similar to their subaerial counterparts. In map view they generally exhibit lobate and hummocky bathymetry. In cross-section, a wedge-shaped region of deformed material thins down-slope and is underlain by a gently-sloping planar dislocation surface (sometimes referred to as a basal detachment or 'decollement') separating the deformed carapace from the underlying undeformed substratum (Fig. 2). An upslope extensional head-scarp region transitions into a contractional fold belt towards the toe. The normal faults in the upslope region typically intersect the surface at high angles (> 45 degrees) and are manifested as scalloped-shaped scarps at the head of the slide that separate regions of differentially tilted fault blocks; in the sub-surface they may continue at high angles until they intersect the basal decollement, or they may sole with depth either into the decollement or into another sub-horizontal slip-surface [24]. The contractional regions are characterized by folded and bulging layers, closed depressions, and steep toes [20,21,25]. Moore et al. [8] separated the Hawaiian submarine landslides into two principal types: 'slumps' and 'debris avalanches'. The slumps are wide (up to ∼ 100 km), deep-seated (∼ 10 km thick), and have surface inclinations of up to 3 degrees while the debris avalanches are long (up to ∼ 230 km), shallowly-seated (50 m–2 km thick), and have surface slopes generally less than 3 degrees.

Concomitant with the mapping of the landslide features has been the increasing recognition that sudden submarine landslide movement can cause tsunami with destructive implications for coastal societies e. g. [26]. A particularly well-known example of this scenario is the 1929 Grand Banks failure [27]. Moreover, in the 1990s alone workers have attributed at least 5 tsunami events to catastrophic landslide failure sources: (1) 1992 Flores Island, Indonesia [28]; (2) 1994 Mindoro, Phillipines [29]; (3) 1998 Papua New Guinea e. g. [30]; (4) Kocaeli, Turkey [31]; (5) 1999 Pentecost Island, Vanuatu [32]. In Hawaii, the $M_w 7.7$ 1975 Kalapana earthquake, most likely

due to slip of the fault surface underlying an active submarine landslide [33,34,35], caused local loss of life and damage in Southern California.

From a hazards standpoint it is particularly important to understand how tsunami are generated by submarine landslides because the propagation time between tsunami generation to runup is typically on the order of minutes. For instance, a catastrophic failure of the west side of the island of Hawaii would likely send tsunami waves around the Hawaiian islands that would reach the densely populated areas of Oahu's Waikiki beaches in less than an hour and more likely ∼ 30 min (G. Fryer, personal communication, 2007). Simulating waves generated by a sudden, chaotic disturbance of the seafloor, as expected from a submarine landslide, is quite complicated e. g. [36,37] and not all workers agree on approaches or results. Murty [38], however, stressed that parameters such as slide angle, water depth, density, speed, duration of the slide are second order, while instantaneously displaced volume is likely the most important parameter controlling tsunami generation.

Despite the increasing awareness of their hazard, little is known about how submarine landslides actually move, largely because of the challenge of installing instruments and retrieving data from the submarine environment. Moore et al. [8] recognized that while slumps more likely move relatively slowly, debris avalanches could be deposited very rapidly based on, for instance, uphill flow of material in the distal portions of the landslide deposits. In agreement with this, the estimated downhill velocities from the 1929 Grand Banks event was 60–100 km/h [39] whereas many studies have documented ∼ 6–10 cm/yr horizontal and vertical velocities associated with a submarine landslide flanking the Island of Hawaii's Kilauea volcano, the Hilina Slump [4,5,6,40,41,42]. Recently, GPS data from the Hilina Slump have elucidated that not only does the slump move at the above-stated, fairly smooth, background velocities, but also that the slump will occasionally deform in discrete accelerated cm-scale motions equivalent to $M6$ earthquakes but without the shaking [4,5,6]. These 'slow earthquakes' last hours and accommodate cm's of ground displacement (Fig. 3). It is not currently known, however, how the occurrence of a slow-earthquake in a submarine landslide system will affect its future movement by either making it more or less probable of failing catastrophically.

Slow Earthquakes

The term 'slow earthquake' has been used to describe a variety of transient aseismic deformation phenomena including slow precursor events preceding large earthquakes [43,44,45,46,47,48], afterslip following earthquakes [49,50,51], variable fault creep rates [52,53,54,55], certain subduction zone thrust events with unusually long durations and large amplitude tsunamis for their size [56], and discrete fault-slip events that do not produce detectable seismic shaking but are accompanied by ground displacements very similar to those produced during earthquakes [1,2,3,4,5,6,57]. Hereafter, when we use 'slow earthquake' we will refer to this latter description although the term was first used in the modern literature to describe a slow precursor to the great Chilean 1960 earthquake [43].

In contrast to slow precursor events whose ground motions, like traditional earthquakes, are measured in seconds or minutes, slow earthquake (SE) displacements usually accrue over time periods ranging from hours to days and so they have been typically sensed with geodetic methods. In the last decade, the proliferation of continuous GPS (CGPS) networks has led to numerous SE observations and the discovery of some very rich behavior. In certain regions SEs have occurred with very regular periods [2,4,58], they are often associated with non-volcanic tremor [59,60] and, apparently, SEs follow very different scaling laws (moment vs. duration) than traditional earthquakes [61]. Explanations for SE slip behavior has varied to date. For subduction zones, the combination of deep (> 35 km) SE sources and their association with tremor (a phenomenon initially thought to be caused by forced fluid flow [62] but more recently also explained in terms of shear failure [63,64]) led to one current hypothesis that SE mechanics are controlled by water released during metamorphic phase changes at the interface between a subducting and overriding plate [65,66]. Other explanations have invoked rate- and state-variable frictional behavior to suggest that SEs occur preferentially at transitions between velocity strengthening and weakening regimes on a fault plane [67,68,69] and that temporally varying climatic load changes could help explain SE periodicity [58].

Due, in part, to their large magnitude deformation signal and the high concentration of CGPS networks focused on them, subduction zones have dominantly been the location of the most SEs to date [1,2,57,59,70,71,72]. Recently, the CGPS network on Kilauea volcano's mobile south flank has recorded multiple SEs [4,5,6] (Fig. 4) and it is through the Kilauea events that SEs have come to be associated with submarine landslides.

Monitoring Motion: Subaerial and Submarine Geodetic Methods

Not surprisingly, much more is known about the motion of subaerial than submarine landslides. Geodetic measurements on land combined with contemporaneous measurements of other properties (pore-water pressures, strength of materials, etc.) have allowed, in some cases, a very thorough understanding of how landslide motion is related to driving forces such as gravitational stresses and rainfall. For instance, Baum and Reid [73] instrumented a slow-moving submarine landslide in Honolulu's Manoa valley with extensometers recording at 15 minute intervals and rain gauges and found a direct correlation between rain fall and deformation events. Similarly, Malet et al. [74] showed that GPS-measured surface velocities increased to as high as 20 cm/day following periods of higher rainfall during May 1999 at the Super-Sauze earthflow in the French Alps. At a slightly different scale, Hilley et al. [75] used InSAR to simultaneously map deformation of multiple landslides in California's Berkely Hills at $\sim$ monthly intervals and found that landslide motion correlated with times of high precipitation and that during the 1997–1998 El Nino event displacement rates doubled from the background rate of $\sim$ 27–38 mm/year, albeit with a $\sim$ 3 month time lag between the onset of motion and the high precipitation.

Much of the current knowledge that we have about the motion of submarine landslides comes from their easier-to-monitor subaerial portions, such as at Kilauea's Hilina slump (Fig. 3). In the case of the Hilina Slump, fully 3/4 of the feature resides offshore at depths greater than 2000 m and the deformation monitoring network is necessarily concentrated on the down-dropped blocks near the headwall scarp of the entire system. Recently, however, submarine methods have started to provide geodetic information from the ocean floor itself e. g. [7], e. g. [76,77,78,79]. As these methods become more cost-effective and widespread they will surely yield much insight into submarine landslide kinematics and, eventually, be employed in operational hazard monitoring/mitigation scenarios.

Whether a network is solely subaerial, submarine, or some combination of the two, it is important to consider that monitoring strategies can vary substantially depending on the time duration of the expected signal, the desired threshold of detection, and the desired time latency for individual solutions. For instance, simple detection and warning of catastrophic landslide failure needs the most rapid solution latency but coarse detection thresholds (meter rather than millimeter level, for instance) are appropriate. Conversely, if the goal is to detect small, potentially precursory motions such as slow earthquakes, then detection threshold must be as sensitive as possible along with solution latency being low.

Subaerial Geodesy: GPS

A multitude of geodetic techniques, from mechanically- to electromagnetically-based, are currently employed on landslides to measure motion caused by a range of deformational phenomena spanning opening of small surface cracks to the motion of kilometer sized blocks e. g. [74]. Data from Global Positioning System (GPS) networks has increasingly contributed to the library of observations associated with landslide motion. In particular, for submarine landslides that are large enough so that their motion causes earthquakes or slow earthquakes [4,6,80], a technique which is suitable for inter-station distances measured in kilometers is most appropriate and so below, we concentrate on the use of GPS with submarine landslides.

GPS GPS networks capable of sub-cm to mm-scale 3-dimensional ground motion detection are now deployed in many of Earth's most actively deforming zones (see for example, http://sps.unavco.org/crustal_motion/dxdt/) and readers are referred to thorough reviews of the general technique and its application for geodynamic studies [81,82,83].

Crustal motion GPS networks are usually divided into two types: those that record data continuously (CGPS) and those whose individual monuments are occupied less frequently in survey mode (SGPS). Depending on a variety of factors including the modernity of the receiver, the bandwidth of telemetry networks (should they exist), and the storage capacity of the archival center, CGPS sampling rate generally varies between once every 30 and 1 s (though most modern receivers are capable of sampling at frequencies higher than 1 Hz). SGPS sampling is more varied though it usually comprises re-occupation of sites at intervals ranging from months to years with occupation times of hours to days and sampling rates similar to CGPS. Accordingly, SGPS networks are more useful for wider ranging spatial characterization of deformation phenomena rather than for the rapid detection of motion or for tracking temporal evolution during transient events.

High rates of sampling alone, however, do not guarantee that CGPS network positional solutions will achieve their highest precision and/or accuracy. Assuming that all sites within a CGPS network have stable monuments and high-grade geodetic antennae and dual frequency receivers, the most important components of its error budget for deformation monitoring are: (1) integer ambiguity resolution; (2) orbital estimation; (3) atmospheric delay estimation; (4) antenna multipath; (5) satellite constellation geometry, and (6) intra-network baseline length. For networks monitoring landslides with spatial scales on the order of kms or tens of kms, however, the baselines are short enough that errors scaling with baseline lengths are small contributors to the error budget. In addition, as absolute positioning in a global reference frame is not essential, precise orbital estimation is less important. For the other error sources, freely available software packages such as GAMIT, GIPSY, and BERNESE (http://facility.unavco.org/software/processing/processing.html), and precise orbit processing centers such as the IGS (International GNSS Service, http://igscb.jpl.nasa.gov/) or the Scripps Orbit and Permanent Array Center (SOPAC, http://sopac.ucsd.edu/) usually allow good enough mitigation of these errors so that daily GPS solutions have resolution on the order of 2–5 mm in the horizontal and ~ 2–3 times worse in the vertical e. g. [83]. This resolution rule-of-thumb, however, generally applies to post-processed data with occupation times exceeding ~ 6–8 h, use of precise orbits, and the best atmospheric estimation techniques e. g. [84]. Because of the hours-to-days delay needed for estimating various grades of precise orbits and the computational time needed to estimate all the parameters for all sites with this much data this standard rule-of-thumb cannot necessarily be applied to a real-time or near real-time solution.

Real- and Near-Real Time GPS Processing There are a variety of processing techniques that may be suitable for real-time or near-real time monitoring applications for the subaerial counterparts to submarine landslides. For instance, the well-known real time kinematic (RTK) positioning technique frequently employed by the surveying community applies differential corrections sent via radio link between stations to yield site position estimates with cm-scale precision over baselines up to ~ 10 km in real-time [85]. The technique works best for baseline distances less than ~ 10 km typically, because the assumption of correlated errors between stations is not necessarily valid and differential corrections cannot be accurately applied for larger baselines. Thus, RTK may be a suitable monitoring technique if a more spatially contained portion of a landslide, such as a fault zone, is a particularly good indicator of motion for the overall larger unit.

It is the number of measurement epochs required to resolve the integer-cycle phase ambiguity inherent with GPS data, however, that is the principal factor limiting the temporal latency of high resolution GPS positioning solutions. Kinematic techniques typically require minutes worth of GPS data (when sampled at 1–30 s) in order to resolve integer ambiguities for initialization and reinitialization if a cycle slip or loss of phase lock occurs during measurement, although progress is being made on mitigating ionospheric effects and reducing time of integer ambiguity resolution e. g. [86]. Regardless, if GPS station locations are chosen with relatively good sky-view then loss of lock due to poor satellite visibility should be minimal.

Recently, Bock et al. [87] developed a method of resolving integer ambiguities from a single epoch of dual frequency GPS phase and pseudo range data that provides independent epoch-by-epoch position estimates over baselines as large as ∼ 40 km. Their method allowed instantaneous positioning resolution of 1.5 cm in the horizontal and 7–8 times worse in the vertical coordinates. Langbein and Bock [88] applied the technique to determine offsets in positional time series due to slip events recorded by the Parkfield, California CGPS network which has similar spatial scales to a typical large submarine landslide. They found that offset sensitivity was ∼ 5 mm for a 2 s sampling window and this decreased to ∼ 2 mm when a 60 s window was used [88]. To the best of our knowledge this represents the current state-of-the art in terms of real-time detection of motion over spatial and temporal scales typical of submarine landslides.

At Kilauea, we have developed an automated *near* real-time processing strategy for our monitoring efforts at the Hilina Slump (Figs. 3 and 5) [89]. The CGPS data are telemetered hourly by radio modem back to the USGS Hawaii Volcano Observatory (HVO) where they are retrieved via FTP. We use a sliding window approach, collecting all data available within the most current two-hour period and performing a network solution using the PAGES [90] processing software. We use the 30 s, ionosphere free phase combination as the observable and use and hold fixed the IGS ultra-rapid orbits and apply the NGS antenna phase calibration patterns for each site [91]. We also apply the IERS standard solid Earth tide [92] and Schwiderski ocean tide loading corrections [93,94]. Every half hour we estimate a piece-wise, linear neutral atmosphere (troposphere) correction and one set of N–S and E–W neutral atmospheric gradient corrections for each site. We apply a 'weak' constraint of 10 cm to the atmospheric corrections based on examination of previous adjustments.

Figure 5a shows an example of baseline change time series from indicative stations derived from this approach and re-run in a simulated near real-time mode for the time period bracketing the slow earthquake from January 26–28, 2005 at Kilauea. Generally, the hourly baseline change noise levels are on the order of ±10 mm, although because of some particularly large outliers, the standard deviation of the baseline changes (not including the time period of the SE) is closer to 20 mm (Fig. 5b). Some of the large excursions in the time series not associated with the SE are due to the high amplitude, strongly spatially and temporally varying atmospheric water vapor gradients often associated with tropical islands such as Hawaii e. g. [95]. For instance for the excursion in the MANE-PGF3 baseline in the middle of day 18 (Fig. 5a), the time series takes a sharp upward bend until the start of day 19 when it again begins to oscillate about its mean value from present days. This baseline change gradient is very similar to the onset of the SE near the beginning of day 26. It is clear from the remainder of the time series after day 27 that the ∼ 25 mm offset is permanent, however, and so indicative of a real deformation event.

In a real-time monitoring scenario, because of the 2 h temporal latency and the atmospheric noise levels on the order of 1/3 the maximum signal levels in the baseline change plots, it would probably require on the order of 12–24 h before this event could be definitively classified as a deformational event. This could certainly be useful to hazard mitigators for being aware that a slow event such as an SE was occurring, but not in the event of a rapidly accelerating catastrophic collapse where the detection and warning time must be on the order of minutes. For more rapid warning, more sophisticated filtering techniques could be employed (such as monument motion, and network-wide coherence assessment as described below for the Network Inverse Filter [96]) although regions of large atmospheric gradient will always be hampered by low signal-to-noise ratios unless more sophisticated atmospheric mitigation techniques such as tomographic mapping [97] are employed in a real-time manner. Accordingly, the small detection threshold levels of the epoch-by-epoch processing at Parkfield described above [88] must be taken in the context of the relatively low atmospheric delay environment present there.

Submarine Geodesy

Subaerial geodetic methods have, until now, provided essentially the entirety of geodetic evidence for submarine landslide-related deformation including slow earthquakes. Our understanding of submarine landslide motion and slow earthquake mechanics stands to increase dramatically in the coming decade, however, owing to the rapidly advancing field of submarine geodesy which can now reliably provide in situ measurements of seafloor deformation. The submarine environment is particularly challenging for geodesy techniques especially if they require the propagation of energy across a medium (ocean water) that

can exhibit highly spatially and temporally variable material properties.

Direct Path and Indirect Acoustic Approach One of the submarine geodesy techniques most frequently employed to date is direct path acoustic measurement of baseline length changes using acoustic transponders. This method has been used to make in situ observations of tectonic motions on the seafloor at the Juan de Fuca ridge where one study found cm-scale motion occurring over a period of a few days associated with an on-axis eruption [77] and another found no detectable motion over a period of a few years at a quiescent ridge segment [76]. By interrogating each other, pairs of instruments use two-way travel time measurements to constrain the inter-station distance. After correcting for variations in sound speed that result from changes in water temperature, salinity, pressure, and local tilt of the monument itself, these systems yield sub-cm precision for individual measurements. Operating frequencies typically range from 7.5 to 108 kHz and in deeper isothermal waters, the upward refraction of sound waves prevents signals from one transponder being received by the other at distances greater than ∼ 1 km [79]. Travel-time is determined simply by correlating the transmitted and received signals and picking the peak of the resultant correlogram. In quiet operating environments this can usually be done at the scale of ∼ 5 µs, resulting in a ∼ 4 mm range error [7].

For the greater depth ranges, Sweeney et al. [79] devised an approach that allowed ±2 cm resolution measurements for baselines up to 10 km at 2500–2600 m depths at a stable site on the Juan de Fuca plate. Sweeney et al. [79] suspended an acoustic interrogator hundreds of meters above the seafloor in a position acoustically visible to an array of seafloor-mounted instruments. In a manner similar to Spiess [98] they estimated the relative positions of the stations by moving the interrogator and collecting acoustic range data multiple locations.

The focus of these initial deployments of the direct and indirect acoustic approach systems was on measuring annual tectonic rates, and not necessarily on capturing transient events such as SEs that occur over hours or days. Accordingly sampling rates in current seafloor geodesy projects typically do not exceed a few times per day, largely because providing adequate power to seafloor instruments is still financially prohibitive. However with cabled oceanographic observatories scheduled to come online in 2007–2010 (http://www.neptunecanada.ca/; http://www.orionprogram.org/) the power delivery problem could be solved at high priority seafloor sites.

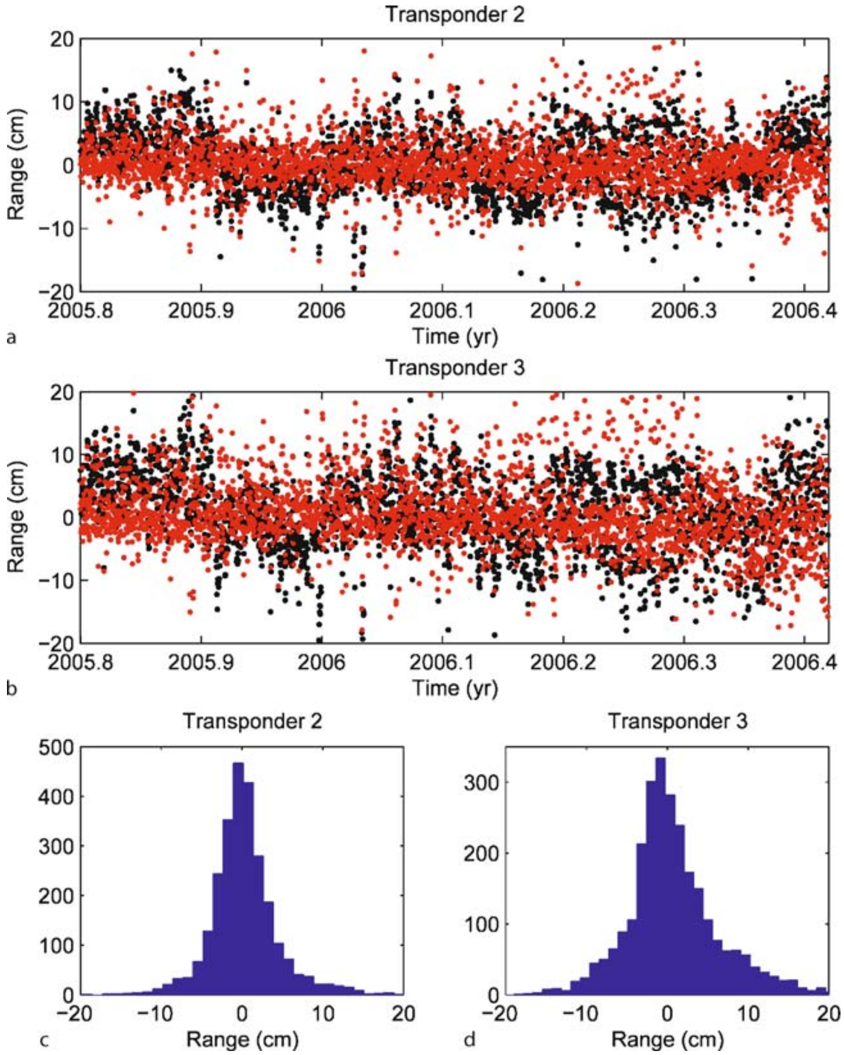
From October, 2005 through June, 2006 we deployed seven 10 kHz Linkquest transponders mounted ∼ 3 m above steel tripods and spaced over a distance of ∼ 3 km on the Hilina Slump (Fig. 3). One of the goals of this pilot project was to evaluate the performance of the transponders for use in submarine landslide monitoring at significant depth; each unit operated at a depth between 2640 and 2690 m. Battery power restrictions for the ∼ 8 month duration of the project meant that the instruments ranged to one another 12 times per day.

In Fig. 6 we show range change time series from two transponder-pair baselines (∼ 530 and 683 m respectively) for which data recovery was complete over the experiment's duration. For the other transponder pairs data recovery was not as complete because either: (1) the unit was knocked over by local mass-wasting events or (2) the baseline distance was too long and data dropouts occurred when the transponders lost sync with one another. The two way travel times were picked from the peak of the correlation function between the outgoing and received waveforms at one end of the baseline. The black dots in Fig. 6a and b show the raw measurements, while the red dots show the distance measurements corrected for the variations in sound speed due to temperature changes, which were measured by an external conductivity and temperature sensor mounted on the transponder frames. The raw time series show significant long-term trends due to temperature variations that are effectively removed using just the temperature measurements at the transponders. We did not correct for salinity variations because all of our conductivity sensors provided contaminated data due to clogging by the local mass wasting events.

For these baseline pairs which were oriented approximately perpendicular to the maximum expected motion of the Hilina Slump we expect essentially no motion for such short baselines and during such a short measurement period. At the 1σ level individual measurement noise is ∼ 4.1 and 5.7 cm respectively, though it is clear that smaller, cm-scale changes would be detectable given a long enough time period. For instance, daily estimates of baseline length have approximately a 1 cm standard deviation. For rapid event detection, baseline changes would need to be on the order of 10 or more cm or measurement frequency would need to be increased.

GPS-Acoustic Method The acoustic measurements described above provide only relative measurements of baseline length changes; however, for submarine landslide monitoring efforts it may be desirable to place submarine and subaerial measurements in a single regional or global reference frame. Largely with the aim of furthering seafloor active tectonics studies, a research group spearheaded by the late Fred Spiess conceived of, and have begun implementing integrated GPS and acoustic seafloor geodesy (GPS-A) studies, described in great detail by Spiess et al. [7] and references therein.

Briefly, GPS-A positions seafloor geodetic markers in a global reference frame by combining kinematic GPS positioning of a sea-surface platform (ship or buoy), precision underwater sound travel time measurement over km-scale path lengths, and a strategy for eliminating the large



Submarine Landslides and Slow Earthquakes: Monitoring Motion with GPS and Seafloor Geodesy, Figure 6
a,b Baseline difference (position – median position) for transponder-transceiver pairs (T2-C1, T3-C1 in Fig. 3) pairs from October 2005 – June 2006. errors in travel time measurement arising from a spatially and temporally varying sound speed structure in the near surface portion of the water column. The error mitigation strategy is based on the recognition that the location of the sea surface midpoint above the center of a triangle of seafloor transponders (themselves positioned via a near-bottom acoustic survey) is the point at which the three sea surface-to-seafloor travel times are identical and so, independent of sound speed.

Spiess et al. [7] reported repeatabilities of ±0.8 cm and ±3.9 cm in the north and east components, respectively, of seafloor measurements on the Juan de Fuca plate from 1994–1995. More recently, Gagnon et al. [78] reported velocities with ~ 5.5 cm magnitudes and 0.6–0.8 cm 1σ errors from surveys between 2001–2003 on the updip portion of the Nazca-South America subduction zone in the Peru trench.

Optical Path Length Zumberge [99] combined commercial subaerial surveying technology (an EDM) with an optical fiber strainmeter in order to devise a low-power, cost-effective system for the harsh seafloor operating environment. EDMs (electronic distance meters) typically can measure distances with 1–2 mm precision over several km by transmitting intensity modulated infra-red energy and measuring travel time from far away reflective surfaces. Zumberge [99] modified the EDM for seafloor geodesy by focusing the transmitted beam into the fiber's core and gathering the reflected light from the fiber's far-end into the EDM receiver optics.

The composite instrument comprises an optical fiber (enclosed in a hermetically sealed stainless steel casing) that stretches between two anchors, one 'active' and one 'passive', separated by several hundred meters on the seafloor. The active anchor houses the EDM and all supporting electronics and the passive anchor's purpose is to fix the fiber to the seafloor. In a test of their instrument, Zumberge et al. [100], report 1mm scatter of distance measurements over a 500-m-long fiber during a 50 day long period.

One of the obvious advantages of the optical path length technique is the high precision, isolation from sea water-borne errors, and the continuous nature of the measurement. The disadvantage, however, is that the technique is limited to short baselines ($< \sim 1$ km) and so the precise location of straining regions must be known a priori. Nonetheless, for monitoring purposes with very well-defined targets such as the headwall portion of an active landslide, the technique holds much promise.

Pressure Sensor Vertical Deformation Phillips et al. [40] recently developed a new technique that used pressure sensors in campaign-mode repeat surveys to measure vertical deformation rates of the seafloor at depths exceeding 2000 m at the offshore portion of the Hilina Slump. Depth and pressure are related to one another in a straightforward manner through the hydrostatic equation, though for measuring seafloor deformation rates at the cm/yr level many other reductions must be performed (Phillips et al. [40] – also her thesis). The pressure sensor method is technologically challenging, requires much ship time, and requires during each site visit both a geodetic monument and a pressure sensor (lowered from a ship) to be operating in close proximity to one another at depth on the seafloor. Because, in each revisit it was not practical to collocate the pressure sensor in a repeatable fashion on the benchmark, Phillips et al. [40] found it necessary to measure the vertical offset between the pressure sensor and the benchmark via acoustic ranging.

Important error sources for this technique are poor knowledge of α the specific volume of the water column (the reciprocal of density) and the speed of sound in depth. Due to changing tides, secular and seasonal barometric changes it is also necessary to utilize a common, stable reference, such as mean sea level (MSL) which, in turn, requires estimation of the geopotential anomaly.

Ultimately, Phillips et al. [40] conclude that their data show significant vertical deformation (9 ± 2.4 cm/yr) in the mid-section of the HS and negligible deformation towards the outer bench (just inboard of the toe of the entire landslide feature). These data are consistent with dislocation models delimiting the potential amount (25.0–28.1 ± 7.3 cm/yr), spatial extent (24.8–27.0 ± 0.5 km seaward of Kilauea's East rift zone), and depth (7 km) of the principal slipping surface below the landslide. This is a significant advance not only because it represents the first data set that allows a glimpse of how strain is partitioned in a massive submarine landslide such as the Hilina Slump, but also because it represents an ongoing monitoring project at a submarine landslide, albeit at temporally sparse sampling rate.

Data Analysis and Inversion

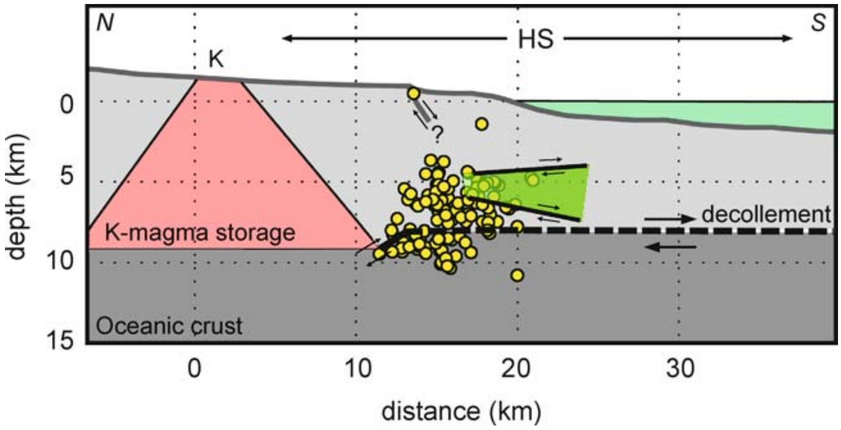
In addition to the challenge of acquiring geodetic data from submarine or even subaerial landslides is the added challenge of inferring sub-surface fault geometry and/or deformation processes, with attendant realistic error bounds on estimated parameters, from a data set of earth surface displacements. We identify two principal types of analysis modes: (1) process-based and (2) hazards-based. Process-based analysis focuses on deriving the most accurate and, if possible, complete assessment of the factors involved in the observed landslide motion. Hazards-based analysis has two primary components: (a) rapid warning and (b) long-term hazards estimation. Rapid warning comprises, with the smallest temporal latency possible, providing information regarding the current state of the landslide system and how it relates to current, short- and long-term dangers to life and infrastructure. Long-term estimation comprises making probabilistic statements about the components and potential future behavior of the system and so temporal latency is not a limiting consideration.

For either of the two types of analysis modes, the first objective is to usually try to relate the measured displacements d, of monuments at the surface of the earth to the source parameters, m, of the buried feature causing the deformation (usually considered a fault) through $G(m)$, a model of the deformation process. For instance, one very common model formalism, the dislocation in an elastic half-space, is a non-linear problem whose model vector m contains 9 parameters describing the location, orientation, and relative displacement of the dislocation approximating a faulting source [101,102].

Determining the most likely components of m and associated errors falls under the wide category of geophysical inversion for which there are a multitude of techniques e. g. [103]. In addition to the computational power available and the total amount of time allotted to the inversion, the choice of inversion method depends upon the nature of the model (for instance, linear vs. non-linear), the number of parameters in m, and the computational cost associated with individual model realizations and misfit assessments. Furthermore, it must be decided if the goal of an inversion is to obtain a rapid solution (a solution that satisfies some predetermined misfit level), an optimal solution (i. e. one 'best-fitting' solution), or rather to probe parameter space as thoroughly as possible with the goal of estimating posterior probability densities for each of the parameters for their value as indicators of resolution and uncertainty e. g. [104]. For instance, the most robust inversion method possible is the direct or 'grid' search, where the misfit for every possible permutation of m in parameter space is calculated. For more complicated or non-linear $G(m)$ however the computational cost associated with each forward model run can make a grid-search time prohibitive, even for a process-based analysis. For these types of more difficult problems, inversion based on Monte Carlo sampling. which collects pseudo-random samples from multidimensional parameter space as a proxy for the problem's true posterior probability density, $\sigma(m)$, has been found to be quite successful [105,106]. Indeed, it is common practice in the tectonic geodesy community to use the Okada model combined with some type of Monte-Carlo method to derive parameters of earthquakes and slow earthquakes from surface displacements observed with GPS [80,104,107].

The recent evolution of the work on the SEs at Kilauea demonstrates how important the inversion results are to the overall analysis either from a process-based or long-term hazards-based perspective. In their initial recognition of the November 2000 SE, Cervelli et al. [5] used a simulated annealing optimization routine [80] and the Okada model to invert the GPS observations and conclude that the most likely dislocation source for the SE occurred on a gently landward-dipping thrust fault plane at 5–6 km depth. Combined with the fact that the SE post-dated by 9 days a burst of local rainfall of nearly 1 m and reasonable estimates of local hydrologic parameters, Cervelli et al. [5] suggested that the increased pore pressure due to deeply percolating rainwater triggered SE motion by inducing a ~ 2 MPa pressure decrease of the effective normal stress on their preferred fault plane. Brooks et al. [4], however, showed from Gibbs Sampling inversion [104] results of GPS data on three additional SEs that posterior distributions of estimated fault parameters allow a wide family of equivalently plausible solutions, ranging from deeper seated decollement solutions at ~ 8 km depth to the more shallow fault plane favored by Cervelli et al. [5] (Fig. 7). Moreover, they showed that the other SEs were not associated with anomalous rainfall. Segall et al. [6] then used the same inversion method of Cervelli et al. [5] for the GPS data of the additional SEs relocations of high-frequency earthquakes triggered by the January 2005 SE, seismicity rate theory [108], and Coulomb stress modeling [109] to conclude that the SE (and other similar events) likely occurred at a depth of $\sim 8 \pm 1$ km on the main decollement plane below the Hilina Slump.

In this case, the crucial addition to the source inversion was the added constraint of the triggered microearthquakes which were relocated to depths near the decollement [6]. In their earthquake relocations, however, Segall et al. [6] did not use the full waveform data; rather, they used a double-difference-derived mapping with manual picks, assuming a 1D velocity model, between triggered events and previous high-precision relocations and tomography from elsewhere at Kilauea [110]. Two other studies, [111,112] performed high precision relocations using waveform cross correlation data and found different depths for the same cluster of events as Segall et al. [6]. Got and Okubo [111] suggested that their relocated events (including those triggered by the 1998 SE) do not illuminate a sub-horizontal fault plane but rather a deeper, steeply south-dipping reverse fault. Wolfe et al. [112] found that the triggered seismicity from the four SEs identified by Brooks et al. [4] consistently relocates on distinct map-view clusters aligned in the direction of the SE displacements themselves and in a subhorizontal band with depths of ~ 5 km. This is a solution consistent with Morgan et al. [21] who used seismic reflection data to identify moderately landward-dipping fault planes at similar depths. While the epicenters are well constrained in the Wolfe et al. [112] study, however, they were concerned that poor station geometry as well as near source velocity heterogeneity may bias the absolute depth of the relocations and the analyses may not be capable of distinguishing between shallow and deep fault zones. Thus, while the decollement is certainly the prime candidate on which a SE would occur (in agreement with the Segall et al. [6] suggestion), the analyses remain somewhat equivocal. This, in turn affects our best understanding of the most important hazard issue, the propensity of the decollement for a catastrophic failure. In order to more definitively answer these questions the above-mentioned research groups in conjunction with the Hawaiian Volcano Observatory of the US Geological Survey (the group charged with hazards analysis and



Submarine Landslides and Slow Earthquakes: Monitoring Motion with GPS and Seafloor Geodesy, Figure 7

mitigation for the region) have teamed up in a joint seismological and geodetic research project aimed at definitively constraining the depths of triggered seismicity, and, hopefully, the depth of SE sources in the region.

While the above example focuses mostly on process and long-term hazards assessment, recent developments focused on deriving the time-dependent history of slip during a deformation event could also potentially be used for automated real-time inversion and event detection [96,113]. The Network Inverse Filter (NIF) [96] is a recursive Kalman filter algorithm that operates on either processed position estimates or raw phase data (rather than derived displacement rates) from an entire network of geodetic stations, includes a stochastic description of local benchmark motion, and finds a non-parametric description of slip rate on a fault plane as a function of time. In current implementations, the NIF employs Green's functions relating slip to surface displacement computed from the analytical solutions for a dislocation in an elastic half-space [101] although there is no reason other deformation models could not be employed [113]. Application of the NIF to the 1999 Cascadia SE allowed McGuire and Segall [113], for instance, to determine that slip rate on the slipping fault plane took up to ~ 20 days to reach its peak and that the southern portion of the fault had finished slipping before the northern portion began to slip. Cervelli et al. [5] and Segall et al. [6] also applied the NIF to the Kilauea SEs to derive source-time functions for the events. One caveat, however, is that the fault plane is not solved for by the NIF, rather, it must be known and held fixed a priori. For subduction zones with greater spatial geodetic coverage above the slipping portion of the fault this condition may be satisfied more satisfactorily than at submarine landslides.

Discussion: Slow Earthquake and Submarine Landslide Process

Largely because of CGPS subaerial measurements at Kilauea there are now a suite of observations of slow earthquakes related to submarine landslide motion. As it seems that SEs are a fairly general fault slip phenomenon, occurring at a variety of subduction zone locales globally, it stands to reason that SEs may be common to submarine landslide-related deformation, at least on the flanks of ocean island volcanoes. Clearly, as seafloor geodesy projects become more common we will learn if this is the case or not. It is also clear that the search for a theoretical understanding of the slow earthquake phenomena will be coupled to further understanding the motion of submarine landslides.

Currently, explanations for slow earthquake slip behavior focus on rock mechanic theory that follows an empirically derived rate- and state-variable frictional constitutive law based on laboratory experiments e. g. [114]. (The description below follows the summary and notation in Scholz [114]). The Dieterich–Ruina or 'slowness' law is expressed as:

$$\tau = [\mu_0 + a\ln(V/V_0) + b\ln(V_0\theta/\zeta)]\sigma \; ,$$

where τ is shear stress, μ_0 is the steady-state friction, σ is effective normal stress, V is slip velocity, V_0 is a reference velocity, a and b are frictional material properties, ζ is the critical slip distance and θ is a state variable that evolves according to:

$$\mathrm{d}\theta/\mathrm{d}t = 1 - \theta V/\zeta \,.$$

The frictional stability of the system, then, depends on $(a - b)$, the velocity dependence of steady-state friction, defined:

$$a - b = \delta\mu/\delta(\ln(V)) \,.$$

In the context of a simple spring-slider model approximating a slipping fault, the boundary between the stable and unstable frictional regimes will occur at a critical value of effective normal stress, σ_c, given by:

$$\sigma_\mathrm{c} = k\zeta / -(a - b) \,,$$

where k is the stiffness. When $(a - b) > 0$ the material is said to follow ‘velocity strengthening’ behavior and the system is stable – earthquakes cannot nucleate in this regime and earthquakes propagating into such regions will be abruptly terminated. When $(a - b) < 0$ the material is said to follow ‘velocity weakening behavior and the system is unstable for $\sigma \geqslant \sigma_\mathrm{c}$ – earthquakes will nucleate in this regime. When $\sigma \leqslant \sigma_\mathrm{c}$ the system exhibits oscillatory behavior and is said to be ‘conditionally stable’, it is stable under quasi-static loading but requires a discrete velocity perturbation in order for earthquakes to nucleate. Others interpret these relations slightly differently suggesting that nucleation occurs when matrix stiffness (scale and stress-rate dependent) drops to a critical value over a spatial scale large enough to promote rupture [68,115].

It may be in the boundary of this stability transition where slow earthquake slip behavior arises. For instance, a common observation of most of the subduction zone SEs is that they occur down-dip of the ‘locked’ zone or near the base of the seismogenic zone where earthquakes nucleate [1,57,58,69,71]. At these depths in subduction zones temperatures are close to the 450°C temperature at which feldspar starts to exhibit plastic behavior and so conditionally stable behavior would be expected [114], although it has recently been shown that transient oscillatory behavior may also arise naturally from system dynamics alone [116]. Faults in the conditionally stable regime, under steady-state loading, slip aseismically unless a perturbation to the system is large enough to push the fault across the stability boundary triggering an earthquake [117]. If the perturbation, however, is not quite large enough to push the fault across the stability regime then a period of stable sliding at increased velocity will occur (i. e. a slow earthquake) as the fault evolves back to steady-state [117]. It is not yet clear, however, how the explanations for subduction-zone related SEs may translate to the submarine landslide environment. While many subduction zone SEs apparently occur down-dip of the ‘locked’ zone where earthquakes nucleate along the subduction interface, at Kilauea, SEs apparently occur up-dip of the zone where the majority of earthquakes occur [4,6].

Recent studies have more explicitly focused on helping to explain SEs in terms of the rate- and state-variable formalism. For instance, Kato [67] used rate- and state friction to simulate the effect that ‘asperities’, velocity weakening regions surrounded by velocity strengthening regions, have on slip behavior and found that episodic SEs occur when the velocity-weakening patch size is close to the critical size of earthquake nucleation. Similarly, Liu and Rice [68] found that when they applied along-strike variations in the frictional $(a - b)$ parameter in models of subduction zone processes, that SE-type transient deformation events emerged spontaneously near the downdip end of the seismogenic zone. They suggested that the downdip end of the seismogenic zone is likely to be in the conditionally stable boundary between unstable- and stable regimes and that this could allow the SE behavior. More recently, Lowry [58] employed further theoretical implications of rate- and state-variable friction under resonant loading conditions [115,118] to suggest that Earth’s response to climatic redistribution of atmospheric, hydrospheric, and cryospheric loads could lead to resonant fault slip behavior that could explain observed periodic slow earthquakes on the Cocos-North America plate boundary at Guerrero, Mexico.

Shibazaki and Shimamoto [119] recently proposed an alternate model of slow earthquakes that was motivated by laboratory experiments on the velocity dependence of frictional stability. They introduced a cutoff velocity to the rate-state formulation to mimic laboratory results where fault surfaces transition from velocity weakening at low sliding velocities to velocity strengthening at higher velocities. Implementing the laboratory values for these transitions reproduced the slip (10^{-7} m/s) and rupture propagation velocities (km/day) seen in subduction zone environments. Their model predicts a linear relationship between these two velocities that can in principle be inferred from high quality continuous geodetic measurements of slow earthquakes. This relationship may be an important way to relate observations of slow earthquakes to mechanical models, particularly in regions such as Kilauea where the fault planes are shallow enough (< 10 km) to allow the details of the rupture to be resolved with high quality instrumentation. We note additionally that other recent model parameterizations [116] yield recurrence intervals and propagation velocities similar to observed events and Lowry [58] also suggested means of relating geodetic observations and model parameters.

Two additional factors that may modulate the frictional properties of faults in submarine landslide environments include local hydrologic and magmatic forces (in regions of active volcanism) [23]. For instance, the Nov. 2000 SE at Kilauea post-dated by 9 days an intense rain storm of nearly 1 m at the southeastern Big Island [5]. Cervelli et al. [5] estimated permeability using regionally appropriate hydrologic parameters for porosity and fault zone diffusivity and suggested that the 1 m of rain could have triggered SE motion by inducing a ~ 2 MPa pressure decrease of the effective normal stress on a gently landward dipping fault at ~ 5 km depth. Brooks et al. [4], however, showed that 3 other SEs at Kilauea were not preceded by anomalous rainfall and that other periods of anomalous rainfall were not accompanied by SEs. Additionally, prior to these events Iverson [23] was skeptical of rainfall triggers as he found from a rigid wedge analysis that, in order for ground water head gradients to be large enough to destabilize the Hilina Slump, implausibly large clay layers ($\sim$ 200 m thick) or very low hydraulic diffusivity ($\sim 10^{-11}$ m^2/s) needed to be present. Others, however, have found that magmatic injection-induced mechanical and thermal pressurization of fluids may help to explain Canary and Cape Verdes Islands flank instabilities [120]. Excess shear stresses exerted on a basal decollement because of rift zone magma injection have also been shown to be of sufficient magnitude to potentially cause slip [22,23]. Although others have suggested from geodetic observations of discrete dike events at Kilauea's rift zones that the dikes are injected passively, as a response to decollement slip, rather than as a trigger for it [121,122].

Future Directions: Slow Earthquakes and Submarine Landslide Monitoring

It is clear that expanded seafloor geodetic monitoring of submarine landslides would be extremely important in bettering our understanding of both the slow earthquake process and the hazards associated with submarine landslides. For instance, at the Hilina Slump, it is not even known how much of submarine portion of the landslide actually displaces the seafloor during a slow earthquake. Given the logistical and financial challenges associated with seafloor geodesy, however, it is reasonable to ask if it is worth it to society to monitor submarine landslides. In the Hawaiian Islands, for instance, one compilation suggests that there have been at least 6 tsunami-generating landslide events in the past 300 000 years [123]. For comparison, the average 50 000 year recurrence interval for such events is 1 to 2 orders of magnitude larger than typical earthquake recurrence intervals in Southern California where substantial resources are focused on earthquake-cycle related monitoring (http://www.wgcep.org/). As discussed above, however, landslide-generated tsunami can be quite damaging both locally and regionally. One study simulated $\sim$ 30 m wave heights reaching the California coast within 6 h of a massive collapse of the Hilina Slump at Kilauea [124]. Clearly minimizing the impact of such an event would be of societal benefit.

Continuous submarine landslide deformation monitoring, although expensive, is not out of the realm of possibility, as costs for seafloor geodetic instrumentation are decreasing. In the coming years, in order to make continuous monitoring efforts more feasible, research will likely focus on two major technical challenges: (1) instrument power delivery and (2) data transmission. While cabling a network via seafloor pathways is certainly one way of satisfying both requirements, cabling may not be the best long-term solution for a number of reasons. First, the costs of large cable lengths and laying them on the seafloor is often measured in the millions of dollars. Second, especially for submarine landslides, the seafloor across which the cable need be lain can be very rough and cable failure can be a quite common occurrence. Third, if cable runs are long then annual maintenance efforts and cost can also be quite high. Accordingly, techniques such as acoustic data transmission [125] and local power generation via a buoy, for instance, will be critical.

Acknowledgments

We thank the Hawaiian Volcano Observatory of the US Geological Survey, in particular Asta Miklius, Maurice Sako, and Kevan Kamibayashi, for their collaboration and efforts in operating the CGPS network at Kilauea. We thank Paul Segall of Stanford University for sharing GPS data from this network. We thank Matt Gould and Nick Witzell of WHOI for engineering support. We thank Capt. Rick Myer and the crew of the R/V Kilo Moana for their help in deploying and retrieving the extensometers. We thank Mark Schenewerk for help with implementing PAGES. We thank Katie Phillips and Dave Chadwell for helpful discussion and sharing a manuscript in preparation. We thank Cecily Wolfe and Gerard Fryer for stimulating discussion. In particular we thank J. Moore, T. Lowry, and D. Chadwell for thorough and insightful reviews which improved this contribution. This research was supported by the Geophysics and Geochemistry programs of the US National Science Foundation, grants from School of Ocean and Earth Science and Technology at the University of Hawaii, and a grant from the Deep Ocean Exploration Institute of the Woods Hole Oceanographic Institution.

Article Outline

Glossary

Swarm Intelligence (Definition 1, Sect. "Definition of the Subject"). The *intuitive* notion of "Swarm Intelligence" is that of *a "swarm" of agents (biological or artificial) which, without central control, collectively (and only collectively) carry out (unknowingly, and in a somewhat-random way) tasks normally requiring some form of "intelligence"*. (Definition 5, Sect. "Swarms of Intelligent Units"). The capability of universal computation carried out with natural asynchrony by a dynamic cellular computing system, none of whose cells can predict the computation done by the swarm.

Swarm Robotics The technology of robotic systems capable of Swarm Intelligence.

Stigmergy Indirect communication through modification of the environment.

Pheromone A chemical that triggers an innate behavioral response in another member of the same animal species

Elementary Swarm An ordered set of N units described by the N components v_i ($i = 1, 2, \ldots, N$) of a vector $\boldsymbol{v}$; any unit i may update the vector, at any time t_i, using a function f of K_i vector components.

$$\forall i \in N\colon\ v_i(t+1) = f(\mathbf{v}_{k \in K(i)}(t))$$

Cellular automaton A system, evolving in discrete time steps, with four properties: a grid of cells, a set of possible states of the cells, a neighborhood, and a function which assigns a new state to a cell given the state of the cell and of its neighborhood.

von Neumann architecture Computer design that uses one processing unit and one storage unit holding both instructions and data.

Cellular-computing architecture Computer design that uses cellular automata, and related machines, as processors and as storage of instruction and data.

Intelligence (working definition for Swarm Intelligence) Ability to carry out universal computation.

Natural asynchrony Asynchronous updating characterized by three properties: more than one unit may update at each time step; any unit may update more than once in each updating cycle; and the updating order varies randomly for every updating cycle.

Optimization algorithms Algorithms to satisfy a set of constraints and/or optimize (e. g., minimize) a function by systematically choosing the values of the variables from an allowed set.

Swarm optimization Ant colony optimization, Particle swarm optimization, and related probabilistic optimization algorithms.

Ant colony optimization Probabilistic optimization algorithm where a colony of artificial ants cooperate in finding solutions to optimization problems.

Particle swarm optimization Probabilistic optimization algorithm where a swarm of potential solutions (particles) cooperate in finding solutions to discrete optimization problems.

Game of Life A cellular automaton designed to simulate life-like phenomena.

Dynamic cellular computing system Cellular computing system whose cells are mobile.

Unpredictable system A system such that complete knowledge of its state and operation at any given time is insufficient to compute the system's future state before the system reaches it.

Definition of the Subject

The research area identified as "Swarm Intelligence" has evolved rapidly. The term "Swarm Intelligence" first appeared in 1989 [1,2]; by 2007 "Swarm Intelligence" was in the title of four books [3,4,5,6], two series of conference proceedings [7,8] and in a new technical journal [9], without mentioning other areas in which the term swarm itself has become popular. As the use of the term "Swarm Intelligence" has increased, its meaning has broadened to a point in which it is often understood to encompass almost any type of collective behavior. And since the term "Swarm Intelligence" has popular appeal, it is also sometimes used in contexts which have limited scientific or technological content. Other meanings, however, refer rigorously to precise concepts. The following treatment of Swarm Intelligence is based only on concepts that can be clearly defined and quantified. Hence it is more restricted than some broader Swarm Intelligence presentations but, even so, it describes an interrelated scientific/technical core which forms a solid basis for a well-defined multidisciplinary research area.

Definition 1 The intuitive notion of "Swarm Intelligence" is that of a "swarm" of agents (biological or artificial) which, without central control, collectively (and only collectively) carry out (unknowingly, and in a somewhat-random way) tasks normally requiring some form of "intelligence".

A more specific definition requires a detailed discussion and so it is given at the end of the article. (Sects. "Characteristics of Swarm Intelligence" and "Swarms of Intelligent Units").

Although this notion of Swarm Intelligence might seem vague, we will see in the course of this article that in fact it has many specific implications. Note that the notion is broad, which partly explains its widespread use, but not so broad as to include any type of collective action of groups of simple entities, as will become clear later.

These characteristics of Swarm Intelligence are also those of several biological systems, e. g., some insect societies or some components of the immune system, so that Swarm Intelligence has become important for understanding certain mechanisms in biology.

Technologically, the importance of 'swarms' is mainly based on the potential advantages over centralized systems. The potential advantages are: (1) *economy*; the swarm components (units) are simple, hence, (in principle) mass producible, modularizable, interchangeable, and disposable; (2) *reliability*, due to the redundancy of the components; destruction/death of some units has negligible effect on the accomplishment of the task, as the swarm adapts to the loss of few units; (3) ability to perform *tasks beyond those of centralized systems*, e. g., escaping enemy detection.

From this initial perspective on potential advantages, the actual application of Swarm Intelligence has extended to many areas, described in the body of this article, and its potential for future applications remains high, as discussed in the concluding section.

Some current, proposed and/or potential applications are in defense and space technologies, (e. g., control of groups of unmanned vehicles in land, water, or air), flexible manufacturing systems, advanced computer technologies (biocomputing), medical technologies, and telecommunications.

Introduction

Swarm Intelligence (SI) investigations were initially motivated by studies of groups of simple robotic units which offered promise for technology. These 'swarms' are modeled as collections of simple quasi-identical units with decentralized control and independent clocks [10]. The number of units is intermediate between those of typical systems investigated in physics and other traditional science fields; in fact, the swarm is of the order of 10^2 to 10^s units, where $s \ll 23$, i. e., the swarm is not composed of so many units that statistical physics methods can be applied to it, nor of such a few units that its dynamic can be solved exactly (or numerically to high precision).

These features are typical also of many biological systems, such as insect societies. They are also the features of robotic systems potentially economic, reliable and capable of tasks beyond the capabilities of centralized systems.

There are various established fields of science and technology that deal to a certain extent with the intuitive notion of SI: Artificial Life, Ethology, Robotics, Artificial Intelligence, Computation, Self-Organization, Complexity, Economics, and Sociology. In all these fields there is at some level, or in some application, the need to understand, model, and predict the operation of groups of units which only by working together (in a not very structured way, and 'unaware' of the evolution of the group) carry out "intelligent" tasks. A simple illustration is provided by classic economics. In a free market economy, people trade with each other in an unstructured way: each makes independent decisions at unpredictable times and unaware of the global results. But the outcome is the solution to a complex problem – the problem of correct pricing. Such a 'swarm' solves a problem not (or poorly) solvable by centralized control economies, thus exhibiting, in a certain sense, a high form of "intelligence".

From this example it is clear that the intuitive notion of SI is easy to grasp. But it is not so easy to make it less vague and more precise and quantitative, i. e., to make it a useful working concept for science and technology. That the concept of SI is not easy to quantify follows from the difficulty of defining several of the key components of the intuitive notion of SI (Definition 1). First, "intelligence" is a notoriously ambiguous concept. Second, "randomly" is also not easily defined and quantified. Third, "only collectively" must be specified in terms of the critical number of agents required for the emergence of SI. In what sense is a unit 'simple' or, 'un-intelligent', and the task carried out 'complex' or, 'intelligent'? Fourth, "unknowingly" implies that the global status and the goal of the swarm are, at least to some extent, unknown to the single agents. Which algorithms and communication schemes result in tasks carried out 'unknowingly' by the agents?

Because of these difficulties, in this article we first use the aforementioned (Definition 1) intuitive notion of SI to describe the current main areas of studies considered to be SI. This will provide an overview of the current status of the field; it will make it possible to quantify the four vague concepts ('intelligence', 'randomly', 'collectively', 'unknowingly') and to reach a more sharply defined concept of SI. From this, we will be able to see more clearly the limitations of SI, and so, its realistic potential for future applications.

In this article, the main areas of SI studies are described by making three very broad distinctions: (1) scientific interest vs. technological interest (Sects. "Biological Systems"–"Definition of Swarm"); (2) standard mathematics vs. cellular computational mathematics (Sects. "Standard-Mathematics Methods"–"Cellular-Computing Methods"); (3) synchronous operation vs. asynchronous operation (Sects. "Randomness in Swarm Intelligence"– Swarms of Intelligent Units"). These distinctions in turn will provide a guide to clarifying the four vague concepts in the intuitive definition of SI (Definition 1) and, thus, a conceptual orientation for future studies and applications; they will also provide criteria for evaluating the promise of SI to solve complex problems that traditional approaches cannot.

Focusing on the first distinction (scientific vs. technological interest), the main scientific interest in SI originated with the work of biologists studying insect societies [3]. The main technological interest originated with roboticists trying to design distributed robotic systems [1,2]. A valuable reference on the development of SI is [3], dealing, in parallel, with these two interrelated interests.

Biological Systems

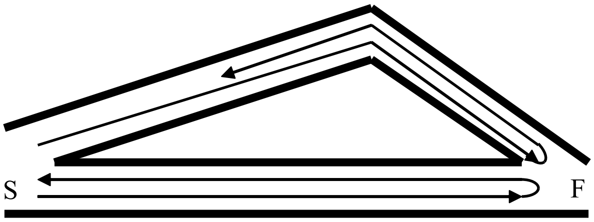
Probably the best known and seminal biology experiment in SI is the 'double bridge' experiment by Goss et al. [11]. While studying the foraging of ants they observed that if ants, starting from a point *S*, could reach food at a point *F* via two paths of different lengths, the ants would at first choose one of the two paths randomly; but after some ants had returned from *F* to *S*, more ants would choose to go from *S* to *F* via the shortest path; and eventually practically all the ants would choose the shortest path (see Fig. 1).

The key insight was the realization that the ants were finding the best path via *stigmergy*, that is, by *communicating through modification of the environment*. Ants are blind but they communicate chemically via pheromones. By laying pheromones along the path when returning from the food source F, the ants effectively marked the shortest path by laying more pheromones on it. After that, the ants that would start from *S*, would choose the path marked by more pheromones, i. e., the shortest path.

Thus it was observed and understood a method of self-organization and a method to solve a nontrivial problem by a form of collective intelligence, with many of the elements of the intuitive definition of SI given above.

Later, Dorigo [12] realized that this method could be abstracted and generalized to design algorithms that rely on 'artificial ants' to solve much more complex problems (see Sect. "Swarm Optimization"). Thus the close connection between biological studies of SI and its potential for technological application was first clearly demonstrated.

Many other experiments in ants and other social insects have confirmed the potential for developing bio-inspired algorithms [3,13,14,15]. For actual insect societies, various ant algorithms have been applied to model



Swarm Intelligence, Figure 1
Illustration of the double bridge experiments. The ants following the shorter path (the lower path) return to the source before the ants which have taken the longer path. In this way the shorter path has a higher density of pheromones; as a result, ants starting at *S* will now prefer the shorter path

tasks such as: division of labor, cemetery organization, brood care, carrying of large objects, constructing bridges, foraging, patrolling, chaining, sorting eggs, nest building and nest brooming. Social insects constitute 2% of insects, half being ants. Besides ants, termites, bees, and wasps, have been observed to exhibit some forms of SI behavior as in the aforementioned tasks.

Apart from insects, many other biological groups exhibit behavior with some of the features of SI, such as flocks of birds and schools of fish. A seminal model of artificial flocks and schools of fish was proposed by Craig Reynolds in 1987 [16].

It is a computational model for simulating the animation of a group of entities called "boids", i. e., it is intended to represent the group movement of flocks of birds and fish schools. In this model, each boid makes its own decisions on its movement according to a small number of simple rules that react to the neighboring members in the flock and the environment it can sense. The simple local rules of each boid generate complex global behaviors of the entire flock. In addition to being used to simulate group motion in a number of movies and games, this flocking behavior has been used, e. g., for time-varying data visualization [17].

In studying these biological systems several concepts of relevance to SI were recognized. They can be summarized as:

(1) Multiple communication (of various types) among units;
(2) Randomness (random fluctuations);
(3) Positive feedback, to reinforce random fluctuations;
(4) Negative feedback for stabilization.

Of the various types of communication, we have already noted *stigmergy*, i. e., *indirect communication* by modification of the environment. On the other hand, *direct communication* may occur *unit-to-unit*, contact being a special case, (e. g., via antennae or mandibles in insects) or by *broadcasting* within a certain range (e. g., acoustically or chemically). The type and specific mode of communication has been found to be critical to the task performed, as e. g., in what types of patterns are formed [18].

Finally, the most basic lesson from biological studies of SI is that biology has found solutions to hard computational problems, and that the design principles used in doing this, can be imitated.

Robotic Systems

The actual realization of SI systems as collections of robots is a very hard problem; in fact, it is quite difficult to make even small groups of robots perform useful tasks [19,20]. Making even a single mobile, autonomous robot work in a reliable way (even in simplified environments) is a complex project. Often the technical problems with small groups of robots are quite far from the goal of SI, so there is not much reason to use the term 'swarm'. Terms such as "collective robotics", "multi-robot systems", and "distributed autonomous robotic systems" are generally, and more appropriately, used. But, whenever the tasks carried out by these robotic systems become scalable to large numbers, the term "swarm robotics" is appropriate and, in fact, it has come into use. More typically, "swarm robotics" simply describes the design of groups of robotic units performing a collective task. Each robotic unit cannot solve the task alone; and collectively the robotic units try to accomplish a common task without centralized control.

As for any robotic system in general, each robotic unit, and the group as a whole, require design of: mechanics, control, and communications. The emphasis of current research, in relation to swarm robotics, is primarily on the latter two: (1) effective *communication* among the robot units [21], and (2) effective *control* via decentralized algorithms and robustness [22].

(1) Research in robotic *communication* has become important with the growth of wireless communication networking and the lower cost of building robotic units, thus opening a new range of applications for multi-robot systems with networking capabilities, including swarm robotics. In fact swarm robotics provides the common ground for convergence of information processing, communication theory and control theory [21].
(2) Research in *control* of robotic swarms is particularly important to guarantee the stability of the swarm since the swarm does not have a centralized control. The stability of a swarm is a special case of the general problem of distributed control. In fact, after swarm robotics algorithms for task implementation have been devised, the practical realization requires stability, and robustness, i. e., proper control. Swarm control presents new challenges to robotics and control engineers: various types of controllers for swarms are currently being investigated, e. g. neural controllers [23].

The control theory example coming closest to the problem of swarm control is perhaps that of 'formation' control, e. g., the control of multi-robot teams or autonomous aircrafts or land or water vehicles. These studies, when extended to decentralized systems, lead to consider problems of asynchronous stability of distributed robotic systems and swarms. [24]

Although much progress has been made in swarm robotics, the application of SI algorithms is still underdeveloped; one reason is that often the SI behavior emerges only above a critical number which is too large to make the construction of a robotic swarm practical, because too complex or expensive. Investigations of this type are thus generally carried out by simulation [22,25].

These simulations are specialized methods of swarm robotics. An example is 'executable models' [25] which can run in simulation or on a mobile robotic unit and can execute all aspects of a robotic unit behavior (sensing, information processing, actuation, motion), i. e., they fully represent how perception is translated into action by each robotic unit. They can be used to test either experimentally or in simulation how a group of robotic units behaves. Executable models are an evolution of early protocols (so called 'behavior-based' protocols) designed around the subsumption architecture [26]. Behavior-based protocols have now been generalized into Markov-type methods, i. e., protocols where the transitions between the possible states of a robotic unit are specified by a probability transition matrix as in Markov processes [27].

Looking at applications, swarm robotics has by now accumulated a collection of standard problems which recur often in the literature. One group of problems is based on *pattern formation*: aggregation, self-organization into a lattice, deployment of distributed antennas or distributed arrays of sensors, covering of areas, mapping of the environment, deployment of maps, creation of gradients etc. A second group of problems focuses on *some specific entity in the environment*: finding the source of a chemical plume, homing, goal searching, foraging, prey retrieval, etc. And a third group of problems deals with more *complex group behavior*: cooperative transport, mining (stick picking), shepherding, flocking, containment of oil spills, etc. This is not an exhaustive list: other generic robotic tasks, such as obstacle avoidance and all terrain navigation, are also swarm robotics tasks.

One envisioned application of swarm robotics which has received media attention is the ANTS (autonomic nanotechnology swarm) project by NASA [28,29]. This project envisions *nanobots* (i. e., a swarm of microscopic robots) operating autonomously to form structures for space exploration. The idea is inspired by the example of insect societies; it envisions a technology of self-similar, reconfigurable, miniaturized robotic units with a software strategy to endow the swarm with 'intelligence'. This ANTS 'intelligence' is at an intermediate level between traditional Artificial Intelligence (i. e., highly symbolic) and reactive responses 'intelligence', i. e., intelligence without internal representation [30]. Its basis is a software construct called a 'neural basis function' to bridge the gap between lower and higher level functions and to be capable of autonomous behavior. In one potential implementation, a Saturn autonomous ring array would launch 1,000 spacecraft with specialized instruments—organized as 10 subswarms—to perform in situ exploration of Saturn's rings to understand their constitution and formation.

The European Union sponsored swarm robotics project [31,32] was completed in 2005 after demonstrating several critical tasks, such as: autonomous self-assembly, cooperative obstacle avoidance, and group transport. For this project a new type of robot, called an s-bot was developed. A swarm-bot is any device composed of more than one s-bot, which is a mobile robot unit capable of connecting or disconnecting from another s-bot. S-bots have relatively simple sensors and motors and limited computational capabilities. Using their grippers, s-bots can assemble into a swarm-bot that is able to solve problems too difficult for a single s-bot. For example, a swarm-bot could transport an object too heavy for a single s-bot. [33]

Although swarm robotics could be defined as the robotic implementation of SI (Definition 1), so far, as noted, this implementation remains a distant goal. Meanwhile, concepts from SI can be usefully applied to collections of cooperating robots. Thus, referring to the intuitive notion of SI (Definition 1), the robotic swarm, can be characterized by the type of algorithm and of (decentralized) control, the number of units above which new behavior emerges, the communication method (range, topology, bandwidth), the processing and memory capability of each unit, and the heterogeneity of the group.

Swarm robotics, besides the implementation of SI algorithms, includes the material (mechanical and electronic) realization of the units comprising the swarm. This is, as noted, an arduous task which often becomes the emphasis of research in swarm robotics. But, as it was emphasized in the early years of SI, even if the material construction of the swarm were accomplished, SI algorithms would remain as the most difficult challenge for swarm robotics. This can be easily seen from the fact that a 'robot' swarm with very advanced hardware is already available for experimentation: it is a group of human beings. Each person could be limited in a controlled way, e. g., by allowing each person to handle only a specific device according to specific rules. Algorithms to make such a swarm doing intelligent tasks are in the province of SI, but they are not simple to devise, as common experience shows.

Artificial Life Systems

The areas of *Self-organization*, *Complexity* and *Artificial Life (or A-life)* are all older and broader fields than SI and overlap with it to various extents.

A-life is conceptually placed somewhere between science and technology, and between biology and robotics. During the mid-1980s attempts at imitating living systems with machines grew rapidly and resulted in the formation of the research field of "Artificial Life" [34]. A-life investigates phenomena characteristic of living systems primarily through computational and (to a lesser extent) robotic methods.

Its scope is wide, ranging from investigations of how life-like properties develop from inorganic components to how cognitive processes emerge in natural or artificial systems. It includes research on any man-made systems that mimic the characteristics of natural living systems. By this criterion it includes SI, but actual, current A-life research is not much focused on SI; rather it focuses on origin and synthesis of life; evolutionary robotics; morphogenesis, learning, etc.

The basic theories at the foundation of A-life, and of relevance to SI, are the theories of *self-organization* and *complexity*. A-life studies systems which are typically characterized by many strongly coupled degrees of freedom. Systems of this type are more generally investigated within the science of *complexity* which began to be an active field of research in the early '80s. It is multidisciplinary and it investigates physical, biological, computational, and social science problems, including a vast range of topics [35] from environmental sciences to economics as it is clear from the content of this Encyclopedia. One basic feature that these systems have in common is the emergence of complex behavior from simple components, a notion we also find in SI.

In regard to self-organization, we note that, as many systems in nature, A-life systems may start disordered and featureless, and then spontaneously organize themselves to produce ordered structures, i. e., they self-organize. The theory of self-organization, going back to the 1950's [36], grew out of a variety of disciplines, but mainly from thermodynamics, non-linear dynamics and control theory. Self-organization can be defined as the spontaneous creation of a globally coherent (i. e., entropy lowering) pattern out of local interactions – a concept also relevant to SI.

Because of its distributed character, self-organization tends to be robust, resisting perturbations. The dynamics of a self-organizing system is typically non-linear, because of feedback relations between the components. Positive feedback leads to fast growth, which ends when all components have been absorbed into the new configuration, leaving the system in a stable, negative feedback state. Non-linear systems have in general several stable states, and this number tends to increase (bifurcate) as an increasing input of energy forces the system away from its thermodynamic equilibrium. To adapt to a changing environment, the system needs a variety of stable states that is large enough to react to perturbations but not so large as to make its evolution uncontrollably chaotic. The most adequate states are selected according to their fitness, either directly by the environment, or by subsystems that have adapted to the environment at an earlier stage.

Formally, the basic mechanism underlying self-organization is the (often driven by randomness) variation which explores different regions in the system's state space until it enters an attractor. This precludes further variation outside the attractor, and thus restricts the freedom of the system's components to behave independently. It is equivalent to the decrease of statistical entropy that defines self-organization.

It is useful to keep this brief sketch of self-organization theory in mind as we proceed in describing SI, since the concepts in the theory of SI are evolved from a combination of concepts of self-organization and computation.

Definition of Swarm

After having looked, in the previous three sections, at actual robotic, biological, and A-life systems and ideas of complexity and self-organization related to SI, we can return to the intuitive definition of SI (Definition 1) and make it more quantitative.

The intuitive notion consists of four elements: SI is "intelligence" achieved "collectively", "randomly", and "unknowingly". An elementary swarm retaining these four elements can be defined as

Definition 2 Elementary Swarm An ordered set of N units described by the N components v_i $(i = 1, 2, \dots, N)$ of a vector $\mathbf{v}$; any unit i may update the vector, at any time t_i, using a function f of K_i vector components. $\forall i \in N\colon \mathbf{v}_i(t+1) = f(v_{k\in K(i)}(t))$

The Elementary Swarm describes an internally driven "collective" action. External input may be added in f. "Randomness" is built in the updating times. The evolution occurs "unknowingly" since the units have no processing capability. The Elementary Swarm can be generalized so that randomness appears also in the parameters of the function f. A further generalization is obtained by letting each vector component to be not just one number but a set of parameters.

Hereinafter we call '*Swarm*' (capital S) any system capable of SI. It is worth noting that even in Swarms more general than the Elementary Swarm, the modeling is assumed restricted in such a way that *no unit is capable of computing the Swarm's next global state,* (see also Sect. "Swarms of Intelligent Units"). Finally, "intelligence" is expected to be achieved by running appropriate algorithms via the updating function f. If and how this is going to be possible requires a more mathematical discussion, which is the subject of Sects. "Standard-Mathematics Methods"–"Cellular-Computing Methods".

Standard-Mathematics Methods

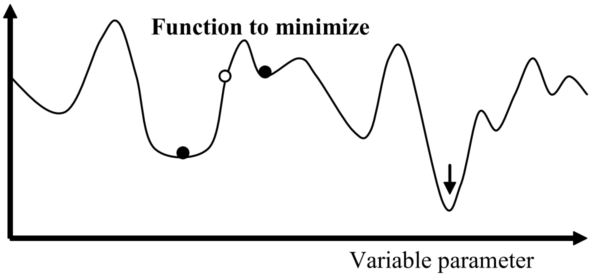
The science of biological swarms and the engineering of robotic swarms, as well as research in A-life relevant to SI, have progressed by using a broad range of mathematical techniques. All these techniques can be classified in two main groups: (1) '*standard-mathematics' methods* and (2) *cellular-computational methods.*

By *standard-mathematics methods* (SMm) we mean any method that is based on the standard tools of applied mathematics and computations based on standard (Von Neumann) computer architectures. Examples are methods in differential equations, stochastic techniques, linear systems, and optimization. By *cellular-computing methods* (CCm) we mean highly parallel and local computational methods, with simple cells as the basic units of computation, typically carried out on ▶ Mathematical Basis of Cellular Automata, Introduction to (CA) [37].

These two mathematical approaches reflect two distinct trends in the evolution of SI research, as described below. We consider first (Sects. "Swarm Optimization"–"Limitations of Standard-Mathematics Methods") the approach to SI based on SMm, since the greatest number of significant results in the area of SI has been obtained, so far, by standard-mathematics methods; specifically in the areas of *optimization* and *non-linear dynamics*. We consider them in turn in the next two sections.

Swarm Optimization

Optimization is by far the largest research area associated with SI. This is due to two extremely successful optimization methods, whose origin is related to models of SI. The two methods are the Ant Colony Optimization (ACO) [12,13] and the Particle Swarm Optimization (PSO) [4,38]. Both ACO and PSO, originated in the early nineties and have resulted in hundreds of applications based on variations of the original algorithms. So much so that the field of "Swarm Optimization" could stand alone, apart from its relation to SI with which it is sometimes even identified. A thorough and recent description of swarm optimization techniques is in [6]. Here only the key concepts of swarm optimization are reviewed, as they relate to SI.



Swarm Intelligence, Figure 2
Simplified illustration of the typical problem encountered in optimization. Starting from the value represented by the *open circle* and varying the parameter continuously the algorithm will find one of the nearest local minima (*black circles*) rather than the global minimum (indicated by the *arrow*)

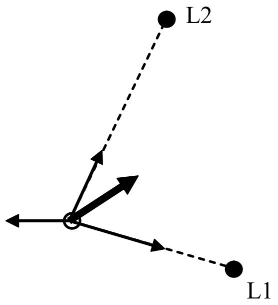
In PSO and ACO, as in any optimization methods, a function must be optimized, e. g., minimized. To find the minimum of the function, the variable is changed in a systematic way – the optimization method. Generally, the variable spans a multidimensional space. The search for the global minimum is nontrivial since the function may have many local minima, and the search could end into one of them (see Fig. 2). Various techniques to avoid this trapping have been developed by using some degree of randomness in the search strategy. For example, simulated annealing [39] was developed to overcome the limitations of non-random methods, e. g., the gradient descent [40]. PSO and ACO belong to this class of optimization techniques that make use of randomized searches.

Particle Swarm Optimization (PSO)

PSO was developed by Kennedy and Eberhart in 1995 [38] inspired by the social behavior of bird flocking and fish schooling [16].

In PSO, the position of each unit of the swarm is a point in the variable space of the function to be minimized. Every unit tries to reach the position corresponding to the minimum of the function. Each unit is assumed to know the global minimum value of the function, and to detect the value of the function at its location as well as the value of the function at the locations of a group of neighbors. The size of the group of neighbors is a parameter and could be the whole swarm.

The algorithm is, schematically, as follows. The units are initially in random locations. Every unit moves in



Swarm Intelligence, Figure 3
Illustration of the velocity update mechanism in PSO. A unit (*white circle*) originally moving to the left, changes its velocity by adding the two components in the direction of L1 (the unit's best location so far) and of L2 (the neighbors' best location so far). The magnitude of these components is determined by random weights. The new velocity (*heavy solid line*) generally tends to be in the direction of the global optimum

the variable space and remembers the location L1 where, among the locations visited so far, the function had minimum value. It also remembers the location L2 where, among the locations visited by all its neighbors, the function had minimum value.

At each time step, each unit calculates its distances from L1 and from L2; forms a weighted average of L1 and L2 using random weights; and changes its velocity in proportion to this weighted average (see Fig. 3). As a result every unit tends to move toward the location of the global minimum by taking advantage of its and its neighbors' knowledge. The process stops either when a unit is sufficiently close (by a chosen tolerance) to the location of the global minimum or when a chosen maximum number of iterations has been run.

PSO belongs to the category of stochastic, population-based algorithms, such as, e. g., genetic algorithms. The PSO's great merit is its simplicity. In many cases it outperforms genetic algorithms. Similarly to all optimization algorithms of this type, PSO convergence relies on the use of heuristics; and convergence does not mean convergence to the optimum. In fact, the basic PSO does not guarantee convergence even to a local minimum. The basic PSO is also inefficient in dynamic optimization problems, i. e., problems in which the optimum location changes. However, variations of the basic PSO have been proven to have improved performance in dynamic problems and to be capable of convergence to local minima.

Many improvements of the PSO basic algorithm have been developed and applied successfully to a wide range of optimization problems: continuous and discrete, constrained and unconstrained, single and multi-objective, static and dynamic. Specific applications cover just about all areas of applied optimization. The main classes of applications have been in areas such as:

(1) Neural networks (training, supervised and unsupervised learning, architecture selection, etc.);
(2) Game learning;
(3) Clustering;
(4) Design (aircraft wings, antennas, circuits);
(5) Scheduling & Planning (maintenance, traveling salesman, power transmission, etc.);
(6) Controllers (flight path, air temperature, power stabilizers, etc.);
(7) Data mining. For more detail see, e. g., [6].

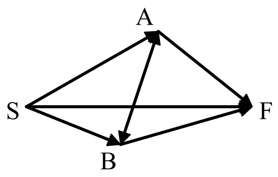
Ant Colony Optimization (ACO)

The key idea of ACO [12,13] is an abstraction and generalization of the Goss et al. [11] two-path experiment with ants. A first generalization of the two-path problem is finding the shortest path between the starting point S and the final point F when between S and F there are many possible paths.

The two-path problem can be represented by a graph with 3 vertices (S, A, F) and three arcs $(S \to A,\ A \to F,\ S \to F)$. The short path is $S \to F$ and the long path is $S \to A \to F$.

If we add another vertex B, and make the graph complete (i. e. we join with an arc each vertex to every other vertex) we obtain five possible paths: $S \to F$, $S \to A \to F$, $S \to B \to F$, $S \to A \to B \to F$, $S \to B \to A \to F$ (see Fig. 4). The idea is easily generalized to a complete graph with more vertices. The number of paths increases exponentially so checking the length of all the possible paths becomes computationally unfeasible for a large enough number of vertices.

A number N of 'ants' start at vertex S choosing randomly which vertex to go next. At every new iteration, each ant decides which arc to traverse next, with probability proportional to the amount of pheromone on the arc relative to the total amount of pheromone on the possible arcs that the ants could choose.



Swarm Intelligence, Figure 4
The five possible paths from S to F: $S \to F$; $S \to A \to F$; $S \to B \to F$; $S \to A \to B \to F$; $S \to B \to A \to F$

After an ant, k, reaches the destination F, the length of its path L_k is remembered (if an ant reaches the destination via loops, L_k is calculated after removing the loops). The ant retraces exactly the path (without loops) and deposits pheromones on the arcs in proportion to $1/L_k$.

In this way, the marking (with pheromones) of the paths by all the ants modifies the graph so that the probability of any ant taking the shortest path at the next trip from S to F increases. Eventually all the ants will follow the same path, if the algorithm converges, and the path will be the shortest if the convergence is to the global minimum. As in most optimization methods, this is never guaranteed.

The idea of the original ACO algorithm [12] adds to the foregoing sketch of the basic model three more elements. First, each arc has an a priori propensity to be traversed (regardless of pheromone content); second, each ant keeps in memory a tabu list of arcs not to be traversed, to avoid loops; and third, the pheromones evaporate at a given rate.

ACO key insight is the application of the concept of stigmergy to stochastic optimization. The ants communicate by modifying the environments (graph) and act probabilistically on the basis of the modified environment.

Many variations of the basic ACO algorithm have been proposed and implemented. The many variations take advantage of specific knowledge about the specific problem, i. e., they use heuristics, e. g., by setting the a priori propensity of traversing an arc, or by setting the evaporation rate.

ACO eventually resulted in a meta-heuristic which is a strategy for designing ACO heuristics. Various ACO-based metaheuristics have been developed. Similarly to PSO, ACO algorithms have been applied to all the basic types of optimization problems: continuous and discrete, constrained and unconstrained, single and multi-objective, static and dynamic. The first application of ACO was to the Traveling Salesman Problem, which is an NP -hard combinatorial optimization problem, and it is the most frequently attacked problem using various ACO heuristics. The main classes of other applications are to problems of

(1) Ordering (scheduling, routing);
(2) Assignment (Neural network training, image segmentation, design);
(3) Subsets finding (maximum independent set);
(4) Grouping (clustering, bin packing).

Clearly " swarm optimization" successfully uses concepts from the general notion of SI, but optimization is not in itself a necessary characteristic of SI. In fact, many tasks actually or potentially carried out by swarms are not-optimal in any sense.

Non-Linear Differential Equations Methods

One fruitful approach to modeling swarms has been to treat each individual as a discrete particle. These "individual-based" models have been employed in quite a few biological and mathematical studies. They are based on simple rules of motion for each individual, involving some combination of self-propulsion, random movement, and interaction with neighboring organisms. The models typically take the form of coupled ***non-linear*** difference or differential equations, which may be stochastic or deterministic, depending on the particular features of each model. Numerical simulations have revealed collective behavior. But a main disadvantage of such models is that, for realistic numbers of individuals, analytical results for the collective motion are difficult or impossible to obtain. It is worth mentioning that some progress has been made in obtaining analytical results for stationary groups. In [41], a discrete model was formulated, and a Lyapunov functional was used to successfully predict an equilibrium state of equally spaced organisms. However, analytical (nonstatistical) descriptions of nonequilibrium states in discrete swarm models are few.

Other investigations of swarming have been carried out in a continuum setting, in which relevant quantities are described as scalar or vector fields. This approach goes back to 1980; reviews are provided in [42]. Continuum models may be constructed a priori or by coarse-graining a particle model. In general, continuum models provide a convenient setting in which to study large populations, since one may apply machinery from the analysis of *partial differential equations*. In the context of swarms, the focus has generally been on models in which the population density satisfies a convection-diffusion equation ensuring that the population density is conserved while individuals travel with a set average velocity. Recent models of this type [43] can predict, e. g., whether a population aggregates or disperses, the regions of aggregation, and length scales of the density patterns.

Limitations of Standard-Mathematics Methods

In describing the SI investigations in the previous two sections, we have encountered the concepts of *optimization* and *non-linearity* (and earlier, in Sect. "Artificial Life Systems", *complexity* and *self-organization* arising from nonlinearity). To see more precisely the relation of these four concepts to SI we refer back to the definition of Elementary Swarm (Definition 2). Note that, by this definition, the Swarm is in principle capable of optimization, complexity and self-organization. In fact, it is clear that a Swarm is a *self-organizing* system, by definition, and that, depending on the choice of the updating function f, the pattern formed by the swarm components might, in principle, achieve high *complexity*.

As for non-linearity, it is convenient to think of f as a function of a function,

$$f = f(g(K_i)$$

where g represents the dependence from the neighbors. While g maybe linear or non-linear, the function f, representing the mode of updating, will typically be non-linear and/or probabilistic. In spite of this, the evolution of the Swarm only in special cases can be modeled by standard *non-linear dynamics* as studied via nonlinear differential equations (as we have seen in the previous section).

In regard to *optimization*, the Elementary Swarm can be easily designed to be an optimizer. In fact, if the updating is sequential, and f and v_i are chosen appropriately, one obtains a simple PSO system.

Thus, the Elementary Swarm describes a simple but powerful system capable, in principle, of self-organizing, and to produce complex structures and optimal solutions. On the other hand, even the Elementary Swarm is more general than these properties; a Swarm is not restricted by the notions of optimization or non-linear dynamics (and self-organization or complexity tied to non-linear dynamics). All these can be properties of the swarm but none is a requirement for SI. To find out what SI can do that is beyond what we have described so far, we must look at the computational capabilities of swarms. And for this we need to look at cellular-computing methods since standard-mathematics methods are ill suited to deal with computation.

Cellular-Computing Methods

Some of the first studies in SI were based on computational models, and, more precisely, on distributed algorithms applied to robotic units [44,45,46].

In these computational models, the swarm was developed as an evolution from a distributed system of processors, as follows. In *distributed computing* the algorithms are designed for a 'static' set of processing units, where, 'static' is meant literally as 'not moving'. For illustration, if a set of CPU's, computing in a distributed way, via wireless communication, started moving around, this system would look very much like a robotic swarm. In fact, referring to the intuitive notion of SI (Definition 1), all points of the SI definition would be satisfied by such a dynamic, distributed computing system provided the CPU's had, in some sense, limited capabilities.

The main point is that this distributed computing swarm differs from the robotic, and non-robotic, swarms described in the previous sections (Sects. "Standard-Mathematics Methods"–"Limitations of Standard-Mathematics Methods") in that the *intelligent task of the swarm is now seen as a 'computation'*. And this focus on computation leads us now to consider the other broad set of techniques used in SI research, i. e. techniques based not on standard-mathematics but on *cellular computing*.

Cellular computing differs qualitatively from the standard Von Neumann computing architecture. The latter is based on one complex processor that sequentially performs, at each time step, a single complex task. In contrast, in *cellular computing*, a very large number of simple processors (cells) are the units of computation. They compute (typically) in parallel with local connections between cells. The qualification 'simple' can be made precise by requiring, e. g., each cell to be a 'finite state' machine. Cellular automata are the most obvious examples of cellular computing systems but cellular computing applies to many other systems as well [47].

By definition, then, cellular computing contains several of the features of SI. The Elementary Swarm of Definition 2 can be regarded as performing a cellular computation. And in fact, cellular computing has been used extensively in A-Life studies, including systems with strong relation to SI [34]. Cellular computing systems offer SI something that the SI systems described in the 'standard-mathematics' Sects. "Standard-Mathematics Methods"–"Limitations of Standard-Mathematics Methods") lack, i. e., a clear characterization of *intelligent task*.

Intelligence as Universal Computation

Intelligence is an ambiguous concept, escaping a unique definition [48]. By identifying 'intelligence' with 'computation', the concept is restricted, but, at the same time, it can be made precise. In fact, in SI we define intelligence unambiguously as the '*ability to carry out universal computation*'.

Universal computation (or universality) is the property of a computer system (or language) which, with appropriate programming, can be made to perform exactly the same set of tasks as any other computer system (or language).

Universal computation (i. e., the ability to emulate a universal computer), is essentially the limit of any model of computation (Church–Turing thesis) [49]. It was first proven by Turing in 1936 that no system can ever carry out explicit computations more sophisticated than those carried out by a Turing machine. Subsequently, universality has been found to be a widespread property of many cellular computing systems [50].

One of the first cellular computing systems shown to be capable of universal computation, is Conway's game of life [51]. This CA is also the prototypical example of A-life systems. And it is also an example of the strong connection between universal cellular computing and bio-inspired systems.

More recently, a large number of simple cellular computing systems have been found to be capable of universal computation [50]. Many of these systems are CA, or related systems, using very simple rules of evolution with local interactions. And so they are useful starting points for modeling SI.

In particular, cellular computing is the most appropriate to endow the swarm with the property of *unpredictability*. The latter property was an original motivation for SI [1,2] and it is crucial in the task of escaping detection by a predator; it is also of importance in engineering swarms for strategic defense applications.

Unpredictability is almost a built-in property of cellular computing systems because, if one observes the rules of evolution in their raw form, it is usually almost impossible to tell much about the overall behavior they will produce.

Relations to Standard-Mathematics Methods

SMm cannot provide the swarm with the element of universal computation, which we have taken as the working definition of 'intelligence'. The only way would be to make each unit a von Neumann (i. e. standard) computing system. In a sense, this violates the notion of Swarm, since in a Swarm, by definition each unit must be 'simple'. (This point will be further clarified in Sect. "Swarms of Intelligent Units"). On the contrary, the main advantage of cellular computing systems over standard mathematics systems is the possibility of universal computation by simple units.

For this reason CCm are the natural paradigm for the understanding and designing SI systems, in spite of the fact that the approach to SI based on cellular computing has so far produced fewer so-called SI applications than the approach based on SMm. Indeed, SMm have basic limitations for modeling SI. This is because the use of SMm tends to restrict the range of tasks performable by the Swarm. And this happens because SMm typically solve problems by specifying *constraints*, i. e., conditions to be satisfied by the solution, e. g., by specifying equations. But most computational problems cannot be solved in this way.

The optimization methods described in the previous sections (PSO, ACO, etc.), illustrate the point. In these iterative methods, the key issue is what kind of changes should be made at each iteration step. Starting from a random pattern, at each step a change is made to get the pattern closer to satisfying the constraint(s). Since direct methods (e. g., gradient descent) rarely work as the pattern gets stuck into local minima, randomness in updating is added. In this way, larger portions of the solution space are sampled. The larger the changes made, the faster one can potentially approach a global minimum, but the greater the chance of overshooting. The result is that no iteration technique of this type can guarantee a solution to general combinatorial optimization problems. As we have seen, the swarm optimization methods (ACO, PSO) rely on heuristics to adjust the search and obtain often (non-optimal but) satisfactory solutions. But, in general, for the great majority of combinatorial optimization problems (e. g., the Traveling Salesman Problem [52]), no polynomial upper bound on the time complexity has been found so far. And this happens in many problems whose solution is sought by using randomness to satisfy the imposed constraints. As an example, a set of identical balls cannot be shaken into an ordered, closed-packed configuration. With extremely high probability, they lock into some configuration or another, not the optimal (close-packing) one.

This fact has *important implications* for SI. What it says is that no matter how much randomness is added to the system, it may never evolve to reach the solution specified by the constraints. Although, ultimately, constraints can be set up as a way of specifying algorithms, and hence computing, it is far simpler to specify algorithms via rules of evolution, as it is done in cellular computing.

The conclusion is that methods based on constraints and other SMm are not ideally suited for systems evolving with great complexity, and in particular they are not suitable for universal computation. Thus, if SI is to be a framework for (biological or engineered) swarms to carry out 'intelligent tasks' with the greatest generality, a methodology that allows for the swarm to carry out universal computation is necessary. To this aim, CCm are the most suitable.

Unfortunately, although CCm have many advantages over SMm for modeling SI, they address only three of the four key elements of the notion (Definition 1) of SI ('intelligence', 'collectively', 'randomly', 'unknowingly'), leaving out the element of 'randomness'. Generally, CCm operate deterministically and do not include 'randomness', as, e. g., 'swarm optimization' systems do. But this does not have necessarily to be the case. The issue is addressed in the next section.

Randomness in Swarm Intelligence

Randomness is a key element in the notion of SI (cfr. Definition 1 and Definition 2). Examples from biology justify this requirement. Randomness is not easily quantified precisely but, whatever the form and measure chosen, the point is that for swarms some form of randomness is necessary – otherwise they would fail to be models for analyzing a large class of biological systems. But what kind of randomness is essential to model these biological systems?

Randomness in the number and type of agents is not important – the agents could be strictly identical and remain in the same number. Randomness in the initial conditions is not essential either. Many swarms evolve from regular initial conditions into highly complex and random patterns. Randomness of external input from the environment is not always present, and it is certainly not a requirement for biological swarm behavior.

What about the randomness artificially added to the units, as in swarm optimization?

The randomness added to the units in PSO or ACO algorithms is modeled as originating from the random behavior of each unit. This is a plausible assumption in relation to biological systems. But the swarms in PSO and ACO are updated in an orderly (non-random) way, typically sequentially (there are also some parallel implementations [13]) whereas, in biological systems, the units update in a disordered, random fashion.

And it is this type of randomness that is both necessary in any biologically relevant model of swarms and sufficient to provide many (but not all) of the advantages of randomness in solving swarm engineering problems.

The conclusion is that the only randomness that is truly essential for SI is randomness in the times of operation of the units. Each unit has its own clock, not synchronized with other units' clocks. Other types of randomness in the behavior of the units or the environment may be required to solve specific problems, but randomness in times or operation is necessary for any biologically realistic model.

Interestingly though, many applications so far considered in the area of SI do not yet include this randomness in the models. We have already mentioned that typical optimizing swarms update sequentially; and CA systems operate largely in parallel, i. e. synchronously. Synchronous or sequential operations are by far the most common updating modes in either SMm or CCm.

The Implicit Assumption of Asynchrony Irrelevance

As noted, it is a basic fact that biological agents, apart from exceptional cases, do not operate synchronously (or sequentially) in groups. It is also a fact that people in social groups do not operate synchronously, or sequentially. If SI is supposed to model biological and social swarms, SI must be based on models that do not operate synchronously or sequentially [53].

And if biological swarms are capable of solving problems (including optimization) without synchrony (nor sequentially), as they do, then models that imitate those swarms should operate asynchronously (not sequentially).

But, as noted, the main modeling paradigms for bio-inspired algorithms, standard-mathematics and cellular computing, are either essentially sequential or synchronous.

An example from SMm is the solution of partial differential equations: they operate synchronously on every point (clearly seen in solving them numerically and iteratively). This unrealistic use of differential equations in biological processes has been pointed out, e. g., in the problem of morphogenesis [54]. The Turing diffusion-reaction model [55], being based on differential equations, implies synchronicity and central control, hence it is physically not realistic for a scale of the order of 100 cells.

In fact, synchronicity leads to realistic models only whenever the spatio-temporal resolution is high, as, e. g., for phenomena typically studied in physics. But when the units studied are complex or few enough to have a less fine spatio-temporal resolution, as in biology or human societies, synchronicity is not realistic, as it is obvious by observation.

Thus, in using synchronous methods for biological or human societies, implicitly a strong assumption is being made, i. e., that the synchronously (or sequentially) and non-synchronously (and not sequentially) obtained solutions would coincide.

But this assumption has no validity. In fact, it has been shown, for example, that CA, when running in synchronous and non-synchronous ways, normally produce totally different results [56]. This has been noted already in the nineties [57] in A-Life studies. In [57] two well-known CA were compared: Conway's "game of life" [52], and the Immune Network model. The former is a 2-dimensional CA capable of universal computation when run synchronously. But the behavior is totally different when run without synchrony: the Game of Life stops producing complex patterns and converges to a fixed point.

The Immune Network model is asynchronous and the Game of Life synchronous. The crucial factor in the different behavior of the two systems was identified as the synchronous vs. asynchronous updating. In fact, it was concluded that, in this case, asynchrony induces stability in CA. This agrees qualitatively with studies in standard-mathematics [58].

In conclusion, the assumption that asynchrony makes no difference has been found not to be valid. Hence, asynchronous systems must be studied as such, not by using synchronous models. Moreover, different types of asynchrony yield different results, as discussed in Sect. "Asynchronous Swarms".

Asynchronous Swarms

Several cellular computing studies in the nineties [37,59] led to a variety of results emphasizing the role that different types of asynchrony play in the results. Studying asynchronous systems is complicated because, among other things, deviation from synchronicity, i. e., from the mode of updating all units in parallel at each time step, may occur in several different ways. For example, sequential updating and random updating are both asynchronous but very different.

Types of Asynchrony

Unfortunately, there is no standard vocabulary for the various types of asynchrony. Thus we use the following classification to describe the possible types of asynchrony.

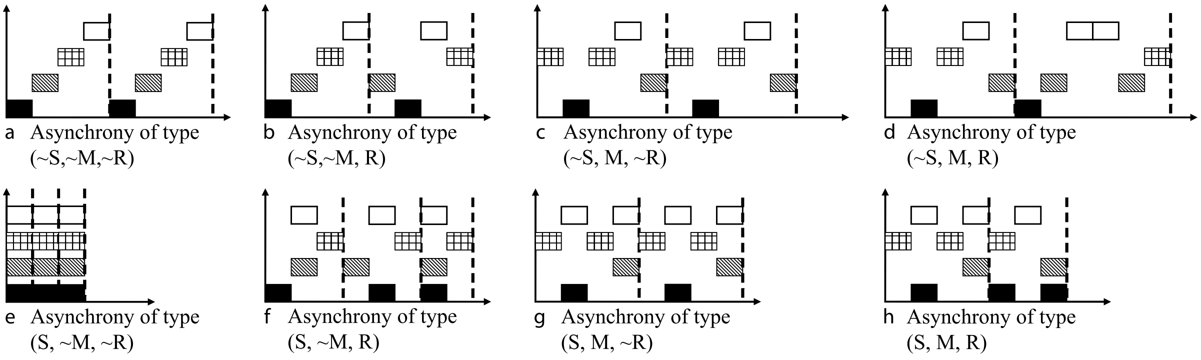
Consider an updating cycle (UC), i. e., the time interval at the end of which all units have been updated at least once. Eight types of UC can be identified by the presence or absence of any of following three properties: (*S*) *Synchronicity*: more than one unit may update at each time step; (*M*) *Multiplicity*: any unit may update more than once in each UC; (*R*) *Randomness*: the updating order varies randomly for every UC (see Fig. 5).

These eight basic types of asynchronous updating, can be further specialized. For example, if all three properties are absent ($\sim S$, $\sim M$, $\sim R$), the updating is sequential. But the sequential updating order of the units can be fixed in different ways. Studies of CA have proven that the behavior differs markedly not only for the eight types of asynchrony, but even among different sequential ordering [37,56].

In [56] the (S, M, $\sim R$) form of updating has been applied to describe processes where each unit has independent clocks but the clocks have a fixed, non random frequency. This type of asynchrony is considered a good model for forest ecosystems, fire spread, and other natural and artificial systems. The results are very different when updating of the type ($\sim S$, M, R), ($\sim S$, $\sim M$, R), or sequential ($\sim S$, $\sim M$, $\sim R$) are applied to the same system.

In conclusion, the crucial point is that [56] the exact manner of updating can have a profound effect on overall system behavior. The implication of this is that when comparing models of natural systems or artificial multi-agent systems it must be stated which updating scheme has been used, otherwise meaningful comparison between different studies may not be possible.

In particular, returning to swarm optimization, one may ask whether in tasks such as finding the shortest path, it is realistic to apply to natural systems (such as in-



a Asynchrony of type (~S,~M,~R)
b Asynchrony of type (~S,~M, R)
c Asynchrony of type (~S, M, ~R)
d Asynchrony of type (~S, M, R)

Asynchrony of type (S, $\sim M$, $\sim R$); f. Asynchrony of type (S, $\sim M$, R); g. Asynchrony of type (S, M, $\sim R$); h. Asynchrony of type (S, M, R); Illustration of the 8 types of updating, according to Synchronicity, Multiplicity, and Randomness. Four units are represented by rectangles with different patterns, from black (*bottom*) to white (*top*). The horizontal axis measures time steps in units equal to the base of a rectangle. The vertical dashed line indicates the end of an updating cycle (i. e., all units have updated at least once). The label below the horizontal axis specifies the type of updating (∼ means 'not'). The standard 'parallel' and 'sequential' updating are, respectively, (S,$\sim M$,$\sim R$), Fig. 5e, and ($\sim S$, $\sim M$, $\sim R$), Fig. 5a

sect societies) swarm models which are sequential (such as swarm optimization models) or synchronous (such as models based on differential equations). While these models work effectively as artificial swarms there is no proof that they apply to natural systems, which are asynchronous.

Modeling Asynchrony by Synchronous Swarms

Because of the widespread use of synchronous methods in simulations of SI, one might wonder under what conditions a synchronous but stochastic model could be equivalent to an asynchronous one.

To answer this question, let us consider the two types of stochastic models most commonly used to model randomness in synchronously updated systems. The randomness may be included in (1) the possible outcomes of the updating function or (2) in the choice of the function applied to the updating.

Referring to the definition of Elementary Swarm (Definition 2) the two cases correspond to generalizing the updating function as follows:

$$\text{Case (1)} \quad \forall i \in N\colon v_i(t+1) = f(\mathbf{v}_{k \in K(i)}(t)\,\zeta)$$

where ζ is a random variable.

$$\text{Case (2)} \quad \forall i \in N\colon v_i(t+1) = f_{(t)}(\mathbf{v}_{k \in K(i)}(t))\,;$$

where $P[f_{(t)} = f_\gamma]$ is the probability mass function of choosing $f_{(t)} = f_\gamma$ out of a set of N_f possible functions $\{f_\gamma; \gamma = 1, \ldots, N_f\}$.

Case (1) is typical of probabilistic CA, and it is also the method used in PSO. In these systems the state vector, at each time step, evolves according to a fixed rule which produce a new state vector from the previous one. The rule is based on the state of the neighbors of each unit and does not change from step to step but the outcome of the rule is probabilistic.

Case (2) is what is done for example in probabilistic Iterated Function Systems [23]. In probabilistic Iterated Function Systems a vector evolves via a set of maps (a map is a function whose domain and range coincide); at each time step a map is chosen, probabilistically, from a set of possible maps.

In either cases (1) or (2), the updating scheme fails to model the actual time evolution of natural systems not so much because the updating are applied synchronously but because the randomness is applied *collectively*, i. e. to all the units in the same way. On the other hand a synchronous algorithm realistically simulating independent random updating can be run as case (2) applied *individually* to each unit, as follows:

$$\text{Case (3)} \quad \forall i \in N\colon v_i(t+1) = f_{(t)i}(\mathbf{v}_{k \in K(i)}(t))$$

where $P[f_{(t)1} = f_{\gamma 1},\ f_{(t)2} = f_{\gamma 2}, \ldots, f_{(t)N} = f_{\gamma N}]$ with $f_{(t)i} \in \{f_\gamma; \gamma = 1, \ldots, N_f\}$ is the joint probability mass function of each unit i updating, at time t, according to the function $f_{(t)i}$.

In the simplest embodiment of case (3), the set of possible updating functions consists only of the identity and of another function f, with probabilities p and $(1-p)$ respectively (i. e., a Bernoulli process). In such a case, every unit, at each time step, either does not update, with probability p, or updates according to the function f, with probability $(1-p)$. Running this algorithm synchronously is equivalent to asynchronous independent updating of the units in a random way – a realistic description of a random swarm. So, under these independently stochastic conditions, running a simulation synchronously, represents correctly the physical asynchronous updating of the swarm units. On the other hand, this does not change the fact that different results are obtained when using this random updating (whether simulated with stochastic synchrony or not) instead of synchronous or sequential updating.

Local Synchrony and Self-Synchronization

Another approach to dealing with the problem of random updating by the swarm units, is to explore the possibility of self-synchronization. If the swarm can self-synchronize, then all the results for synchronous swarms could be applied.

To look into this, let us return to the classification of the types of asynchrony, i. e., the SMR classification above. If the SMR properties are applied to blocks of units rather than individual units, the resulting updating orders are referred to as '*locally synchronous*'.

CA with cells organized into blocks have been investigated [60]. These CA relax the normal requirement of all cells having the same update rule. Cells within a block are updated synchronously, but blocks are updated asynchronously. They experimented with different SMR types of asynchrony and concluded that synchronous and asynchronous CA can be evolved with equivalent computational properties, but CA of the asynchronous type may require a larger number of cells [60]. Another study [61] has shown cases in which local synchronization can lead to the same outcome as with global synchronization. But how can local synchronization be achieved?

A number of schemes have appeared in which the order of updating depends on local interactions and leads to local synchronization. In effect, what local interactions (or constraints) can do is to force a unit to wait to update until others are ready, and so this creates a local synchronization. An asynchronous CA model that can behave as a synchronous CA has been demonstrated [62]; it functions by the addition of extra constraints on the order of updating, effectively providing a type of local synchronization. Whether these methods of self-synchronization may in some cases result in realistic models of natural systems of SI remains an open question.

The Natural Asynchrony of Swarms

We have seen that the implicit assumption of asynchrony-synchrony equivalence must be rejected and that different types of asynchrony give different results. But what type of asynchrony is most relevant to SI? There is no easy answer. For example, ants work and rest; active and resting periods have an aperiodic pattern for individual ants, but for the whole colony there are synchronized periodic patterns of active and resting periods.

In spite of the difficulty of finding a clear cut answer to the question of the natural mode of SI updating, from observations of biological systems, and from local synchronization models, it may be plausible to assume that the essential form of asynchrony in SI is the randomness in the working of the individual clocks, as argued in Sect. "Randomness in Swarm Intelligence"; hence the SI asynchrony must be characterized by the presence of all three asynchrony properties, i. e., (SMR).

In conclusion, at this stage of our discourse, the Swarm remains defined as in Definition 2, qualified by SMR asynchronous updating, which hereinafter we call *'natural'* asynchrony. Note that stochastic synchronous simulations of this model can also be carried out as, e. g., in case (3) above.

The Realization of Asynchronous Swarms

So far we have established the importance and type of asynchronous models in SI, but what SI investigations using asynchronous swarms are there?

As noted in Sect. "Asynchronous Swarms", research in asynchronous models is still very limited, relative to synchronous models, and this in spite of the fact that the very first models of SI were all asynchronous, using SMm based on finite differences [46]. Explicit updating schemes in finite difference methods can also be regarded as parallel CA, thus belonging to both SMm and CCm. Investigations of asynchronicity in finite difference methods are not common [58]. Examples include a non-linear updating rule was based on a linear relation between two neighboring units [45]. A gradient type of swarm updating, was also proposed in modeling morphogenesis [54].

For swarms updating with 'natural' asynchrony, i. e., according to (SMR), a recent study [58] gives a proof of convergence to the same state as by using synchronous or sequential iterations. It was also shown that, under certain conditions, the (SMR) asynchronous updating leads to convergence while synchronous updating does not. This is another example of the advantages of randomness in allowing the swarm to reach a fixed state.

At the end of Sect. "Cellular-Computing Methods" we concluded that CCm have, for SI modeling, many advantages over SMm. The most crucial advantage is the possibility of universal computation which we took as the definition of intelligence for SI. We also noted, however, that studies based on CCm which include randomness are scarce. We described a few in Sect. "Randomness in Swarm Intelligence", especially in discussing the qualitative differences with synchronous CA and in relation to mechanisms of local and self-synchronization.

Generally these studies model relatively trivial phenomena but cannot model nontrivial phenomena such as universal computation. In fact, there are very few studies of universal computation in asynchronous CA. Significant advances have been made only recently. The first attempts were made by simulating a synchronous CA on an asynchronous CA [63] after which a synchronous model, as a Turing Machine, was simulated on the synchronous CA. However, this asynchronous CA is, in practical realization, synchronous.

Improved asynchronous CA do not rely on global synchronization but conduct asynchronous computation directly by simulating Delay-Insensitive circuits, i. e., circuits in which delays of signals do not affect the correctness of the circuit operation [64]. This method essentially uses local synchronization with undetermined exact timing between transitions. In this way an asynchronous CA, with a hexagonal cell structure, capable of universal computing has been realized [65]. Although relying on local synchronization, this type of asynchronous CA can mimic natural phenomena as, e. g., phenomena that rely on chemical reactions which occur only when the right molecules are available in the right positions at the right times.

More recently a computation-universal and construction-universal asynchronous CA has been designed [66] and used to implement self-reproducing [67,68] machines. Besides computational universality, construction universality is important in SI because it allows the swarm to be hardware reconfigurable, an important characteristic of many biological systems.

We note that the recent interest in asynchronous CA stems not directly from SI but from nanotechnology. In fact nanocomputer architectures with asynchronous updating may reduce heat dissipation, an important limiting factor in scaling down the size of computing chips [64]. In this respect, it is likely that SI concepts will play a major role in nanoscale systems.

In conclusion, the recent realization [66] of universal asynchronous CA is a major step toward the realization of true SI.

Characteristics of Swarm Intelligence

The demonstration of universal computation in asynchronous CA, amounts to a validation of the concept of SI. In fact we can now combine universal computation with the Elementary Swarm definition (Definition 2) to quantify the intuitive definition of SI (Definition 1), as

Definition 3 SI is the study of *universal cellular-computing systems updating with natural asynchrony*.

Here 'natural' means SMR-asynchrony (see Sect. "Asynchronous Swarms") or updating randomly in parallel, as in case (3) of Sect. "Asynchronous Swarms". We call it 'natural' since it models the natural mode of updating of typical biological swarms and human societies.

A few remarks about Definition 3. The four elements of the intuitive notions (Definition 1) are made precise by Definition 3: 'collectively' and 'unknowingly' are inherent in the structure of cellular computing; 'intelligence' is in universal computation; and 'randomness' is in the natural asynchronous operation.

Definition 3 deals with CCm and may appear to exclude SMm in SI; but this is not the case. In fact, many SMm, as used in SI, can be regarded as special cases of cellular computing methods, as, e. g., are swarm optimization and iterative methods in finite differences.

Also Definition 3 does imply that every SI system must be capable of universal computation; what Definition 3 does is to establish a focus of attention for the SI area of studies and at the same time give a precise and realistic meaning to the kind of 'intelligence' aimed at in SI, rather than the often vague and exaggerated meanings given in the popular literature.

Definition 3 also indicates how SI becomes of relevance beyond biological systems and robotics. In fact SI will likely be an important concept in the future of computation. At very small scales, time delays between computational components cannot guarantee synchrony; the various components must have independent clocks, thus beginning to resemble the operation of a biological swarm. So, swarms are likely to be studied extensively in connections with nanocomputing.

The above arguments bring up the question as to whether SI is nothing more than asynchronous cellular computing. The answer is that designs of asynchronous CA, as investigated in computer engineering, are generally not models of SI. A first, basic reason is that, with one recent exception [66], asynchronous CA, do not update 'naturally'. A second, more fundamental reason, is that in most SI studies (both in natural and technological systems) **the units are dynamic**. When the units of an asynchronous CA are made mobile, a different, and more complex set of problems need to be solved due to the changing neighborhoods of each cell. These issues of dynamic reconfigurations of cells have not been addressed in asynchronous cellular computing designs and are likely to remain outside the scope of research aimed at improved computer architectures. The computational problems arising from dynamically reconfiguring cells are central in SI. We address this issue next.

Dynamics in Swarm Intelligence

In the definitions of SI and Swarm given so far (Def. 1., Def. 2., Def. 3.), there has been no mention of the dynamics of the units. But a general characteristic of the units of a swarm is that almost invariably they are mobile. In fact we have already discussed the dynamic nature of swarms in Sects. "Biological Systems" and "Robotic Systems" in relation to biological and robotic swarms. The reason we have so far omitted this dynamic character of the units from the progressively more precise definitions of SI is simply for clarity of exposition: if the dynamics is introduced after all the other elements of SI have been defined and quantified it is easier to single out its real importance.

From Definition 3, with appropriate specializations, all aspects of SI considered so far can be included in a common core of studies. The most general notion of SI is in fact that of *universal computation carried out with 'natural asynchrony' by a cellular computing system*. But we should add, *whose cells are, in general, mobile units*.

The latter qualification would be unnecessary if the description of the dynamic state could be included among the state variables of the cell. But this is not possible in computing cells since the computation depends on neighbors that change their locations. The fact that *dynamic cellular computing systems* (also called *cellular robotic systems*) are not equivalent to (and very hard to simulate by) cellular computers has been emphasized since the very beginning of SI studies [44]. Thus, we conclude by stating a definition of SI which, while remaining grounded in the intuitive ideas (Definition 1), includes all the concepts discussed quantitatively in this article.

Definition 4 SI is the capability of universal computation carried out with 'natural' asynchrony by a dynamic cellular computing system.

As we have seen, studies in the area of SI so far have been concerned with models of collective behavior which, to some limited degree, approach SI as defined above. Even though, to date, no system with SI (Def. 4.) has been built (or designed), significant progress has been made and, from what we have seen, it is reasonable to expect that it can be done.

In fact, although there is not yet proof of universal computation carried out with 'natural' asynchrony by a *cellular robotic system* (i. e., a dynamic cellular computing system), the recent proof [66] for 'static' cellular computers indicates that this may be possible in the near future. Other future perspectives for SI are discussed in Sect. "Future Directions".

Unpredictability in Swarm Intelligence

We are now in a position to consider an aspect of SI which has been inherent to the concept of SI from its inception, i. e., the unpredictability [1,2] of the Swarm.

The unpredictability of the Swarm agrees with the common intuition that it is usually difficult to predict what a program will do by reading its code, and the more so the lower the level of the language used by the program. More precisely, a Swarm, like other universal computers, may be impossible to predict in the sense that even if one knows the rules of evolution and an initial state, it can still take an irreducible [50,69] amount of computation to actually predict future states. Furthermore, the unpredictability of the Swarm is of a more general character than that of any universal computer because of the randomness inherent in its evolution and because of its dynamics.

The unpredictability of a Swarm by a Von Neumann universal computer has been argued in [1,10] on the basis of its dynamics. The unpredictability of a Swarm by a cellular automaton has also been discussed [1,10]. Although unpredictability is difficult to quantify, it is generally engineered by adding randomness to the system as in camouflage and cryptography. Also, in animals, randomness and dynamics are used by a herd to avoid predators by becoming unpredictable. And so in team sports, such as soccer, unpredictability by the opponent is usually achieved by a combination of randomness and dynamics.

Therefore, intuitively we may conjecture that among systems capable of universal computation, a Swarm, because it operates with randomness and dynamically, would be *the least predictable*.

Swarms of Intelligent Units

We can now consider collections of intelligent units, i. e., such that each unit is capable of universal computation. These seem excluded from the definitions of SI given so far – a key characteristic of SI is that intelligence is an emergent property, happening only above a certain critical number of units, and not a property of any of the individual units. On the other hand, some of these groups are often included in broad considerations of SI [4] as applied to human societies. Under what conditions can these groups be regarded as swarms?

A simple answer to this question runs as follows. Consider the special case of Definition 4, when the cells are not finite state machines but universal computing units. As long as the task at hand cannot be accomplished by a single unit, but only by more than a critical number of units, the system operates as a swarm. That this can be the case is supported intuitively and from computational considerations, as follows.

Intuitively, we may refer back to the example of the free market model mentioned as illustration of SI at the beginning of the article. Each individual contributes only as a trader; the 'computation' of the market price is done by the swarm collectively and could not be done by any individual agent. The point is that each unit, albeit 'intelligent', uses only a fraction of its capability, i. e., the trading ability, thus operating, effectively, in a restricted, 'non-intelligent' capacity.

Computationally, we have noted in discussing unpredictability that, in spite of theoretical computational equivalence among universal computers, the capability for one universal computer to predict another is limited. And, in fact, at the end of Sect. "Swarms of Intelligent Units", we put forth the conjecture that a Swarm is the least predictable universal computer.

But even if this conjecture were not true, it still makes sense to think of a case when a Swarm of universal computers is unpredictable by any of the units comprising it, as it has been argued for the case of units capable of universal computation with Von Neumann architecture [1,10]. In this sense we may think of a swarm of universal computers as being more capable than any one of its units, in spite of the fact that the Swarm and any of its units are computationally equivalent. For these reasons, it makes sense to apply, under appropriate conditions, the notion of SI also to human societies.

We may give then a more complete definition of Swarm by adding the characteristic of unpredictability of the Swarm by its units.

Definition 5 SI is the capability of universal computation carried out with 'natural' asynchrony by a dynamic cellular computing system, none of whose cells can predict the computation done by the Swarm.

The latter specification is obviously redundant for common cellular computing systems but it is useful to exclude from SI trivial cases of human social activities; for example, activities of human groups whose association cannot be proven to solve a problem that could not have been solved by any individual alone.

Many popular interpretations of SI have appropriated the label SI to refer to almost any trivial human group activity, such as brainstorming. In such activities often there is no way of proving that the final output of the group could not have been predicted by one of the members of the group. Ultimately, however, these considerations require an understanding of the relation between human thinking and computation, and thus fall beyond the scope of this article.

Similarly, beyond the scope of this article and SI, fall studies of multiagent systems in Artificial Intelligence [70]. In the Artificial Intelligence area, the emphasis on multi-agent systems is in finding decision algorithms, i. e. 'agents', for open environments in which these agents must operate robustly and rapidly, i. e. 'intelligently'. Generally, however, the problem of collective decision making, organization theory, distributed reasoning and distributed Artificial Intelligence is typically beyond the scope of SI.

SI deals with human groups only when they operate at a low level of intelligence. Definition 5 includes human groups of individuals that operate under restrictions which the Swarm can overcome. An example is that of groups of individuals each with a limited computation device connected wirelessly to neighbors as in a cellular computing system. With appropriate algorithms such a Swarm could compute universally while the individual device cannot. This concept is applicable in, e. g., defense operations or emergency mass evacuations strategies.

In conclusion, Definition 5 embodies the intuitive definition of SI (Definition 1) and indicates why SI methods can be used to solve problems not solvable by traditional methods. Besides having all the properties of universal CA, the Swarm operates, as natural systems do, by independent clocks with no centralization and can be designed to be dynamic and unpredictable by any system including any its own units.

Future Directions

The field of SI is still less than 20 years old and it is in a formative phase, with SI researchers engaged in a broad range of disciplines. During these formative years the 'conversation' about SI has followed several strands around some common themes with various emphases ranging from speculative inquiries to practical interests, as we have seen in this article.

The meaning of the term SI has tended to broaden, covering now many areas, apparently only weakly related by the some intuitive notions. We have seen, however, how all these SI ideas have a 'center of attraction' in a basic concept of SI that can be made precise and quantified (Definition 4 or 5), and thus used to provide unity, continuity, and boundaries, thus preventing the area from broadening to the point of being unable to sustain an effective research community.

With this perspective, SI can also be seen as having an ultimate theoretical goal for the practical realization of engineered Swarms, whether robotic, biological or simply computational.

Practically, the goal of SI will remain two-fold: to provide models to explain biological societies and to engineer algorithms and devices with capability beyond those of traditional technologies. It will continue to include Swarm Robotics and bio-inspired algorithms such as swarm optimization methods.

But although commonly regarded as a typical example of bio-inspired technology, SI applications are likely to go beyond bio-inspired systems. We can see this if we consider how nature-inspired technologies have evolved.

Science discovers laws of nature, and technology makes inventions using those laws, often together with design ideas also derived from nature. Thus, for example, laws of physics and designs inspired by crystal structures are now applied to nanotechnologies; similarly, laws of biology and designs inspired by genetic configurations are applied to make artificial organisms in biotechnology. More recently a new kind of science [50] is discovering the laws and designs of computing machines as though they were natural systems, and these discoveries are likely to be used to invent new software algorithms and hardware implementations of those algorithms. SI, besides being bio-inspired, can be said to be inspired also by this new science, which, in some respects, can be more general than biology.

In this perspective, SI will evolve into the study of what amounts to be very powerful computing systems. Designing the simplest of these, i. e., the simplest universal dynamic cellular-computing system updating with natural asynchrony, is an example of a future theoretical and practical challenge for SI. More immediate, future applications can be extrapolated from the examples given throughout the article.

Article Outline

Glossary

In this glossary, we give only brief descriptions of key terms. We refer to specific sections in the text for more precise definitions.

Almost conjugacy (Sect. "Other Coding Problems") A common extension of two shift spaces given by factor codes that are one-to-one almost everywhere.

Automorphism (Sect. "The Conjugacy Problem") An invertible sliding block code from a shift space to itself; equivalently, a shift-commuting homeomorphism from a shift space to itself; equivalently, a topological conjugacy from a shift space to itself.

Dimension group (Sect. "The Conjugacy Problem") A particular group associated to a shift of finite type. This group, together with a distinguished sub-semigroup and an automorphism, captures many invariants of topological conjugacy for shifts of finite type.

Embedding (Sect. "Shift Spaces and Sliding Block Codes") A one-to-one sliding block code from one shift space to another; equivalently, a one-to-one continuous shift-commuting mapping from one shift space to another.

Factor map (Sect. "Shift Spaces and Sliding Block Codes") An onto sliding block code from one shift space to another; equivalently, an onto continuous shift-commuting mapping from one shift space to another. Sometimes called *Factor Code*.

Finite equivalence (Sect. "Other Coding Problems") A common extension of two shift spaces given by finite-to-one factor codes.

Full shift (Sect. "Shift Spaces and Sliding Block Codes") The set of all bi-infinite sequences over an alphabet (together with the shift mapping). Typically, the alphabet is finite.

Higher dimensional shift space (Sect. "Higher Dimensional Shift Spaces") A set of bi-infinite arrays of a given dimension, determined by a collection of finite forbidden arrays. Typically, the alphabet is finite.

Markov partition (Sect. "Origins of Symbolic Dynamics: Modeling of Dynamical Systems") A finite cover of the underlying phase space of a dynamical system, which allows the system to be modeled by a shift of finite type. The elements of the cover are closed sets, which are allowed to intersect only on their boundaries.

Measure of maximal entropy (Sect. "Connections with Information Theory and Ergodic Theory") A shift-invariant measure of maximal measure-theoretic entropy on a shift space. Its measure-theoretic entropy coincides with the topological entropy of the shift space.

Road problem (Sect. "Other Coding Problems") A recently-solved classical problem in symbolic dynamics, graph theory and automata theory.

Run-length limited shift (Sect. "Coding for Data Recording Channels") The set of all bi-infinite binary sequences whose runs of zeros, between two successive ones, are bounded below and above by specific numbers.

Shift equivalence (Sect. "The Conjugacy Problem") An equivalence relation on defining matrices for shifts of finite type. This relation characterizes the corresponding shifts of finite type, up to an eventual notion of topological conjugacy.

Shift space (Sect. "Shift Spaces and Sliding Block Codes") A set of bi-infinite sequences determined by a collection of finite forbidden words; equivalently, a closed shift-invariant subset of a full shift.

Shift of finite type (Sect. "Shifts of Finite Type and Sofic Shifts") A set of bi-infinite sequences determined by a *finite* collection of finite forbidden words.

Sliding block code (Sect. "Shift Spaces and Sliding Block Codes") A mapping from one shift space to another determined by a finite sliding block window; equivalently, a continuous shift-commuting mapping from one shift space to another.

Sofic shift (Sect. "Shifts of Finite Type and Sofic Shifts") A shift space which is a factor of a shift of finite type; equivalently, a set of bi-infinite sequences determined by a finite directed labeled graph.

State splitting (Sect. "The Conjugacy Problem") A splitting of states in a finite directed graph that creates a new graph, whose vertices are the split states. The operation that creates the new graph from the original graph is a basic building block for all topological conjugacies between shifts of finite type.

Strong shift equivalence (Sect. "The Conjugacy Problem") An equivalence relation on defining matrices for shifts of finite type. In principle, this relation characterizes the corresponding shifts of finite type, up to topological conjugacy.

Topological conjugacy (Sect. "Shift Spaces and Sliding Block Codes") A bijective sliding block code from one shift space to another; equivalently, a shift-commuting homeomorphism from one shift space to another. Sometimes called *conjugacy*.

Topological entropy (Sect. "Entropy and Periodic Points") The asymptotic growth rate of the number of finite sequences of given length in a shift space (as the length goes to infinity).

Zeta function (Sect. "Entropy and Periodic Points") An expression for the number of periodic points of each given period in a shift space.

Definition of the Subject

Symbolic dynamics is the study of shift spaces, which consist of infinite or bi-infinite sequences defined by a shift-invariant constraint on the finite-length sub-words. Mappings between two such spaces can be regarded as codes or encodings. Shift spaces are classified, up to various kinds of invertible encodings, by combinatorial, algebraic, topological and measure-theoretic invariants.

The subject is intimately related to many other areas of research, including dynamical systems, ergodic theory, automata theory and information theory. Shift spaces and their associated shift mappings are used to model a rich and important class of smooth dynamical systems and ergodic measure-preserving transformations. These models have provided a valuable tool for classifying and understanding fundamental properties of dynamical systems. In addition, techniques from symbolic dynamics have had profound applications for data recording applications, such as algorithms and analysis of invertible encodings, and problems in matrix theory, such as characterization of the set of eigenvalues of a nonnegative matrix.

Introduction

This article is intended to give a picture of major topics in symbolic dynamics. Section "Origins of Symbolic Dynamics: Modeling of Dynamical Systems" reviews the roots of symbolic dynamics in modeling of dynamical systems. Section "Shift Spaces and Sliding Block Codes" lays the foundation by defining the kinds of spaces and mappings considered in the subject. Section "Shifts of Finite Type and Sofic Shifts" focuses on distinguished special classes of spaces, known as shifts of finite type and sofic shifts. Section "Entropy and Periodic Points" introduces the most fundamental invariants, periodic points and topological entropy. Sections "The Conjugacy Problem" and "Other Coding Problems" survey progress on the conjugacy problem and other classification/coding problems for shifts of finite type and sofic shifts. In Sect. "Coding for Data Recording Channels", we present applications to coding for data recording. Section "Connections with Information Theory and Ergodic Theory" provides a link with information theory and ergodic theory. Finally, Sect. "Higher Dimensional Shift Spaces" treats higher dimensional symbolic dynamics.

While this article covers many of the most important topics in the subject, others have been omitted or treated lightly, due to space limitations. These include one-sided shift spaces, countable state symbolic systems, orbit equivalence, flow equivalence, the automorphism group, cellular automata, and substitution systems. References to work in these sub-areas can be found in the sources mentioned below.

For introductory reading on symbolic dynamics and its applications, beyond this article, one can consult the textbooks Kitchens [65] and Lind and Marcus [78]. There are also excellent introductory survey articles, such as Boyle [23], Lind and Schmidt [79], and S. Williams [132]. In addition there are very good expositions which focus on other aspects of the subject. These include Beal [11], which focuses on connections between symbolic dynamics and automata theory, the lecture notes Marcus–Roth–Siegel [83], which focuses on constrained coding applications, and Immink [54], which focuses on applications to data storage. There are also several excellent collections of articles on special areas of the subject, such as [17,133], and [128]. The book [15] by Berstel and Perrin treats the subject of variable length codes and contains many ideas related to symbolic dynamics. Finally, there is an excellent recent survey by Boyle on Open Problems in Symbolic Dynamics [24].

Origins of Symbolic Dynamics: Modeling of Dynamical Systems

Symbolic dynamics began as an effort to model dynamical systems using sequences of symbols. A *dynamical system* is a pair (X, T) where X is a set and T is a transformation from X to itself. For definiteness, we assume that T is invertible, although this is not a necessary restriction.

Since T maps X to itself, we can iterate T: $T^2 = T \circ T$, $T^3 = T \circ T \circ T$, etc. The *orbit* of a point $x \in X$ is the sequence of points: $\dots, T^{-2}(x), T^{-1}(x), x, T(x), T^2(x), \dots$ In the theory of dynamical systems, one asks questions about orbits such as the following: Are there periodic orbits (i. e., x such that $T^n(x) = x$ for some $n > 0$)? Are there dense orbits (the orbit of x is dense if for any point y in X, $T^n(x)$ is "close" to y for some n)? How does the behavior of an orbit vary with x? How can we describe the collection of all orbits of the dynamical system? When is the dynamical system "chaotic"? For more information on dynamical systems, we refer the reader to [16,38,47].

The subject of dynamical systems has its roots in Classical Mechanics; in that setting, X is the set of all possible states of a system (e. g., the positions, momenta of all particles in a physical system), and the transformation T is the time evolution map, which maps the state of the system at one time to the state of the system at one time unit later.

Symbolic dynamics provides a model for the orbits of a dynamical system (X, T) via a space of sequences. This is done by "quantizing" X into cells, associating symbols to the cells and representing points as bi-infinite sequences of symbols. For instance in Fig. 1, X is a square, and T is some transformation of the square.

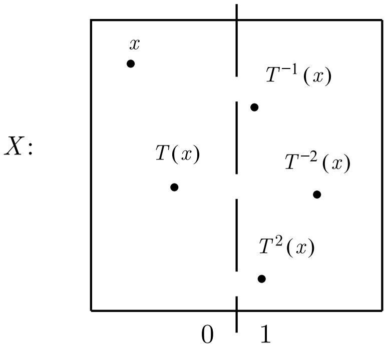
We have drawn a portion of the orbit of a point $x \in X$ for the dynamical system (X, T). We have also quantized X into two cells: the left half, called '0', and the right half, called '1'. Then the point x is represented by the bi-infinite sequence $s(x) = \dots s_{-2}s_{-1}.s_0s_1s_2 \dots$ where s_n is the label of the cell to which $T^n(x)$ belongs (here, we use the decimal point to separate coordinates s_i, $i < 0$ from s_i, $i \geq 0$). So, for x as given in Fig. 1, we see that

$$s(x) = \dots 11.001 \dots$$

for instance $s_0 = 0$ because x belongs to the left half of the square, and $s_2 = 1$ because $T^2(x)$ belongs to the right half of the square. Now, if x is represented by the sequence $s(x)$, then $T(x)$ is represented by the shift of $s(x)$:

$$s(T(x)) = \dots 110.01 \dots .$$

So, T is represented 'symbolically' as the shift transformation.



Symbolic Dynamics, Figure 1
Representing points symbolically

By representing all points of X as bi-infinite sequences, we obtain a *symbolic dynamical system* (Y, σ) where Y is a set of sequences (representing X) and σ is the shift transformation (representing T). The "symbolic" refers to the symbols, and the "dynamical" refers to the action of the shift transformation.

For this representation to be faithful, distinct points should be represented by distinct sequences, and this imposes extra conditions on how X is quantized into cells. Also, Y is typically a set of sequences constrained by certain rules, such as a certain symbol may only be followed by certain other symbols.

In this way, one can use symbolic dynamics to study dynamical systems. Properties of orbits of the original dynamical system are reflected in properties of the resulting sequences. For instance, a point whose orbit is periodic becomes a periodic sequence, and the distribution of the orbit of a point x in X is reflected in the distribution of finite strings within $s(x)$. Beginning with Hadamard [46] in 1898 and followed by Hedlund, Morse and others in the 1920s, 1930s and 1940s [48,49,92,93], this method was used to prove the existence of periodic, almost periodic and other interesting motions in classical dynamical systems, such as geodesic flows on surfaces of negative curvature; this was done by finding interesting sequences satisfying the constraints defined by the corresponding symbolic dynamical system. Later on, this was extended to general hyperbolic systems, where the symbolic dynamics is constructed using a *Markov Partition*, which is a disjoint collection of open sets whose closures cover X, each of which looks like a "rectangle", with vertical (resp., horizontal) fibers contracted (resp., expanded) by T. Markov Partitions were developed by Adler and Weiss [5], Sinai [120] and Bowen [18,19]; see also [13] and Sect. 6.5 in [78].

In more recent years, symbolic dynamics has been used as a tool in classification problems for dynamical systems. Here, the problem of determining when one dynamical system is 'equivalent' to another becomes, via symbolic dynamics, a coding problem. Roughly speaking, two dynamical systems, (X_1, T_1) and (X_2, T_2), are *equivalent* if there is an invertible mapping from X_1 to X_2 which makes T_1 "look like" T_2. If the corresponding symbolic dynamical systems are denoted (Y_1, σ) and (Y_2, σ), then an equivalence between (X_1, T_1) and (X_2, T_2) becomes a time-invariant, invertible encoding from Y_1 to Y_2 (time-invariant because the shift transformation represents the dynamics). Thus, the classification problem in dynamical systems leads to a coding problem between constrained sets of sequences.

We have described dynamical systems as the discrete-time iteration of a single mapping. However, continuous-time iterations have been studied since the inception of the subject. These are known as continuous-time flows, with the main example being the set of solutions to a system of ordinary differential equations. Indeed, the work of Hedlund and Morse mentioned above was done in this context.

Shift Spaces and Sliding Block Codes

Let $\mathcal{A}$ be an alphabet of symbols, which we assume to be finite. The principal objects of study in symbolic dynamics are certain kinds of collections of sequences of symbols from $\mathcal{A}$. Typically, these sequences are infinite $x = x_0x_1x_2\ldots$, but it is often more convenient to deal with *bi-infinite sequences* $x = \ldots x_{-2}x_{-1}x_0x_1x_2\ldots$ For some problems, the results are similar in the infinite and bi-infinite categories, while for other problems, they are quite different. In this article, we focus on the bi-infinite setting.

The symbol x_i is the ith *coordinate* of x. When writing a specific sequence, we need to specify which is the 0th coordinate. As suggested in Sect. "Origins of Symbolic Dynamics: Modeling of Dynamical Systems", this is done with a decimal point to separate the x_i with $i \geq 0$ from those with $i < 0$: $x = \ldots x_{-2}x_{-1}.x_0x_1x_2\ldots$. A *block* or *word* over $\mathcal{A}$ is a finite sequence of symbols from $\mathcal{A}$. A block of length N is called an N-*block*. For blocks u, v, the block uv is the concatenation of u and v, and for a block w, the concatenation of N copies of w is denoted w^N.

The *full $\mathcal{A}$-shift* $\mathcal{A}^{\mathbf{Z}}$ is the set of all bi-infinite sequences of symbols from $\mathcal{A}$. The *full r-shift* is the full shift over the alphabet $\{0, 1, \ldots, r-1\}$. The *shift map* σ on a full shift maps a point x to the point $y = \sigma(x)$ whose ith coordinate is $y_i = x_{i+1}$.

The *orbit* of a point in a full shift is its orbit under the shift map. The full shift contains many different types of orbits. For instance, it contains a dense orbit (namely, any sequence which contains every block in the alphabet) and periodic orbits (namely, any sequence which is periodic).

We are interested in sets that can be specified by a list (finite or infinite) of forbidden blocks. Namely, given a collection $\mathcal{F}$ of "forbidden blocks" over $\mathcal{A}$, the subset X consisting of all sequences in $\mathcal{A}^{\mathbf{Z}}$, none of whose subwords belong to $\mathcal{F}$, is called a *shift space* (or simply *shift*), and we write $X = X_{\mathcal{F}}$. When a shift space X is contained in a shift space Y, we say that X is a *subshift* of Y.

Example 1 X is the set of all binary sequences with no two 1's next to each other. Here $X = X_{\mathcal{F}}$, where $\mathcal{F} = \{11\}$. This shift is called the *golden mean shift*, for reasons that will become apparent later.

Example 2 X is the set of all binary sequences so that between any two 1's there are an even number of 0's. We can take for $\mathcal{F}$ the collection

$$\{10^{2n+1}1 \colon n \geq 0\}\,.$$

This example is naturally called the *even shift*.

Example 3 X is the set of all binary sequences such that between any two successive 1's number of 0's is prime. We can take for $\mathcal{F}$ the collection

$$\{10^n1 \colon n \text{ is composite}\}\,.$$

This example is naturally called the *prime shift*.

Alternatively (and equivalently), shift spaces can be defined as closed, shift-invariant subsets of full shifts. Here, "closed" means with respect to a metric, for which two points are close if they agree in a large "central block"; one such metric is $\rho(x, y) = 2^{-k}$ if $x \neq y$, with k maximal such that $x_{[-k,k]} = y_{[-k,k]}$ (with the conventions that $\rho(x, y) = 0$ if $x = y$ and $\rho(x, y) = 2$ if $x_0 \neq y_0$).

Let X be a subset of a full shift, and let $\mathcal{B}_N(X)$ denote the set of all N-blocks that occur in elements of X. The *language of* X is $\mathcal{B}(X) = \cup_N \mathcal{B}_N(X)$. It can be shown that the language of a shift space determines the shift space uniquely, and so we can equally well describe a shift space by specifying the "occurring" or "allowed" blocks, rather than the forbidden blocks. For example, the golden mean shift is specified by the language of blocks in which 1's are isolated.

This establishes a connection with automata theory [6,11], which studies collections of blocks, rather than infinite or bi-infinite sequences. The languages that occur in symbolic dynamics, i. e. as $\mathcal{B}(X)$ for some shift space X, are simply those sets $\mathcal{L}$ of blocks that satisfy two simple properties: every sub-block of an element of $\mathcal{L}$ belongs to $\mathcal{L}$, and every element $w \in \mathcal{L}$ is extendable to a larger block $awb \in \mathcal{L}$, with $a, b \in \mathcal{A}$.

Some examples are best described by allowed blocks. One example is the famous *Morse shift*.

Example 4 Let $A_0 = 0$ and inductively define blocks $A_{n+1} = A_n\overline{A_n}$, where $\overline{A_n}$ denotes bitwise complement. The shift space whose allowed blocks are the sublocks of the A_n is called the *Morse shift*.

This shift space has an alternative description as follows. Since each A_n is a prefix of A_{n+1}, the sequence of blocks A_n determines a unique right-infinite sequence x^+ (with each A_n as a a prefix). If we denote x^- as the left-infinite sequence obtained by writing x^+ backwards, then the Morse shift is the closure of the orbit of the point $x^-.x^+$. The sequence x^+ is known as the Prouhet–Thue–Morse (PTM) sequence, since Prouhet and Thue introduced it earlier, but for different purposes.

While it is not immediately obvious, it can be shown that the PTM sequence is not periodic; moreover, the Morse shift is a *minimal shift*, which means that all its orbits are dense [91]. In contrast, while the full, golden mean, even and prime shifts all have dense orbits, each also has a dense set of periodic orbits.

There are two simple, but very important, constructions in symbolic dynamics that construct from a given shift space a new version which in some sense looks deeper into the space at the cost of a larger alphabet and more complex description.

Let X be a shift space over the alphabet $\mathcal{A}$, and $\mathcal{A}^{(N)} = \mathcal{B}_N(X)$. We can consider $\mathcal{A}^{(N)}$ as an alphabet in its own right, and form the full shift $(\mathcal{A}^{(N)})^{\mathbf{Z}}$. Define the *Nth higher block code* by

$$(\beta_N(x))_i = x_{[i,i+N-1]} \, .$$

Then the Nth *higher block shift* or *higher block presentation* of a shift space X is the image $X^{[N]} = \beta_N(X)$ in the full shift over $\mathcal{A}^{(N)}$.

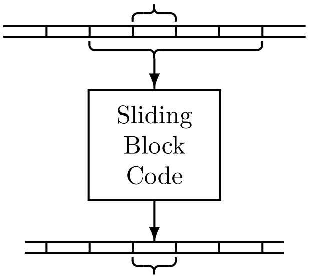
Similarly, define the *Nth higher power code* $\gamma_N \colon X \to (\mathcal{A}^{(N)})^{\mathbf{Z}}$ by

$$(\gamma_N(x))_i = x_{[iN,iN+N-1]} \, .$$

The Nth *higher power shift* X^N of X is the image $X^N = \gamma_N(X)$ of X. The difference between $X^{[N]}$ and X^N is that the former is constructed by considering overlapping blocks and the latter by non-overlapping blocks.

Next, we turn to mappings between shift spaces. Suppose that $x = \ldots x_{-1}.x_0x_1\ldots$ is a sequence in a shift space X over $\mathcal{A}$. We can transform x into a new sequence $y = \ldots y_{-1}.y_0y_1\ldots$ over another alphabet C as follows. Fix integers m and n with $-m \le n$. To compute the ith coordinate y_i of the transformed sequence, we use a function Φ that depends on the "window" of coordinates of x from position $i-m$ to position $i+n$. Here $\Phi\colon \mathcal{B}_{m+n+1}(X) \to C$ is a fixed *block map*, called an $(m+n+1)$-*block map* from allowed $(m+n+1)$-blocks in X to symbols in C, and so

$$y_i = \Phi(x_{i-m}x_{i-m+1}\ldots x_{i+n}) = \Phi(x_{[i-m,i+n]}) \, .$$



Symbolic Dynamics, Figure 2
Sliding block code

This is illustrated in Fig. 2.

Let X be a shift space over $\mathcal{A}$, and $\Phi\colon \mathcal{B}_{m+n+1}(X) \to C$ be a block map. Then the map $\phi\colon X \to C^{\mathbf{Z}}$ defined by $y = \phi(x)$, with y_i given by Φ above, is called the *sliding block code* with *memory m* and *anticipation n induced by Φ*. We will denote the formation of ϕ from Φ by $\phi = \Phi_\infty^{[-m,n]}$, or more simply by $\phi = \Phi_\infty$ if the memory and anticipation of ϕ are understood. If not specified, the memory is taken to be 0. If Y is a shift space contained in $C^{\mathbf{Z}}$ and $\phi(X) \subseteq Y$, we write $\phi\colon X \to Y$.

In analogy with the characterization of shift spaces as closed shift-invariant sets, sliding block codes can be characterized in a topological manner: namely, as the maps between shift spaces that are continuous and commute with the shift. This result is known as the Curtis–Hedlund–Lyndon theorem [50].

Example 5 Let $\mathcal{A} = \{0,1\} = C$, $X = \mathcal{A}^{\mathbf{Z}}$, $m = 0$, $n = 1$, and $\Phi(a_0a_1) = a_0 + a_1 \pmod 2$. Let $\phi = \Phi_\infty\colon X \to X$.

Example 6 The sliding block code, generated by $\Phi(00) = 1$, $\Phi(01) = 0 = \Phi(10)$, maps the golden mean shift onto the even shift.

Example 7 There is a trivial sliding block code from the full 2-shift into the full 3-shift, generated by $\Phi(0) = 0$, $\Phi(1) = 1$.

If a sliding block code $\phi\colon X \to Y$ is onto, then ϕ is called a *factor code* or *factor map*, and Y is a *factor* of X. If $\phi\colon X \to Y$ is one-to-one, then ϕ is called an *embedding* of X into Y. The sliding block code in Example 7 is an embedding but not a factor code, while the codes in Examples 5 and 6 are factor maps, but not embeddings.

A major (and unrealistic) goal of symbolic dynamics is to classify in an explicit way shift spaces up to the following natural notion of equivalence. A sliding block code $\phi\colon X \to Y$ is a *conjugacy* (or *topological conjugacy*) if it is invertible with sliding block inverse. Equivalently, a conjugacy is a bijective sliding block code and therefore simultaneously a factor code and an embedding. If there is a conjugacy from one shift space X to another Y, we say that X and Y are *conjugate*, denoted $X \cong Y$.

As an example, the higher block map β_N is a conjugacy between a shift space X and its higher block shift $X^{[N]}$. Via this code, we can "re-code" any sliding block code as a 1-block code (though typically a conjugacy and its inverse cannot, by this artifice, be simultaneously re-coded to 1-block codes).

In this section, we have given examples of relatively simple sliding block codes. But the typical conjugacy, as well as factor code and embedding, can be much more complicated.

Shifts of Finite Type and Sofic Shifts

A *shift of finite type (SFT)* is a shift space that can be described by a finite set of forbidden blocks, i. e., a shift space X having the form $X_{\mathcal{F}}$ for some finite set $\mathcal{F}$ of blocks. The terminology shift of finite type (or *subshift of finite type*) comes from dynamical systems (Smale [121]).

An SFT is *M-step* (or has *memory M*) if it can be described by a collection of forbidden blocks all of which have length $M+1$. It is easy to see that any SFT is M-step for some M.

Since any shift space can be defined by many different collections of forbidden blocks, it is useful to have the following equivalent condition expressed in terms of allowed blocks: an SFT is M-step if and only if whenever u is an allowed block of length at least M, u' is the suffix of u with length M and a is a symbol, then ua is allowed if and only if $u'a$ is allowed. In other words, in order to tell whether a symbol can be allowably concatenated to the end of an allowed word u, one need only look at the last M symbols of u. This is analogous to the "finite memory" property of M-step Markov chains.

The golden mean shift X is is a 1-step SFT, since it was defined by a forbidden list consisting of exactly one block: $\mathcal{F} = \{11\}$. Equivalently, it is only the last symbol of an allowed block that determines whether a given symbol can be concatenated at the end. In contrast, the even shift is not an SFT: for any M, the symbol 1 can be concatenated to the end of exactly one of the (allowed) words 10^M and 10^{M+1}.

Recall that the higher block code β_M is a conjugacy from X to $X^{[M]}$. Via this code, any SFT can be recoded to a 1-step SFT. And so any sliding block code on a shift space can be recoded to a 1-block code on a 1-step SFT. It is useful to have a concrete description of 1-step SFT's. In fact, these are precisely the shift spaces consisting of all bi-infinite sequences of vertices along paths on a finite directed graph. These are called *vertex shifts*. We find it more convenient to work with sequences of edges instead. To be precise:

Let G be a finite directed graph (or simply graph) with vertices (or *states*) $\mathcal{V} = \mathcal{V}(G)$ and *edges* $\mathcal{E} = \mathcal{E}(G)$. For an edge e, $i(e)$ denotes the initial state and $t(e)$ the terminal state. A *path* in G is a finite sequence of edges in G such that the terminal state of an edge coincides with the initial state of the following edge; a *cycle* in G is path that begins and ends at the same state. We will assume that G is *essential*, i. e., that every state has at least one outgoing edge and one incoming edge.

The *adjacency matrix* $A = A(G)$ is the matrix indexed by $\mathcal{V}$ with A_{IJ} equal to the the number of edges in G with initial state I and terminal state J. Since a graph and its adjacency matrix essentially determine the same information, we will frequently associate a graph G with its adjacency matrix A and a nonnegative integer matrix A with a graph G.

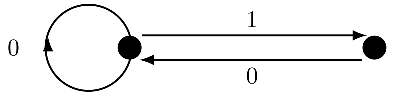
The *edge shift* X_G or X_A is the shift space over the alphabet $\mathcal{A} = \mathcal{E}$ defined by

$$\begin{aligned} X_G &= X_A \\ &= \left\{\xi = (\xi_i)_{i\in\mathbf{Z}} \in \mathcal{E}^{\mathbf{Z}} \colon \text{ each } \xi_{i+1} \text{ follows } \xi_i\right\} . \end{aligned}$$

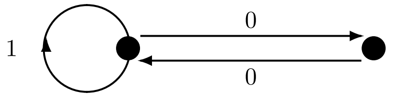
It can be readily verified that edge shifts are 1-step SFT's. While edge shifts do not include all 1-step SFT's, any 1-step SFT can be recoded to an edge shift, and, compared with vertex shifts, edge shifts offer the advantage of a more compact description.

For many purposes, one can study a general shift space X by breaking it into smaller, more well-behaved pieces. A shift space is *irreducible* if whenever u and w are allowed blocks, there is a "connecting" block v such that uvw is allowed. While shift spaces do not always decompose into disjoint unions of irreducible shifts, every SFT can be written as a finite disjoint union of irreducible SFT's X_i together with "transient" one-way connections from one X_i to another. And irreducible edge shifts can be characterized in a particularly concrete form: namely, X_G is irreducible if and only if G is *irreducible*, i. e., for every ordered pair of vertices I and J there is a path in G starting at I and ending at J.

There is a stronger notion which is defined by a uniformity condition on the length of the connecting block. A shift space is *mixing* if whenever u and w are allowed blocks, there is an N, possibly depending on u and w, such that for all $n \geq N$, there is block v of length n such that uvw is allowed. And an edge shift X_G is mixing if and only if G is *primitive*, i. e., there is an integer N such that for any $n \geq N$ and any ordered pair of vertices I and J there is



Symbolic Dynamics, Figure 3
Presentation of golden mean shift



Symbolic Dynamics, Figure 4
Presentation of even shift

a path in G of length n starting at I and terminating at J. It follows that for SFT's in the definition of mixing, the uniform connecting length N can be chosen independent of the allowed blocks u and w.

It can be shown that, in some sense, any irreducible SFT X can be broken down into a union of disjoint maximal mixing shifts; namely, X can be written as the disjoint union of finitely many sets X_i, $i = 0, \ldots, p-1$ such that $\sigma(X_i) = X_{i+1} \bmod p$ and for each i, σ^p restricted to X_i can be regarded as a mixing SFT. This is a consequence of Perron–Frobenius theory, upon which symbolic dynamics relies heavily; see Seneta [118] for an introduction to this theory.

A *sofic shift* is the set of bi–infinite sequences obtained from a finite labeled directed graph $\mathcal{G} = (G, \mathcal{L})$; here, G is a finite directed graph and $\mathcal{L}$ is a labeling of the edges of G. The labeled graph is often called a *presentation* of the sofic shift. The golden mean shift and even shift are sofic, with presentations given in Figs. 3 and 4.

SFT's are sofic because any M-step SFT can be presented by a graph whose states are allowed M-blocks. Note also that any sofic shift is a factor of an SFT, namely via a (1-block) factor code $\mathcal{L}_\infty$ on the edge shift X_G based on a presentation $(G, \mathcal{L})$. In fact, the converse is true, and so the sofic shifts are precisely the shift spaces that are factors of SFT's. This was the original definition of sofic shifts given by Weiss [130].

Typically, the labeling is *right resolving*, which means that at any given state, all outgoing edges have distinct labels (as in Figs. 3 and 4).

Theorem 1

(a) *Any sofic shift has a right resolving presentation.*
(b) *Any irreducible sofic shift has a unique minimal right resolving presentation.*

Part (a) is a direct consequence of the subset construction in automata theory [6,11] which constructs a right resolving presentation from an arbitrary presentation; see also Coven and Paul [33,34]. Part (b) makes use of the the state-minimization algorithm from automata theory [6,11], but requires an idea beyond that found in automata theory (Fischer [39,40]). The unique presentation in part (b) may be regarded as a canonical presentation. We remark that for an irreducible (resp. mixing) sofic shift, the underlying graph of the unique minimal right resolving presentation is irreducible (resp., primitive).

Sometimes it is useful to weaken the concept of right resolving to *right closing*, which means "right resolving with delay"; more precisely a labeling is right closing, with delay D if all paths of length $D+1$ with the same initial state and the same label have the same initial edge. Also, we sometimes consider *left resolving* and *left closing* labellings (replace "outgoing" with "incoming" in the definition of right resolving, and replace "initial" with "terminal" in the definition of right closing).

While the class of SFT's is defined by a "finite-memory" property, the more general class of sofic shifts is defined by a "finite-state" property, in that the possible symbols that can occur at time 0 are determined by the past via one of finitely many states. In a presentation, the vertices can be viewed as state information which connects sequences in the past with sequences in the future.

It is not difficult to show that neither the prime shift (Example 3) nor the Morse shift (Example 4) are sofic and therefore also not SFT. For the prime shift, this can be done by an application of the pumping lemma from automata theory [6] (or p. 68 of [78]).

There are uncountably many shift spaces, but only countably many sofic shifts. So, it is not surprising that the behavior of sofic shifts is very special. However, they are very useful in modeling smooth dynamical systems (Sect. "Origins of Symbolic Dynamics: Modeling of Dynamical Systems") and in information theory and applications to data recording (Sect. "Coding for Data Recording Channels"), where they arise as *constrained systems*, although this term is usually reserved for the set of (finite) blocks obtained from a finite directed labeled graph [83].

Entropy and Periodic Points

An invariant of conjugacy is an object associated to a shift space that is preserved under conjugacy. It can be shown that many of the concepts that we have already introduced are invariants: irreducibility, mixing, as well as the properties of being a shift of finite type or sofic shift. Beyond these qualitative invariants, there are many quantitative invariants that can, in many cases, be computed explicitly. Foremost among these is topological entropy.

The *(topological) entropy* (or simply *entropy*) of X is:

$$h(X) = \lim_{N \to \infty} \frac{\log |\mathcal{B}_N(X)|}{N} ;$$

here, $|\cdot|$ denotes cardinality, and for definiteness the log is taken to mean $\log_2$ but any base will do. A subadditivity argument shows that the limit does indeed exist [127]. It should be evident that $h(X)$ is a measure of the "size" or "complexity" of X, as it is simply the asymptotic growth rate of the number of blocks that occur in X. Topological entropy for continuous dynamical systems was defined by Adler, Konheim and McAndrew [3], in analogy with measure-theoretic entropy.

Since a k-block sliding block code from a shift space X to a shift space Y maps $\mathcal{B}_{N+k-1}(X)$ into $\mathcal{B}_N(Y)$, it is not hard to see that entropy is an invariant of conjugacy and that it cannot increase under factors and cannot decrease under embeddings.

In many cases, one can explicitly compute entropy. For example, for the full r-shift X, $|\mathcal{B}_N(X)| = r^N$, and so $h(X) = \log r$. And from the defining sequence of the Morse shift, we see that the number of distinct 2^N-blocks is at most $4(2^N)$, it follows that the growth rate cannot be exponential and so the entropy of the Morse shift is zero.

For SFT's and more generally for sofic shifts, entropy can be computed explicitly. The key to this computation is the following result, which is based on the Perron–Frobenius theorem.

Theorem 2 [99,119] *For any graph G, $h(X_G) = \log \lambda_{A(G)}$, where $\lambda_{A(G)}$ is the largest eigenvalue of $A(G)$.*

The rough idea is that the number of N-blocks in X_G is the number of paths of length N and thus also the sum of the entries of $A(G)^N$, which is controlled by the largest eigenvalue. This is proven first for primitive graphs, whose adjacency matrices have a unique eigenvalue of maximum modulus and this eigenvalue is positive; in fact, for a primitive graph and a pair of states I, J, the number of paths of length N from I to J grows like $\lambda_{A(G)}^N = 2^{Nh(X_G)}$. For general graphs, one uses the decomposition into primitive, and then irreducible, graphs.

To extend this to a sofic shift Y, one uses a right resolving presentation $(G, \mathcal{L})$ of Y. Since every block of Y is the label of at most most $\mathcal{V}(G)$ paths in G, it follows that:

Theorem 3 *Let $\mathcal{G} = (G, \mathcal{L})$ be a right-resolving labeled graph presenting a sofic shift Y. Then $h(Y) = h(X_G)$.*

From Fig. 3, we see that the golden mean shift is obtained as a right resolving presentation of the graph with adjacency matrix:

$$A = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix} .$$

A computation shows that λ_A is the golden mean, and so the entropy of the golden mean shift is the log of the golden mean; this is one explanation of the meaning of the term golden mean shift. From Fig. 4, we see that the even shift has the same entropy.

One cannot overstate the importance of entropy as an invariant. Yet, it is somewhat crude; it is perhaps not surprising that a single numerical invariant would not be sufficient to completely capture the many intricacies of shift spaces, even of sofic shifts or SFT's.

An invariant finer than entropy is the zeta function, which combines information regarding the numbers of periodic sequences of all periods, described as follows.

For a shift space X, let $p_n(X)$ denote the number of points in X of period n (i. e., the number of $x \in X$ such that $\sigma^n(x) = x$). It is straightforward to show that each $p_n(X)$ is an invariant. Since distinct periodic sequences define distinct blocks, it follows that

$$\limsup_{n \to \infty} \frac{1}{n} \log p_n(X) \le h(X) .$$

The inequality can be strict; for example, there are shift spaces (such as the direct product of the Morse shift with the full 2-shift) with positive entropy but no periodic points at all.

However, for irreducible SFT's and sofic shifts, the entropy $h(X)$ can be recovered from the sequence $p_n(X)$. The key to understanding this is the fact that for an edge shift $X = X_A$, $p_n(X) = \mathrm{tr}(A^n)$ and thus is the sum of the nth powers of the (non-zero) eigenvalues of A; in the case that A is primitive, the largest eigenvalue λ_A strictly dominates the other eigenvalues, and thus for large n,

$$\log p_n(X) = \log \mathrm{tr}(A^n) \sim n \log \lambda_A \sim nh(X) .$$

This shows that for a mixing SFT, the entropy equals the growth rate of numbers of periodic points. In fact, this result applies to all SFT's and sofic shifts.

Theorem 4 *For a sofic shift X,*

$$\limsup_{n \to \infty} \frac{1}{n} \log p_n(X) = h(X) .$$

The lim sup turns out be a limit in the case that X is a mixing sofic shift.

Most of what we have stated for $p_n(X)$ here applies equally well to $q_n(X)$, the number of points of *least* period n in X. This follows from the fact that "most" periodic points of period n have least period n.

The periodic point information can be conveniently combined into a single invariant, known as the *zeta function*. For a shift space X,

$$\zeta_X(t) = \exp\left(\sum_{n=1}^{\infty} \frac{p_n(X)}{n} t^n\right) .$$

For an edge shift X_A, one computes the zeta function to be the reciprocal of a polynomial:

$$\zeta_{X_A}(t) = \frac{1}{t^r\,\chi_A(t^{-1})} = \frac{1}{\det(I - tA)} ,$$

which is completely determined by the non-zero eigenvalues (with multiplicity) of A (Bowen and Lanford [21]). As an example, the zeta function of the golden mean shift is $1/(1-t-t^2)$.

The discussion above applies equally well to SFT's since they are conjugate to edge shifts. For a sofic shift, the zeta function turns out to be a rational function, i. e., quotient of two polynomials. This can be shown by analyzing properties of a right resolving presentation of the sofic shift. From this it turns out that the zeta function of the even shift is $(1-t)/(1-t-t^2)$. The technique for computing zeta functions of sofic shifts was developed by Manning [80] (actually, Manning developed the technique to compute zeta functions of hyperbolic dynamical systems).

So, for sofic shifts, all of the periodic point information is determined by a finite collection of complex numbers, namely the zeros and poles of the zeta function.

Finally, we mention another simple invariant obtained from the periodic points. The *period*, per(X), of a shift space X is the gcd of lengths of periodic points in X, i. e., the gcd of the set of n such that $p_n(X) \neq 0$. If $X = X_G$ is an edge shift and G is irreducible, then $\mathrm{per}(X_G) = \mathrm{per}(G)$, which is defined to be the gcd of cycle lengths in G and coincides with the gcd of the lengths of all cycles in G based at any given state. For an irreducible graph with period p and any state I, the number of cycles of length N, a multiple of p, at I grows like $\lambda^N_{A(G)} = 2^{Nh(X_G)}$. Also, an irreducible graph G is primitive if $\mathrm{per}(G) = 1$.

The Conjugacy Problem

The conjugacy problem for SFT's and sofic shifts is a major open problem. After much effort, it remains unsolved today. Much of what we know goes back to R. Williams [131] in the 1970s. One of Williams' main results was that any conjugacy can be decomposed into simple building blocks, as follows.

Let A and B be nonnegative integral matrices, with associated graphs G and H. An *elementary equivalence from A to B* is a pair (R, S) of rectangular nonnegative integral matrices satisfying

$$A = RS\,, \quad B = SR\,. \tag{1}$$

In this case we write $(R, S)\colon A \equiv B$. A *strong shift equivalence of lag ℓ from A to B* is a sequence of ℓ elementary equivalences

$$\begin{aligned}&(R_1, S_1)\colon A = A_0 \equiv A_1\,,\\ &(R_2, S_2)\colon A_1 \equiv A_2\,,\\ &\ldots\,,\\ &(R_\ell, S_\ell)\colon A_{\ell-1} \equiv A_\ell = B\,.\end{aligned}$$

In this case we write $A \approx B(\text{lag } \ell)$. We say that A is *strong shift equivalent to B* (and write $A \approx B$) if there is a strong shift equivalence of some lag from A to B.

Via the matrix Equation (1), one creates a graph K whose state set is the disjoint union of $\mathcal{V}(G)$ and $\mathcal{V}(H)$; for each $I \in V_G$ and $J \in V_H$, the graph has R_{IJ} edges from I to J and S_{JI} edges from J to I. The equation $A = RS$ allows one to associate each edge e of G with a unique path $r(e)s(e)$ of length two running from $\mathcal{V}(G)$ to $\mathcal{V}(H)$ to $\mathcal{V}(G)$. Similarly, the equation $B = SR$ allows one to associate each edge e of H with a path $s(e)r(e)$ of length two running from $\mathcal{V}(H)$ to $\mathcal{V}(G)$ to $\mathcal{V}(H)$. One can show that the 2-block sliding block code defined by $\Phi(ef) = s(e)\,r(f)$ defines a conjugacy from X_A to X_B, and so whenever $A \approx B$, $X_A \cong X_B$. Williams proved this and its converse:

Theorem 5 *(R. Williams [131]) The edge shifts X_A and X_B are conjugate if and only if A and B are strong shift equivalent.*

In fact, Williams showed that any conjugacy can be decomposed into a composition of conjugacies defined by elementary equivalences. This can be interpreted in a way that shows that X_A and X_B are conjugate if and only if we can pass from G to H by a sequence of state splittings and amalgamations, defined as follows.

Let G be a graph with states $\mathcal{V}$ and edges $\mathcal{E}$. For each $I \in \mathcal{V}$, partition the outgoing edges from I into disjoint nonempty sets $\mathcal{E}^1_I, \mathcal{E}^2_I, \ldots, \mathcal{E}^{m(I)}_I$. Let $\mathcal{P}$ denote the resulting partition of $\mathcal{E}$, and let $\mathcal{P}_I$ denote the partition $\mathcal{P}$ restricted to $\mathcal{E}_I$. The *out-split graph H formed from G using $\mathcal{P}$* has states $I^1, I^2, \ldots, I^{m(I)}$, where I ranges over the states in $\mathcal{V}$, and edges e^j, where e is any edge in $\mathcal{E}$ and

$1 \le j \le m(t(e))$. If $e \in \mathcal{E}$ goes from I to J, then $e \in \mathcal{E}_I^i$ for some i, and we define the e^j to have initial state I^i and terminal state J^j, The 2-block code generated by $\Phi(ef) = e^j$, where $f \in \mathcal{E}_{t(e)}^j$, defines a conjugacy, called an out-splitting code, from X_G to X_H. Similarly, one defines an in-splitting code. Inverses of these conjugacies are called out-amalgamation and in-amalgamation codes.

Figure 5 depicts an out-splitting. The graph (a) on the left has three states I, J, K and the partition elements that define the splitting are $\mathcal{E}_I^1 = \{a\}, \mathcal{E}_I^2 = \{b, c\}, \mathcal{E}_J^1 = \{d\}$, $\mathcal{E}_K^1 = \{e\}, \mathcal{E}_K^2 = \{f\}$; the graph (b) is the resulting split graph.

By interpreting state splitting and amalgamation in terms of adjacency matrices one can show that such operations generate elementary equivalences. And one can decompose elementary equivalences into splittings and amalgamations. It follows that:

Theorem 6 (R. Williams [131]) *Every conjugacy from one edge shift to another is the composition of splitting codes and amalgamation codes.*

This classification for edge shifts naturally extends to SFT's since every SFT is conjugate to an edge shift. It also extends to sofic shifts, and we describe this in the context of irreducible sofic shifts.

Recall that an irreducible sofic shift has a unique minimal right resolving presentation. Any labeled graph can be completely described by a symbolic adjacency matrix, which records the transitions (edges) in the underlying physical graph, as well as the labels of the edges. Namely, the symbolic adjacency matrix is indexed by the states of the underlying graph and the (I, J)-entry is the formal sum of the labels of edges from I to J. It turns out that the notions of elementary equivalence, and hence strong shift equivalence, can be extended to more general categories, in particular to symbolic adjacency matrices.

Theorem 7 (Krieger [72], Nasu [97]) *Let X and Y be irreducible sofic shifts. Let A and B be the symbolic adjacency matrices of the minimal right-resolving presentations of X and Y, respectively. Then X and Y are conjugate if and only if A and B are strong shift equivalent.*

The classification, provided by these results, would be of limited use if the story ended here. Fortunately, Williams showed that strong shift equivalence yields a strong, delicate and somewhat computable necessary condition for conjugacy.

Let A and B be nonnegative integral matrices and $\ell \ge 1$. A *shift equivalence* of lag ℓ is a pair (R, S) of rectangular nonnegative integral matrices satisfying the shift equivalence equations

$$AR = RB\,, \quad SA = BS\,, \quad A^\ell = RS\,, \quad B^\ell = SR\,.$$

We denote this situation by $(R, S)\colon A \sim B(\text{lag } l)$. We say that A is *shift equivalent* to B, written $A \sim B$, if there is a shift equivalence from A to B of some lag. It is not hard to see that an elementary equivalence is a shift equivalence of lag 1 and that shift equivalence is an equivalence relation. It follows that:

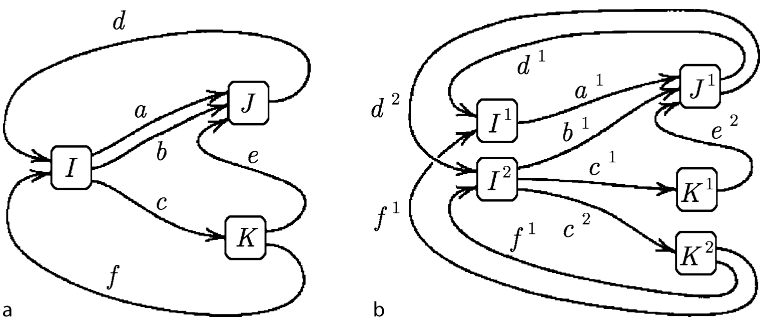
Theorem 8 (Williams [131]) *Strong shift equivalence implies shift equivalence. More precisely, if $A \approx B(\text{lag } \ell)$, then $A \sim B(\text{lag } \ell)$.*

Recall from Sect. "Entropy and Periodic Points" that for an edge shift X_A, the set of nonzero eigenvalues, with multiplicity, of A determines the zeta function and hence this set is an invariant of conjugacy. Using the shift equivalence equations, one can show more: the entire Jordan form corresponding to the nonzero eigenvalues is an invariant. This information depends only on properties of the adjacency matrix considered as a linear transformation (over $\mathbf{R}$ or $\mathbf{Q}$). However, A is a nonnegative, integral matrix and both nonnegativity and integrality provide substantially more information. One such invariant, that follows from shift equivalence and makes use of integrality is the Bowen–Franks group [20], $BF(A) = Z^r/Z^r(I - A)$.

Until recently all of the information contained in known conjugacy invariants, such as those above, was subsumed in shift equivalence. And Kim and Roush showed that shift equivalence is decidable [60,61], meaning that there is a finite decision procedure via a Turing machine that decides whether two given edge shifts, and therefore two given SFT's, are conjugate (they also showed that a notion of shift equivalence for sofic shifts, formulated by Boyle and Krieger [26], is decidable [62]). So, a central focus of the subject was the question: is shift equivalence a complete invariant of conjugacy? The answer turns out to be No, as proven by Kim and Roush [63]; see also the survey article [125]. However, it is a complete invariant of a weaker form of conjugacy; we say that X_A and X_B are *eventually conjugate* if all sufficiently large powers are conjugate. It is not hard to show that if $A \sim B$, then X_A and X_B are eventually conjugate, and the converse is true as well:

Theorem 9 (Kim and Roush [60], Williams [131]) *Edge shifts X_A and X_B are eventually conjugate if and only if A and B are shift equivalent.*

Also the Kim–Roush counterexamples and subsequent work do not bear on a special case of the conjugacy problem: if A is shift equivalent to the 1×1 matrix $[n]$, is



Symbolic Dynamics, Figure 5
A state splitting

X_A conjugate to the full n-shift? This question, known as the *little shift equivalence problem*, is particularly intriguing because in this case the condition $A \sim [n]$ is simply the statement that A has exactly one non-zero eigenvalue, namely n.

Shift equivalence can be characterized in another way that has turned out to be very useful. Let A be an $r \times r$ integral matrix. Let R_A denote the real eventual range of A, i.e, $R_A = R^r A^r$. The *dimension group* of A is defined:

$$\Delta_A = \{v \in R_A : vA^k \in \mathbf{Z}^r \text{ for some } k \geq 0\} .$$

The *dimension group automorphism* δ_A of A is the restriction of A to Δ_A, so that $\delta_A(\mathbf{v}) = \mathbf{v}A$ for $\mathbf{v} \in \Delta_A$. The *dimension pair* of A is (Δ_A, δ_A).

If A is also nonnegative, then we define the *dimension semigroup* of A to be

$$\Delta_A^+ = \{v \in R_A : vA^k \in (Z^+)^r \text{ for some } k \geq 0\} .$$

The *dimension triple* of A is $(\Delta_A, \Delta_A^+, \delta_A)$.

It can be shown that the dimension triple completely characterizes shift equivalence, i. e., two nonnegative integral matrices are shift equivalent if and only if their dimension groups are isomorphic by an isomorphism that preserves the dimension semigroup and intertwines the dimension group automorphisms. Also, by associating equivalence classes of certain subsets of the shift space X_A to elements of Δ_A^+, one can interpret the dimension triple in terms of the action of the shift map on X_A [27,68]. And the dimension triple arises prominently in the study of the automorphism group of an SFT, which we now briefly describe. The dimension group for SFT's was developed by Krieger [68,69].

In many areas of mathematics, objects are studied by means of their symmetries. This holds true in symbolic dynamics, where symmetries are expressed by automorphisms. An *automorphism* of a shift space X is a conjugacy from X to itself. The set of all automorphisms of a shift space X is a group under composition, and is naturally called the *automorphism group*, denoted aut(X).

The goals are to understand aut(X) as a group (What kinds of subgroups does it contain? How "big" is it?) and how it acts on X, e. g., given shift-invariant subsets U, V, such as finite sets of periodic points, when is there an automorphism of X that maps U to V?. One might hope that the automorphism group would shed new light on the conjugacy problem for SFT's. Indeed, tools developed to study the automorphism group eventually paved the way for Kim and Roush to find examples of shift equivalent matrices that are not strong shift equivalent. On the other hand, the automorphism group cannot tell the entire story. For instance, aut(X_A) and aut($X_{A^\top}$) are isomorphic, since any automorphism read backwards can be viewed as an automorphism of the transposed shift, yet X_A and $X_{A^\top}$ may fail to be conjugate (for an example due to Kollmer, see p. 81 of [105]). It is not even known if the automorphism groups of the full 2-shift and the full 3-shift are isomorphic.

A good deal of our understanding of the action of the automorphism group on an SFT comes from understanding its induced representation as an action of the dimension group; this action is known as the *dimension representation*. For a much more thorough exposition on aut(X), we refer the reader to Wagoner [125,126].

Other Coding Problems

The difficulties encountered in attempts to solve the conjugacy problem motivated the formulation and study of weaker, but meaningful, notions of equivalence. For instance, we might say that two shift spaces are equivalent if one can be invertibly encoded to the other by some kind of "finite-state machine". A precise version of this is as follows.

Shift spaces X and Y are *finitely equivalent* if there is an SFT W together with finite-to-one factor codes $\phi_X : W \to X$ and $\phi_Y : W \to Y$. We call W a *common extension*, and ϕ_X, ϕ_Y the *legs*.

Here, by "finite-to-one" we mean merely that each point has a finite number of inverse images. It can be shown that any finite-to-one factor code from one shift space to another must preserve entropy, and so entropy is an invariant of finite equivalence. For irreducible sofic shifts, entropy is a complete invariant:

Theorem 10 *(Parry [100]) Two irreducible sofic shifts are finitely equivalent if and only if they have the same entropy.*

Note that from this result and the fact that finite-to-one codes between general shift spaces preserve entropy, for irreducible sofic shifts, we could have just as well defined finite equivalence with the common extension W merely being a shift space. However, if W is an SFT, we get a more concrete coding interpretation as follows. First, we recode W to an edge shift X_G and recode the legs, $\phi_X = (\Phi_X)_\infty$ and $\phi_Y = (\Phi_Y)_\infty$, to one-block codes, and (with a bit more argument) we can assume that G is irreducible. In this set-up, the finite-to-one condition translates to the so-called "no-diamond" condition, which means that for any given pair of states I, J and finite sequence w, there is at most one path from I to J with label w [33,34]. Since, for any fixed state I, the number of cycles of length n, a multiple of $p = \mathrm{per}(G)$, at I grows like $2^{nh(W)}$, we have, in this set-up a means to invertibly encode a "large" set of allowed blocks in X to allowed blocks in Y: namely, fix state I, and a large n, which is a multiple of p; for any cycle γ of length n at state I encode the Φ_X-label of γ to the Φ_Y-label of γ.

For encoding and decoding, one can dispense with state information if the legs are "almost invertible". A factor code ϕ is *almost invertible* if it is one-to-one on sequences that are typical in the following sense: x is typical if every allowed block appears infinitely often in x both to the left and the right. We then say that shift spaces X and Y are *almost conjugate* if there is an SFT W and almost invertible factor codes $\phi_X : W \to X$, $\phi_Y : W \to Y$. We call (W, ϕ_X, ϕ_Y) an *almost conjugacy* between X and Y.

For irreducible sofic shifts, it can be shown that any almost invertible factor code is finite-to-one, and so almost conjugacy implies finite equivalence. Thus, entropy is again an invariant, and together with a second very mild invariant, it is complete:

Theorem 11 *(Adler–Marcus [4]) Let X and Y be irreducible sofic shifts with minimal right resolving presentations $(G, \mathcal{L})$ and $(H, \mathcal{M})$. Then X and Y are almost conjugate if and only if $h(X) = h(Y)$ and $\mathrm{per}(G) = \mathrm{per}(H)$.*

In particular, if X and Y are mixing, then $\mathrm{per}(G) = 1 = \mathrm{per}(H)$ and entropy itself is a complete invariant.

Thus, with an an almost conjugacy, one can invertibly encode most sequences in X to those of Y without the need for auxiliary state information. Moreover, if X and Y are almost conjugate, then there is an almost conjugacy of X and Y in which one leg is right-resolving and the other leg is left-resolving (and the common extension is irreducible [4]). This gives an even more concrete interpretation to the encoding.

The proofs of Theorems 10 and 11 are actually quite constructive. For illustration we consider a very special, but historically important, case.

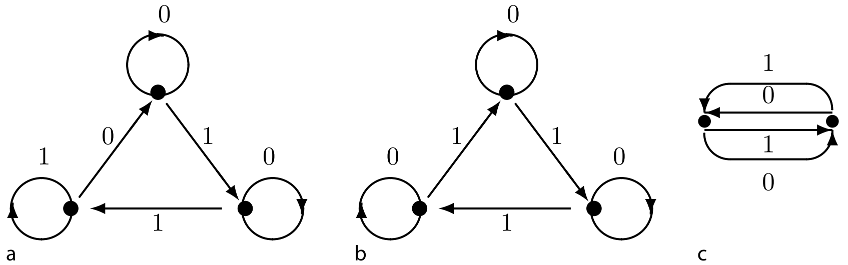
Let G be a graph with constant out-degree n. A *road coloring* Φ is a labeling of G such that at each state of G, each symbol $0, \dots, n-1$ appears exactly once as the label of an outgoing edge. An n-ary word w is *synchronizing* if all paths that are labeled w end at the same state. Figure 6 gives examples of road-colorings, with $n = 2$.

For a road-coloring, a binary word may be viewed as a sequence of instructions given to drivers starting at each of the states. A synchronizing word is a word that drives everybody to the same state. For instance, in Fig. 6a, the word 11 drives everybody to the state in the lower-left corner. But Fig. 6b does not have a synchronizing word because whenever a driver takes a '0' road he stays where he is and whenever a driver takes a '1' road he rotates by 120 degrees. The road-coloring in Fig. 6c is essentially the only road-coloring of its underlying graph, and there is no synchronizing word because drivers must always oscillate between the two states.

Now, let X be the full n-shift and Y be an irreducible SFT with entropy $\log n$. Suppose that we could find a presentation $(G, \mathcal{L})$ of Y with G having constant out-degree n and $\mathcal{L}_\infty$ finite-to-one. Then, define Φ to be any road coloring of G. Then Φ_∞ would be a finite-to-one (in fact, right resolving!) factor code from X_G to X. And we would obtain a finite equivalence with $X = X_G$, $\phi_Y = \mathcal{L}_\infty$ and $\phi_X = \Phi_\infty$. If, moreover, we could choose $\mathcal{L}$ and Φ such that ϕ_Y and ϕ_X are almost invertible, then we would have an almost conjugacy.

It turned that this could be arranged for ϕ_Y via a construction related to state splitting [2]. And if Y were mixing, then G could be chosen to be primitive and ϕ_Y almost invertible. In this setting, $\phi_X = \Phi_\infty$ would be almost invertible iff Φ has a synchronizing word; the sufficiency follows from the fact that every bi-infinite binary sequence which contains w infinitely often to the left would be the label of exactly one bi-infinite sequence of edges (to see this, use the synchronizing and road-coloring properties).

The construction of such a labeling Φ became known



Symbolic Dynamics, Figure 6
Some road-colorings

as the Road Problem, which remained open for thirty years. In the meantime, a weaker version of the the road problem was solved and applied to yield this special case of Theorem 11 (see [2]). Nevertheless, the problem remained an important problem in graph/automata theory and was only recently solved:

Theorem 12 *(Road theorem (Trachtman [122])) If G is a finite directed primitive graph with constant out-degree n, there a road-coloring of G which has a synchronizing word.*

Trachtman's approach relies heavily on earlier work of Friedman [44] and Kari [57].

The primitivity assumption above is close to necessary. Clearly some kind of connectivity is required and in the presence of irreducibility, primitivity would be necessary since otherwise there would be a "phase" introduced in the graph that would never allow a word to synchronize, as in Fig. 6c.

So far, we have focused on equivalences between symbolic systems. There has also been considerable attention paid to problems of embedding one system into another and factoring one onto another.

One of the most striking results of this type is the Krieger embedding theorem. It is not hard to show that any proper subshift of an irreducible SFT must have strictly smaller entropy. Thus, a necessary condition for a proper embedding of a shift space into an irreducible SFT is that it have strictly smaller entropy. This condition, together with a trivially necessary condition on periodic points, turns out to be sufficient. Recall that $q_n(X)$ denotes the number of points of least period n in X.

Theorem 13 *(Embedding Theorem (Krieger [70])) Let X and Y be irreducible shifts of finite type. Then there is a proper embedding of X into Y if and only if $h(X) < h(Y)$ and for each $n \geq 1$, $q_n(X) \leq q_n(Y)$.*

In fact, Krieger's theorem shows that these conditions are necessary and sufficient for a proper embedding of any shift space into a mixing shift space. The analogous problems for embedding into irreducible or mixing sofic shifts are still open, though there are partial results [22].

Using the embedding theorem and other tools from symbolic dynamics, Boyle and Handelman [25] obtained a stunning application to linear algebra: namely, a complete characterization of the non-zero spectra of primitive matrices over **R**. In fact, they obtained characterizations of non-zero spectra for primitive matrices over many other subrings of **R**. While they did not obtain a complete characterization over **Z**, they formulated a conjecture for **Z** and obtained many partial results towards that conjecture, which was later proven using other tools. The result, stated below, shows that three simple necessary conditions on a set of nonzero complex numbers are actually sufficient. In order to state these conditions, we need the following notation:

Let $\Lambda = \{\lambda_1, \ldots, \lambda_k\}$ be a list of nonzero complex numbers (with multiplicity). Let $f_\Lambda(t) = \prod_{i=1}^{k}(t - \lambda_i)$, and $\mathrm{tr}_n(\Lambda) = \sum_{d/n} \mu(n/d) \sum_{i=1}^{k} \lambda_i^k$, with μ being the Mobius Inversion function.

- Integrality Condition: $f_\Lambda(t)$ is a monic polynomial (with integer coefficients).
- Perron Condition: There is a positive entry in Λ, occurring just once, that strictly dominates in absolute value all other entries. We denote this entry by λ_Λ.
- Net Trace Condition: $\mathrm{tr}_n(\Lambda) \geq 0$ for all $n \geq 1$.

Theorem 14 *(Kim–Ormes–Roush [64]) Let Λ be a list of nonzero complex numbers satisfying the Integrality, Perron, and Net Trace Conditions. Then there is a primitive integral matrix A for which Λ is the non-zero spectrum of A.*

These conditions are all indeed necessary for Λ to be the non-zero spectrum of a primitive integral matrix. The integrality condition is that Λ forms a complete set of algebraic conjugates; the Perron condition states that Λ must satisfy the conditions of the Perron–Frobenius theorem for primitive matrices; and the Net Trace condition assures that the number of periodic points of least period n would be nonnegative.

We now turn from embeddings to factors. One special case, which is somewhat related to the Road Problem above and also important for data recording applications (Sect. "Coding for Data Recording Channels") is:

Theorem 15 [1,81] *An SFT X factors onto the full n-shift iff* $h(X) \geq \log(n)$.

While this special case treats both the equal entropy case ($h(X) = \log(n)$) and unequal entropy case ($h(X) > \log(n)$), in general, the factor problem naturally divides into two cases: lower entropy factors and equal entropy factors. In either case, a trivial necessary condition for Y to be a factor of X is that whenever $q_n(X) \neq 0$, there exists a d/n such that $q_d(Y) \neq 0$. This condition is denoted $P(X) \searrow P(Y)$. Building on ideas from Krieger's embedding theorem, this necessary condition was shown to be sufficient.

Theorem 16 *(Lower entropy factor theorem (Boyle* [22]*)) Let X and Y be irreducible SFT's with* $h(X) > h(Y)$. *Then there is a factor code from X to Y if and only if* $P(X) \searrow P(Y)$.

As with the embedding theorem, the lower entropy factors problem for irreducible sofic shifts is still open.

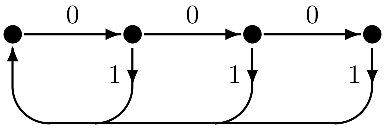
The equal entropy factors problem for SFT's is quite different. Clearly, $P(X) \searrow P(Y)$ is a necessary condition. A second necessary condition involves the dimension group and is simplest to state in the case of mixing edge shifts X_A and X_B.

We say that a subgroup Δ of the dimension group Δ_A is *pure* if whenever an integer multiple of an element $v \in \Delta_A$ is in Δ, then so is v; intuitively Δ does not have any "rational holes" in Δ_A. The condition is that there is a pure δ_A-invariant subgroup Δ of Δ_A such that (Δ_B, δ_B) is a quotient of $(\Delta, \delta_A|_\Delta)$.

In the equal entropy case, this condition and the trivial periodic point condition, $P(X) \searrow P(Y)$, subsume all known necessary conditions for the existence of a factor code from one mixing edge shift to another. It is not known if these two conditions are sufficient. For references on this problem, see [9,27,66].

Coding for Data Recording Channels

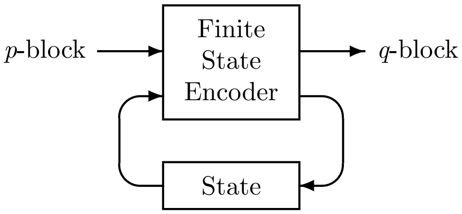
In magnetic recording, within any given clock cell, a '1' is represented as a change in magnetic polarity, while a '0' is represented as an absence of such a change. Two successive 1's (separated by some number, $m \geq 0$, of 0's) are read as a voltage peak followed by a voltage trough (or vice versa). If the peak and trough occur too close together, *intersymbol interference* can occur: the amplitudes of the peak and trough are degraded, and the positions at which they occur are distorted. In order to control intersymbol interference, it is desirable that 1's not be too close together, or equivalently that runs of 0's not be too short. On the other hand, for timing control, it is desirable that runs of 0's not be too long; this is a consequence of the fact that only 1's are observed: the length of a run of 0's is inferred by connection to a clock via a feedback loop, and a long run of 0's could cause the clock to drift more than one clock cell.



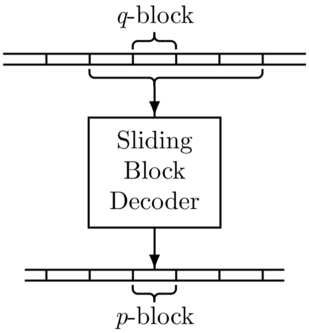
Symbolic Dynamics, Figure 7
$X(1,3)$

This gives rise to *run-length-limited shift spaces*, $X(d,k)$, where runs of 0's are constrained to be bounded below by some positive integer d and bounded above by some positive $k \geq d$. More precisely, $X(d,k)$ is defined by the constraints that 1's occur infinitely often in each direction, and there are at least d 0's, but no more than k 0's, between successive 1's. Note that $X(d,k)$ is an SFT with forbidden list $\mathcal{F} = \{0^{k+1}, 10^i1, 0 \leq i < d\}$. Figure 7 depicts a labeled graph presentation of $X(1,3)$. The SFT's $X(1,3)$, $X(2,7)$, and $X(2,10)$ have been used in floppy disks, hard disks, and the compact audio disk, respectively.

Now in order to record completely arbitrary information, we need to build an encoder which encodes arbitrary binary sequences into sequences that satisfy a given constraint (such as $X(d,k)$). The encoder is a finite-state machine, as depicted in Fig. 8. It maps arbitrary binary data sequences, grouped into blocks of length p (called p-blocks), into constrained sequences, grouped into blocks of length q (called q-blocks). The encoded q-block is a function of the p-block as well as an internal state. When concatenated together, the sequence of encoded q-blocks must satisfy the given constraint. Also, the encoded sequences should be decodable, meaning that given the initial encoder state, a string of p-blocks can be



Symbolic Dynamics, Figure 8
Encoder



Symbolic Dynamics, Figure 9
Sliding block decoder

recovered from its encoded string of q-blocks, possibly allowing a fixed delay in time.

If the constrained sequences satisfy the constraints of a sofic shift X, we say that such a code is a *rate p:q finite-state code into X*. In terms of symbolic dynamics, such a code consists of an edge shift X_G, a right resolving factor code ϕ_1 from X_G onto the full 2^p-shift and a right closing sliding block code ϕ_2 into X^q (the right closing condition expresses the decodability condition).

In most applications, it is important that a stronger decoding condition be imposed. Namely, a *sliding block decodable* rate p:q finite-state code into X consists of a finite-state code given by (X_G, ϕ_1, ϕ_2) and a sliding block code $\psi: X^q \to X_{2^p}$ such that $\psi \circ \phi_2 = \phi_1$. This means that the decoded p-block depends only upon the local context of the received q-block – that is, decoding is accomplished by applying a time-invariant function to a window consisting of a bounded amount of memory and/or anticipation, but otherwise is state-independent (see Fig. 9, which depicts the situation where the memory is 1 and the anticipation is 2). The point is that whenever the window of the decoder passes beyond a raw channel error, that error cannot possibly affect future decoding; thus, sliding block decoders control error propagation.

Symbolic dynamics has played an important role in providing a framework for constructing such codes as well as for establishing bounds on various figures of merit for such codes. Specifically, by modifying the constructions used in the proofs of Theorems 10 and 11, in the early 1980's, Adler, Coppersmith and Hassner (ACH) established the following results:

Theorem 17 *(Finite-state coding theorem* [1]*) Let X be a sofic shift and p, q be positive integers. Then there is a rate p:q finite-state code into X if and only if $p/q \le h(X)$.*

Theorem 18 *(Sliding block decoding theorem* [1]*) Let X be an SFT and p, q be positive integers. Then there is a rate p:q sliding-block decodable finite-state code into X if and only if $p/q \le h(X)$.*

We have described all of this in the context of the binary alphabet for data sequences. In fact, it works just as well for any finite alphabet, and the method used to prove Theorem 18 solved, at the same time, a special case of the factor problem for SFT's: namely, Theorem 15 above. Sometimes, Theorems 17 and 18 are stated only for rate 1 : 1 codes but in the context of arbitrary finite alphabets (e. g. see Chap. 5 in [78]), this easily extends to the general $p : q$ case by passing to powers.

The ACH paper was the beginning of a rigorous theory of constrained coding. Theorem 18 has been extended to a large class of sofic shifts, and bounds have been established on such figures of merit as number of encoder states as well as the size of the decoding window of the sliding block decoder. While the state-splitting algorithm does construct codes with "relatively small" decoding windows, it is not yet understood how to construct codes with the smallest such windows. This is of substantial engineering interest since the smaller the decoding window, the smaller the error propagation. There is now a substantial literature on the construction of these types of codes, including the state-splitting algorithm as well as many other methods of encoder/decoder design and a wealth of examples that go well beyond the run length limited constraints. See for example the expositions [11,54], and [83] as well as the papers [7,8,10,12,31,41,42,43,53,56].

Connections with Information Theory and Ergodic Theory

The concept of entropy was developed by Shannon [119] in information theory in the 1940's and was adapted to ergodic theory in the 1950's and to dynamical systems, and in particular symbolic dynamics, in the 1960's. Shannon focused on entropy for random variables and finite sequences of random variables, but the concept naturally extends to stationary stochastic processes, in particular stationary Markov chains. Roughly speaking, for a stationary process μ, the entropy $h(\mu)$ is the asymptotic growth rate of the number of allowed sequences, weighted by the joint stationary probabilities of μ (for background on entropy and information theory see Cover and Thomas [35]).

A Markov chain on a graph G is defined by assigning transition probabilities to the edges. Let P denote the stochastic matrix indexed by states of G, with P_{IJ} equal to the sum of the transition probabilities of all edges from I to J. This, together with a stationary vector for P, completely defines the (joint distributions of the) Markov chain.

So, a graph itself can be viewed as specifying only which transitions are possible. For that reason, one could view G as an "intrinsic Markov chain", and Parry [99] used this terminology when he introduced SFT's based on graphs and matrices.

More generally, a stationary process on a shift space X is any stationary process which assigns positive probability only to allowed blocks in X.

For an irreducible graph G with strictly positive transition probabilities on all edges, by Perron–Frobenius theory, P will always have a unique stationary vector. And there is a particular such Markov chain μ_G on G that in some sense distributes probabilities on paths as uniformly as possible. This Markov chain is the most "random" possible stationary process (not just among Markov chains) on X_G in the sense that it has maximal entropy; moreover, its entropy coincides with the topological entropy of X_G.

The Markov chain μ_G is defined as follows: let λ denote the largest eigenvalue of $A(G)$ and w, v denote corresponding left, right eigenvectors, normalized such that $w \cdot v = 1$; for any path γ of length n from state I to state J, we define the stationary probability of γ:

$$\mu_G(\gamma) = \frac{w_I v_J}{\lambda^n} .$$

It is clear from the formula that this distribution is fairly uniform, since all paths with the same initial state, terminal state and length have the same stationary probability.

This defines a joint stationary distribution on allowed blocks of X_G, and it is not hard to show that it is consistent and Markov, given by assigning transition probability $v_J/(v_I \lambda)$ to each edge from I to J. To summarize:

Theorem 19 *Let G be an irreducible graph.*

- *Any stationary process* μ *on G satisfies* $h(\mu) \le \log \lambda$, *and*
- *The Markov chain* μ_G *is the unique stationary process on G such that* $h(\mu_G) = \log \lambda$.

The construction of μ_G is effectively due to Shannon [119] and uniqueness is due to Parry [99] The unique entropy-maximizing stationary process on irreducible edge shifts naturally extends to irreducible SFT's and irreducible sofic shifts (this process will be M-step Markov for an M-step SFT).

Many results in symbolic dynamics were originally proved using μ_G. One example is the fact that any factor code from one irreducible SFT to another of the same entropy must be finite-to-one [32]. This result, and many others, were later proven using methods that rely only on the basic combinatorial structure of G and X_G. Nevertheless, μ_G provides much motivation and insight into symbolic dynamics problems, and it illustrates a connection with ergodic theory, which we now discuss.

For background on ergodic theory (such as the concepts of measure-preserving transformations, homomorphisms, isomorphisms, ergodicity, mixing, and measure-theoretic entropy), we refer the reader to [107,113,127]. Observe that a stationary process on a shift space X can be viewed as a measure-preserving transformation: the transformation is the shift mapping and the measure on "cylinder sets", consisting of $x \in X$ with prescribed coordinate values $x_i = a_i, \ldots, x_j = a_j$, is defined as the probability of the word $a_i \ldots a_j$; the stationarity of the process translates directly into preservation of the measure. The symbolic dynamical concepts of irreducibility and mixing correspond naturally to the concepts of ergodicity and (measure-theoretic) mixing in ergodic theory.

It is well-known [107,127] that the measure-preserving transformation (MPT) defined by a stationary Markov chain μ on an irreducible (resp., primitive) graph G is ergodic (resp., mixing) if μ assigns strictly positive conditional probabilities to all edges of G.

Now, suppose that G and H are irreducible graphs and $\phi\colon X_G \to X_H$ is a factor code. For a stationary measure μ on G, we define a stationary measure $\nu = \phi(\mu)$ on X_H by transporting μ to X_H: for a measurable set A in X_H, define

$$\nu(A) = \mu\left(\phi^{-1}(A)\right) .$$

Then ϕ defines a measure-preserving homomorphism from the MPT defined by μ to the MPT defined by ν. Since measure-preserving homomorphisms between MPT's cannot reduce measure-theoretic entropy, we have $h(\nu) \le h(\mu)$.

Suppose that now ϕ is actually a conjugacy. Then it defines a measure-preserving isomorphism, and so $h(\mu) = h(\nu)$. If $\mu = \mu_G$, then by uniqueness, we have $\nu = \mu_H$. Thus ϕ defines a measure-theoretic isomorphism between the MPT defined by μ_G and the MPT defined by μ_H. In fact, this holds whenever ϕ is merely an almost invertible factor code. This establishes the following result:

Theorem 20 *Let* G, H *be irreducible graphs, and let* μ_G, μ_H *be the stationary Markov chains of maximal entropy on* G, H. *If* X_G, X_H *are almost conjugate (in particular, if they are conjugate), then the measure-preserving transformations defined by* μ_G *and* μ_H *are isomorphic.*

Hence conjugacies and almost conjugacies yield isomorphisms between measure-preserving transformations defined by stationary Markov chains of maximal entropy.

In fact, the isomorphisms obtained in this way have some very desirable properties compared to the run-of-the-mill isomorphism. For instance, an isomorphism ϕ between stationary processes typically has an infinite window; i. e., to know $\phi(x)_0$, you typically need to know all of x, not just a central block $x_{[-n,n]}$ (these are the kinds of isomorphisms that appear in general ergodic theory and in particular in Ornstein's celebrated isomorphism theory [98]). In contrast, by definition, a conjugacy always has a finite window of uniform size. It turns out that an isomorphism obtained from an almost conjugacy, as well as its inverse, has finite expected coding length in the sense that to know $\phi(x)_0$, you need to know only a central block $x_{[-n(x),n(x)]}$, where the function $n(x)$ has finite expectation [4]. In particular, by Theorem 11, whenever X_G and X_H are mixing edge shifts with the same entropy, the measure-preserving transformations defined by μ_G and μ_H are isomorphic via an isomorphism with finite expected coding length.

The notions of conjugacy, finite equivalence, almost conjugacy, embedding, factor code, and so on can all be generalized to the context of stationary measures, in particular to stationary Markov chains. For instance, a conjugacy between two stationary measures is a map that is simultaneously a conjugacy of the underlying shift spaces and an isomorphism of the associated measure-preserving transformations. Many results in symbolic dynamics have been generalized to the context of stationary Markov chains. There is a substantial literature on this, in particular on finitary isomorphisms with finite expected coding time, e. g., [71,84,101,114], and [90]. The expositions [102,105] give a nice introduction to the subject of strong finitary codings between stationary Markov chains. See also the research papers [45,85,86,103,104,123,124].

Higher Dimensional Shift Spaces

In this section we introduce higher dimensional shift spaces. For a more thorough introduction, we refer the reader to Lind [76]. For the related subject of tiling systems, see Robinson [112], Radin [110], and Mozes [94,95].

The *d-dimensional full $\mathcal{A}$-shift* is defined to be $\mathcal{A}^{\mathbf{Z}^d}$. Ordinarily, $\mathcal{A}$ is a finite alphabet, and here we restrict ourselves to this case. An element x of the full shift may be regarded as a function $x\colon \mathbf{Z}^d \to \mathcal{A}$, or, more informally, as a "configuration" of alphabet choices at the sites of the integer lattice $\mathbf{Z}^d$.

For $x \in \mathcal{A}^{\mathbf{Z}^d}$ and $F \subseteq \mathbf{Z}^d$, let x_F denote the restriction of x to F. The usual metric on the one-dimensional full shift naturally generalizes to a metric on $\mathcal{A}^{\mathbf{Z}^d}$ given by $\rho(x, y) = 2^{-k}$, where k is the largest integer such that $x_{[-k,k]^d} = y_{[-k,k]^d}$ (with the usual conventions when $x = y$ and $x_{\mathbf{0}} \neq y_{\mathbf{0}}$). In analogy with one dimension, according to this definition, two points are "close" if they agree on a large cube $[-k, k]^d$.

We define higher dimensional shift spaces, with the following terminology. A *shape* is a finite subset F of $\mathbf{Z}^d$, and a *pattern f* on a shape F is a function $f\colon F \to \mathcal{A}$. We say that X is a *d-dimensional shift space* (or *d-dimensional shift*) if it can be represented by a list $\mathcal{F}$ (finite or infinite) of "forbidden" patterns

$$X = X_{\mathcal{F}} = \big\{x \in \mathcal{A}^{\mathbf{Z}^d} : \sigma^n(x)_F \notin \mathcal{F} \\ \text{for all } n \in \mathbf{Z}^d \text{ and all shapes } F\big\} .$$

Just as in one dimension, we can equivalently define a shift space to be a closed (with respect to the metric ρ) translation-invariant subset of $\mathcal{A}^{\mathbf{Z}^d}$. Here "translation-invariance" means that $\sigma^n(X) = X$ for all $n \in \mathbf{Z}^d$, where σ^n is the translation in direction n defined by $(\sigma^n(x))_m = x_{m+n}$.

We say that a pattern f on a shape F *occurs* in a shift space X if there is an $x \in X$ such that $x_F = f$. Hence the analogue of the language of a shift space is the set of all occurring patterns.

A *d-dimensional shift of finite type* X is a subset of $\mathcal{A}^{\mathbf{Z}^d}$ defined by a finite list $\mathcal{F}$ of forbidden patterns. Just as in one dimension, a d-dimensional shift of finite type X can also be defined by specifying allowed patterns instead of forbidden patterns, and there is no loss of generality in requiring the shapes of the patterns to be the same. Thus we can specify a finite list $\mathcal{L}$ of patterns on a fixed shape F, and set

$$X = X_{\mathcal{L}^c} = \big\{x \in \mathcal{A}^{\mathbf{Z}^d} : \text{ for all } n \in \mathbf{Z}^d\,,\ \sigma^n(x)_F \in \mathcal{L}\big\} .$$

In fact, there is no loss in generality in assuming that F is a d-dimensional cube $F = [0, k]^d$.

Given a finite list $\mathcal{L}$ of patterns on a shape F, we say that a pattern f' on a shape F' is *$\mathcal{L}$-admissible* (in the shift of finite type $X = X_{\mathcal{L}^c}$) if each of its sub-patterns, whose shape is a translate of F, belongs to $\mathcal{L}$. Of course, any pattern which occurs in X is $\mathcal{L}$-admissible. But an $\mathcal{L}$-admissible pattern need not occur in X.

The analogue of vertex shift (or 1-step shift of finite type) in higher dimensions is defined by a collection of d transition matrices $A_1, \ldots, A_d$ all indexed by the same set of symbols $\mathcal{A} = \{1, \ldots, m\}$. We set

$$\Omega(A_1, \ldots, A_d) \\ = \big\{x \in \{1, \ldots, m\}^{\mathbf{Z}^d} : A_i(x_n, x_{n+e_i}) = 1 \text{ for all } n, i\big\},$$

where e_i is as usual the ith standard basis vector and $A_i(a, b)$ denotes the (a, b)-entry of A_i. Such a shift space is called a *matrix subshift*. When $d = 2$, this amounts to a pair of transition matrices A_1 and A_2 with identical vertex sets. The matrix A_1 controls transitions in the horizontal direction and the matrix A_2 controls transitions in the vertical direction. Note that any matrix subshift is a shift of finite type and, in particular, can be specified by a list $\mathcal{L}$ of patterns on the unit cube $F = \{(a_1, \dots, a_n)\colon a_i \in \{0, 1\}\}$; specifically, $\Omega(A_1, \dots, A_n) = X_{\mathcal{L}^c}$ where $\mathcal{L}$ is the set of all patterns $f\colon F \to \{1, \dots, m\}$ such that if $n, n + e_i \in F$, then $A_i(f(n), f(n + e_i)) = 1$. When we speak of admissible patterns for a matrix subshift, we mean $\mathcal{L}$-admissible patterns with this particular $\mathcal{L}$. Just as in one dimension, we can recode any shift of finite type to a matrix subshift.

Higher dimensional SFT's can behave very differently from one dimension. For example, there is a simple method to determine if a one-dimensional edge shift, and therefore a one-dimensional shift of finite type, is nonempty, and there is an algorithm to tell, for a given finite list $\mathcal{L}$, whether a given block occurs in $X = X_{\mathcal{L}^c}$. The corresponding problems in higher dimensions, called the *nonemptiness problem* and the *extension problem*, turn out to be undecidable [14,111]; see also [67]. Even for two-dimensional matrix subshifts X, these decision problems are undecidable. On the other hand, there are some special classes where these problems are decidable. This class includes any two-dimensional matrix subshift such that A_1 commutes with A_2 and $A_2^{\top}$. For this class, any admissible pattern on a cube must occur, and so the nonemptiness and extension problems are decidable; see [87,88].

A point x in a d-dimensional shift X is *periodic* if its orbit $\{\sigma^n(x)\colon n \in \mathbf{Z}^d\}$ is finite. Observe that this reduces to the usual notion of periodic point in one dimension. Now an ordinary (one-dimensional) nonempty shift of finite type is conjugate to an edge shift X_G, where G has at least one cycle. Hence a one-dimensional shift of finite type is nonempty if and only if it has a periodic point. This turns out to be false in higher dimensions [14,111], and this fact is intimately related to the undecidability results mentioned above. While one can formulate a notion of zeta function for keeping track of numbers of periodic points, the zeta function is hard to compute, even for very special and explicit matrix subshifts, and, even in this setting, it is not a rational function[77].

In higher dimensions, the entropy of a shift is defined as the asymptotic growth rate of the number of occurring patterns in arbitrarily large cubes. In particular, for two-dimensional shifts it is defined by

$$h(X) = \lim_{n\to\infty} \frac{1}{n^2} \log |X_{[0,n-1]\times[0,n-1]}| ,$$

where $X_{[0,n-1]\times[0,n-1]}$ denotes the set of occurring patterns on the square

$$[0, n-1] \times [0, n-1]$$

that occur in X. Recall from Sect. "Entropy and Periodic Points" that it is easy to compute the entropy of a (one-dimensional) shift of finite type using linear algebra. But in higher dimensions, there is no analogous formula and, in fact, other than the group shifts mentioned below, the entropies of only a very few higher dimensional shifts of finite type have been computed explicitly. Even for the two-dimensional "golden mean" matrix subshift defined by the horizontal and vertical transition matrices

$$A_1 = A_2 = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}$$

an explicit formula for the entropy is not known. However, there are good numerical approximations to the entropy of some matrix subshifts (e. g., [30,96]). And recently the set of numbers that can occur as entropies of SFT's in higher dimensions has been characterized [51,52]; this characterization turns out to be remarkably different from the analogous characterization in one dimension [74].

One of the few 2-dimensional SFT's for which entropy has been computed is the domino tiling system (see [58], Chap. 5 in [115]), which consists of all possible tilings of the plane using the 1 × 2 and 2 × 1 dominoes. This can be translated into an SFT with four symbols L, R, T, B, subject to the constraints:

- $x_{i,j} = L \Rightarrow x_{i+1,j} = R$,
- $x_{i,j} = R \Rightarrow x_{i-1,j} = L$,
- $x_{i,j} = T \Rightarrow x_{i,j-1} = B$,
- $x_{i,j} = B \Rightarrow x_{i,j+1} = T$.

The entropy of this SFT is given by a remarkable integral formula:

$$\frac{1}{4}\int_0^1 \int_0^1 (4 - 2\cos(2\pi s) - 2\cos(2\pi t))\, \mathrm{d}s\, \mathrm{d}t$$

Further work along these lines can be found in [59,117].

One can formulate notions of irreducibility and mixing for higher dimensional shift spaces. It turns out that for SFT's there are several notions of mixing that all coincide in one dimension, but are vastly different in higher dimensions. For instance, a higher dimensional shift space is *strongly irreducible* if there is an integer $R > 0$ such that for any two shapes F, F' of distance at least R, any occurring configurations on F and F' can be combined to form an occuring configuration on $F \cup F'$ [29,129]. For one-dimensional SFT's, this is equivalent to mixing, but much stronger than mixing for two-dimensional SFT's.

Just as in one dimension, we have the notion of sliding block code for higher dimensional shifts. For finite alphabets $\mathcal{A}, \mathcal{B}$, a cube $F \subset \mathbf{Z}^d$ and a function $\Phi\colon \mathcal{A}^F \to \mathcal{B}$, the mapping $\phi = \Phi_\infty\colon \mathcal{A}^{Z^d} \to \mathcal{B}^{Z^d}$ defined by

$$\Phi_\infty(x)_n = \Phi(x_{n+F})$$

is called a sliding block code. By restriction we have the notion of sliding block code from one d-dimensional shift space to another. As expected, for d-dimensional shifts X and Y, the sliding block codes $\phi\colon X \to Y$ coincide exactly with the continuous translation-commuting maps from X to Y, i. e., the maps which are continuous with respect to the metric ρ, defined above, and which satisfy $\phi \circ \sigma^n = \sigma^n \circ \phi$ for all $n \in \mathbf{Z}^d$. Thus it makes sense to consider the various coding problems, in particular the conjugacy, factor and embedding problems, in the higher dimensional setting, but these are very difficult.

Even the question of determining when a higher dimensional SFT of entropy at least $\log n$ factors onto the full n-shift seems very difficult (in contrast to Theorem 15). However, there are some positive results for strongly irreducible SFT's. For instance, it is known that any strongly irreducible SFT of entropy strictly larger than $\log n$ factors onto the full n-shift [37,55]. In fact, that result requires only a weaker assumption than strong irreducibility, but still much stronger than mixing; recent examples [28] show, among other things, that one cannot weaken that assumption to mere mixing.

There are results on other coding problems as well. For instance, a version of the Embedding theorem in one dimension (Theorem 13) holds for SFT's in two dimensions with a strong mixing property [73]; however, it is required that the shift to be embedded contains no points that are periodic in any single direction. And some other results on entropy of proper subshifts of strongly irreducible SFT's carry over from one dimension to higher dimensions [106,109]. But in many cases where versions of the result carry over, the proofs are much different from those in one dimension.

Measures of maximal entropy for two-dimensional SFT's behave very differently from the one dimensional case. For instance, even with very strong mixing properties, such as strong irreducibility, there can be more than one measure of maximal entropy [29], and the relationships among entropy-preserving, finite-to-one, and almost invertibility for factor codes discussed in Sect. "Other Coding Problems" can be very different in higher dimensions [89]. Other differences with respect to entropy can be found in [108].

There is also the natural notion of higher dimensional sofic shifts, which can be defined as those shift spaces that are factors of SFT's. Recall that every one-dimensional sofic shift is a right-resolving, and hence entropy-preserving, factor of an SFT. It is not known if there is an analogue to this fact in higher dimensions, although recently there has been some progress: every sofic shift Y is a factor of an SFT with entropy arbitrarily close to $h(Y)$ [36].

Finally, there is a subclass of d-dimensional SFT's which is somewhat tractable, namely d-dimensional shifts with group structure in the following sense. Let $\mathcal{A}$ be a (finite) group. Then the full d-dimensional shift over $\mathcal{A}$ is also a group with respect to the coordinate-wise group structure. A (higher-dimensional) *group shift* is a subshift of $\mathcal{A}^{\mathbf{Z}^d}$ which is also a subgroup. For a survey on results for this class, we refer the reader to [79].

Future Directions

The future directions of the subject will likely be determined by progress on solutions to open problems. In the course of describing topics in this article, we have mentioned many open problems along the way. For a much more complete list on a wealth of sub-areas of symbolic dynamics, we refer the reader to the article [24]. While it is difficult to single out the most important challenges, certainly the problem of understanding multi-dimensional shift spaces, especially of finite type, is one of the most important.

Article Outline

Glossary

Synchronization A problem in time-keeping, requiring the coordination of events to operate a system or a task in unison.

Distance A measure between two nodes, defined as the number of edges connecting them through the shortest paths.

Average distance The mean distance, averaged over all pairs of nodes on the network.

Clustering coefficient The probability that two randomly-selected neighboring nodes of a node are directly connected each other.

Node-degree The number of edges incident from a node.

Random-graph network A type of graph obtained by starting with a set of nodes and then adding edges between them at random.

Small-world network A type of graph in which most nodes are not neighbors of each other, but most nodes can be reached from any other node by a small number of connection steps; thus, a small-world network is highly clustered like a regular graph, and yet with a small average distance, just like a random graph.

Scale-free network A type of graph in which a small number of nodes have a large number of connections while a large number of nodes have a small number of connections, whose node-degree distribution typically follows a power-law form, with both structure and dynamics being independent of the network size.

Node-betweenness A measure of the extent to which a given node is occupied by the amount of information passing through it via shortest paths between other nodes, namely, the portion of shortest paths between all pairs of nodes which have data traffic going through this particular node in the network.

Definition of the Subject

The subject under consideration is synchronization on complex networks, with respect to the phenomena and particularly the ability of achieving synchrony of a network of dynamical systems. The subject of synchronization is quite old, but it is a significant one continuously calling for serious and systematic investigation. Ever since the careful study of two synchronous pendulum clocks by the great Dutch scientist Christian Huygens in 1665, the subject has evolved to be an independent and indispensable field of scientific research. The current study of complex networks, on the other hand, is pervading all kinds of sciences, ranging from physical to biological, even to social sciences. Its impact on modern engineering and technology is prominent and will be far-reaching. Typical complex dynamical networks include the Internet, the World Wide Web, various wireless communication networks, metabolic networks, biological neural networks, social relationship networks, financial and economic networks, and so on. As it has turned out today, the study of synchronization phenomena and synchronous behaviors of dynamical systems such as oscillators on complex networks has become overwhelming. This article offers an overview of the state-of-the-art advances and developments of the subject of synchronization on various complex networks, with emphasis on network synchronizability and performance.

Introduction

Many biological, social and technological systems can be properly described by complex networks with nodes representing individuals or organizations and edges characterizing the interactions among them [1,2,3,4,5]. One of the goals in the current studies on complex networks is to understand and explain how the topological properties of a network affect the behaviors of dynamical systems built upon the network. Typical examples include understanding how the topology of the Internet affects the spread of the computer viruses [6,7,8,9,10], how the structure of a power grid affects the cascading failures over time [11,12,13,14,15], how the connecting patterns of an intercommunication network affect its data traffic and dynamics [16,17,18,19,20], and so on.

Synchronous behaviors have been observed in various complex networks in nature and human society [23,24,25,26], and they have been studied for hundreds of years since the systematic investigation of pendulum synchrony by the great Dutch scientist Christian Huygens in 1665 [27].

To understand how network structure affects the synchronizability of a network not only has broad theoretical interest [28], but also has important practical value [29]. One typical case in point is the synchronicity of sensors in biological neural networks, where neurons communicate with each other through synaptic junctions for which a mechanism called asynchronous release is important [30]. There are many careful studies about collective synchronization in the earlier literature, with a basic assumption that dynamical systems of coupled oscillators evolve either on regular networks [31,33,34] or on random networks [35,36]. However, the structures of most real-world networks are neither completely regular nor completely random, but rather, somewhere in between. Thus, it becomes important and even necessary to consider how network structure affects the synchronization process and the synchronizability of the dynamical systems on such networks. Recently, it has been found that networks with small-world effects and scale-free properties are quite different from, and oftentimes achieve synchronization more easily than, regular networks such as lattices [37,38,39,40,41,42,43,44].

The study of synchronization on complex networks has gone through several stages in the past decade, encompassing several important aspects of the subject: various synchronization phenomena on complex networks and their stability analysis, the relationships between structural ingredients and a network's synchronizability, the enhancement or reduction of network synchronizability, etc. The first two are quite well understood today while the last one will be further addressed in this article. First, some basic concepts about synchronization of networked dynamical systems and the associated stability analysis are introduced. Second, some intrinsic relations between network structure and synchronizability are discussed. Third, three types of methods, namely, regulating coupling patterns, modifying network structures, and designing output functions, are introduced for enhancing network synchronizability. Finally, some open questions are posed which are deemed significant for further studies of the important subject of complex network synchronization.

To proceed, some notations are introduced [5], among which three are most significant with respect to network synchronization: average distance L, clustering coefficient C, node-degree k_i of node i, and the corresponding probability density function of degree distribution $p(k)$.

In the past few years, by taking advantage of both high-speed computing power and the huge amount of real data available on the web, scientists were able to search and find some common statistical characteristics shared by many real-world networks. It is found that most real networks have a very small average distance, scaled approximately as $L \sim \ln N$, where N is the size of the network (i. e., the total number of its nodes), while their clustering coefficient is rather large, as compared with *random-graph networks*

(Erdös and Rényi [28]). A network having both of these two characteristics is referred to as a *small-world network*, described by Watts and Strogatz [21]. Moreover, the degree distributions of many real networks obey a power-law form $p(k) \sim k^{-\gamma}$, where $p(k)$ is the probability density function for the corresponding degree distribution, and γ is the power-law exponent (typically $2 < \gamma < 3$) [1,2,3]. The power-law distribution falls off much more gradually than an exponential one, allowing for a few nodes with very large degrees to exist. Networks with power-law degree distributions usually belong to the class of *scale-free networks*, characterized by Barabási and Albert [22].

Basic Concepts of Network Synchronization

A general model of coupled identical oscillators on a network can be described by [40,41]

$$\dot{\boldsymbol{x}}_i = \boldsymbol{F}(\boldsymbol{x}_i) - \sigma \sum_{j=1}^{N} G_{ij} \boldsymbol{H}(\boldsymbol{x}_j) , \quad i = 1, \ldots, N , \qquad (1)$$

where $\dot{\boldsymbol{x}}_i = \boldsymbol{F}(\boldsymbol{x}_i)$ governs the dynamics of the ith oscillator, with state vector $\boldsymbol{x}_i$; $\boldsymbol{H}(\boldsymbol{x}_j)$ is the output function; σ is the coupling strength; $G = [G_{ij}]$ is an $N \times N$ coupling matrix determined by the given coupling pattern among the N oscillators.

In the typical situation when the oscillators are symmetrically coupled, the coupling matrix G has the same form as the graph Laplacian L, i. e., $G = L$, with

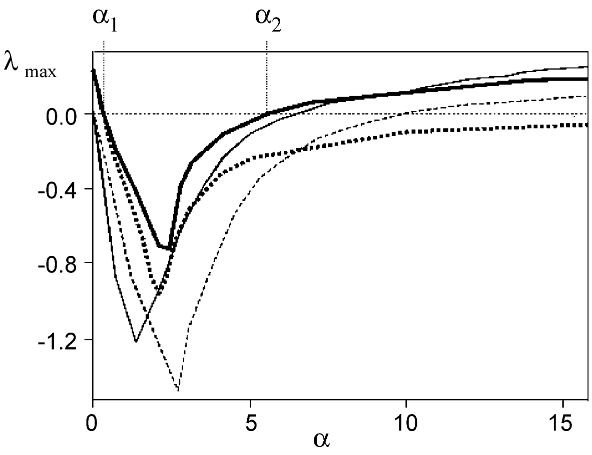
$$L_{ij} = \begin{cases} k_i & \text{for } i = j \\ -1 & \text{for } j \in \Lambda_i \\ 0 & \text{otherwise ,} \end{cases} \qquad (2)$$

where k_i is the degree of node i and Λ_i is the set of its neighboring nodes. In this setting, L is symmetrical and semi-positive definite, and all the rows of L have a zero sum, so that its smallest eigenvalue λ_1 is always a single zero and all the other eigenvalues are strictly positive. Thus, the eigenvalues of L can be ranked as

$$0 = \lambda_1 < \lambda_2 \leq \lambda_3 \leq \cdots \leq \lambda_N .$$

For network (1), the synchronization manifold is an invariant manifold: $\boldsymbol{x}_1 = \boldsymbol{x}_2 = \cdots = \boldsymbol{x}_N = \boldsymbol{s}$, typically satisfies $\dot{\boldsymbol{s}} = \boldsymbol{F}(\boldsymbol{s})$ in engineering applications.

For a dynamical system, the so-called master stability function is usually defined to be the ratio of the largest Lyapunov exponent versus a connectivity parameter of the system [42,45]. For some dynamical systems, the master stability function is negative when $\lambda_2 > \alpha_1/\sigma$ for some constant α_1. In this case, the largest Lyapunov exponent is negative, and consequently the network is synchronizable; moreover, the larger the λ_2 is, the better the network synchronizability will be [40,41].



Synchronization Phenomena on Networks, Figure 1
Four typical master stability functions for coupled Rössler oscillators: chaotic (*bold curve*) and periodic (*regular curve*); with *y*-coupling (*dashed curve*) and *x*-coupling (*dotted curve*). The *vertical ordinate* shows the change of the largest Lyapunov exponent. Curves are all scaled for clearer visualization (after [42])

For some other dynamical systems, the master stability function is negative only within a finite interval (α_1, α_2) [46], over which the largest Lyapunov exponent is negative [42,45], where α_1 and α_2 are constants. In this case, the network is synchronizable for some σ when the eigenratio $R = \lambda_N/\lambda_2$ satisfies $R < \alpha_2/\alpha_1$; moreover, a smaller R indicates a better network synchronizability.

The former case corresponds to networks for which the synchronized region is unbounded (the bold-dashed curve in Fig. 1), and the latter, bounded (the bold-solid curve and the two regular lines in Fig. 1) [42]. In both cases, the right-hand side of the above two inequalities depends only on the dynamics of each individual oscillator and the output function of the network, while the eigenvalue λ_2 and eigenratio R depend only on the Laplacian L. Therefore, the problem of synchronization can be divided into two parts: choosing suitable dynamics (including the aforementioned parameters and output function) and analyzing the eigenvalues of the Laplacian. In fact, these two cases can co-exist [32,101].

The same stability analysis can also be applied to some more complicated coupling patterns [40,41,42,45,47], including the case where G is non-diagonalizable (see Fig. 2 and [48]).

Network (1) has only identical oscillators, while in the real world parameter mismatch between oscillators is very common, so that both the amplitudes and phases of different oscillators become different. However, quite often, only the frequencies of oscillations are of concern in some applications, while the amplitudes are not important. In such cases, phase synchronization is the topic for study, for which the *Kuramoto model* [49,50,51,52,53] is a representative platform.

In the Kuramoto model, oscillators run at arbitrary frequencies and they are coupled through a periodic (e. g., sine) function of their phase differences. More precisely, the model consists of a population of N coupled phase-oscillators $\theta_i(t)$ having natural frequencies ω_i distributed with a given probability density $g(\omega)$, governed by

$$\dot{\theta}_i = \omega_i - \sigma \sum_{j=1}^{N} G_{ij} \sin(\theta_i - \theta_j)\,, \quad i = 1, \ldots, N\,. \tag{3}$$

To measure the synchronization phenomena, an order parameter M is introduced:

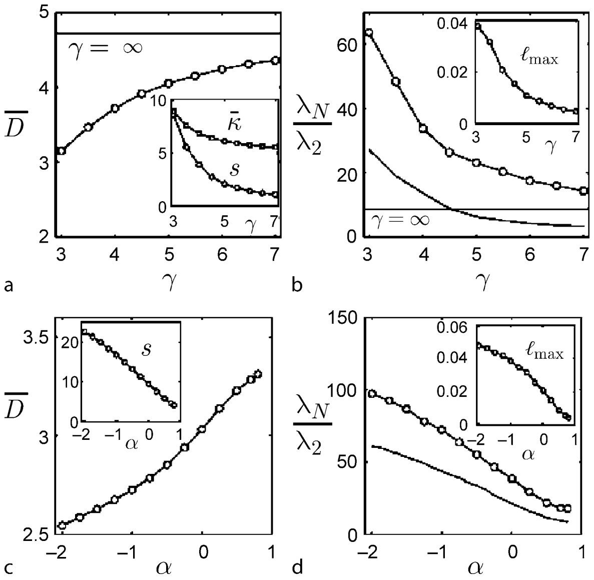
$$M \equiv \left[\left\langle \left| N^{-1} \textstyle\sum_{j=1}^{N} \mathrm{e}^{i\phi_j} \right| \right\rangle \right]\,, \tag{4}$$

where ϕ is a function of θ, and $\langle\cdot\rangle$ and $[\cdot]$ denote the average over time and over different configurations, respectively.

Initially, each node is assigned a random phase. Without coupling, all the oscillators run independently and, at any time, the phases of the oscillators are distributed almost uniformly on the interval $[0, 2\pi]$, yielding $M = O(1/\sqrt{N})$. In this situation, the oscillators are generally not synchronized. With coupling, as the coupling strength gradually increases to beyond a certain threshold, interactions among oscillators become stronger and more inter-influential, which gradually dominate the individual self-oscillations. Eventually, collective synchronization of all oscillators emerges spontaneously. During this transition process, the order parameter M increases from 0 to 1.

Synchronizability Versus Structure

Previous studies have demonstrated that both scale-free and small-world networks are much easier to synchronize than regular lattices [37,38,39,40,41,42,43,44]. At this point, a natural question arises: what makes them easier to synchronize? An intuitive answer might be their average distance, which is much shorter than that of a regular network with the same size. However, after some systematic investigations on the relation between structural ingredients and the network synchronizability, Nishikawa et al. [54] found that as the network becomes more heterogeneous, i. e., the degree distribution becomes wider, a network can become less synchronizable even though its average distance becomes much shorter. Figure 2 gives two examples of this phenomenon. In a semi-random model [55], with the increase of the power-law exponent γ, which makes the network more homogeneous, the network average distance $\bar{D}$ becomes longer and the standard deviation of the degree distribution reduces (Fig. 2a and inset); meanwhile, the eigenratio λ_N/λ_2 of its Laplacian becomes smaller (Fig. 2b), indicating improvement of the network synchronizability. In a growing model of scale-free networks with aging nodes [56], it is also observed that as the average distance increases and the degree distribution becomes more homogeneous, the network gains a better synchronizability (Fig. 2c,d).

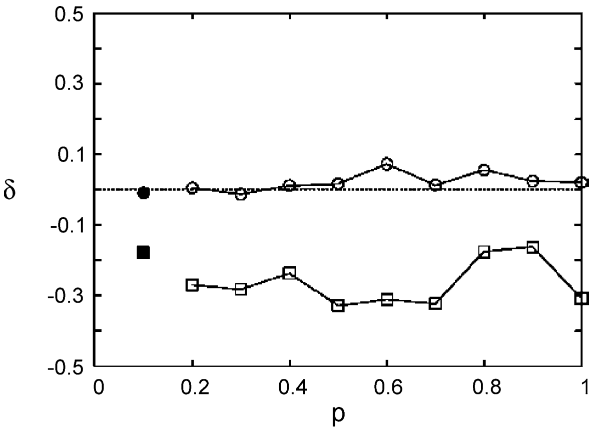


Synchronization Phenomena on Networks, Figure 2

Synchronization of scale-free networks. a, b the semi-random model; c, d the growing model with aging of nodes. The small *insets* are the responses of the indicated parameters with respect to the changing parameters γ or α under the same conditions (after [54])

A heuristic exploration may be given: in a network with a heterogeneous degree distribution, a few "central" oscillators, which interact with a large number of other oscillators, tend to be overloaded by the traffic passing through them. When too many independent traffic signals with different phases and frequencies are traversing through a node at the same time, they cause congestion, leading to the reduction of network synchronizability. The same also happens to overloaded edges [54].

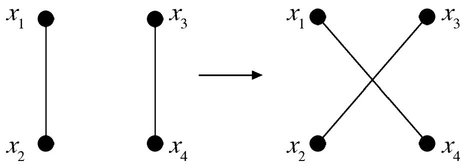
On the other hand, based on experience with WS small-world networks, Hong et al. [57] concluded that the



Synchronization Phenomena on Networks, Figure 3
Behavior of the difference δ of the eigenratio in a WS network with rewiring probability p (after [57])

maximal node betweenness [58,59,60] is a good indicator for network synchronizability: the smaller, the better, and vice versa. To confirm their observation, they calculated the difference of the eigenratio before and after the removal of a node from a WS network [21]. Figure 3 plots the difference $\delta \equiv (\lambda_N/\lambda_2)_{\text{after}} - (\lambda_N/\lambda_2)_{\text{befor}}$. The reduction of the ratio is brought about by the removal of the node with the maximal betweenness (empty squares in the figure). In comparison, random removal of a node makes the eigenratio almost unchanged (empty circles in the figure). This implies that the node with the maximal betweenness plays an important role in determining the synchronizability of the network. However, for scale-free networks, this "maximal betweenness indicator" may not work, as pointed out in [61] with a counterexample given in [62].

In the above studies, a network is usually modified in order to see how the synchronizability changes as the network structure varies. It is worth emphasizing that during the modification process all the topological ingredients [5] have been changed at the same time, therefore it is impossible to obtain any accurate relation between one particular ingredient and the network synchronizability. Knowing this problem, by using the edge-exchange operation [63,64], Zhao et al. [62] derived some fairly accurate relations between the synchronizability and the average distance as well as the heterogeneity of the degree distribution, on small-world and scale-free network models. Figure 4 presents a sketch of maps of their random interchanging algorithms. The algorithmic operations will change only the network average distance while keeping the degree of each node unchanged. Thus, the relations between the two concerned ingredients can be investigated separately. Extensive simulations have verified that either shortening the average distance or lowering the heterogeneity may lead to a better synchronizability, but only their combination can always ensure that the network will synchronize easily.



Synchronization Phenomena on Networks, Figure 4
Sketch of maps of the random interchanging algorithm (after [62])

McGraw and Menzinger [65] investigated the relations between the clustering coefficient and network synchronizability, and concluded that for both random-graph and scale-free networks, increasing the clustering coefficient hinders global synchronization if the coupling strength is strong, but it promotes the synchronization of scale-free networks when the coupling strength is weak. Figure 5 shows this phenomenon. The main reason is that the clusters around the hub-nodes promote the formation of frequency-synchronized clusters, but they will inhibit the synchronization of the network as a whole. The early hub synchronization accounts for the slightly enhanced order parameter when the coupling is weak [65,66]. This analysis is based on non-identical oscillators in the Kuramoto model. On the other hand, by means of master stability analysis, Wu et al. [67] reported a negative correlation between the clustering coefficient and synchronizability through a scale-free network model with a tunable clustering coefficient [68].

Besides the main focus on small-world effects and scale-free properties, as described by the clustering coefficient, average distance and degree distribution, some further studies on the effects of other topological ingredients on network synchronization have also been reported, particularly the degree-degree correlation. A network is said to show *assortative* (or *disassortative*) *mixing*, if the nodes having many connections tend to connect to other nodes with many (or few) connections. The extent of this degree-degree correlation can be measured by the Pearson coefficient [69]: its positive (or negative) value indicates assortative (or disassortative) mixing. Di Bernardo et al. found that disassortative networks generally have a better synchronizability than the assortative ones [70,71]. However, later works [72,73] show that the degree distribution, coupling pattern, and degree-degree correlation among the nodes compete with each other in an intrinsic manner,

Synchronization Phenomena on Networks, Figure 6

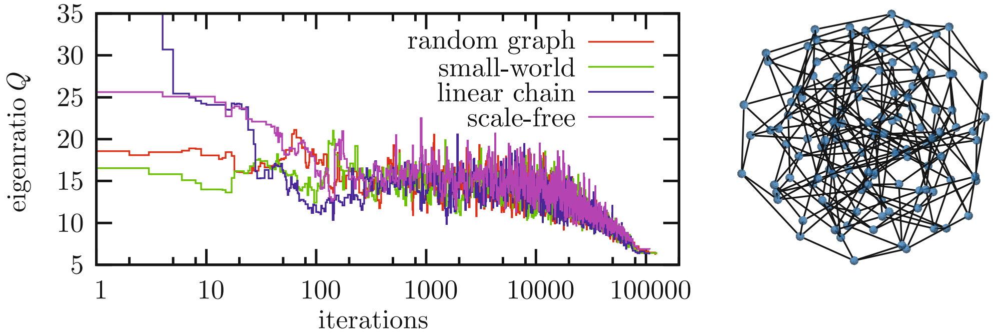
Order parameter M vs. community strength C for different values of the coupling strength σ (after [76])

thereby together determining the network synchronizability. That is, for one coupling pattern, disassortative mixing may predict better synchronizability, while for another coupling pattern, the result can be the opposite.

As we gain more knowledge of various network structures, more attention is paid to the effects of local structures of complex networks on their global behaviors and dynamics. Huang et al. [74] found that in complex networks with prominent clusters, the synchronizability is determined by the interplay between intercluster and intracluster edges: a network is mostly synchronizable when the numbers of the two types of edges are approximately equal. If not equal, for example as the number of intracluster edges increases, an abnormal synchronization phenomenon appears: although the network average distance becomes smaller, the network synchrony is weakened or even destroyed.

Furthermore, the synchronization phenomenon of a complex network with a community structure has also been discussed. Qualitatively, a *community* is defined as a subset of nodes within a network with the property that the connections among the nodes therein are denser than those within the other parts of the network [75]. Zhou et al. studied phase synchronization in a network with a community structure [76]. Defining the edges connecting two nodes in one community as *internal edges*, and those connecting nodes between two communities as *external edges*, the ratio of the number of external edges to the number of internal edges can be used to characterize the strength of the community structure, denoted by C. Clearly, a smaller C corresponds to sparser external edges thus a more prominent community structure. Figure 6 shows the relationship between the order parameter M and the community strength C for different coupling strengths σ. It is found from Fig. 6 that a strong community structure will hinder global synchronization no matter what the coupling strength is, but this effect will vanish when the fraction of external connections exceeds 0.1.

Using a modified simulated annealing algorithm, Donetti et al. [77] generated an entangled network with optimal synchronizability. These kinds of networks are shown to have an extremely homogeneous structure: distributions of node degrees, distances, betweenness, and loops are all very uniform. Also, these networks are characterized by short average distances and large loops, with no well-defined community structures. In the approach of [77], rewiring is applied, i. e., at each time step, the number of rewiring trials is randomly extracted from an exponential distribution. Except for rewiring which reduces or increases the eigenratio, and except for operations that



Synchronization Phenomena on Networks, Figure 7
Eigenratio *Q* as a function of the number of algorithmic iterations. Starting from different initial configurations, all the networks are converted via iterations to *entangled networks* (after [77])

disconnect the network, for different initial configurations the optimization process will always lead to the same optimal result. Figure 7 shows the changes of the eigenratio in the optimizing process and the resultant network configuration.

Enhancing Network Synchronizability

With a clearer understanding of the relations between the network structure and synchronizability, a natural question about how to enhance the network synchronizability is in order. Some effective synchronizability-enhancement methods are introduced in this section.

Coupling Pattern Regulation

In general, scale-free networks are much harder to synchronize than random networks with the same size and the same average degree. One reason is that in scale-free networks, there are some "central" oscillators that interact with a large number of other nodes [54]. Thus, when too many independent signals with different phases and frequencies are traversing through a "central" oscillator at the same time they may have conflicts, thereby causing traffic congestion. Hence, generally speaking, the more heterogeneous the degree distribution, the more difficult for the network to synchronize. It is also known that in scale-free networks, when the oscillators are coupled symmetrically, oscillators with larger degrees usually approach the final synchronized state first, and then the others with smaller degrees synchronize to them gradually [65]. Therefore, when the oscillators are coupled asymmetrically, if the coupling strength from the "central" oscillators to the other nodes are stronger than the reverse, the network will synchronize much easier and faster.

Based on this idea, Motter, Zhou and Kurths [78,79,80] proposed a new coupling pattern, which we will call the MZK pattern, which can sharply improve network synchronizability. After that, quite a few methods for regulating coupling patterns are brought forward to improve network synchronizability, some static and some dynamic.

Static Coupling Patterns

In static coupling patterns, the elements of the coupling matrix are formulated based on the MZK pattern, as

$$G_{ij} = L_{ij}/k_i^{\beta} \,, \tag{5}$$

where β is a tunable parameter. The coupling is weighted when $\beta \neq 0$, and unweighted when $\beta = 0$. In spite of the asymmetry of this coupling matrix G, it can be proved that all the eigenvalues of G are nonnegative reals with only one eigenvalue being zero if the network is connected. Rewrite Eq. (5) as

$$G = D^{-\beta} L \,, \tag{6}$$

where $D = \operatorname{diag}(k_1, \dots, k_N)$ is a diagonal matrix and L is the Laplacian. From the identity

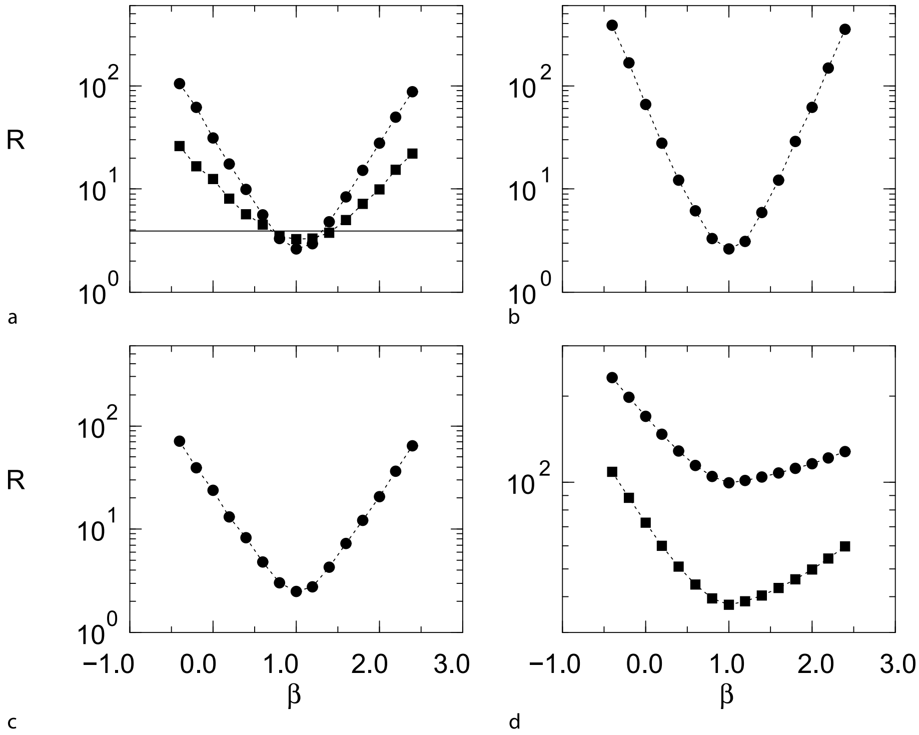
$$\det(D^{-\beta} L - \lambda I) = \det(D^{-\beta/2} L D^{-\beta/2} - \lambda I) \,, \tag{7}$$

where I is the $N \times N$ identity matrix, one can prove that the spectrum of G is the same as that of the following symmetric matrix:

$$H = D^{-\beta/2} L D^{-\beta/2} \,. \tag{8}$$

Similarly to the case of matrix G, if the network is connected then all eigenvalues of H other than the single $\lambda_1 = 0$, are positive. With $\beta = 1$, the matrix H is a normalized Laplacian. Thus, if the network is connected and $N \geq 2$, then

$$0 < \lambda_2 \leq N/(N-1) \,, \quad 2 \leq \lambda_N \leq N/(N-1) \,. \tag{9}$$



Synchronization Phenomena on Networks, Figure 8

Eigenratio *R* as a function of β for four kinds of complex networks specified in [78]. For each model, the synchronizability peaks at $\beta = 1.0$ (after [78])

Figure 8 shows the changes of the eigenratio R with the parameter β in four kinds of complex networks specified in [78]. It can be seen that the eigenratio R has a well-defined minimum at $\beta = 1$ in all cases. Mathematically, this means that the best results are obtained when the matrix D has a square-root. It is also clear that the more heterogeneous the network is, the more prominent the minimum of the eigenratio R becomes.

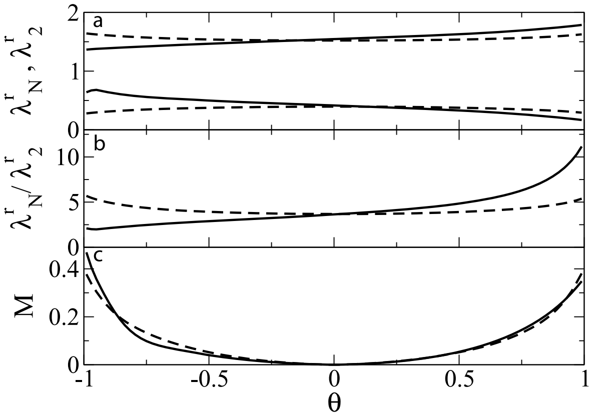
By explicitly relating the asymmetry in the connections to an age order among different nodes, Hwang et al. [81] found that age-ordered networks provide a better propensity for synchronization. The main reason is that an older node becomes weaker, therefore more easily influenced by other nodes. In this coupling pattern, the off-diagonal entries of the zero-row-sum coupling matrix G are

$$G_{ij} = -a_{ij} \frac{\Theta_{ij}}{\sum_{j \in \Lambda_i} \Theta_{ij}} , \tag{10}$$

where a_{ij} are the elements of the adjacency matrix A ($a_{ij} = 1$ if nodes i and j are connected, and $a_{ij} = 0$ otherwise), and $\Theta_{ij} = (1 - \theta)/2$ (or $\Theta_{ij} = (1 + \theta)/2$) for $i > j$ (or $i < j$). The parameter $\theta \in (-1, 1)$ governs the coupling asymmetry in the network: the limit $\theta \to -1$ (or $\theta \to 1$) gives a unidirectional coupling, where the old (or young) nodes drive the young (or old) ones. When $\theta = 0$, the coupling pattern degenerates to the MZK pattern at $\beta = 1$.

For a generic θ, the spectrum of the coupling matrix G is in the complex plane and the complex eigenvalues appear in pairs of complex conjugates ($\lambda_1 = 0$; $\lambda_\ell = \lambda_\ell^r + j\lambda_\ell^i$, $\ell = 2, \ldots, N$). It can be proved that (i) $0 < \lambda_2^r \leq \cdots \leq \lambda_N^r \leq 2$, and (ii) $|\lambda_\ell^i| \leq 1, \forall \ell$. The best propensity for synchronization is then ensured when both the ratio $\lambda_N^r / \lambda_\ell^r$ and $M \equiv \max_\ell \{|\lambda_\ell^i|\}$ are simultaneously made as small as possible.

In scale-free network models, the age of a node can be denoted by the time when it is being added to the network. The class of scale-free networks under study is generated from the Barabasí–Albert model [82,83]. For comparison, a highly homogeneous random network with an arbitrary initial age ordering is considered, with the average degree being equal to that of the scale-free network. Figure 9 shows the variation of the synchronizability of the two networks versus the parameter θ. For the random network, symmetric coupling makes the ratio $\lambda_N^r / \lambda_2^r$ smallest, while for the scale-free model, the propensity for synchronization is better (or worse) when $\theta \to -1$ (or $\theta \to 1$). As for M, there are only very small differences between



Synchronization Phenomena on Networks, Figure 9

a λ^r_N **and** λ^r_2**, b** λ^r_N/λ^r_2**, and c** M**, vs.** θ**, for a scale-free network (**$m = 5$ **and** $B = 0$**,** ***solid curves*****) and random network (*****dashed curves*****) (after [81])**

the scale-free and the random-network models. Thus, it is concluded that in scale-free networks, the network synchronizability is enhanced when the dominant coupling direction is from older to younger nodes [84].

Taking the edge-weights into account, Chavez et al. [85,86] investigated the propensity for synchronization of some weighted complex networks, where the weight in an arbitrary edge, ℓ_{ij}, is defined as its traffic load [87], which quantifies the traffic of shortest paths which make use of that edge. In this coupling pattern, the off-diagonal entries of the zero-row-sum coupling matrix G are

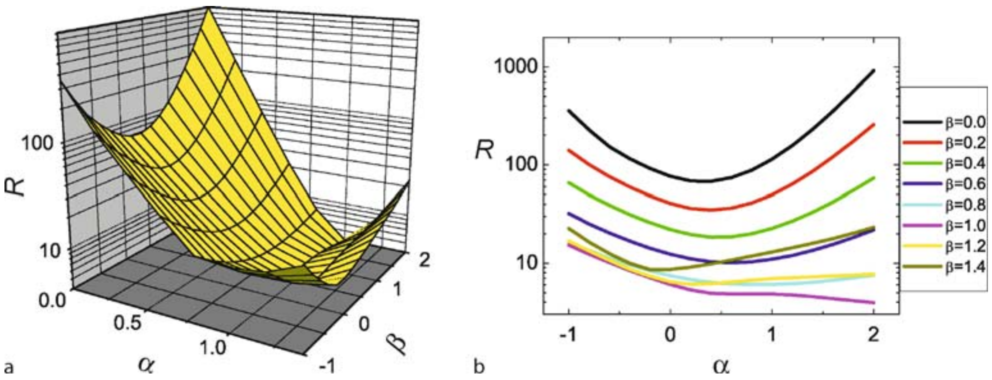
$$G_{ij} = -\frac{\ell^{\alpha}_{ij}}{\sum_{j\in\Lambda_i}}\,\ell^{\alpha}_{ij}\,, \tag{11}$$

where α is a tunable parameter, and ℓ_{ij} is the load of the edge connecting nodes i and j.

Although G is asymmetric for all α, just like the MZK pattern, it can be proved that all its eigenvalues are nonnegative reals with only one zero eigenvalue if the network is connected. The case of $\alpha = 0$ corresponds to the best synchronizability condition for the MZK pattern. From Eq. (11), it can be seen that in the limit of $\alpha = +\infty$ (or $\alpha = -\infty$) only the edges with the largest (or smallest) loads ℓ_{ij} are selected as the incoming edges for each node i. Therefore, this generates a network with at least N directed edges, which can be either connected or disconnected. In the connected (or disconnected) case, the ratio λ_N/λ_2 will be equal to 2 (or $+\infty$), thus yielding a very strong (or weak) condition for synchronization.

Figure 10a shows the logarithm of λ_N/λ_2 in the parameter space (α, B) for the above-discussed model [82,83]. Parameter B is used to regulate the heterogeneity of the degree distribution. It can be observed that the surface of λ_N/λ_2 has a prominent minimum when $\alpha \simeq 1$ for all values of B above a given threshold $B_c > 0$, which means that the weighting procedure based on edge loads always enhances the network propensity for synchronization. The quantity $\Gamma = \log(\lambda_N/\lambda_2) - [\log(\lambda_N/\lambda_2)]_{\alpha=0}$ shown in Fig. 10b may be used to quantify the synchronizability enhancement.

The coupling patterns proposed by both Hwang et al. [81] and Chavez et al. [85,86] can enhance the propensity for network synchronization. The former works well only for age-ordered networks, while the latter requires the knowledge of the load on each edge of the whole network. Therefore, a general coupling pattern using only local information would be very desirable. Based on the idea that different nodes should play different roles in a network, Zhao et al. [73] proposed a coupling pattern which



Synchronization Phenomena on Networks, Figure 11
a Eigenratio R in the parameter plane (α, β). b R vs. α for different values of parameter β (after [73])

requires only the degrees of neighboring nodes. The coupling matrix G of this pattern is given by

$$G_{ij} = \begin{cases} -k_j^{\alpha}/S_i^{\beta} & \text{for } j \in \Lambda_i \\ S_i/S_i^{\beta} & \text{for } i = j \\ 0 & \text{otherwise}\,, \end{cases} \tag{12}$$

where $S_i = \sum_{j \in \Lambda_i} k_j^{\alpha}$. When $\alpha = \beta = 0$, this coupling pattern degenerates to the symmetric coupling pattern [45], where the case of $\alpha = 0$ corresponds to the MZK pattern [78] and the case of $\beta = 1$ is equivalent to the one introduced in [80] (see Eq. (15) in [80] for more details). Although this G is asymmetric for all α with $\beta \neq 0$, it can also be proved that all its eigenvalues are non-negative reals with only one zero eigenvalue, if the network is connected. Figure 11 shows some simulation results. From the figure, it can be concluded that there is always some parameter region in which the eigenratio R is smaller than that of the symmetrically coupled case ($\alpha = \beta = 0$) and that of the optimal case with the MZK pattern ($\alpha = 0$ and $\beta = 1$).

From the viewpoint of gradient fields, Wang et al. [88] also derived a coupling pattern that has the same configuration as Eq. (12) with $\beta = 1$.

Dynamic Coupling Patterns

The coupling patterns discussed above are all based on a network having a fixed structure which remains unchanged throughout the synchronizing process.

Zhou et al. [89] investigated synchronization in a scale-free network of chaotic oscillators, where the coupling strength of a node develops adaptively according to the local synchronizing property between the node and its neighbors. In this coupling pattern, the off-diagonal entries of the zero-row-sum coupling matrix G are

$$G_{ij} = -a_{ij} W_{ij}\,, \tag{13}$$

where $W_{ij} > 0$ is the coupling strength from node j to node i if they are connected. Here, suppose that the strength between node i and all its k_i neighbors increases uniformly among the k_i connections, in order to suppress its difference Δ_i from the mean activity of its neighbors; namely,

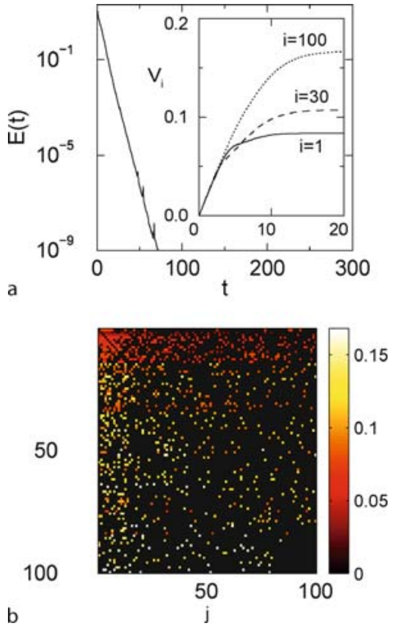
$$G_{ij}(t) = -a_{ij} V_i(t)\,, \quad \dot{V}_i = \gamma \Delta_i/(1 + \Delta_i)\,, \tag{14}$$

where $\Delta_i = |\boldsymbol{H}(\boldsymbol{x}_i) - (1/k_i) \sum_j a_{ij} \boldsymbol{H}(\boldsymbol{x}_j)|$, and $\gamma > 0$ is the adaptation parameter. It is clear that, in this adaptive coupling scheme, the input weight ($W_{ij} = V_i$) and the output weight ($W_{ji} = V_j$) of node i are generally asymmetrical.

Next, synchronization of a network of coupled Rössler oscillators and a chaotic foodweb model on Barabasí–Albert scale-free networks are considered, and two cases of unbounded and bounded stability zones are investigated, respectively. When the stability zone is unbounded, the transition to synchronization is shown in Fig. 12a. Starting from random initial conditions on the chaotic attractors, the local synchronization difference $\Delta \gg 1$, and the input weights of each node, both increase uniformly on the whole network, i. e., $W_{ij} = V_i(t) \approx \gamma t$ (Fig. 12a, inset). After a short period of time, the weights V_i of different nodes develop at different rates and then converge to different values $\tilde{V}_i$. The input weight is smaller on average for nodes with larger degrees k_i (Fig. 12b). Here, the synchronization error is measured by averaging all local errors over the nodes: $E(t) = \langle |\boldsymbol{x}_i - \langle \boldsymbol{x}_i \rangle| \rangle$.

The dependence of the input weight of a node on its degree follows a power law,

$$V(k) \sim k^{-\theta}\,, \tag{15}$$



Synchronization Phenomena on Networks, Figure 12

a Transition to synchronization in an adaptive network of Rössler oscillators, indicated by the (averaged) synchronization error $E(t) = \langle |x_i - \langle x_i \rangle | \rangle$. *Inset*: the input strength $V_i(t)$ vs. time over three nodes. b The weighted coupling matrix $\tilde{G}$ crystallized after the adaptation (for the foodweb model) (after [89])

with exponent $\theta = 0.48 \pm 0.01$ for both oscillator models. Importantly, this scaling is also robust to the variation of network parameters, such as the minimal degree M (Fig. 13b), which should not be confused with the order parameter M elsewhere, the system size N (Fig. 13c), and the orders of magnitudes of the adaptation parameter γ (Fig. 13d).

When the stability zone is bounded, synchronization can always be achieved by the adaption mechanism of Eq. (14) if $\gamma \leq \gamma_c$ for a threshold γ_c somewhat depending on N and the oscillator dynamics. The two resulting weighted networks display the same power-law behavior as in Eq. (15), but with different exponents: $\theta = 0.54 \pm 0.01$ (Rössler oscillator) or $\theta = 0.36 \pm 0.01$ (foodweb). The eigenratio R for the weighted networks, after the adaptation, and for the unweighted networks (symmetric coupling) is calculated as a function of N (Fig. 14a), and as a function of the ratio $S_{\max}/S_{\min}$ (Fig. 14b), where $S_{\max}$ and $S_{\min}$ are the maximum and minimum intensities of the variable coupling strengths of the model. Clearly, this adaptive coupling scheme is more effective than symmetric coupling for network synchronization.

Huang [90] investigated another adaptive coupling pattern, in which a node is coupled with its neighbors non-uniformly through different coupling strengths, and showed that they have better synchronizability than other networks with symmetric coupling patterns.

In all the coupling patterns discussed above, whether the coupling pattern is static or dynamic, only the coupling strength is tunable while the connectivity matrix always remains unchanged. However, as is intuitively clear, network synchronizability can also be significantly improved by evolving the graph topology giving rise to a time-varying connectivity matrix. This has been recently confirmed by Boccaletti et al. [91].

It has been shown [91] that to make a network synchronizable, either the coupling matrix $G(t) = G$ remains unchanged, or if starting from an initial wiring condition $G(0) = G_0$, the coupling matrix $G(t)$ commutes at any time with G_0, i. e., $G_0 G(t) = G(t) G_0, \forall t$. At any time, a zero-row-sum symmetric commuting matrix $G(t)$ can be constructed, as

$$G(t) = V \Lambda(t) V^{\mathrm{T}} , \tag{16}$$

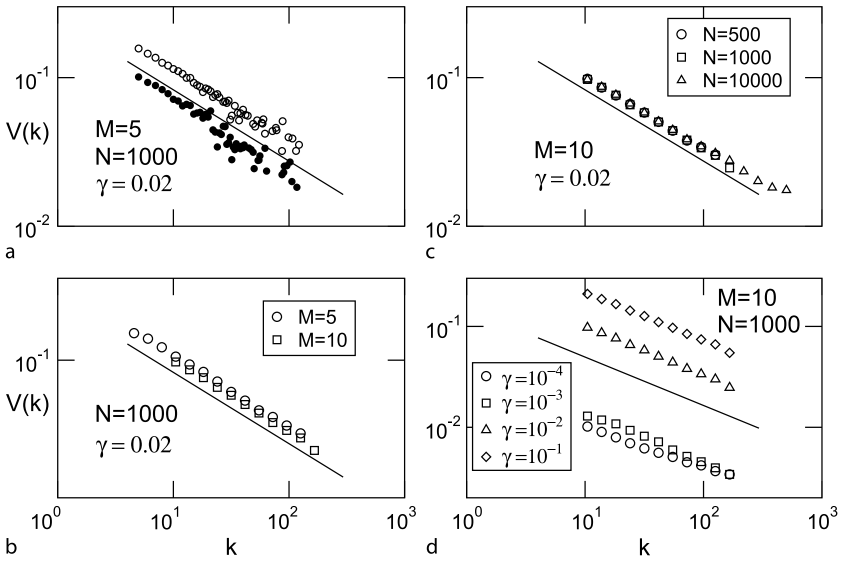
where $V = \{\boldsymbol{v}_i, \ldots, \boldsymbol{v}_N\}$ is an orthogonal matrix with columns being the eigenvectors of G_0, and $\Lambda(t) = \mathrm{diag}[0, \lambda_2(t), \ldots, \lambda_N(t)]$ with $\lambda_i(t) > 0, \forall i > 1$. This set of matrices is referred to as the dissipative commuting set of $G(0)$. A condition to ensure the network synchronization will be stable is

$$S_i = \lim_{T \to \infty} \frac{1}{T} \int_0^T \Lambda_{\max}(\sigma \lambda_i(t')) \mathrm{d}t' < 0 \quad \forall i \neq 1 , \tag{17}$$

where $\Lambda_{\max}(\sigma \lambda_i)$ is the maximal transversal (conditional) Lyapunov exponent along the direction of the ith eigenvector, and S_i is its time average. Hence, it does not require $\Lambda_{\max}(\sigma \lambda_i(t)) < 0$ at all times. One can even construct a commutative evolution such that at each time there exists one eigenvalue λ_i for which $\Lambda_{\max}(\sigma \lambda_i(t)) > 0$, and yet obtain a stable synchronization manifold. Thus, interestingly, synchronization in a dynamical network can be achieved even in the case where each individual commutative graph does not give rise to synchronized behavior.

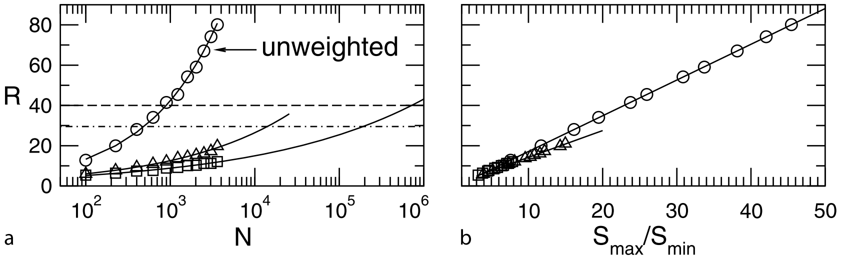
Modifications of Network Structures

It is well known that the synchronizability of a dynamical network is determined simultaneously by the network coupling pattern, the dynamical characteristics of the oscillators on its nodes, and the network structure. In the above, several cases with variable coupling patterns have been discussed. For some real-world networks, however, the coupling pattern cannot be modified at will. Thus, if the dynamics of the oscillators are given and fixed, and



Synchronization Phenomena on Networks, Figure 13

Average input weight $V(k)$ of nodes with degree k as a function of k for a network of Rössler oscillators (*empty circles*) and the food-web model (*filled circles*) (a), and its dependence on various parameters, M (b), N (c), and γ (d), where the M should not be confused with the order parameter M elsewhere (after [89])



Synchronization Phenomena on Networks, Figure 14

Eigenratio R as a function of N (a), and S_{max}/S_{min} (b). The networks are synchronizable if $R < R_\epsilon$ in a, Rössler oscillators (*squares*), $R_\epsilon = 40$ (*dashed curve*), foodweb model (*triangles*), $R_\epsilon = 29$ (*dashed-dotted curve*) (after [89])

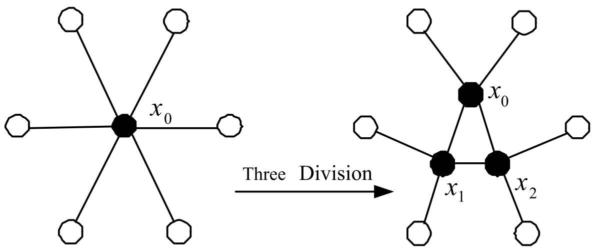
if the coupling patterns cannot be changed, then the only way to enhance the network synchronizability is to make a change to the network structure.

There are some effective techniques to enhance the network synchronizability by modifying the network structure, as further discussed below in the rest of this section.

Reducing Maximal Betweenness

In scale-free networks, the average distance is often very short while the node-degree and node-betweenness distributions are both quite broad. The bottleneck for the network synchronizability seems to be the maximal node betweenness [57]. In order to reduce the node betweenness of the hubs, Zhao et al. [92] suggested a method of structural perturbations. Specifically, for a hub x_0, $m - 1$ auxiliary nodes, labeled as $x_1, \dots, x_{m-1}$, are added around it. These m nodes are fully connected together. Then, all the edges incident from x_0 are re-distributed to all the nodes x_i (including x_0 itself), $i = 0, 1, \dots, m - 1$. After this process, the betweenness of x_0 is divided into m almost equal parts associating with these m nodes. This process is called m-division. A sketch map of a 3-division process on node x_0 is shown in Fig. 15.

Due to the huge sizes of many real-life networks, it is usually impossible to obtain the node betweenness from a complex network. Fortunately, studies have shown that there exists a strongly positive correlation between the node-degree and the node-betweenness in Barabasí–Albert networks and some other heterogeneous networks [87,93]. That is, a node with larger degree has

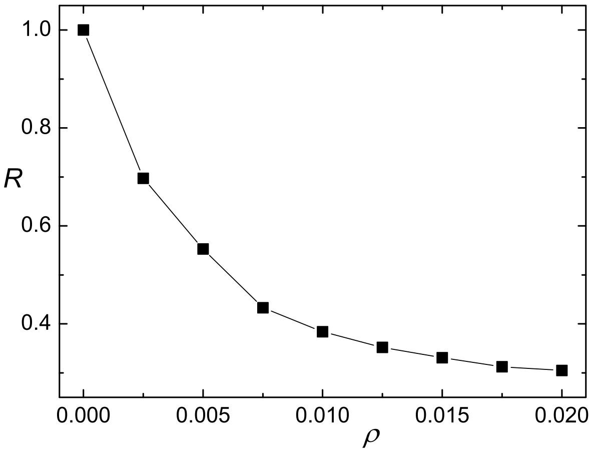


Synchronization Phenomena on Networks, Figure 15

Sketch map for the 3-division process on x_0. The *solid circle* on the *left* is the node x_0 with degree 6. After the 3-division process, this x_0 is divided into 3 nodes, x_0, x_1 and x_2, which are fully connected. The six edges incident from x_0 are then re-distributed to all the three nodes (after [92])

higher node-betweenness statistically. Therefore, for practical reasons, it can be assumed that nodes with higher betweenness are those with larger degrees in Barabasí–Albert networks.

To further explore how the structural perturbations affect the network synchronizability, the eigenratios before and after the m-division process were compared in [92] for a Barabasí–Albert scale-free network with the coupling matrix being Laplacian. For use in the rest of the article, we define a characteristic value $R = r'/r$, in which r and r' are the eigenratios before and after the division, respectively. Figure 16 shows the correlation between R and the probability ρ of the divided nodes. It is clear that even the m-division of a tiny fraction of nodes can sharply enhance network synchronizability.



Synchronization Phenomena on Networks, Figure 16

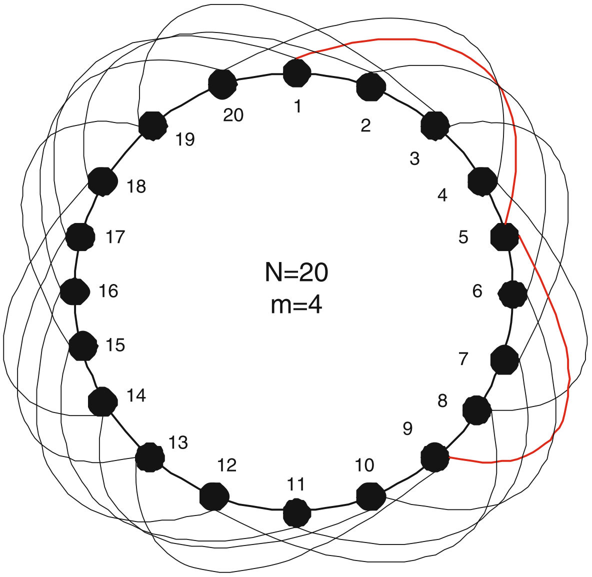
Behavior of value R vs. the fraction of divided nodes ρ. As the number of divided nodes increases, R is reduced, leading to better synchronization (after [92])

Shortening the Average Distance

Zhou et al. [94] investigated the synchronizability of a network model named *crossed double cycles* (CDCs). They not only clarified the relationship between average distance and network synchronizability, but also provided a possible way to make a network more synchronizable.

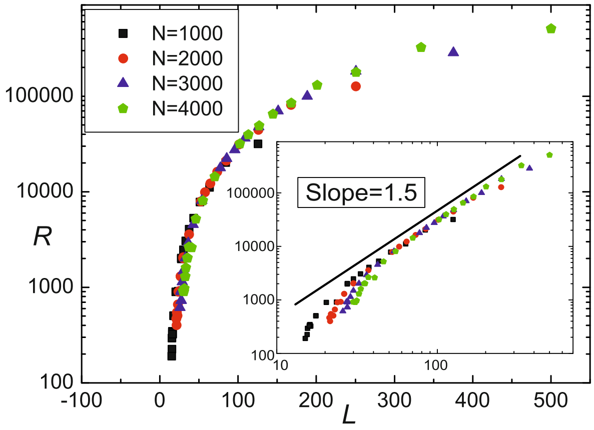
In the language of graph theory [95,96,97], a cycle C_N denotes a network consisting of N nodes (vertices) x_1, $\dots, x_N$. These N nodes are arranged in a ring, and the nearest two nodes are connected to each other. Thus, C_N has N edges connecting the nodes $x_1x_2, x_2x_3, \dots,$ $x_{N-1}x_N, x_Nx_1$. The set of all such CDCs, denoted by $G(N, m)$, can be constructed by adding two edges, called crossed edges, to each node in C_N. The two nodes connecting by a crossed edge have distance m within C_N. For example, the network $G(N, 3)$ can be constructed from C_N by connecting $x_1x_4, x_2x_5, \dots, x_{N-1}x_2, x_Nx_3$ together. A sketch map of $G(20, 4)$ is shown in Fig. 17 for illustration.

Figure 18 shows how the average distance L affects the network synchronizability (measured by the characteristic value R). It is clear that the network synchronizability is very sensitive to the average distance: as L increases, R sharply spans more than three magnitudes. And the network synchronizability is remarkably enhanced by reducing L. When the crossed length m is not too small or too large (compared to N), networks with the same average distance have approximately the same synchronizability,



Synchronization Phenomena on Networks, Figure 17

Sketch map of $G(20, 4)$ (after [94])



Synchronization Phenomena on Networks, Figure 18
Characteristic value *R* vs. average distance *L* of CDCs. The *black squares*, *red circles*, *blue triangles* and *green pentagons* represent the cases of $N = 1000$, 2000, 3000 and 4000, respectively. The *inset* shows the same data in log-log plot, indicating that the characteristic value *R* approximately obeys a power-law form $R \sim L^{1.5}$. The *solid line* has slope 1.5, for comparison (after [94])

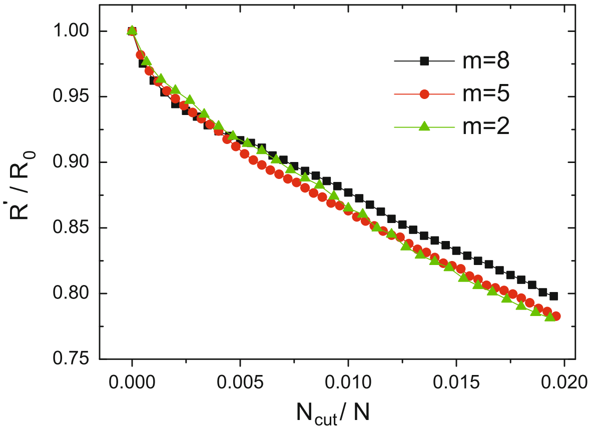
regardless of the network sizes. More interestingly, the numerical results show that the characteristic value R approximately obeys a power-law form, as $R \sim L^{1.5}$ (inset of Fig. 18).

Decoupling Nodes by Removing Heavily-Loaded Edges

In the synchronization process, not only hubs may be the bottlenecks but some edges with large loads may also limit the network synchronizability. Yin et al. [99] found that a scale-free network can become more synchronizable after some of its heavily-loaded edges have been removed. To reduce the computational cost, they used local information to approximately rank the edges, according to the values of $k_i \times k_j$, where i and j denote two adjacent nodes connected by an edge. Subsequently, at each time step, an edge with the highest rank is removed, i. e., the two nodes are decoupled at both sides of their connecting heavily-loaded edge. After this operation, the characteristic value is decreased, as shown by Fig. 19.

Designing the Output Function

Very recently, the relationship between graph theory and network synchronizability received some special attention [100]. For example, Duan et al. [101,102,103] found that for networks with disconnected complementary graphs, adding edges will often increase their synchronizability. The complementary graph of a given graph G is defined to be the graph consisting of all the nodes of G and all the edges that are not in G.

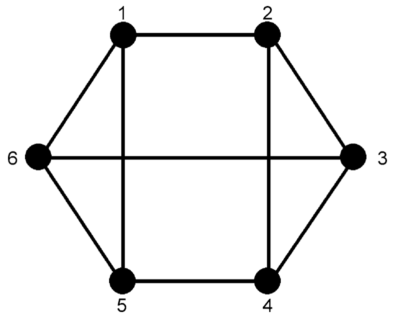


Synchronization Phenomena on Networks, Figure 19
Changes of the synchronizability as a function of the proportion of cut edges N_{cut}/N for different values of the average distance (after [99])

In addition, they found [101,102] that when the couplings between nodes are symmetric, an unbounded synchronized region is always easier to analyze than a bounded synchronized region (see Sect. "Basic Concepts of Network Synchronization" to recall their definitions). Therefore, to effectively enhance network synchronizability, they presented a design method for the output function (i. e., $\boldsymbol{H}$ in network (1), or the inner linking matrix in the linear coupling case), such that the resultant network has an unbounded synchronized region, for the case where the synchronous state is an equilibrium of the network.

If the synchronous state is an equilibrium, then both $D\boldsymbol{F}(\boldsymbol{s}(t))$ and $D\boldsymbol{H}(\boldsymbol{s}(t))$ in network (1), as discussed in Sect. "Enhancing Network Synchronizability" (part B), reduce to constant matrices, denoted by F and H, respectively. The synchronized region is the stability region of the matric pencil $F + \alpha H$ with respect to parameter α. It can be proved that there exists a matrix H of rank 1 (meaning that only one component in each state vector is used for coupling), such that the stability region is unbounded. The method for obtaining the desired output function is outlined below: first, take a column vector b such that (F, b) is stabilizable [104]; then, find a matrix $P = P^{\mathrm{T}}$ such that $FP + PF^{\mathrm{T}} - 2bb^{\mathrm{T}} < 0$; consequently, taking $k = b^{\mathrm{T}} P^{-1}$ leads to the stability of $F - \alpha bk$ for all α in the unbounded region; finally, $H = bk$ is the matrix to be found.

For illustration, synchronization of a simple 6-node network (shown in Fig. 20) is studied, where each node



Synchronization Phenomena on Networks, Figure 20
A network of 6 nodes (after [101])

is located with a third-order smooth Chua's circuit [105]. At first, arbitrarily take the output function

$$H = \begin{pmatrix} 0.8348 & 9.6619 & 2.6591 \\ 0.1002 & 0.0694 & 0.1005 \\ -0.3254 & -8.5837 & -0.9042 \end{pmatrix} . \qquad (18)$$

But the network does not synchronize. The states of node 1 are shown in Fig. 21a. Then, let $b = (0, 0, 1)^{\mathrm{T}}$ and $k = (0.0708, -0.15590, 0.4296)$, and then set $H = bk$, so synchronization is achieved as guaranteed by the theory. Figure 21b shows that the states of node 1 quickly reach the equilibrium.

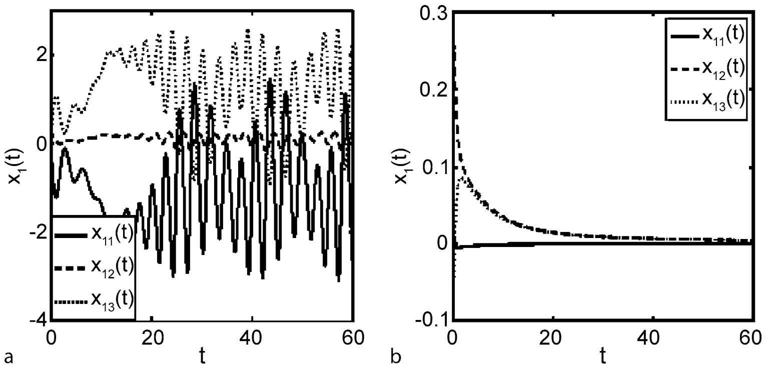
Future Research Outlook

Complex network synchronization is a rapidly growing subject attracting increasing attention from various fields of physics, engineering, mathematics, and biology alike. Despite the current great advances and progress, there are still many important open questions.

In the studies of static coupling, Nishikawa and Motter [48] once pointed out that optimal global synchronizability, with eigenratio being equal to 1, can be obtained from a directed network structure without loops. Even if adding one loop of length 2 (in a directed network, two opposite edges between node *i* and node *j* can be considered as a loop of length 2), the eigenratio will be doubled [73,85]. Another scenario is shown by extending the conclusion in [48] to the case of non-identical oscillators [106]. Some further works in this direction will be helpful for in-depth understanding about the role of loops in network synchronization.

In the studies of dynamic coupling, the cost of coupling has not been taken into account. However, cost is usually very significant in some self-driven systems (for example, in wireless sensor networks [107,108] and in distributed autonomous robotic systems [109]). For each node to report its current state to the neighbors (or to detect the states of all its neighbors) requires a certain amount of power, while the total power assigned to each node is often limited, even if such communications are possible. Yet, as found in collective behaviors of biological swarms, a few effective leaders can well organize the whole population [110]. And a recent study has pointed out that partial coupling is more than enough to keep the coherence of self-propelled particles [111]. Therefore, it is very natural to expect to synchronize a complex network with a very low cost, which is an important issue for further investigation.

Very recently, there are some attempts at detecting the network structures with the help of the synchronization phenomenon on complex networks [112,113,114]: to discover the hierarchical community structure by the dynamic time scales of the network synchronization process [112,113], or to infer the complete connectivity of a network from its stable response dynamics [114], etc. These seem quite useful for optimal network design, analy-



Synchronization Phenomena on Networks, Figure 21
States of node 1 (after [101])

sis, and utilization in general, therefore should be pursued with special efforts.

Similar to the aforementioned open questions, many theoretically attractive and practically important problems about various aspects of synchronization on complex networks can be posted and described. As the network research further evolves in different fields, many new dynamical phenomena and analytic issues will also emerge. Importance notwithstanding, the subject of "Synchronization Phenomenon of Networks" will continue to prove itself an theoretically interesting and technically challenging subject for scientific research in the years to come.

Synergetics: Basic Concepts

HERMANN HAKEN
Institut für Theoretische Physik, Universität Stuttgart, Stuttgart, Germany

Article Outline

Glossary

Synergetics Science of cooperation.

Pattern A pattern is essentially an arrangement. It is characterized by the order of the elements of which it is made rather than by the intrinsic nature of these elements (Norbert Wiener).

Self-organization Formation of spatio-temporal patterns (structures) and/or performance of functions without an “ordering hand”.

State vector Set of time- or time-independent variables that characterize the state of a system.

Evolution equations Determine the temporal evolution of the state vector. May be deterministic, stochastic or both.

Control parameter One or a set of (mostly externally) fixed parameters in the evolution equations.

Spectrum Set of eigenvalues belonging to linear stability equations with boundary conditions.

Stability of a system System returns after a (small) perturbation of its state vector into original state.

Instability Loss of stability.

Order parameters Collective variables that determine the macroscopic behavior of systems.

Slaving principle A general theorem that allows the reduction of the variables of a system to order parameters (close to instability).

Trajectory Smooth curve $q(t)$ of solution of evolution equation in q-space.

Attractor Region in the state vector space ("q-space") to which all neighboring states are attracted in the course of time.

Fixed point, stable Point in q space to which all neighboring trajectories converge in course of time.

Limit cycle, stable A closed trajectory to which all neighboring trajectories converge.

Probability distribution function Function that determines the probability of a random variable r to have fixed value $r = r_0$.

Fokker Planck equation Evolution equation for probability density function, based on drift and diffusion.

Normal form Especially simple polynomial expression that still captures the essential features, e. g. of the right hand side of deterministic evolution equations.

Schrödinger picture of quantum mechanics In it operators are time-independent, while the wave-function ("state vector") is time-dependent and determined by the Schrödinger equation.

Heisenberg picture in quantum mechanics The state vector is time-independent, while the operators are time-dependent and determined by Heisenberg equations of motion.

Fluctuating forces Stochastic (random) forces appearing in evolution equations.

Quantum classical correspondence Establishes relation between quantum mechanical density matrix and classical quasi-probability distribution.

Symmetry Invariance of a system against specific transformations (e. g. mirror symmetry).

Group Set of elements with specific multiplication rules (axioms).

Dynamical system System whose state vector changes in the course of time deterministically.

Langevin equation Originally: evolution equation for velocity of a Brownian particle subject to damping and fluctuating force.

Generalized Langevin equation General evolution equations that contain both a deterministic and a stochastic part ("fluctuating forces").

Hamilton operator Classical Hamilton function, in which variables, e. g. position x and momentum p, are replaced by quantum mechanical operators.

Spatial coordinate (vector *x*) in one, two or three dimensions.

$$\Delta \quad \text{Laplace operator (in 1,2 or 3 dimensions)}\,.$$

$$\nabla \quad \text{Vector} \left(\frac{\mathrm{d}}{\mathrm{d}x_1}, \frac{\mathrm{d}}{\mathrm{d}x_2}, \frac{\mathrm{d}}{\mathrm{d}x_3}\right) \text{ in 1,2 or 3 dimensions}\,.$$

The Role of Synergetics in Science

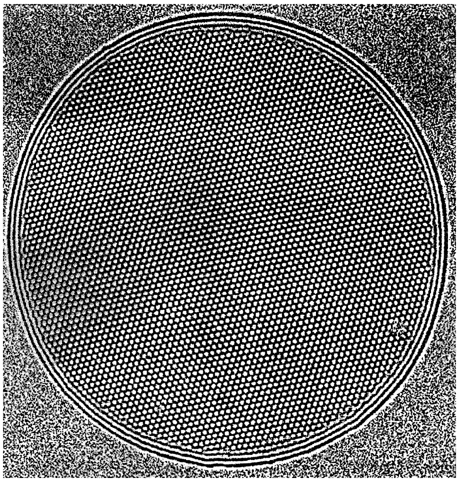
In science, we may essentially distinguish between two trends:

1. The accumulation of knowledge
2. Information reduction in the sense of finding general principles, common features.

In physics, such unifying approaches are well known: the unification of magnetism, electricity and, later on, weak and other interactions leading eventually to a unified field theory. General relativity unifies concepts of space, time and gravitation. While these unifications take place at a fundamental level, one may ask whether it is worthwhile to look also for unifications at say more macroscopic or phenomenological levels. One example is thermodynamics, another the theory of phase transitions of systems in thermal equilibrium by means of the renormalization group approach, or the concept of fractals, etc.

The main goal of Synergetics is the search for unifying principles for systems that are composed of many individual parts or components, and that may show the phenomenon of self-organization, i. e. the spontaneous formation of spatial, temporal, spatial-temporal or functional structures. The systems under discussion are, in the widest sense of the word, open physical systems whose states are maintained by an in- and outflux of energy, matter and /or information. A typical and well known example is that of a fluid in a pan that is uniformly heated from below. When the temperature difference between the lower and upper surface exceeds a critical value, the formerly homogeneous fluid develops roll or hexagonal patterns in which the fluid moves in a specific manner (Fig. 1).

As it turned out, the general principles originally elaborated in physics, can also be applied to many other systems, such as in biology, economy, ecology, sociology,



Synergetics: Basic Concepts, Figure 1
Hexagonal pattern of a fluid (liquid helium) uniformly heated from below [12]

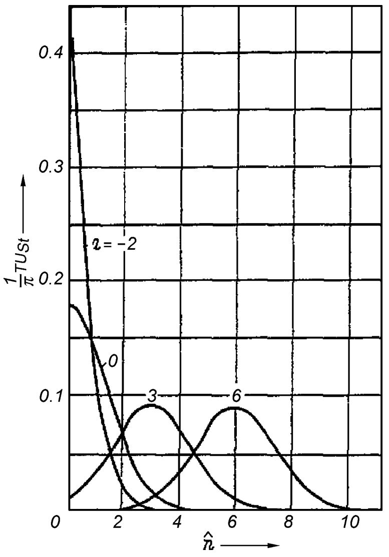
management theory, psychology etc. In spite of the great variety of the individual systems with their components quite different in nature, such principles apply to large classes of phenomena. This is achieved by restricting the study to situations where the systems undergo qualitative changes at macroscopic scales. Here macroscopic means "with time and length scales large compared to those of the individual components".

This leads to the definition of Synergetics as given in the preamble of the Springer Series in Synergetics: "An ever increasing number of scientific disciplines deal with complex systems. These are systems that are composed of many parts which interact with one another in a more or less complicated manner. One of the most striking features of many such systems is their ability to spontaneously form spatial or temporal structures. A great variety of these structures are found, in both the inanimate and the living world. In the inanimate world of physics and chemistry, examples include the growth of crystals, coherent oscillations of laser light, and the spiral structures formed in fluids and chemical reactions. In biology we encounter the growth of plants and animals (morphogenesis) and the evolution of species. In medicine we observe, for instance, the electromagnetic activity of the brain with its pronounced spatio-temporal structures. Psychology deals with characteristic features of human behavior ranging from simple pattern recognition tasks to complex patterns of social behavior. Examples from sociology include the formation of public opinion and cooperation or competition between social groups."

In recent decades, it has become increasingly evident that all these seemingly quite different kinds of structure formation have a number of important features in common. The task of studying analogies as well as differences between structure formation in these different fields has proved to be an ambitious but highly rewarding endeavor. The Springer Series in Synergetics provides a forum for interdisciplinary research and discussions on this fascinating new scientific challenge. It deals with both experimental and theoretical aspects. The scientific community and the interested layman are becoming ever more conscious of concepts such as self-organization, instabilities, deterministic chaos, nonlinearity, dynamical systems, stochastic processes, and complexity. All of these concepts are facets of a field that tackles complex systems, namely Synergetics.

The Laser Paradigm

This example elucidates central concepts used in Synergetics in a qualitative fashion. An example for the laser device (an acronym for light amplification by stimulated emission of radiation, originally called optical maser [121]) is the gas laser in which gas atoms are enclosed in a tube at the end-faces of which mirrors are mounted. The mirrors serve the purpose of reflecting light running in axial direction sufficiently often so that the corresponding light wave stays for an extended period in this device and can interact intensely with the atoms. The atoms are excited from the outside, e. g. by a pump light source. After having been excited, each atom can spontaneously emit a light wave track. In the usual case of a *lamp*, these wave tracks are emitted independently of each other and the amplitudes are Gaussian distributed. When the pump intensity is increased beyond a critical value, the present state gives way to a single wave with *stable amplitude* on which small *amplitude fluctuations* and *phase diffusion* are superimposed [53]. The pump intensity serves as *control parameter*. At its critical value, the old state becomes *unstable*. The emerging coherent wave acts as *order parameter* that via stimulated emission forces the electrons of the gas molecules to emit light waves in a coherent fashion. This action of the order parameter on the individual parts of the system is called *slaving principle*. If the pump power is increased further, more instabilities can appear, and a variety of temporal but also spatio-temporal patterns of light waves may appear, such as laser light chaos [55] or ultrashort laser pulses. The first laser threshold shows the typical features of a phase transition of a system in thermal equilibrium, namely critical slowing down, critical fluctuations and symmetry breaking [25,46,53,58,119], as well as the emergence of a c-number amplitude of the quantized light field (Fig. 2).



Synergetics: Basic Concepts, Figure 2

The stationary distribution function of the laser light intensity as a function of the normalized intensity $\hat{n}$. The individual *curves* refer to different normalized pump power values a, where $a < 0$ below threshold, $a = 0$ at threshold, $a > 0$ above threshold (after [116])

The Hierarchical Structure of Synergetics

Before I discuss the mathematical approach in detail and to provide the ground for farther reaching applications, I hint at the three levels of Synergetics:

1. *The microscopic theory*, based either on microscopic equations, such as in the laser example, those of quantum mechanics and quantum field theory, or in biology on mathematical models on the behavior of individual parts of a system. At this level, concepts, such as order parameters and enslavement (cf. Sect. "The Laser Paradigm"), can be mathematically derived.
2. *Phenomenological Synergetics* directly starts from concepts, such as order parameters and enslavement, which then may be cast into mathematical relations.
3. *Semantic Synergetics* deals with cases where a mathematical formulation is (at present or in principle) not possible, but still formulations using concepts and relationships unearthed in Synergetics are applicable.

A general goal of Synergetics consists in elaborating relationships between levels 1, 2, 3.

In the present article I will mainly focus my attention on the mathematical formulation dealing with 1. and 2.

Basic Equations

The basic equations are classical or quantum mechanical evolution equations, in which the temporal evolution of the microscopic quantities under consideration is described by ordinary or partial differential equations. Since the systems are open, the inputs and outputs of energy, matter and/or information must be taken care of, which, quite often, appears in the form of coupling to heat baths in the sense of thermodynamics. In open systems, these heat baths must be kept at different temperatures, in order to maintain the non-equilibrium state of the system. The heat bath variables can be eliminated which gives rise to differential equations which contain "pumping" and "damping" terms as well as fluctuating (stochastic) forces. In the case of quantum mechanical equations the stochastic forces are operators. With the inclusion of stochastic forces, the classical or quantum mechanical equations acquire the character of stochastic differential equations which may be called "generalized Langevin equations".

Depending on the definition of the random forces, we may distinguish between the $\hat{I}$ to, the Statonovich and the Klimontovich approach [62,72,134]. As is well known in statistical physics, Langevin equations can be converted into equations for distribution functions, such as e. g. the Fokker–Planck equation. A further approach, mainly used in quantum mechanics, but also in models on sociodynamics, is the master equation.

In order not to overload this article, I will focus my attention on the treatment of evolution equations.

This approach seems to be particularly suited for the treatment of phase transition- like phenomena, i. e. the transitions between qualitatively different states of a system. If noise is neglected and transients are not treated, these transitions are called bifurcations [5,22,49,71,79, 84,91].

At the microscopic level the systems are described by a state vector q with components $q_1, \ldots, q_n$ which may also be space dependent, $q_j = q_j(x, t)$, where x is a one, two or three dimensional vector. The time dependence is described by evolution equations of the form of a vector equation.

$$\dot{q} = N(q, \nabla, \alpha) + F(q, \nabla, \alpha) \,. \tag{1}$$

The dot $^{\cdot}$ means time-derivative. N is a vector valued function that depends on q in a nonlinear fashion. ∇ indicates spatial derivatives (of any order) or non-local integrations e. g. of the form

$$\int K(x, x')q(x')\,\mathrm{d}x' \tag{2}$$

where K is a matrix.

α represents a set of fixed control parameters. If not otherwise stated, we explicitly treat only one control parameter. Equation (1) must be supplemented by appropriate boundary and initial conditions. F is a vector valued stochastic function of time with vanishing mean.

Method of Solution

We assume that for a certain control parameter value α_0 the state vector as solution of Eq. (1) is known, $q = q_0$. The following cases have been considered, see e. g. [62]:

a) q_0 is a stable fixed point (Section "Instability of a Fixed Point")
b) q_0 is a stable limit cycle (Section "Instability of a Limit Cycle, $q_0(t)$ [62]")
c) q_0 is a stable n-dimensional torus. (Section "Instability of Tori [62]")

Now the control parameter value is changed and the stability of the system is checked by means of linear stability analysis [52].

Instability of a Fixed Point We first elucidate our general procedure by means of the instability of an originally stable fixed point. This procedure differs from the classical approach of bifurcation theory [90,124] in two important aspects:

1. The role of the fluctuating forces is fully taken into account in order to be able to make contact with the theory of phase transitions in the Landau sense [86].
2. The approach covers the surrounding of the fixed point in order to deal with relaxation processes towards the newly evolving stable states.

The hypothesis

$$q(t) = q_0 + W(t) \tag{3}$$

is inserted into (1) and the Eq. (1) with $F \equiv 0$ linearized with respect to $W(t)$,

$$\dot{W} = LW \tag{4}$$

where L may be a linear differential (or integral) linear operator.

The solutions are of the form

$$W(x,t) = \mathrm{e}^{\lambda_k t} \sum_{d=0}^{D} t^d v_{k,d}(x) \tag{5}$$

where $D > 0$ may happen if the corresponding eigenvalue λ_k is degenerate. In the following we consider $D = 0$ and $v_{k,d} = v_k$. The unstable modes $v_k \equiv v_u$ are connected with

$$\operatorname{Re}\lambda_k \geq 0\,, \tag{6}$$

the stable modes $v_k \equiv v_s$ with

$$\operatorname{Re}\lambda_k < 0\,. \tag{7}$$

It is assumed that $\operatorname{Re}\lambda_k < A < 0$, A fixed, if the eigenvalues are discrete.

We decompose the wanted solution to the original non-linear and stochastic equations into a super position of modes determined by the instability analysis whereby we distinguish between the unstable and stable modes. The amplitudes of the unstable modes are the order parameters. Inserting

$$q(t) = q_0 + \sum_u \xi_u(t) v_u(x) + \sum_s \xi_s(t) v_s(x) \tag{8}$$

into the Eqs. (1) and projecting both sides of the resulting equation on the stable and unstable modes, we obtain equations of the form

$$\dot{\xi}_u = \lambda_u \xi_u + \hat{N}_u\left(\{\xi_u\}, \{\xi_s\}\right) + \hat{F}_u\left(\{\xi_u\}, \{\xi_s\}\right) \tag{9}$$

$$\dot{\xi}_u = \lambda_s \xi_s + \hat{N}_s\left(\{\xi_u\}, \{\xi_s\}\right) + \hat{F}_s\left(\{\xi_u\}, \{\xi_s\}\right)\,. \tag{10}$$

λ_u, λ_s are the eigenvalues (6), (7), which are assumed to be discrete. By a suitable, in general nonlinear, transformation to new variables, $\tilde{N}(\{\xi_u\})$ can be cast into a particularly simple form ("normal form" theory [101,103], initiated by Poincaré [113]).

If the eigenvalues $\lambda_u, 0 > \operatorname{Re}\lambda_s > -|B|$ are a continuous function of an index, e. g. a wave number k, wave packets of $\xi_u(t)$ are used as new order parameter variables Ξ and $\lambda_u(k)$ is replaced by an operator $\Lambda_u(-i\frac{\mathrm{d}}{\mathrm{d}x})$ in one space-dimension or, more generally, $\Lambda_u = (-i\nabla)$ [62]. For a related approach in fluid dynamics cf. [105].

The central idea of further procedure consists in eliminating the amplitudes of the stable modes. This is achieved by the *slaving principle* [56,62,65,148] which allows us to express the amplitudes of the stable modes in terms of the unstable modes

$$\xi_s(t) = f_s\left(\{\xi_u(t)\}, t\right)\,, \tag{11}$$

where ξ_s, ξ_u are taken at the same time t. The explicit time-dependence of f_s stems exclusively from that of the fluctuating forces. f_s can be explicitly calculated in terms of a series expansion in powers of the order parameters. For practical purposes, in general only a few terms are needed.

For a general discussion of the convergence of this series see [62]. When noise is neglected, contact can be made with center manifold theory [76,112], which originally was a mere existence theory and was not constructive. For more recent developments, see books on bifurcation theory. A related approach is based on time-scale separation: The slowly damped or undamped modes serve as order parameters, which enslave the rapidly damped modes. A special case is adiabatic elimination.

Resulting Langevin Equations The enslaved mode amplitudes can be expressed by the order parameters and inserted in (9), so that closed equations for the order parameters alone result.

$$\dot{\xi_u} = \lambda_u \xi_u + \tilde{N}_u\left(\{\xi_u\}\right) + \tilde{F}_u\left(\{\xi_u\}, t\right) \tag{12}$$

where $\tilde{N}$ is a polynominal of $\xi(x, t)$ starting with at least second order. $\tilde{F}$ is a stochastic force. A simple, yet prototypical example is (with a single order parameter $\xi = \xi_u$)

$$\dot{\xi} = \lambda\xi + a\xi^2 - b\xi^3 + F(t)\,, \quad b > 0 \tag{13}$$

or

$$\dot{\xi} = -\frac{\partial V(\xi)}{\partial \xi} + F(t)\,, \tag{14}$$

with the potential

$$V = -\frac{\lambda}{2}\xi^2 - \frac{a}{3}\xi^3 + \frac{b}{4}\xi^4\,. \tag{15}$$

If λ_u, λ_s (6), (7) represent a continuous spectrum, (generalized) Ginzburg–Landau equations result [62]. For example, the complex Ginzburg–Landau equation with fluctuating force reads [6].

$$\begin{aligned} &(\xi(x, t) \equiv \xi_u\,,\ \text{complex order parameter})\\ &\dot{\xi} = \lambda\xi + a\Delta\xi - c\,|\xi|^2\,\xi + F(t)\,. \end{aligned} \tag{16}$$

A further example is given by the Swift–Hohenberg equation [135], see also [24] (which was derived differently, however)

$$\dot{\xi}(x, t) = (a - b\Delta)^2\xi(x, t) + c\xi(x, t) - d\xi(x, t)^3\,. \tag{17}$$

The Eqs. (12,13,16,17) allow for a great variety of solutions. In the case of real λ and a single order parameter, a nonequilibrium phase transition occurs (see below). In case of λ complex, and (at least) one complex order parameter, Landau–Hopf bifurcation [67,68], i. e. formation of a limit cycle may happen. In case of (at least) three order parameters and no noise, deterministic chaos may occur [89,118,132] (in the presence of noise, mixed effects may occur).

Fokker–Planck Equation Below and above the instability point in control parameters space, in a first step the fluctuations can be neglected and then, in the next step, taken care of by means of lowest order perturbation theory. In order to cover the transition region, under well defined conditions a Fokker–Planck equation for the probability density function $f\left(\{\xi_u\}\right)$ of the order parameters can be derived. For details see [62,63a}] and the article by T. Frank, this volume.

The Fokker–Planck equation is of the general form

$$\dot{f}\left(\{\xi_u\}\right) = -\sum_u \frac{\partial}{\partial \xi_u}\left(\tilde{N}_u f\right) + \frac{1}{2}\sum_{uv}\frac{\partial^2}{\partial \xi_u \partial \xi_v}\left(Q_{uv} f\right)\,. \tag{18}$$

It is assumed that $\tilde{F}_u$ in (12) is δ correlated in time,

$$\langle \tilde{F}_u(t)\tilde{F}_v(t')\rangle = Q_{uv}\delta(t - t')\,. \tag{19}$$

If $\tilde{F}_u$ depends on ξ_u, the $\hat{I}$ to, Stratonovich or Klimontovich procedure must be applied.

In the case of a single order parameter, where the Langevin equation [88], originally with $\tilde{N} = -\alpha\xi$) is given by

$$\dot{\xi} = \tilde{N}(\xi) + F(t)\,, \quad \langle F(t)F(t')\rangle = Q\delta(t - t')\,. \tag{20}$$

The steady state distribution function of (18) is given by [62,116]

$$f(\xi) = N\exp\left(-2\int^{\xi}(\tilde{N}(\xi')/Q\mathrm{d}\xi') \equiv N\exp(-2V(\xi)/Q\right) \tag{21}$$

provided the boundary conditions are

$$f(\xi) \to 0 \quad \text{for } |\xi| \to \infty\,. \tag{22}$$

In the second Eq. (21), $Q = $ const. is assumed. N is a normalization constant. A generalization of (18) to continuous variables, $\xi_u(x, t)$, gives rise to a functional Fokker–Planck equation. An explicit solution of the Fokker–Planck equation in the case of several discrete or continuous order parameters can be found if the drift and diffusion coefficients obey the rules of detailed balance [45,47].

Nonequilibrium Phase Transition. Connection with Landau Theory The explicit form of the solution of the Fokker–Planck Eq. (21) allows us to make contact with the theory of phase transitions in the sense of the Landau theory [86] where

$$\begin{aligned} f(\xi) &= N\exp\left(-F(\xi, T)/(kT)\right)\,,\\ F(\xi, T) &= F(0, T) + a(T - T_c)\xi^2 + \frac{\beta}{4}\xi^4\,. \end{aligned} \tag{23}$$

In (21), V corresponds to the free energy F and the noise strength Q corresponds to *absolute* temperature T. T_c is the critical temperature, and (23) refers to a second order phase transition. In case of a first order phase transition, an additional term $\gamma\xi^3$ appears in (23).

An important difference between phase transitions at thermal equilibrium and in the present case of non-equilibrium should be mentioned, however. The decisive constants in the case of non-equilibrium [62] phase transitions are rate constants in contrast to thermodynamic quantities in (23). While non-equilibrium phase transitions described by (21) were experimentally very well verified for instance in the case of lasers [116] (Fig. 1), in the case of thermal equilibrium the Landau theory can not be considered as a good approximation and had been replaced by the concept of critical exponents etc. as dealt with by renormalization group theory [75,146]. For a treatment of the time dependent Fokker–Planck equations see Risken [117].

In a number of cases the drift- and diffusion coefficients of the Fokker–Planck equation are by themselves expectation values, defined on the probability density function so that the Fokker–Planck equation becomes non-linear. For more details see the article by T.D. Frank in this volume.

Instability of a Limit Cycle, $q_0(t)$ [62] The instability is checked by linear stability analysis by means of the hypothesis

$$q(t) = q_0(t) + W(t)\,, \tag{24}$$

where $q_0(t)$ is a time-periodic solution to (1) with $\alpha = \alpha_0$, $W(t)$ a small deviation.

Inserting (24) into (1) with $F \equiv 0$ and linearization leads to an equation of the form (4), where L because of $q_0(t)$ has become also a time-periodic function with the same period as $q_o(t)$. According to Floquet theory [35], the solutions to (4) with periodic $L(t)$ are given by

$$W(t) = \mathrm{e}^{\lambda_f t} v_j(t) \tag{25}$$

(in the case of nondegeneracy), where $v_j(t)$ has the same period as q_0, i. e. L.

Depending on $\operatorname{Re}\lambda_j \geq 0$ or < 0 we distinguish between unstable and stable modes (6, 7), respectively. One eigenvalue is $= 0$ and corresponds to an indeterminate phase shift, which in nonlinear analysis is taken care of by a phase $\phi(t)$ that acts as additional order parameter. In order to solve the fully nonlinear and stochastic equations, the hypothesis

$$q(t) = q_0(t + \phi(t)) + \sum_u \xi_u(t) v_u\left(t + \phi(t)\right) + \sum_s \xi_s(t) v_s\left(t + \phi(t)\right) \tag{26}$$

is inserted in the Eqs. (1). The subsequent procedure follows the lines outlined above and leads to order parameter equations of the form

$$\dot{\xi}_u = \lambda_u \xi_u + \hat{N}_u\left(\{\xi_u\}, \phi\right) + \hat{F}_u\left(\{\xi_u\}, \phi\right) \tag{27}$$

$$\dot{\phi} = M\left(\{\xi_u\}, \phi\right) + G\left(\{\xi_u\}, \phi\right) \tag{28}$$

where $\hat{N}, \hat{F}, M, G$ are polynominals in $\{\xi_u\}$ and periodic functions of ϕ.

The novelty as compared to the case of an unstable fixed point consists in the introduction of a phase as order parameter.

When noise is neglected, the newly evolving, i. e. bifurcating solutions are either two (or several) limit cycles or tori. Also basically, depending on the system, also a "back bifurcation" to a stable focus can happen.

Instability of Tori [62] The corresponding theory is rather complex so that a few words must suffice here. The basic idea [62] is based on an extension of (24,26) where q_0 is chosen as a quasi periodic function

$$q_0 = q_0(\omega_1 t, \omega_2 t, \ldots, \omega_M t) \tag{29}$$

where the $\omega' s$ must be sufficiently irrational in the sense of the KAM (Kolmogorov [80], Arnold [3], Moser [100]) theorem. Besides amplitudes as order parameters, also phases $\phi_1(t), \ldots, \phi_M(t)$ are introduced. For details cf. [62], and for alternative approaches [21,128].

A Remark on the Method of Solution of Evolution Eqs. (1)

In this article the central role of order parameters is stressed because this allows us to establish profound analogies between quite different systems. In practical applications it may be preferable, however, to apply other methods of solution, analytical, numerical or mixed, in order to derive the spatial, temporal or spatio-temporal patterns. In this way, the Springer Series in Synergetics have developed a "tool box" of models [98].

Quantum Theoretical Formulation

In a quantum theoretical treatment one deals with quantum mechanical Langevin equations which are Heisenberg equations of motion for operators to which pumping and damping terms as well as random noise sources are added. Here, according to quantum theory, the system's observables are represented by time-dependent quantum mechanical operators, Ω_j. For instance, by the position operator $\hat{x}$ and the momentum operator $\hat{p}$ of a particle, or, in quantum field theory, by creation and annihilation operators $\hat{b}^+, \hat{b}$, respectively. The quantum mechanical Langevin equations read (see, for instance [54,58]):

$$\dot{\Omega}_j = \frac{i}{\hbar}\left[H, \Omega_j\right] + \text{damping} + F_j(t)\,, \qquad (30)$$

where H is the Hamilton operator, and $F_j(t)$ are stochastic operators which usually are assumed to be δ-correlated in time. The quantum mechanical properties can be determined by the postulate of quantum mechanical consistency of Ω_j, (cf. [54], appendix).

If the non-commutativity of operators is taken care of, the procedure to derive order parameter equations is formally the same as in the case of classical Langevin equations as indicated above. The Fokker–Planck equation, however, must be replaced by a density matrix equation, originally introduced as master equation [109]. For nonequilibrium systems, such as the laser, see [50,126,144], also [54,119]. Using methods of quantum classical correspondence, this density matrix equation can be converted into a Fokker–Planck equation under specific conditions. The basic idea is this:

Quantum-Classical Correspondence

There are several ways to define quantum classical correspondence. In the case of position operator $\hat{x}$ and momentum operator $\hat{p}$ with the commutator $[\hat{p}, \hat{x}] = \frac{\hbar}{i}$ and the density matrix ρ, the Wigner distribution function $W(x, p)$ [145] is defined by

$$W(x, p) = \frac{1}{(2\pi)^2} \cdot \int \int_{-\infty}^{\infty} \mathrm{e}^{-ikx-ilp} \cdot \operatorname{tr}\left(\mathrm{e}^{ik\hat{x}+il\hat{p}}\rho\right) \mathrm{d}k\mathrm{d}l \qquad (31)$$

where "tr" means trace.

Thus a relation is established between the quantum mechanical density matrix and a classical quasi-density $W(x, p)$. Based on (31) or (34,35,36), a density matrix equation can be converted into a generalized Fokker–Planck equation [54].

By the transformation of $\hat{x}, \hat{p}$ to creation and annihilation operators b^+, b by means of

$$\hat{b}^+ = \frac{1}{\sqrt{2\hbar}}(\hat{x} + i\hat{p}) \qquad (32)$$

$$\hat{b} = \frac{1}{\sqrt{2\hbar}}(\hat{x} - i\hat{p}) \qquad (33)$$

an alternative form to (31) is given by

$$P(\beta, \beta^*) = \frac{1}{\pi^2} \int \int_{-\infty}^{\infty} \mathrm{e}^{-i\beta k - i\beta^* l} \cdot \operatorname{tr}(\mathrm{e}^{ik\hat{b}^+ + il\hat{b}}\rho)\mathrm{d}k\mathrm{d}l\,. \qquad (34)$$

Because $\hat{b}^+, \hat{b}$ are noncommuting operators, $[\hat{b}^+, \hat{b}] = 1$, different "quasiprobability" distributions P result, if

$$\mathrm{e}^{ik\hat{b}^+ + il\hat{b}}$$

is replaced by

$$\mathrm{e}^{ik\hat{b}^+}\mathrm{e}^{il\hat{b}} \qquad (35)$$

or

$$\mathrm{e}^{ik\hat{b}}\mathrm{e}^{il\hat{b}^+}\,. \qquad (36)$$

(35) gives rise to the Glauber–Sudarshan representation. For details and references see [54].

Regular Spatial and Spatio-Temporal Patterns

One of the most striking features of nonequilibrium systems in physics, chemistry and biology is their capability of forming (more or less) regular spatial pattern (for explicit examples see below). (There is a rich literature on pattern formation in physics, especially fluids [20,24,92,136], but also semiconductors [125] and nonlinear optics [133], chemistry [28,33,83] and biology [7,95,96,102] and general [69,70,98,104,110,111,115,140]. Furthermore, the patterns exhibit striking similarities in spite of the fact that the individual parts are quite different. The methodology of Synergetics (e. g. [62]) provides us with a basic insight into the causes of such analogies.

Pattern formation is determined by at least three causes:

1. internal mechanism, such as e. g. the interplay between reactions and diffusion in large scale chemical processes,
2. the influence of boundaries,
3. initial conditions.

Concerning 1) and 2) between two (limiting) cases can be distinguished.

1. dimensions of the internally evolving patterns are of the same or larger order as those of the boundaries. Here a strong influence of the boundaries must be expected.

2. dimensions of evolving patterns are small compared to those of the boundaries (boundaries → ∞).

To bring out the essential features we consider that originally for a control parameter value α_0 the system is homogeneous and quiescent. The approach can, however, be extended to a space dependent reference state (which, e. g. resulted from a first bifurcation leading to $q_0 = q_0(x)$) and the cases of a limit cycle or torus. The space may be 1, 2 or three dimensional Euclidian or, e. g., a 2 or 3 sphere.

Infinite Boundaries

We start with 2) infinite boundaries, the medium is homogeneous and isotropic. We assume a continuous transition from the homogeneous to the "bifurcating" state. The evolving patterns are determined by the leading terms in (8) that we call the "mode skeleton"

$$q(x,t) = q_0 + \sum \xi_u(t) v_u(x) \tag{37}$$

and the order parameter Eq. (12). The functions $v_u(x)$ are *the space-dependent part of the* solutions to (4) where L is a differential (or integral) operator which is invariant against translation and rotation. Thus, e. g., L commutes with the displacement operator

$$\Omega_a\colon\ x \to x + a\,, \qquad a \text{ constant vector}\,.$$

Thus $v_u(x)$ can be chosen as eigenfunction to Ω_a,

$$\Omega_a v_u(x) = \Lambda v_u(x) \tag{38}$$

with

$$v_u = \mathrm{e}^{ikx} \tag{39}$$

$$\Lambda = \mathrm{e}^{ika} \tag{40}$$

i. e. plane waves. Which waves must be considered in (37) is determined by λ_u in (6) as well as by the order parameter Eq. (12).

The condition $\operatorname{Re}\lambda_u(k) = 0$ defines $k = k_{\text{crit}}$. As was shown by means of many examples $k \approx k_{\text{crit}} \neq 0$. If the boundaries are finite, such a discrete k must be chosen which comes closest to k_{crit}. If the boundaries tend to infinity, a continuous set k is taken care of by (generalized) Ginzburg–Landau equation (see above). If the boundaries are "narrow" in 1 or 2 dimensions, but large in the remaining dimensions, the wave vector k must be split into k_{II} and $k_\perp$ where k_{II} is practically continuous and $k_\perp$ discrete. Quite often only one $k_\perp$ (the most critical) needs to be considered. This leads to practically 2 (or 1) dimensional patterns connected with k_{II}. In the 2-dimensional case, the modes with $|k_{\text{II}}| = k_{\text{crit.}}$ are degenerate. This degeneracy can be lifted by a weak influence of boundaries (leading to roll patterns), by specific initial condition which (by chance) prefers a specific roll pattern, or by terms in the order parameter-equations that lead to specific combinations, e. g.

$$k_1 + k_2 + k_3 = 0\,, \tag{41}$$

where $k_j, j = 1,2,3$ belong to k_{II}.

This gives rise to the formation of hexagons. This is the case if the leading term of $\tilde{N}$ contains

$$\int v_{k_1} v_{k_2} v_{k_3} \mathrm{d}^2 x \neq 0\,. \tag{42}$$

In three dimensions this mechanism may lead to plane wave fronts stabilizing each other which gives rise to icosaeders, as observed in diatomea.

An important class of spatio-temporal patterns (in 2 dimensions) results when the system utilizes *rotation symmetry.* This can best be explained by the following example:

In many cases of practical interest, N in (1) and thus L in (4) contain the Laplace operator Δ. When written in planar polar coordinates r, ϑ, solutions to (4) are of the general form

$$v \propto \mathrm{e}^{i(m\vartheta - kr - \omega t)} \tag{43}$$

(times a rotation symmetric function $g(r)$) which represents *spirals*. $m = 0$ represents concentric rings, while an integer $m > 0$ represents the number of spiral arms. $\omega = 0$ represents standing spirals, $\omega \neq 0$ rotating spirals.

The mode skeleton (37) is composed of functions of the form (43). Which of the functions (43) appear in (37) depends on the competition Eqs. (12) for order parameters, which may also allow for a super position of counter rotating spirals (such as in the sunflower head). As group theory shows (see below), solutions (43) with different m's belong to different irreducible representations, and do not coexist in (37). This does not exclude the coexistence of differently rotating spirals in *different* regions of space, however.

The above results can be cast into the isomorphy principle:

While the "true" q is represented by (we omit the homogeneous q_0)

$$q = \sum_u \xi_u v_u(x) + \text{enslaved modes, with same symmetry.} \tag{44}$$

and v_u "true modes", its symmetry features can be replaced by a "representative" q':

$$q' = \sum_k \xi_k R_k(x)\,, \tag{45}$$

where R_k represent the "elementary" functions showing the symmetry under consideration. While the material significance and explicit form of q according to (44) may be quite different for different material substrates, q' (45) shows the *same* patterns for different systems.

These results can be deepened by invoking group theory, in which also the effect of the boundaries is taken into account.

Symmetries, Group Theory, Representation Theory, Finite Boundaries

Consider a set of transformations G_j of space variables $x \to x'$ so that

$$G_j q \to q' \tag{46}$$

Example 1 G_j induces the translation

$$x \to x + a \quad \text{so that} \quad G_j q(x) = q(x + a)\,. \tag{47}$$

The transformations must be so that they are compatible with the internal properties of the system (1) and the boundary conditions. Example: when dealing with a problem on a 2-dimensional sphere, the transformed coordinates x must not leave the sphere.

Because of the symmetry of the problem, the transformations G_j form a group defined by

1. existence of unity E such

$$G_j E = G_j \quad \text{for all } j \tag{48}$$

2. the product of two group elements is again an element of the group,

$$G_j G_k = G_l \quad \text{for all } j, k \tag{49}$$

3. existence of an inverse G_j^{-1} for all j so that

$$G_j^{-1} G_j = E\,, \tag{50}$$

4. associative law

$$(G_k G_l) G_j = G_k (G_l G_j) \tag{51}$$

for all group elements.

In the following we first ignore random forces, i. e. we consider (1) with $F \equiv 0$.

$$\dot{q}(x, t) = N(q, \Delta, \alpha)\,. \tag{52}$$

Jointly with the boundary conditions, (52) defines a function space S in which all functions to be considered must lie (i. e. can be represented by linear combinations of a complete set of (vector valued) basic functions of S; example: S is a Hilbert space)

Definition 1 The system is invariant against G_j if for all $f \varepsilon S$

$$G_j N\left(G_j^{-1} f\right) = N(f)\,. \tag{53}$$

Example 2

$$G_j\colon\ x \to x + a\,, \tag{54}$$

$$N(f) = \Delta f + V(x) f + f^2\,. \tag{55}$$

Then

$$G_j{\cdot}N\left(G_j^{-1} f\right) = \Delta G_j^{-1} f(x{+}a) {+} V(x{+}a) G_j^{-1} f(x{+}a) + \left(G_j^{-1} f(x + a)\right)^2 \tag{56}$$

$$= \Delta f(x) + V(x + a) f(x) + f(x)^2 \tag{57}$$

$$\neq N(f) = \Delta f(x) + V(x) f(x) + f(x)^2 \tag{58}$$

unless $V(x + a) = V(x)$. If a in (54) is arbitrary, N is not invariant against (54).

Application of G_j to q in (52) leads to

$$\frac{\mathrm{d}}{\mathrm{d}t}(G_j q) = N(G_j q) \tag{59}$$

or because of (53), (with $f = G_j q$), to

$$\frac{\mathrm{d}}{\mathrm{d}t}(G_j q) = G_j N(q)\,. \tag{60}$$

In the spirit of representation theory of groups the action of G_j on f can be understood as an abstract operation, but also as a matrix acting on the vector f in S- space.

By appropriate transformation of basis of q, and using the representation theory of symmetry groups, all matrices U_j belonging to all group elements j can simultaneously be decomposed into "irreducible" representations so that (in the example of 3 irreducible representations)

$$U_j = \begin{pmatrix} \square & \bigcirc & \bigcirc \\ \bigcirc & \square & \bigcirc \\ \bigcirc & \bigcirc & \square \end{pmatrix} \tag{61}$$

Each box □ is a matrix $U_j^{(k)}$ with dimension Dk, so that

$$D1 + D2 + \cdots + Dk = \text{dimension } U_j \,.$$

Example 3 Rotation group applied to 2-sphere (e. g. earth surface). Basis functions are spherical harmonics Y_m^l with "quantum numbers" l, m. Subspace l fixed, $m = 0, \ldots, l-1$. As a consequence, the mode skeleton reduces to (q_0 dropped)

$$q^l = \sum_m \xi_m(t) Y_m^l \,. \tag{62}$$

There is no coupling between different ls, which implies a low dimensional dynamics of ξ_m.

Generally, the original function space S is decomposed into subspaces forming the basis of each irreducible representation. This implies a symmetry reduction beyond bifurcation point, compared to the situation below bifurcation point, where

$$G_j q = q \quad \text{for all } j \,, \tag{63}$$

i. e. q fully symmetric under G.

In our example beyond the bifurcation point q is given by q^l where Y_m^l transforms according to the subgroup G^l, which leaves the space spanned by Y_m^l invariant. If, however, group elements not belonging to G^l are applied to q^l, this space is left. In other words, q^l is connected with a lower symmetry than q (63). By bifurcations, the symmetry of q is lowered and one speaks of "symmetry breaking instability". If fluctuating forces in (1), i. e. in (52) are taken into account, the full symmetry can be restored (under specific conditions on the fluctuating forces).

While group theory has found important and widespread applications to quantum theory, it is less frequently used in problems of Synergetics, though there it may lead to deep insights as pointed out above. (For an in-depth approach see [42,43,120].)

On top of, or jointly with, regular patterns, a variety of defects as well as boundaries between different patterns may occur (cf. contribution by Pismen, this volume and [110,111]).

A Further Mathematical Tool: Shannon Information and the Maximum (Information) Entropy Principle

While evolution equations are the backbone of Synergetics, also other tools are invoked to deal with complex systems. Such a tool is Shannon information [129] which is defined by

$$i = -\sum_j p_j \log_2 p_j \tag{64}$$

where p_j is the relative frequency of the event j or, in a different interpretation, the probability of finding the realization j in an experiment. The maximum (information) entropy principle as formulated by Jaynes [73,74], for an earlier proposal see [27]), allows one to make unbiased guesses on systems on which only incomplete data are known by maximizing the informations, i. e. (64) = max! or = extremum! under given constraints.

A simple example is provided by a gas composed of N particles, where the total kinetic energy $\mathrm{E}_{\text{kin}}^{\text{tot}}$ is fixed. Denoting the kinetic energy of a particle with mass m and velocity v_i by $f_i = (m/2)v_i^2$, the mean kinetic energy per particle is

$$\sum_i p_i f_i = \mathrm{E}_{\text{kin}}^{\text{tot}}/N \tag{65}$$

To fix p_i, (64) must be maximized under the normalization condition

$$\sum_i p_i = 1 \tag{66}$$

and the constraint (65).

Using Lagrange multipliers, λ, λ_1, the result reads

$$p_i = \exp\left(-\lambda - \lambda_1 m v_i^2/2\right) \tag{67}$$

i. e. the Maxwell–Boltzmann distribution function. Also relations between the Lagrange multipliers λ, λ_1 can be established which, evidently, have fundamental thermodynamic significance.

This approach has been extended to the treatment of nonequilibrium phase transitions, i. e. determination of order parameters, enslaved modes and emerging patterns [60]. The crucial idea consists in the proper choice of constraints, as which the moments of the variables q_i are chosen:

$< \ldots >$ means average over the joint distribution function $f(q_1, q_2, \ldots, q_n)$ which replaces p_j and the vector $(q_1, \ldots, q_N)$ replaces j. The variables q_j may be discrete or continuous.

$$f_i =< q_i >, \quad i = 1, 2, \ldots, N \,. \tag{68}$$

$$f_{ij} =< q_i q_j > \,. \tag{69}$$

$$f_{ijkl} =< q_i q_j q_k q_l >, \quad i, j, k, l = 1, 2, \ldots, N \,. \tag{70}$$

The resulting distribution function is given by

$$q = \exp V(\lambda, q) \tag{71}$$

with

$$V(\lambda, q) = \lambda + \sum_i \lambda_i q_i + \cdots + \sum_{ijkl} \lambda_{ijkl} q_i q_j q_k q_l \,. \quad (72)$$

(71) is a starting point to make contact with the Landau or Ginzburg–Landau theory of phase transitions [86], and to guessing Fokker–Planck equations. The approach allows one to calculate the efficiency of self-organizing systems close to their instability points.

The method has been extended to the "unbiased modeling" of stochastic processes: how to guess path integrals, Fokker–Planck equations and Langevin-Îto equations [60]. The central quantity to be searched for is the probability density P_n of paths.

Let $q(t)$ be the state vector $q = (q_1, \ldots, q_N)$ at time t, then

$$P_n(t_n, t_{n-1}, \ldots, t_0) = P_n\left(q(t_n), t_n; q(t_{n-1}), t_{n-1}; \ldots ; q(t_0), t_0\right) , \quad t_n > t_{n-1} > \ldots > t_0 \,. \quad (73)$$

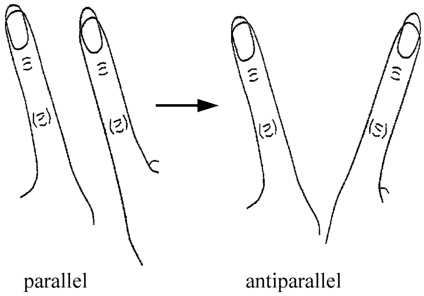
This task is simplified if the Markov hypothesis on the process holds, i. e.

$$P_n(t_n, t_{n-1}, \ldots, t_0) = \hat{P}\left(q(t_n), t_n \middle| q(t_{n-1}) t_{n-1}\right) \cdot P_{n-1} \quad (74)$$

where $\hat{P}$ is the transition probability so that only transition probabilities between subsequent states (with $\Delta t \to 0$) must be guessed in addition to P_0. In the frame of the present approach, this task is fulfilled by use of the maximum information principle. The constraints to be used are essentially conditional first order moments and two-time correlation functions of the state vectors $q(t)$, $q(t')$.

Phenomenological Synergetics

In many fields of science, including medicine, the microscopic variables and their dynamics are not well-known or not known at all. Nevertheless, in quite a number of cases, namely where dramatic macroscopic changes of the system's behavior take place, general insights, gained by Synergetics, can be invoked. A paradigm for this procedure is the modeling of Kelso's finger experiments [77,78] (Fig. 3). He instructed subjects to move their index fingers in parallel which was accordingly performed. However, when the speed of the fingers was increased, the parallel movement was replaced by a symmetric movement quite involuntarily and spontaneously. In other words, a transition from a parallel to an anti-parallel phase takes place. In terms of Synergetics, the interpretation is simple: the control parameter consists in the prescribed frequency ω of the finger movement, whereas the macroscopic quantity, i. e. the order parameter that changes dramatically is provided by the relative phase of the two index fingers. According to the experience made in Synergetics, the order parameter, here called ϕ obeys a typical order parameter equations of the form [64]



Synergetics: Basic Concepts, Figure 3
Transition between finger movements from parallel to symmetric in Kelso's experiment [64]

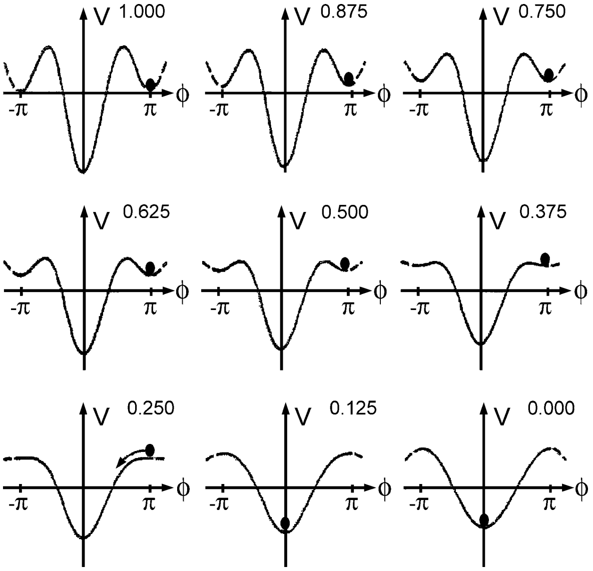
$$\dot{\phi} = -\frac{\partial V}{\partial \phi} + F(t) \,, \quad (75)$$

where $V(\phi, \omega)$is a potential function and F a fluctuating force. When the control parameter ω is changed, the potential runs through a series of forms as depicted in Fig. 4. As was shown in detail, at a critical value of ω, the transition from one potential minimum to another one occurs, as related to the change of the kind of finger movement. The mathematical analysis shows hysteresis, critical slowing down and critical fluctuations [59] which reject the idea that the brain acts like a computer via a motor program but rather via self-organization.

Another application is made by the Synergetic computer [61] (Figs. 5, 6), where to each pattern to be recognized a specific order parameter is attached. Pattern recognition is then achieved via a competition between order parameters. The competition equations are given by

$$\dot{\xi}_k = \frac{\partial V}{\partial \xi_k} V(\xi_1, \ldots, \xi_M) = -\frac{1}{2} \sum_k \lambda_k \xi_k^2 + \beta \sum_{k,k'} \xi_k^2 \xi_{k'}^2 - C \sum_k \xi_k^4 \,. \quad (76)$$

This approach may serve also for modeling of brain functions: both recognition as well as movements are governed by the establishing of order parameters which may wander from one quasi attractor to another one. Quasi attractors are defined as attractors that vanish after the task has been accomplished, e. g. after a pattern has been recognized or movement performed.



Synergetics: Basic Concepts, Figure 4
Sequence of potential curves of the Haken–Kelso–Bunz model of Kelso's experiment [64]

Based on the concept of order parameters, a learning procedure for Synergetic computers has been developed [61]. Here the number of patterns to be recognized is prescribed and then a special functional must be minimized. In the case of the Synergetic computer, it is possible to make contact between the microscopic and the mesoscopic description, i. e. the microscopic variables are pixel values q_j, j pixel index, whereas the mesoscopic (or macroscopic) quantities are the order parameters ξ_k.

The relation between ξ_k, q_j is given by

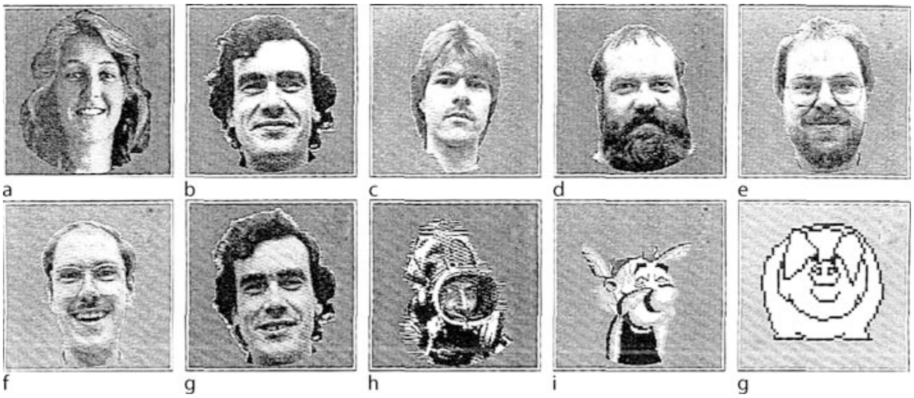
$$\xi_k = \sum_j v_j^{k+} q_j \,, \tag{77}$$

where v_j^{k+} are adjoint prototype patterns, with k pattern index, j pixel index.

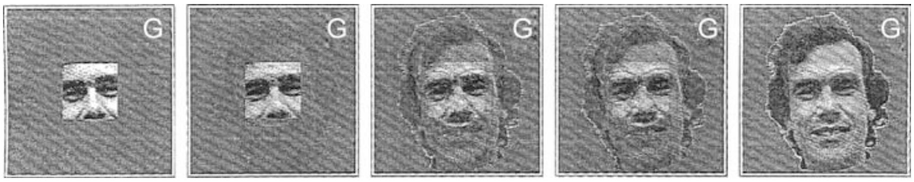
The relation between prototype patterns v_j^k and their adjoints is given by

$$\sum_j v_j^{k+} v_j^{k'} = \delta_{kk'} \tag{78}$$

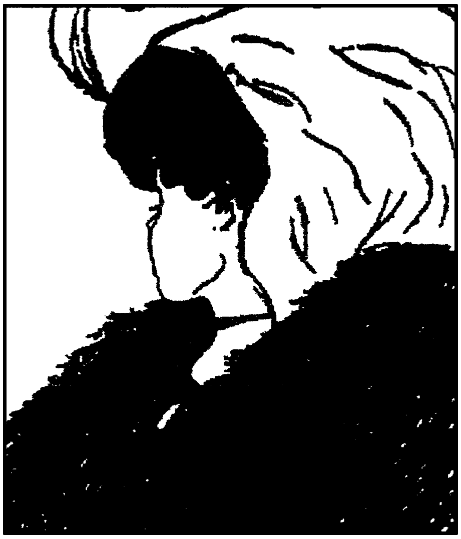
At the phenomenological level the order parameter concept allows us to interpret and model complex movement patterns, e. g. learning to ride on a pedalo [59]. In the experiments, LED's are fixed at the joints of the subject and their positions measured which gives rise to a series of time-dependent tracks. Then, in a first step, a principle component analysis is performed, in the next step, by means of a variational principle, the best fit is searched in



Synergetics: Basic Concepts, Figure 5
Recognition of faces by the synergetic computer: stored or learned prototype patterns [61]



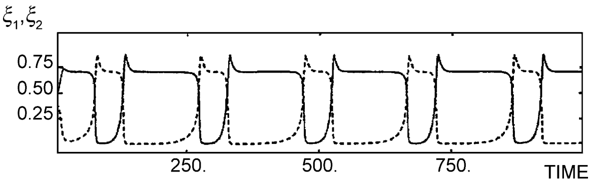
Synergetics: Basic Concepts, Figure 6
Pattern recognition by the synergetic computer: recognition of a specific face of which initially only a subset of pixels is presented [61]



Synergetics: Basic Concepts, Figure 7
Example of an ambivalent figure: young / or old woman? [34]

terms of order parameters and their equations of motion, in order to mimic the actual tracks. While in the learning phase several order parameters are needed, at the end the whole movement is governed by a rather simple equation for a complex order parameter.

During the development of Synergetics it turned out that there are strong relations to gestalt theory [85] as well as to psycho physics. A typical example is provided by ambivalent figures where (Fig. 7) [34] shows an example. An observer may either perceive a young woman or an old woman, but not both simultaneously, rather the perception switches between these two percepts. In the mathematical modeling to each percept an order parameter is attached [61], which obeys the typical equations of Synergetics. The control parameter invoked here is attention. According to an early suggestion by Wolfgang Köhler [85], when a pattern is recognized, the corresponding attention fades away. This has been modeled mathematically based on a competition dynamics between two order parameters, when the control parameter (attention) of one pattern fades away, the other pattern gets the possibility of being perceived. Then in the next step the corresponding attention parameter fades away and the first pattern may re-appear (Fig. 8) [61]. This model describes details of the observed phenomena, such as the dependence of the duration of the perception of one face as compared to that of the other face, dependent on the bias which face is recognized first. Also, one may distinguish between slow, medium and fast observers, depending on the individual parameters.



Synergetics: Basic Concepts, Figure 8
Order parameter oscillations belonging to the recognition young woman / old woman with bias towards the young woman [59]

Quite generally, order parameters may have properties of gestalt in the sense that they are invariant against size, orientation and perception of objects in space.

In medicine, a syndrome has the characteristic features of an order parameter. On the one hand it is generated by the co-operation, or at least by the simultaneous presence of specific features, on the other hand once the syndrome (order parameter) is established, it acts on the individual parts of the system, where the slaving principle induces specific phenomena at the level of individual parts. Clearly, the concept of circular causality plays an important role here. It shows that the syndrome, at least in general, can not be cured by curing an individual symptom, but rather by curing a decisive majority of individual causes.

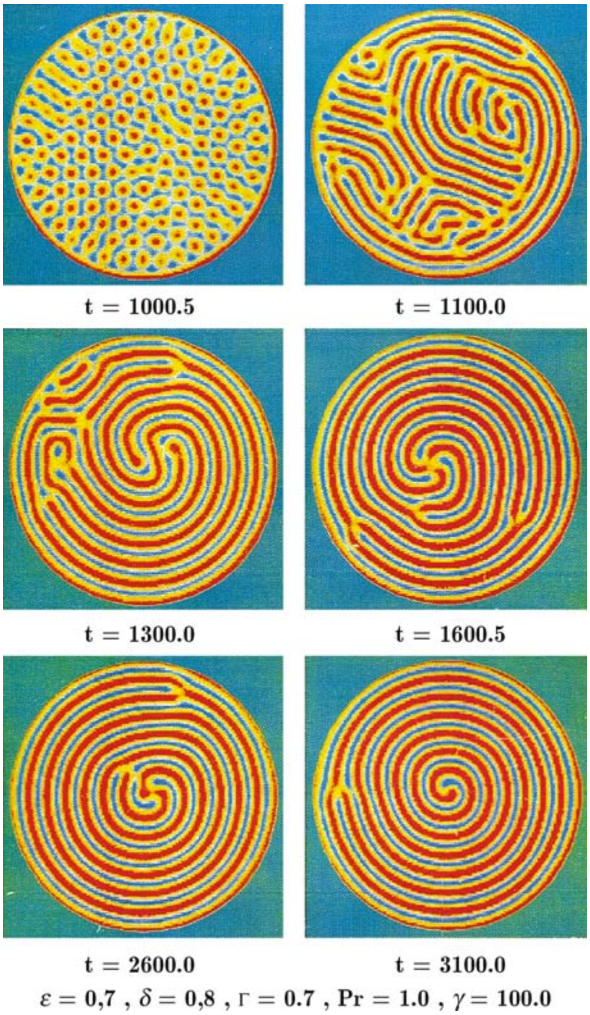
Semantic Synergetics

In soft sciences, but also in medicine and other fields, a mathematical modeling, even at the level of order parameters may not be possible. Nevertheless, Synergetics may provide us with qualitative insights into basic mechanisms. In psychology and psychiatry [122], quite often specific mental states can be ascribed to a patient. For instance in bipolar patients a depressive phase or a manic phase may appear or in depressive patients a normal phase and a depressive phase. Another example is provided by patients with a compulsory action. In the spirit of Synergetics, as a theory of indirect control, one may ask, whether there are appropriate control parameters by means of which the behavior of a person can be changed. Let the two states be represented by the positions of a ball in a landscape with two valleys. In this situation, direct control means to push the ball from the unwanted position to the wanted. Indirect control means to lower the potential hill between the two valleys so that the wanted transition may occur via self-organization. This may happen through interventions used in cognitive psychology, a change of environmental conditions, or/and by specific medication. The central issue here is that the patient is not directly influenced, e. g. by saying you must do this or that, but rather by a soft changing of his/her point of view. A number of successes have been reported about this method which is, to some extent, well known in psychiatry, but finds here a scientific theoretical basis. For more details see the article by G. Schiepek and V. Perlitz, this section, and in a somewhat related form [66].

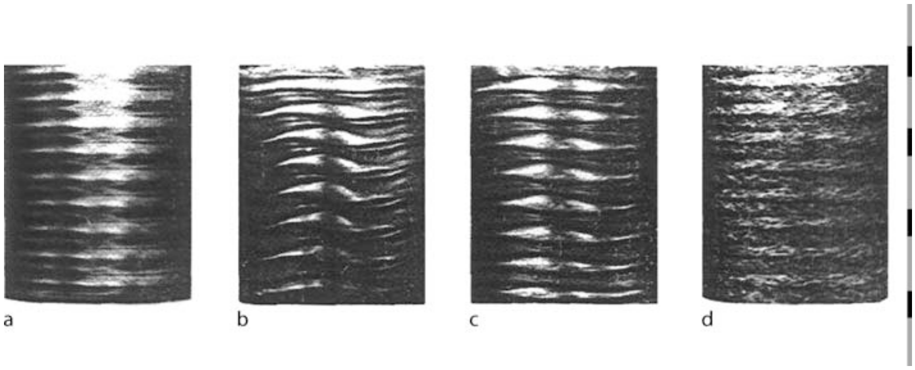
Some Selected Examples

The study of nonlinear, self-sustained oscillations [1,2,13] be it in radio-engineering, mechanics or other fields, has a long tradition. In the context of bifurcation theory, their origin was unearthed by Hopf [67,68].

Nonlinear optics [99] and, when quantum effects are important, quantum optics [57,97,123,142] provide us with a wealth of phenomena, in particular of the formation of coherent oscillations. A device, closely related to the laser, is the parametric oscillator [44], in which, within a nonlinear crystal, incoming pumplight is split into a signal and an idler. Then, similar to the laser light, the signal light becomes amplified, and its generation can be described as that of a nonlinear quantum-mechanical oscillator. Fluid dynamics is rich of pattern formations (including chaos) [12,16,17,18,31,41,89,92,105,115, 118,127,135,136], to mention just a few. In a fluid heated uniformly from below, with increasing temperature difference, several instabilities may occur for instance giving rise to stationary patterns, such as rolls, hexagons (Fig. 9) or squares. In the next step the rolls may start to show oscillations, and still more complex patterns may occur (Fig. 3). In the case of the Taylor instability [137], a liquid is placed in between two coaxial cylinders, where the outer one is rotating. With increasing rotation speed, a hierarchy of instabilities is reached, first the formation of roles, then oscillating rolls at one frequency, then oscillation of rolls at two frequencies, and finally weak turbulence, i. e. chaos occurs (Fig. 10) [31,93]. Important phenomena are the establishing of boundaries and of defects as described in the article by Pismen [110,111] and other articles of this Encyclopedia. A rich variety of pattern formation may occur in semiconductors [125], where electrons and holes as well as currents form specific spatio-temporal patterns. In meteorology, atmospheric convection patterns and other instabilities are treated [38]. In chemistry, oscillations and large scale patterns arise by means of the interplay of chemical reactions and diffusions [9,15,28,32,33,149], e. g. concentric ring patterns, each starting from a center, which then annihilate each other when colliding. An important class is provided by spiral patterns which may have one to several arms (Fig. 11). In biology, specific models on morphogenesis were treated, such as the formation of stripe or spot patterns on animal furs or skins of fish (Fig. 12) or still more complicated patterns on sea shells [39,62,95,96,102]. The basic idea which can be traced back to Turing [139] is this: originally unspecialized cells produce activator and inhibitor molecules which by reaction and diffusion form a prepattern, a morphogenetic field [147]. At positions of high activator concentration, genes are switched on which then leads to cell differention producing e. g. pigments. In aggregating slime mold, spiral or concentric ring patterns are observed [14,37]. Mathematical models on prebiotic evolution [26] study the competition between species of



Synergetics: Basic Concepts, Figure 9
Model calculation of the motion of a fluid in a circular pan uniformly heated from below (after [29]). *Upper left corner*: above a critical temperature difference between lower and upper surface of the fluid layer, a hexagonal pattern appears. If the boundary is also heated uniformly, a transition to the spiral pattern with one or several arms can be found (*lower right corner*)



Synergetics: Basic Concepts, Figure 10
Pattern hierarchy in the Taylor–Couette instability. A fluid in between two vertical coaxial cylinders of which the outer one rotates, shows no macroscopic movement pattern, if the movement of the outer cylinder is slow. When the rotation speed is increased, first a role pattern appears in which the fluid moves outwards at one height, and then inwards at another height. This movement pattern is periodic with respect to height [137]. At a further critical rotation speed, the pattern shows oscillations which at a further speed transform into a motion with two frequencies until eventually chaotic motion appears. The experiments were done by [31], the modeling was done for the first transition (homogeneous to roles) and especially the second transition (roles to oscillating roles) by [93]

Synergetics: Basic Concepts, Figure 11
Belousov–Shabotinsky reaction: the occurrence of spirals (courtesy A.T. Winfree). They may show one to several arms. The centers of the spirals may occur at different positions. Spirals hitting each other, annihilate each other

Synergetics: Basic Concepts, Figure 12
Stripe pattern on a tropical fish

biomolecules and the "survival" of the fittest, where pronounced analogies with the dynamics of laser photons can be unearthed, fully in line with Synergetics [62]. In the understanding of brain function, for instance, steering of movements, pattern recognition or decision making, the reduction of degrees of freedom of the numerous neurons to few order parameters is central [59].

The concepts and principles of Synergetics shed new light on important relationships in economy, such as cooperation and competition between companies, the important role of indirect steering by means of control parameters, such as taxes, interest rates. It can be shown, that a fusion of companies does not necessarily lead to so called synergy effects, but rather critically depends on initial conditions and details of the cooperation between the previously separated firms. Important insights are also gained into fundamental processes of climatology, as well as in ecology such as the by now well-known and publicly discussed effects that even small concentrations of chemicals in the atmosphere can change the climate dramatically. The same is true for lakes, in which beyond a critical pollution, fish population dies out entirely.

In this way, the numerous examples collected in the field of Synergetics, provide not only scientists but also the public with impressive examples of dramatic changes (instabilities) provoked by even a slight change of control parameters. Clearly, an important research subject of Synergetics is a detailed study of which control parameters are critical and to which control parameters a system is rather insensitive. Sociology is an important field for the application of stochastic models [8]. In particular, basic concepts of Synergetics have proven useful in the developing field of sociodynamics, where e. g. phase transition-like phenomena may occur [143].

History and Relations to Other Fields

The term Synergetics was coined by H. Haken in 1969 in a lecture at University of Stuttgart. A first description of the goals of this field was given by H. Haken and R. Graham in 1971 [63] where the unifying role of the concept of order parameters is outlined. A relationship exists to the general system theory due to von Bertalanffi [10], which also aims at the exploration of analogies between different systems, but on the level of the individual elements rather than on the level of order parameters. Von Bertalanffi coined the term flux equilibrium (Fließgleichgewicht) in order to characterize homeostasis in active systems [11]. A general mathematical frame for Synergetics is provided by dynamic systems theory (see, for instance, [49]) which, however, in the traditional approach ignores stochastic processes (mainly chance events) which are also of great relevance for Synergetics. Here the theory of Markov processes with their typical equations, such as Langevin equations, Fokker–Planck equations, Chapman–Kolmogorov equations, the Kramers–Moyal expansion etc. is important (see for instance [134] and ▶ Linear and Non-linear Fokker–Planck Equations by T. Frank).

A basic feature of Synergetics consists in dealing with nonlinearities in complex systems and studying, mainly quantitatively, qualitative changes at macroscopic scales. Qualitative changes of systems at macroscopic levels are studied also by catastrophe theory [5,138], which may be interpreted as a study of the surfaces of equilibrium points of few order parameters, where different cases are classified according to the (low) number of control and order parameters. Chaos theory studies the mostly irregular dynamics of deterministic low dimensional continuous [89,106,118,132] or discrete dynamic systems [23,30,48,94,130], where the behavior is mainly characterized by so called Lyapounov exponents, various kinds of fractal dimensions and chaotic attractors. The slaving principle of Synergetics provides a basis for an application of chaos theory to multi-component systems in that Synergetics shows the possibility of reducing the degrees of freedom. Synergetics shares some of its topics with singularity theory [4,42,43], which applies to bifurcation points and their surrounding. Another point of contact is bifurcation theory (see the quotations in previous chapters), in which the branching of solutions of the dynamic system close to instability points is studied. The term dissipative structure was coined by Prigogine [40] to characterize evolving structures in systems away from thermal equilibrium where as in all such non-equilibrium systems dissipation occurs. A typical example is that of the convection instability. Prigogine tried to base his approach on thermodynamics, introducing concepts of entropy production and excess entropy production. As we now know, these concepts are, however, insufficient to deal with structure formation in such systems [87]. Based on a fundamental idea of A. Turing [139], Prigogine and Nicolis [114], see also [108], treated macroscopic pattern formation in a specific chemical reaction model. For more recent work see [107].

Because of the fundamental importance of thermodynamics, we elucidate its relationship to Synergetics more closely.

Thermodynamics (see for instance [19]) deals with systems in and out of thermal equilibrium. A central concept is entropy. In a closed system, it tends to its maximum value. Thermal equilibrium is characterized by the equipartition theorem: each degree of freedom has an average energy of $1/2\ kT$, $k =$ Boltzmann constant, T absolute temperature. This may refer e. g. to gas atoms as well as to collective excitations in crystals. These systems are in thermal equilibrium with their surrounding (heatbaths, reservoirs).

Irreversible thermodynamics [51] treats systems which are not in thermal equilibrium but close to it. It mainly deals with transport and relaxation processes. A central concept is entropy production.

In the domains of physics, chemistry, biology, Synergetics deals with systems far from (thermal) equilibrium . This state is caused and maintained by an in- and outflow of matter, energy and / or information. This is achieved by a coupling of the “proper system” to heat baths (reservoirs) at different temperatures. The former concepts of thermodynamics, in particular the first and second law, are still valid for the total system (“proper” plus reservoirs), but no more sufficient to deal with the kinetics of the proper system. Now the central concept is growth and decay rates. In systems far from thermal equilibrium, collective modes are formed. One or several of them compete best for the external supply of matter, energy, information and grow at the expense of all other degrees of freedom (or modes). Thus the equipartion theorem is no more valid. In general, the behavior of the system is governed by few degrees of freedom (order parameters). Inci-

Synergetics: Basic Concepts, Scheme 1
Quantum optics, example laser (after [54])

dentally, this "growth and competition" principle applies to a great variety of fields out of physics, chemistry and biology, where "modes" may not only be special physical structures, but may mean behavioral patterns, special functions etc. Quite often, a "mode" is initiated by a chance event (fluctuation). Clearly, a generalized Darwinian principle can be seen: The interplay between *mutations* (microscopic chance events) and *selection* (competition between mascropic modes) leads to macroscopic patterns (structures) in the widest sense of the word.

In present days research, a new name is spreading, namely complexity or complexity theory. There seems to be no precise definition of this field available in the scientific community. Of what is known so far, we may conclude that this field has strong ties to the original field of Synergetics in that it searches also for general principles but, in addition, it allows the collection or accumulation of knowledge on all kinds of complex systems, as is witnessed in the excellent Complexity Digest, weekly edited by Gottfried Mayer. What "complexity" eventually might mean is reflected by the present encyclopedia.

Future Directions

Synergetics is surely not a closed scientific discipline but quite open to further research. On the one hand we may think of further applications of the principles of Synergetics that have been hitherto elaborated on, such as order parameters etc. Here a wide field of application is provided by robotics, construction of prostheses, automatic steering of cars etc. On the other hand, new ideas to endow systems with self-organizing properties are needed, e. g. groups of mobile agents for the execution of specific tasks. First steps have been done for instance by Kornienko [81].

Bibliography

Basically, the individual volumes of the Springer Series in Synergetics and selected volumes of the Springer Series on Complexity provide further information. Here, because of lack of space, only a few basic papers can be quoted.

The number of books, reviews and original papers on the topic of the present article is enormous. I have tried to achieve a fair balance between original contributions and reviews / books. Nevertheless, my selection must remain – to some extent – arbitrary and incomplete.

Synergetics, Introduction to

HERMANN HAKEN
Institut für Theoretische Physik, Universität Stuttgart,
Stuttgart, Germany

Synergetics (Greek **synergeon**: science of cooperation) is an interdisciplinary field of research that deals with the behavior of complex systems, i. e. systems composed of many individual parts that in general may produce complex behavior. The systems considered may belong to a great variety of fields, ranging from natural sciences with physics, chemistry, biology, through medicine and psychology to economy, ecology, management theory etc. The central topic of the synergetics enterprise is this: By means of their cooperation, the individual parts of a system can spontaneously produce structures, i. e. special arrangements between the elements or specially coordinated behavior without specific steering from the outside, i. e. without the interference of an external agent. The physical systems, studied by synergetics, are away from thermal equilibrium. The structures may be spatial patterns, be it regular or irregular, temporal patterns, i. e. all kinds of self-sustained oscillations, ranging from harmonic oscillations to chaotic behavior, spatio-temporal patterns, or functional patterns such as produced, for instance, by the brain of humans or animals, giving rise to specific behavior. The basic question synergetics asks is this: Are there general principles that govern the self-organization of systems, irrespective of the nature of the individual parts? When this question was posed some 40 years ago by H. Haken, the problem put forward seemed to be absurd in view of the great variety of possible elements. However, this research program has turned out to be quite successful as witnessed, for instance by the Springer Series in Synergetics, as well as by an independent book series in Russian. The price to be paid for approaching this goal is as follows:

1. Focus the study on those situations where the **macroscopic state** of a system changes **qualitatively**.
2. Start from comparatively simple systems that are provided either by systems in physics (e. g. lasers or fluids) or model systems dealing with self-organization processes in a variety of fields, such as biology.

As has become evident over the past few decades, self-organization phenomena occur in a vast variety of fields whose presentation actually would fill a whole encyclopedia, which would have led to an encyclopedia within an encyclopedia. Indeed the reader him- or herself may find numerous examples in his/her own field of research. In view of this situation, I felt it would be wise to present to the reader a few basic concepts and only a few prototypical examples. It is, indeed, an outstanding fact that few concepts allow us to cover a great variety of self-organization phenomena from a unifying point of view. Among these concepts are stability, instability, control parameters, order parameters and the slaving principle. Future research will have to add more concepts as has already happened, for instance, in chaos theory.

As the reader will note, from the theoretical point of view, synergetics has become a meeting place between bifurcation theory and mathematical theories related to it, the theory of stochastic processes, and phase transition theory, actually in the sense of the Landau theory. The mathematical tools employed are generalized Langevin equations and the Fokker–Planck equation, and to some extent also the density matrix equation. In physics, it has become possible to start from first principles. For instance in quantum optics, based on Heisenberg equations of motion for operators, the coherence properties of laser light (and other non-linear optical devices) were derived in every detail (its explicit presentation would require, however, a whole handbook article, so that the reader is referred to the original literature). Fluid dynamics was chosen as a highly illustrative and prototypical example of pattern formation in systems away from thermal equilibrium. When a fluid is energetically excited, with an increasing degree of excitation it may run through a hierarchy of spatio-temporal patterns. At comparatively low excitation levels, well defined patterns evolve. While regular patterns stand in the foreground of the article ► Fluid Dynamics, Pattern Formation by Bestehorn, the article by Pismen ► Patterns and Interfaces in Dissipative Dynamics emphasizes defects and interfaces. At higher excitation levels, we reach the field of turbulence, which even after the ground-breaking work by Kolmogorov is still a hot subject of research. Important steps are done here, e. g. by the study of the dynamics of vortices. The work by Friedrich and Peinke, authors of the article ► Fluid Dynamics, Turbulence comprises also the Fokker–Planck equation approach. Actually, in the introductory article ► Synergetics: Basic Concepts by Haken, a method using the concept of information (entropy) is outlined how to derive a Fokker–Planck equation from measured data. Friedrich (private communication) and Peinke found a more direct access, the results of which are briefly outlined in the article by Friedrich and Peinke.

A quite modern line of research on complex systems follows up the method of the Fokker–Planck equation and especially of **non-linear** Fokker–Planck equations. This will be outlined in the article ► Linear and Non-linear Fokker–Planck Equations by Frank.

So far, all these articles deal with "hard" science, especially physics. As it has turned out over past decades, the general concepts of synergetics have great potentialities in fields often called "soft" science such as movement science, medicine, and even psychology and psychiatry. Actually, as the following articles will show, basic concepts of synergetics help to convert soft science into hard science. The article by Fuchs and Kelso ► Movement Coordination deals with movements of humans (and animals). But though these "systems" are highly complex, large classes of transitions between movement coordination can be theoretically and experimentally treated in great detail, even of a prototypical character.

While these approaches might be called "macroscopic", the article by Tass, Popovych and Hauptmann ► Brain Pacemaker penetrates into the microscopic level of brain functions, namely by modeling the collective behavior of neurons and their reactions to external interventions. This paper is remarkable, because it shows a new aspect of the research on coupled nonlinear oscillators. Whereas so far the problem of how such systems synchronize, was in the foreground of research, now for medical reasons, namely to fight Parkinsons's disease, the problem arises how to desynchronize such a system by appropriate interventions.

The mathematical theory of synergetics or perhaps in a wider sense dynamical systems theory with concepts such as attractors, allows one to cast earlier concepts developed by Gestalt theory into clear-cut mathematical models. The order parameters just play the role of Gestalt. Synergetics may be considered as a theory of indirect control of systems, in that it provides psychiatrists with insights for how to intervene with their clients. A comprehensive article, dealing with these aspects, is given in ► Self-Organization in Clinical Psychology by Schiepek and Perlitz. This article shows how methods of mathematical analysis are penetrating more and more into the field of psychiatry, and allowing doctors to monitor the mental and behavioral state of a patient.

In conclusion, in particular with respect to biological systems (but not exclusively), the following remarks are in order:

1. While in physical systems, at least those considered in the article on synergetics, the control parameters are fixed from the outside, in biological systems the control parameters are in general produced by the system itself. They are the slowly varying variables in this case. When their dynamics is admitted, specific phenomena may occur, such as the recognition of ambivalent figures (switching between two or several percepts).
2. In biological and some physical processes, pattern formation (morphogenesis) is a two- or multi-step process. In the first step **dynamic structures** are formed. In a second step these dynamic patterns are transformed into solid patterns. A nice example is provided by radiolarians in which eventually dynamic concentration

patterns of chemicals are transferred into skeletons by means of calcification. The exploration of such two- or multi-step processes is, as it seems, just at its beginning.

In the article ► Intentionality: A Naturalization Proposal on the Basis of Complex Dynamical Systems, W. Tschacher shows how mental processes can be linked to material processes where he tackles the longstanding problem of intentionality and relates it to a gradient dynamics which can be formalized by concepts of synergetics.

Last but not least, Synergetics as a theory dealing with systems composed of many individual parts deals with the interrelation between human individuals and their ability to form specific social groups, viewed as a process of self-organization. An outstanding example is provided by Juval Portugali's article ► Self-Organization and the City.

Article Outline

Glossary

Behavior mode The traditional meaning of the term is the qualitative nature of the observed system behavior, such as damped or expanding oscillations, overshoot and collapse, exponential growth or adjustment to equilibrium, or limit cycles. In linear systems theory, the term has a more specific meaning, cf. the explanation for eigenvalues.

Bode plot (phase and gain plot) A tool used in classical control theory to characterize the frequency response, i. e., the amplification A and phase shift ϕ in the system output variable of interest $x(t) = A \sin(\omega t + \phi)$ compared to the input variable $u(t) = \sin(\omega t)$, as a function of the frequency ω of the input.

Chaos A type of behavior exhibited by nonlinear systems that appears to be approximately periodic but with a seemingly random element. A hallmark of chaotic behavior is that it is sensitive to initial conditions.

Dominant structure A general term for the feedback loops (or possibly external driving forces) that are "most important" in generating a behavior pattern of interest. In nonlinear models, particularly single-transient models, there is frequently a shift in structural dominance, i. e. in the strength and significance of certain feedback loops.

Dynamic decomposition weights (DDW) An application of Eigenvector Elasticity Analysis (EVA) that focuses on how parameter changes influence the relative weights (DDW's) of the system behavior modes in a particular variable.

Eigenvalue An eigenvalue for a square matrix $\boldsymbol{A}$ is a value λ for which the equation $\boldsymbol{Ar} = \lambda \boldsymbol{r}$ has a non-zero solution $\boldsymbol{r} \neq \boldsymbol{0}$. The column vector $\boldsymbol{r}$ is called the (right) eigenvector corresponding to the eigenvalue λ. The eigenvalues and eigenvectors determine the behavior modes (components) in the solution to the linear dynamical system $\dot{\boldsymbol{x}} = \boldsymbol{Ax}$. A real eigenvalue λ leads to an exponential behavior mode $\exp(\lambda t)$ while a complex eigenvalue $\lambda = \tau \pm i\omega$ leads to oscillatory behavior modes $\exp(\tau\, t) \sin(\omega t + \phi)$. The eigenvectors determine the weight, or the degree to which a particular behavior mode is expressed in a particular system variable.

Eigenvalue elasticity analysis (EEA) A method of analyzing the significance of a structural element, say a loop or a link in the model with a gain g, in terms of its marginal effect upon the eigenvalues λ of the system. There are several such measures, such as the *influence measure* $\partial\lambda/\partial g \cdot g$, the *elasticity* $\partial\lambda/\partial g \cdot (g/\lambda)$, or, in the case of complex-valued eigenvalues, the effect upon the damping ratio, natural frequency, damping time, etc., as illustrated in Fig. 7. See also *Loop Eigenvalue Elasticity Analysis (LEEA)*.

Eigenvector See explanation for *Eigenvalue*.

Eigenvector elasticity analysis (EVA) A complement to Eigenvalue Elasticity Analysis (EEA) that looks explicitly at the expression or relative weight of each behavior mode in each system variable. These weights are related to the eigenvectors of the system matrix.

Frequency domain A term used to describe the analysis of signals with respect to frequency. While a time domain graph shows the behavior of the signal over time, the frequency domain graphs shows how much of the signalvariance lies within each given frequency band.

Independent loop set (ILS) Although the number of feedback loops in a model can be very large (theoretically astronomically large), there is a much smaller *independent loop set* that can be considered independent structural elements. For a strongly connected system (where any pair of variables are connected via causal chain in both directions) with N links and n variables, there are exactly $N - n + 1$ independent loops. Simple algorithms exist for constructing independent loop sets, in particular *Shortest Independent Loop Sets (SILS)*. See also explanation for *Loop Eigenvalue Elasticity Analysis (LEEA)*.

Linear dynamical system A system where the rates $\dot{\boldsymbol{x}} = (\mathrm{d}x_1/\mathrm{d}t, \ldots, \mathrm{d}x_n/\mathrm{d}t)$ are a linear function of the state variables $\boldsymbol{x} = (x_1, \ldots, x_n)$ and exogenous or control variables $\boldsymbol{u} = \left(u_1, \ldots, u_p\right)$, expressed by the equation $\dot{\boldsymbol{x}} = \boldsymbol{Ax} + \boldsymbol{Bu}$ where $\boldsymbol{A}$ is an $n \times n$ matrix and $\boldsymbol{B}$ is an $n \times p$ matrix. Unlike nonlinear systems of the general form $\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{u})$, linear systems have analytical solutions based on the eigenvalues and eigenvectors of the matrix $\boldsymbol{A}$ (cf. explanation for *Eigenvalues*).

Linear systems theory The mathematical theory of *linear dynamical systems*.

Loop eigenvalue elasticity analysis (LEEA) A form of eigenvalue elasticity analysis (EEA) that uses graph theory to express structural changes in terms of change in the strength of individual feedback loops. *Independent* loops can be assigned individual (loop) eigenvalue elasticities or influence measures just like other structural elements (see explanation for *Eigenvalue Elasticity Analysis (EEA)* and *Independent Loop Set (ILS)*).

Model simplification approach A way of attributing dynamic behavior to particular pieces of structure by replacing the full model with a simplified structure. See also *Structure contribution approach*.

Nonlinear systems Systems of the form $\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{u})$ where $\boldsymbol{f}$ is a nonlinear function. See explanation for *Linear dynamical systems*.

Pathway participation metric A measure that decomposes the curvature ($\ddot{x} = \mathrm{d}^2x/\mathrm{d}t^2$) of a variable x_i into the individual driving components, $\ddot{x}_i = \sum_j \partial\dot{x}_i/\partial x_j \cdot \dot{x}_j$. By considering the sign of the curvature relative to the slope, i. e., $\ddot{x}/\dot{x}$, one may define behavior as (apparently) dominated by positive $\ddot{x}/\dot{x} > 0$ or negative $\ddot{x}/\dot{x} < 0$ feedback loops. The component (pathway) with the largest absolute value and the same sign as $\ddot{x}/\dot{x}$ is then defined as the dominant structure.

Quasilinear models Models that are almost linear in structure around the operating point of interest so that they may be well approximated by a linear model.

Quasiperiodic behavior A behavior that is a sum of oscillations of incommensurate frequencies so that the system never returns to exactly the same point (which would be the case for periodic behavior).

Shortest independent loop set (SILS) An *Independent Loop Set (ILS)* that consists of the shortest possible loops (in terms of the number of nodes and links in each loop). Since the choice of ILS is far from unique, an SILS provides a more focused choice of loops, which are typically also easier to interpret due to their short length.

Single-transient models Models where the behavior of interest is the transition toward an equilibrium or constant growth rate. Models are typically nonlinear, exhibit patterns such as smooth transition, overshoot and collapse, growth, or stagnation.

Structure contribution approach A way of linking model structure to dynamic behavior by considering how individual pieces of structure (feedback loops or subsystems) contribute to the behavior pattern of interest by turning the structure on or off (in traditional simulation experiments) or by considering the marginal effect of small changes in structure (the eigenvalue approach). See also *Model simplification approach*.

Definition of the Subject

The link between system structure and dynamic behavior is one of the defining elements in the system dynamics paradigm, yet it is only recently that systematic, mathematically rigorous methods for exploring this link have started to become available. In a sense, a simulation model can be viewed as an explicit and consistent theory of the behavior it exhibits. Although this point of view has certain merits, not least the fact that it lifts the discussion from outcomes to causes of these outcomes and from events to underlying structure [11,59], we are concerned here with a more compact explanation of the system's behavior. In fact, most system dynamics modeling projects report their results in terms of simpler explanations of the observed results, typically in terms of dominant feedback loops that produce the salient features of the behavior.

Most often, dominant structure is thought of in terms of feedback loops and, occasionally, external driving forces to the system. For simple systems with relatively few variables it is usually easy to use intuition and trial and error simulation experiments to explain the dynamic behavior as resulting from particular feedback loops. In larger systems, this method becomes increasingly difficult and the risk of incorrect explanations rises accordingly. There is a need, therefore, for analytical methods that provide some consistency and rigor to this process.

These analytical tools are important to the practitioner because the structure-behavior link is the key to finding leverage points for policy initiatives. And they are important to the theorist because a system dynamics theory of a particular phenomenon is an account of how certain feedback loops cause certain dynamic patterns of behavior to appear. The qualitative understanding of the model behavior is often at least as important as the particular numerical predictions obtained, even in applied studies. Yet the rigor of such an account depends directly on the rigor with which structure-behavior link can be made in a given model.

The classical disciplines of linear systems theory and control engineering have provided a set of concepts and tools, particularly system eigenvalues and eigenvectors, that can also be applied under many circumstances to the nonlinear models found in system dynamics, not as a complete theory but as a pragmatic aid. This article reviews the recent advances in analytical tools based on linear systems theory and discusses its future potential for the both the system dynamics practitioner and the theorist.

Though we strongly believe in the utility of these methods, it is important to realize that advances in nonlinear dynamics and complexity theory in recent decades have shown that it is not possible to construct a complete theory of dominant structure because nonlinear systems are capable of exceedingly complex and intricate behavior that is impossible to predict without actually simulating the system. Furthermore, applications of graph theory to system dynamics models have revealed that the concept of feedback loops has some inherent problems and limitations because there are potentially many different loop descriptions of the same system (see [28,40]). Thus, the analytical tools should be viewed as pragmatic aids to model analysis that can guide the modeler's intuition, rather than universal methods that provide automatic answers.

We first provide a brief historical introduction to the different ways scholars have thought about the notion of dominant structure, including an example of the traditional approach to structural analysis. In the next section we present the formal mathematical representation of linear and nonlinear systems and how one may describe the dynamic behavior in terms of behavior modes and system eigenvalues. In the four following sections we present alternative approaches to performing this analysis. We conclude with a summary of the current state of research and a discussion of future directions.

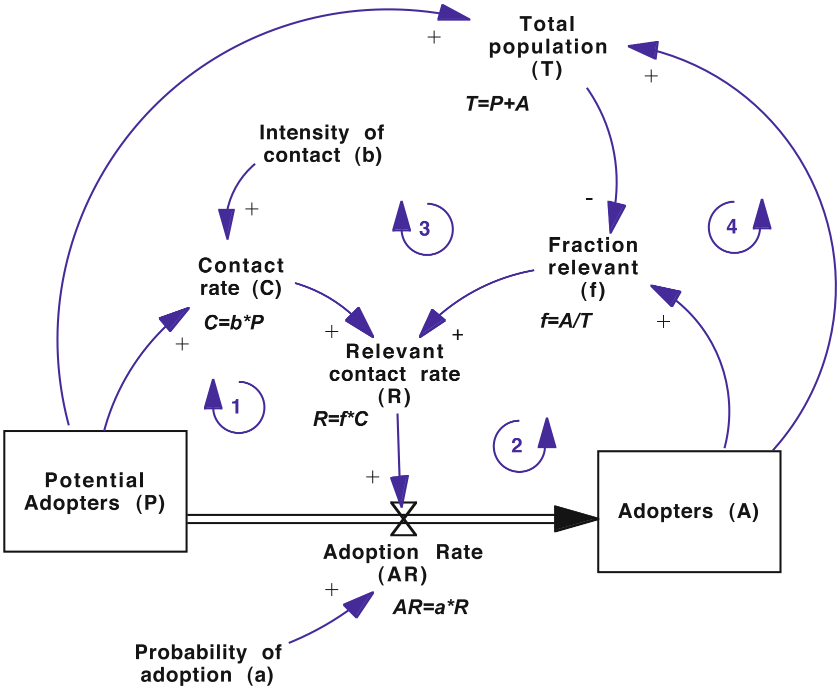
Introduction

Understanding model behavior is closely related to the process of model testing and validation, for which there is a well-established tradition and an extensive literature in the field (e. g., [2,10,17,36,46,47]). Indeed there is no sharp line between model building, testing, validation, and analysis – in practice, the analyst undertakes all these processes simultaneously [17].

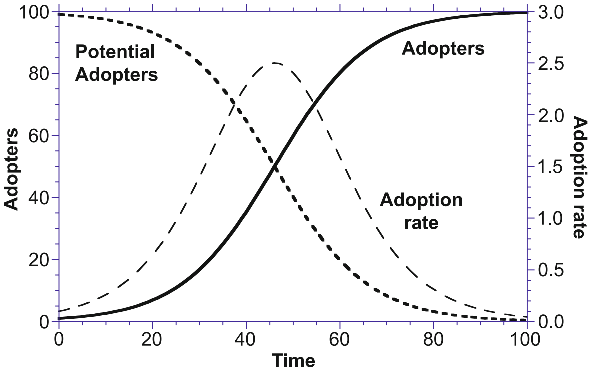
Of particular concern is whether one can identify pieces of structure that are in some sense "important" in generating the observed behavior of interest. Traditionally, system dynamics analysts have relied on trial-and-error simulation to discover these structures, by changing parameter values or switching individual links and feedback loops on and off. The tradition is well developed and includes a set of principles for partial model formulation and testing based the organizational theory of bounded rationality [27,36].

The intuition guiding this effort often relies on simple feedback systems with one or a few state variables, where the behavior is fully documented and understood. In particular, the modeler uses well-understood "generic structures" that seem to appear again and again in system dynamics models, such as "overshoot and carrying capacity collapse", "drifting goal structure", etc. (see [30,56,60] for an account of these structures). Clearly such structures can be a useful aid to understanding if the model is sufficiently simple to allow such simple structures to be identified.

A simple example of a generic structure is the classical model of diffusion, sometimes known as the Bass model ([3], see also Chapter 9 in [59]). The model structure is illustrated in Fig. 1, and the resulting behavior, an s-shaped growth curve, is illustrated in Fig. 2. The idea behind the model is that the adoption of a new technology is driven by the number of users that have already adopted it, through a word-of-mouth effect. One may interpret the s-shaped behavior as the interaction of two feedback loops, namely loop no. 2, the positive "word-of-mouth", and loop no. 1, the negative "exhaustion" loop (see Fig. 1). In the beginning, the positive loop dominates, leading to exponential growth in the number of adopters. Later, however, the negative loop gains strength, and the behavior shifts to an exponential adjustment toward the eventual market saturation. Thus, the traditional feedback loop analysis helps give an intuitive understanding of the dynamics of the model.



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 1
The Bass model of diffusion



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 2
Behavior of the Bass model

In large-scale models with perhaps hundreds of state variables, however, the traditional approach shows significant limitations. In practice, model building and analysis is often done using a "nested" partial model testing approach where one goes from the level of small pieces of structure to entire subsystems of the model, with frequent re-use of known formulations and partial models. Although this approach does carry a long way, it can be very difficult to discover feedback mechanisms that transcend model substructures in ways not anticipated by the modeler in the original dynamic hypothesis. Thus, there is a danger that observed behavior is falsely attributed to certain feedback mechanisms when in fact another set of feedbacks is driving the outcome. Likewise, one may make false inferences about how a particular feedback mechanism modifies the behavior, e. g., whether it attenuates or amplifies a particular oscillation.

Modern software packages can run extensive tests for sensitivity and "reality checks" where a large number of parameters are varied simultaneously [44]. This is clearly a significant improvement over "manual" trial and error methods, particularly when these methods are combined with statistical inference methods such as Kalman Filtering or Monte Carlo maximum likelihood estimation [6,8,39,43,45,55]. A variant of this approach involves using statistical experimental design and correlation methods to screen for significant model structure (parameters), as suggested by Ford and Flynn [9]. Indeed, the prospects of marrying such methods with modern search and optimization methods like classifier systems [26] or genetic algorithms [19] seem very promising. However, these methods are more addressing issues in estimation, validation and testing than inferences about or understanding how (dominant) structure is causing behavior.

Richardson [47] suggested a taxonomy of approaches to the notion of dominant structure, where he distinguishes along three dimensions, namely linear vs. nonlinear systems, model reduction vs. loop contribution, and the characterization of behavior in terms of time graphs vs. eigenvalues or frequency response. Of these, the distinction between model reduction and loop contribution is the most important.

In the model reduction approach, the idea is to replace a large complicated model with a simplified smaller model that captures the "essence" of the dynamics. A good example of this is Sterman's simple model of the economic long wave [58], which was distilled from the much larger System Dynamics National Model [18]. Eberlein [5,7] attempted to tackle model simplification in a systematic way in linear systems by focusing on retaining specific behavior modes. In large part his results were negative: it is generally not possible to build simpler models that reproduce the salient behavior without sacrificing either the accuracy of the behavior or the ability to relate the simplified model variables to those in the full model. It is fair to say that this line of inquiry has largely been abandoned as a result. Extracting the "essence" of a model remains an art more than a science.

The focus here will be on Richardson's second category, the loop contribution or, more generally, the *structure contribution* approach. It reflects the intuitive idea that if one removes the element under consideration, e. g. by weakening a link or switching off a feedback loop, and the behavior then "disappears", one would say that the element in some sense "causes" the observed behavior.

This notion underlies the traditional trial-and-error simulation approach, sometimes supplemented with methods from the classical control engineering, which focuses on how structural elements modify the behavior of the system, viewed in terms of the frequency response. Typically, the method works "backwards" by starting with simple feedback systems of single loops and then considering the marginal effect of adding links and loops. We discuss this approach in Sect. "Traditional Control Theory Approaches" below.

If, instead, one considers marginal (infinitesimal) changes in structure, e. g. in the strength of a particular link, it is possible to derive rigorous analytical results for the resulting change in behavior expressed as the eigenvalues of the linearized model. One would then say that if a change in a system element has a relatively large effect upon the behavior pattern of interest, this element is "significant" in "causing" the behavior. This is what underlies the *eigenvalue elasticity* and *eigenvector* approaches discussed in Sects. "Eigenvalue Elasticity Analysis", "Eigenvectors and Dynamic Decomposition Weights (DDW)". The marginal and experimental approaches may supplement each other well, where a marginal analysis may identify elements that can then be tested experimentally for their significance.

Unlike the traditional control method and the eigenvalue method that work in the structural and *frequency domain*, the *pathway participation* method (PPM) relates directly to the time path of particular system variables and is more concerned with the qualitative nature of the time path, expressed in terms of signs of the slope (whether growing or declining) and curvature (whether convex or concave) than with numerical measures of degree of influence. Briefly stated, the PPM traces the causal links in the variables influencing the system variable in question and then identifies the most important chain of links. We discuss this method in Sect. "Pathway Participation Metrics".

Common to the approaches discussed here is that they all build upon a precise mathematical characterization of the system behavior. In the next section, we demonstrate how the concepts from linear systems theory may be used to give a precise characterization of behavior in terms of component *behavior modes*.

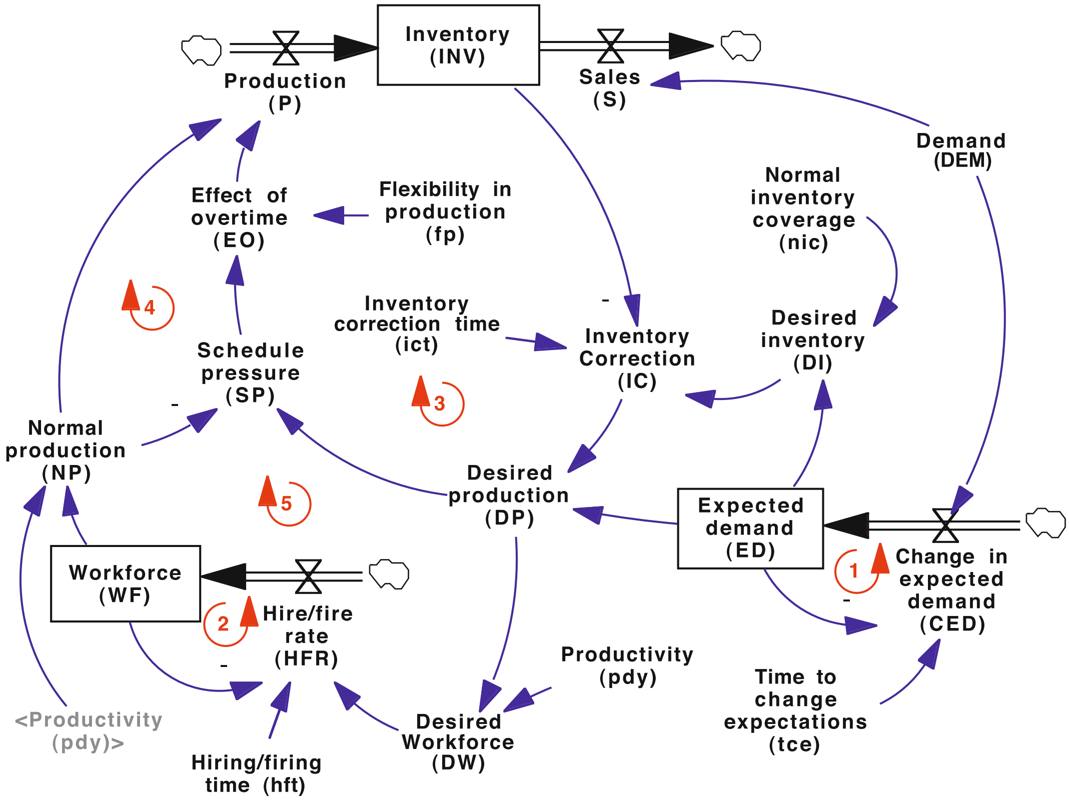
Characterizing Linear and Nonlinear Systems

A system dynamics model can be represented mathematically as a set of ordinary differential equations

$$\frac{\mathrm{d}\boldsymbol{x}(t)}{\mathrm{d}t} \equiv \dot{\boldsymbol{x}}(t) = \boldsymbol{f}(\boldsymbol{x}(t), \boldsymbol{u}(t)) , \qquad (1)$$

where $\boldsymbol{x}(t)$ is a (column) vector of n state variables (levels) $(x_1(t), \ldots, x_n(t))$, $\boldsymbol{u}(t)$ is a column vector of p exogenous variables or control variables $\left(u_1(t), \ldots, u_p(t)\right)$, $\boldsymbol{f}()$ is a corresponding vector function, and t is simulated time. In this paper, we restrict our attention to the state variables (levels) of the model for notational convenience, ignoring the auxiliary variables. Mathematically, a model can always be brought to the *reduced* form (1), but in practice, the auxiliary variables give a more intuitive account of the analysis. Likewise, we do not consider time-varying systems (where time t enters as an explicit argument in the function $\boldsymbol{f}$), since these can usually be accommodated by an appropriate definition of the exogenous variables $\boldsymbol{u}$. In general, $\boldsymbol{f}$ is a nonlinear function of its arguments, and we speak of a *nonlinear* system. Conversely, if $\boldsymbol{f}$ is a linear function, we speak of a *linear* system.

Figure 3 and Table 1 show a well-known example, the inventory–workforce model. It has three state variables, Inventory (INV), Workforce (WF), and Expected Demand



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 3

Flow diagram of the inventory workforce model

(ED), and one exogenous variable, Demand (DEM), i. e.,

$$\boldsymbol{x}(t) = \begin{pmatrix} \text{INV} \\ \text{WF} \\ \text{ED} \end{pmatrix} ; \quad \boldsymbol{u}(t) = (\text{DEM}) , \qquad (2)$$

and the function $\boldsymbol{f}$ is determined by the equations in Table 1.

Given the model structure (1), knowledge of the initial conditions $\boldsymbol{x}(0)$, and the path of the input variables $\boldsymbol{u}(t)$, the behavior of the model is completely determined. It is in this sense that the model structure (1) constitutes a "theory" of the time behavior $\boldsymbol{x}(t)$, as mentioned in the introduction. Yet, we are interested in methods that yield a more compact explanation, short of having to simulate the entire model structure.

It turns out that in its ultimate form, this dream is beyond reach: Since the days of Henri Poincaré, mathematicians have known that it is impossible to find general analytical solutions to nonlinear systems. Furthermore, the development of nonlinear dynamics and chaos theory has proven that such systems, even when they have very few state variables, can produce highly complex and intricate behavior that goes beyond general analytic methods (e. g., [42,48]). Thus, we will never find a final general theory where we can infer the behavior of the system directly from its structure; instead, we will always have to rely on simulation to discover the dynamics implied by the structure. (This is not to say that no general analytical results exist in nonlinear systems. The field of chaos theory has uncovered a number of universal features, e. g., relating to the transition from periodic or quasi-periodic behavior to chaos, where the transitions show both qualitative and quantitative similarities that are independent of the specific forms of the model equations (see, e. g., [42]). However, these universal features relate to specific situations such as period-doubling or intermittency routes to chaos).

The best we can hope for, therefore, is a set of tools that will guide intuition and help identify *dominant structure* in the model. By dominant structure we mean particular feedback loops that are in some sense "important" in shaping the behavior of interest. To the extent that we can identify such dominant structures, we may say that we have found a "theory" of the observed behavior.

Although the term "behavior" may appear rather loose, experience and reflection tells us that there is a limited number, perhaps a dozen or so, of relevant behav-

System Dynamics, Analytical Methods for Structural Dominance Analysis in, Table 1
Equations of the inventory workforce model

Equation	Name	Units
d/dt(ED) = (DEM − ED)/tce, ED_0 = DEM * df	Expected demand	[Units/Month]
d/dt(INV) = P − S, INV_0 = DI	Inventory	[Units]

ior patterns that dynamical systems can exhibit. Some of these behaviors, like exponential growth, exponential adjustment, and damped or expanding oscillations, are typical of linear systems. Others, like limit cycles, quasiperiodic motion, mode-locking, and chaos, can only be exhibited by nonlinear systems.

Common to the approaches considered in this paper is that they are based on tools from linear systems theory, i. e., they approximate the nonlinear model (1) with a linearized version, using first-order Taylor expansion around some operating point $\boldsymbol{x}_0, \boldsymbol{u}_0$, i. e.,

$$\dot{\boldsymbol{x}}(t) \approx \boldsymbol{f}(\boldsymbol{x}_0, \boldsymbol{u}_0) + \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{x}}(\boldsymbol{x} - \boldsymbol{x}_0) + \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{u}}(\boldsymbol{u} - \boldsymbol{u}_0) , \quad (3)$$

or, by redefinition of the variables $\boldsymbol{x} \to \boldsymbol{x} - \boldsymbol{x}_0 - \boldsymbol{f}(\boldsymbol{x}_0, \boldsymbol{u}_0) \times (t - t_0)$ and $\boldsymbol{u} \to \boldsymbol{u} - \boldsymbol{u}_0$,

$$\dot{\boldsymbol{x}}(t) \approx \boldsymbol{A}\boldsymbol{x}(t) + \boldsymbol{B}\boldsymbol{u}(t) , \quad (4)$$

where $\boldsymbol{A}$ is constant $n \times n$ matrix of partial derivatives $\partial f_i / \partial x_j$ and $\boldsymbol{B}$ is constant $n \times p$ matrix of partial derivatives $\partial f_i / \partial u_j$, and all partial derivatives are evaluated at the operating point.

For the linear system (4), there is a well-developed and extensive theory of the system behavior as a function of its structure, expressed in the matrices $\boldsymbol{A}$ and $\boldsymbol{B}$. One may broadly distinguish two parts of the theory, named classical control theory (e. g., [38]) and modern linear systems theory (e. g., [4,31]). We return to the classical control theory in the next section.

Modern control theory or linear systems theory (LST) is concerned with the dynamical properties of the system as a direct function of the system matrices $\boldsymbol{A}$ and $\boldsymbol{B}$. A key element in this theory is the notion of the system *eigenvalues*, i. e., the eigenvalues of the matrix $\boldsymbol{A}$. If, for simplicity, we restrict ourselves to the endogenous dynamics of the system (set $\boldsymbol{u} = 0$), we can write the solution to (4) as

$$x_i(t) = c_{i,1} \exp(\lambda_1 t) + c_{i,2} \exp(\lambda_2 t) + \cdots + c_{i,n} \exp(\lambda_n t) , \quad i = 1, \ldots, n , \quad (5)$$

where $\lambda_1, \ldots, \lambda_n$ are the n eigenvalues of the matrix $\boldsymbol{A}$ and $c_{i.j}$ are constants that depend upon the eigenvectors and the initial condition of the system. In other words, the resulting behavior is a weighted sum of distinct *behavior modes*, $\exp(\lambda t)$. If an eigenvalue is real, the corresponding behavior mode is exponential growth (if $\lambda > 0$) or exponential decay (if $\lambda < 0$). Complex-valued eigenvalues come in complex conjugate pairs $\lambda = \tau \pm i\omega$ which give rise to oscillations $\exp(\tau\, t) \sin(\omega t + \phi)$ of frequency ω that are either expanding (if $\tau > 0$) or damped (if $\tau < 0$).

In this manner, the eigenvalues serve as a compact and rigorous characterization of the behavior (of linear systems).

At any point in time, any system, linear or nonlinear, may be approximated by the expression (5). Whether it remains a good approximation depends upon how much and how quickly the eigenvalues change due to the nonlinearities in the function $\boldsymbol{f}$. If they are more or less constant for significant periods of time, we may speak of *quasilinear systems* that are well approximated by the linear system. In some cases, however, the eigenvalues change so rapidly that it makes little sense to characterize the behavior by equation (5). (See [29] for further discussion).

Traditional Control Theory Approaches

The first set of methods, which we call the traditional approach, has been used for decades and is part of the standard curriculum in system dynamics teaching at the graduate level. It involves using the concepts from classical control theory [38] to very simple systems with only a few state variables.

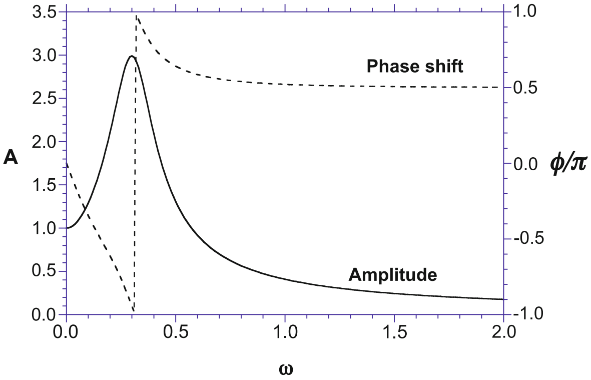
The starting point is the simple first- and second-order positive and negative feedback loops found in any introductory treatment of system dynamics. The advantage of the approach is its simplicity. Although it serves at a guide to intuition, however, the obvious shortage is that it applies rigorously only to simple systems. There have been some attempts to treat higher-order systems by adding a few feedback loops [23], but the step to large-scale models is beyond this method given its inherent limitations.

Graham [23] distills a number of principles that are based on the metaphor of a "disturbance" traveling along the chain of causal links in a feedback loop and getting amplified, damped, and possibly delayed in the process. For major negative feedback loops, which are known to tend to produce oscillation, adding minor negative loops and cross-links, or shortening the delay times increases the damping. Conversely, adding positive loops in to the oscillatory system tends to lengthen the period of oscillation whereas the effect on the damping depends upon the delays in the positive loop. Using the metaphor of pushing a child on a swing, it becomes clear that the timing of the propagation of a disturbance has as much importance for its effect on the damping as its strength.

For analyzing the behavior of positive feedback loops, Graham suggested calculating the Open-loop steady-state gain (OLSSG), a measure of the amplification around the loop. A gain greater than unity will result in exponential growth while gains less than 1 will give exponential adjustment (leveling off or decay). The intuition is perhaps best illustrated by an example: sales-driven growth. Suppose a salesperson can eventually pull in \$100,000 per month in orders (probably with a several-month long delay), and assume that the company allocates 10% of revenue to marketing. Then this eventually leads to \$10,000 per month for sales efforts. If the cost of a salesperson (salary, overhead, expenses etc.) is, say, \$8,000 dollars per month, then the efforts of the current sales force will provide enough revenue to support $10,000/8,000 = 1.25$ persons per current person. Thus, the OLSSG of the positive loop from salespersons → orders → revenues → marketing budget → salespersons is 1.25, and the system will grow exponentially (until other factors limit the growth). Conversely, if the gain is less than 1, one salesperson will not sell enough to support their own cost, and the loop will lead to exponential decay. Graham showed how the actual rate of growth is partly determined by the OLSSG, and partly by the time constants (delays etc.) involved. (See also Subsect. 15.3 in [59]).

In the context of oscillating systems, system dynamics has also employed a concept from classical control theory, frequency response. The frequency response is determined from the transfer function of the system, $G(i\omega)$, which is a complex-valued function that specifies how an input signal $u(t)$ with frequency ω results in an output signal $x(t)$ that may be phase shifted (delayed), and either amplified or attenuated. For linear systems, G can be calculated directly from the system matrices in (4) – the transfer function (matrix) is $\boldsymbol{G}(i\omega) = \boldsymbol{B}(i\omega\boldsymbol{I} - \boldsymbol{A})^{-1}$, where $\boldsymbol{I}$ is the identity matrix (see e. g. [4]). For nonlinear systems, G may be found through simulation experiments.

Usually, G is represented in a *Bode* or *phase-and-gain* diagram. For instance, Fig. 4 shows a Bode diagram of the



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 4
Phase-and-gain diagram (Bode diagram) showing the inventory $A\sin(\omega t + \phi)$ with amplitude A and phase shift ϕ, relative to a sinusoidal demand $\sin(\omega t)$, for varying values of the frequency ω of the demand fluctuation

inventory variable INV (t) relative to the exogenous demand input variable DEM (t) in the inventory workforce model in Fig. 3. The diagram shows how the relative amplitude of the oscillation and the relative phase shift (in radians) between input and output varies as a function of the frequency of the input.

It is clear from the diagram that there is a certain frequency range, around the system's own natural frequency, where fluctuations in demand are greatly amplified compared to other frequencies. Indeed, it is a general phenomenon in systems that they will tend to amplify certain frequencies while attenuating other frequencies. This may be used to explain or understand the role of particular structures in the model in generating oscillation at certain frequencies, even when there are no oscillations coming in from the outside world. (External random noise is enough to produce oscillations in the system because random noise contains fluctuations at all frequencies). In this manner, the approach nicely demonstrates the "endogenous viewpoint" that behavior (oscillations) is generated internally by the system. As an analytic tool for large scale systems, however, the method does not seem to produce any additional insights. Thus, we may conclude that the classical approaches serve mostly as intuitive metaphors to guide the analyst rather than as full analytical tools.

Pathway Participation Metrics

The *pathway participation* method [34,35] represents a further development of an original suggestion by Richardson [46] to provide a rigorous definition of loop polarity and loop dominance. Richardson motivated this with the common confusion associated with positive feedback loops, which may exhibit a wide range of behaviors [23], as Barry Richmond noted with wonderful humor:

"Positive loops are … er, well, they give rise to exponential growth … or collapse … but only under certain conditions … Under other conditions they behave like negative feedback loops …" [49].

Richardson proposed that the polarity of a loop be defined as the sign of the expression

$$\frac{\partial \dot{x}_i}{\partial x_i} = \frac{\partial f_i\,(\boldsymbol{x}\,,\boldsymbol{u})}{\partial x_i}\,, \tag{6}$$

in the model (1), with a positive sign indicating a positive loop and vice-versa. When several loops operate simultaneously, the sign of the expression indicates whether the positive or negative loops dominate. Note, however, that the definition only applies to minor loops (i. e. loops involving a single level). Put differently, it only considers the diagonal elements of the matrix $\boldsymbol{A}$ in the linearized system (4). Richardson [46] demonstrates how even with this limitation, analyzing the system with this metric can (sometimes) yield insights into behavior of higher-order systems.

The expression (6) hints that it is relevant to consider the curvature, i. e., the second time derivative, $\ddot{x}$, of a variable when looking for dominant structure. Although he does not say so explicitly, this is effectively the focus of Mojtahedzadeh's pathway method. Figure 5 shows how one may classify behavior by comparing the first and second time derivatives of a variable. As seen in the figure, the sign of the expression $\ddot{x}/\dot{x}$, which Mojtahedzadeh denotes the total *pathway participation metric* or *PPM*, indicates whether the behavior appears dominated by positive or negative loops, much in line with Richardson's definition of dominant polarity. A zero curvature indicates a shift in loop dominance (cf. the middle column in the figure). Note, however, that the interpretation of the middle row in the figure where the slope $\dot{x}$ is zero has no clear interpretation in terms of loop dominance. Indeed this hints at one of the weaknesses of the approach that we will return to below.

Mojtahedzadeh's method proceeds by decomposing the PPM into its constituent terms as follows,

$$\mathrm{PPM}_i = \frac{\ddot{x}_i}{\dot{x}_i} = \sum_{j=1}^{n} \frac{\partial f_i}{\partial x_j}\frac{\dot{x}_j}{\dot{x}_i}\,, \tag{7}$$

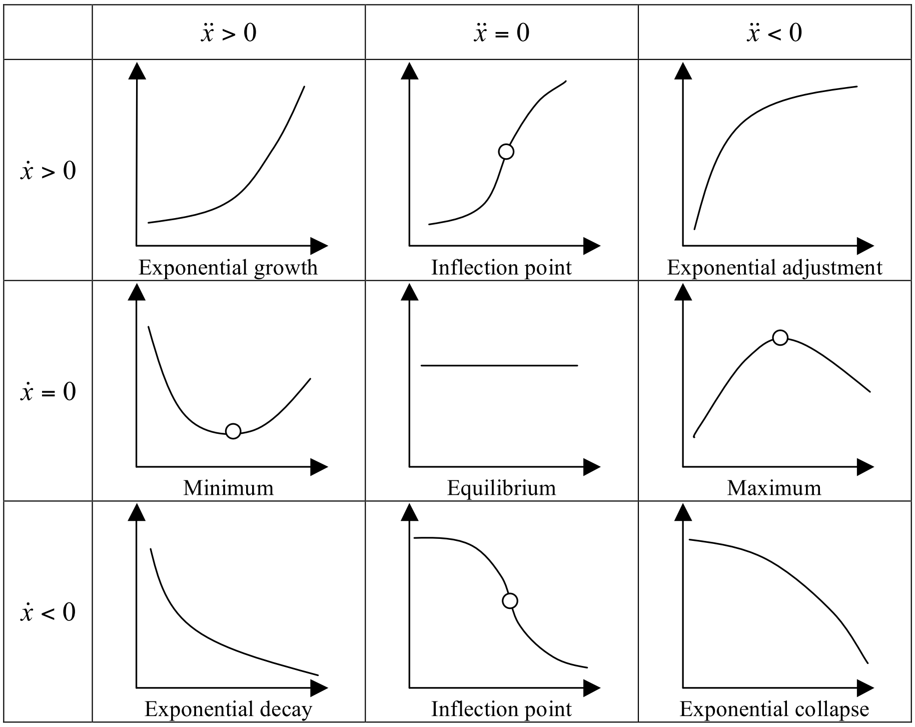
where, for brevity, we have chosen to ignore the exogenous variables u. One might say that each of the terms in the sum in (7) represents the separate influence of each of the systems' state variables on the behavior of x_i. Mojtahedzadeh in fact uses a normalized measure for the terms,

$$\frac{\left(\partial f_i/\partial x_j\right)\dot{x}_j}{\sum_{k=1}^{n}\left|\left(\partial f_i/\partial x_k\right)\dot{x}_k\right|}\,, \tag{8}$$

which can vary between -1 and $+1$, to measure the relative importance of the pathway from variable j. By explicitly considering auxiliary variables y in the model, one may further decompose each term $\partial f_i/\partial x_j$ into a sum of terms

$$\frac{\partial f_i^k}{\partial x_j} = \frac{\partial f_i}{\partial y_1}\cdot\frac{\partial y_1}{\partial y_2}\cdot\cdots\cdot\frac{\partial y_{m-1}}{\partial y_m}\cdot\frac{\partial y_m}{\partial x_j}\,, \tag{9}$$

corresponding to a causal chain or pathway $\pi_k = \{x_j \to y_m \to \cdots y_2 \to y_1 \to \dot{x}_i\}$. Mojtahedzadeh now considers each possible pathway (9) and defines the "dominant" pathway as the one with the largest numerical value



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 5
Characteristic behavior patterns based on the first and second time derivatives

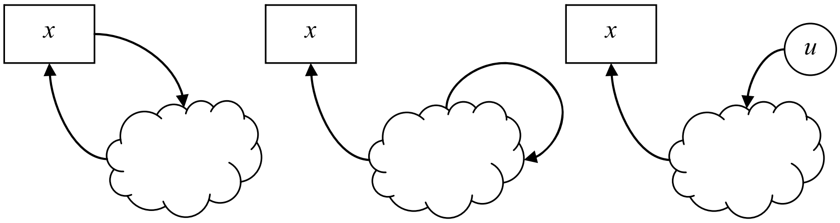
and the same sign as PPM_i. Having selected this dominant pathway, $\pi^*_{ij} = \{x_j \to y_m \to \cdots y_2 \to y_1 \to \dot{x}_i\}$, which originates in the state variable x_j the procedure is repeated for that state variable x_j, and so forth, until one either reaches one of the already "visited" state variables (in which case a loop has been found) or an exogenous variable (in which case an external driving force has been found). Thus, the procedure may result in three alternative forms of dominant structure illustrated in Fig. 6, namely a "pure" minor or major feedback loop, a pathway from a feedback loop elsewhere in the system, or a pathway from an exogenous variable.

By dividing the observed model behavior into different phases according to the taxonomy in Fig. 5 and then applying the method just described at different points in during these phases, one can reveal how the dominant structure changes over time. For illustration, the PPM method is applied to the Bass model and the results are presented in Fig. 7. The figure shows the metrics of four alternative pathways (four feedback loops) and the results accord nicely with the informal analysis done earlier: The method identifies two phases, exponential growth, exponential adjustment, and identifies the "word-of-mouth" positive loop (loop 1) as dominant in the first phase and the "exhaustion" loop (loop 2) as dominant in the second phase.

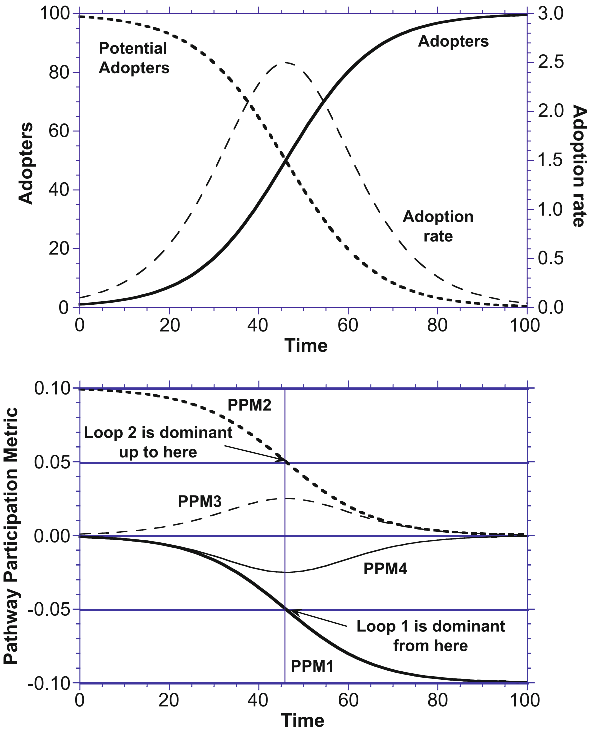
The PPM method is still mostly used at an early explorative stage on rather simple models, where it does appear to aid insight into the dynamics (e. g. [41]), and has been implemented in a software package, *Digest*, [35].

From the studies performed so far, it is clear that the main strength of this method is its relative computational simplicity (it does not require computing eigenvalues, which is a numerically demanding task), and the intuitive and direct connection it makes between the observed behavior and the influencing structural elements. Unlike the other approaches which operate in the "frequency domain", the method considers the time path of a specific variable directly.

There are, however, some important outstanding issues that remain to be clarified. First, the method is not suitable for oscillatory systems. The problem is easy to recognize when one considers how the PPM measure will vary over the course of a sinusoidal outcome: The sign of the PPM will shift twice during each cycle, indicating that the behavior is alternately dominated by positive and negative loops, even though the system structure, and hence the loop dominance, may remain unchanged all the time.



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 6
Three alternative forms of dominant structure in the PPM method



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 7
Pathway participation measures in the Bass model

Richardson [46] already alluded to this problem by noting that the measure only considers the diagonal elements in the system matrix in (4), yet we know that the structure causing oscillation is the major negative loop that involve the off-diagonal elements. This is a significant limitation, given the prevalence and importance of oscillation in system dynamics analysis.

A second limitation of the current implementation of PPM is that it uses a depth-first search for the single most influential pathway for a variable. This strategy does not capture the situation where more than one structure may contribute significantly to the model behavior and, through the depth-first algorithm, may miss alternative paths that could prove to yield a larger total value of the metric. This problem could be addressed by modifying the search algorithm and is most likely of minor importance.

Another issue is how to treat the case when $\dot{x} = 0$ since it appears in the denominator of the terms in (6). However, it is not clear that it is necessary to do this division, given that it is easy to identify the nine cases in the figure by simply examining its sign. Thus, the issue is probably not of much significance.

The fourth issue, on the other hand, is more significant, namely the emphasis on identifying a single “dominant” structure. In reality, of course, the behavior of a variable is influenced by many loops and pathways at once. Reducing the consideration to a single one of these may miss important features of the structure-behavior relationships. For instance, a variable may be influenced by two negative loops and one positive, with the sum of the two negative loops dominating the influence of the positive loop, even though that loop by itself has the strongest influence on the behavior. It is more appropriate to consider the relative importance of alternative pathways, yet the method does not address how one would partition the behavior among pathways (the three structures in Fig. 6) – only among individual links.

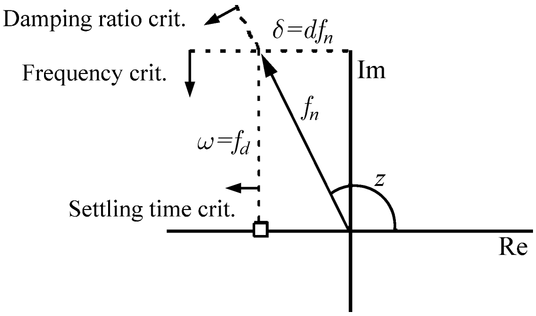
Thus, while the notion of pathways seems an interesting and useful idea, it may be that it will ultimately be more effective to use a list, ranked in order of magnitude, of the pathways that influence a variable.

Finally, the method shares a weakness with the traditional method in that it considers primarily partial system structures rather than global system properties. In contrast, the two eigenvalue methods to which we now turn are based on a rigorous characterization of the entire system (at a given point in time).

Eigenvalue Elasticity Analysis

The third method may be termed *eigenvalue elasticity analysis* (or EEA for short) and builds upon the tools from modern linear systems theory (LST), applied to the linearized model (4). The method is concerned with the structural elements that significantly affect the system eigenvalues or behavior modes – the values λ in (5). Specifically, it measures influence by the elasticity of an eigenvalue λ with respect to some parameter g in the model, defined as $\varepsilon = \left(\partial\lambda/\partial g\right)(g/\lambda)$, i. e. the fractional change in the eigenvalue relative to the fractional change in the parameter. The advantage of this fractional measure is that it is dimensionless, i. e., independent upon the choice of units, including the time scale unit. Sometimes, the influence measure is used instead, defined as $\mu = (\partial\lambda/\partial g)g$. This measure has dimension $[1/time]$ and so depends upon the choice of is time unit, but it is generally easier to interpret for complex-valued eigenvalues and avoids numerical problems with very small or zero eigenvalues (see [29,54]).

The idea behind EEA was first introduced in system dynamics by Forrester [14] in the context of economic stabilization policy. For purposes of policy analysis in oscillating systems, one may define a number of criteria from engineering control theory, all of which relate to the eigenvalues of the system, as summarized in Table 2. Figure 8 provides a graphical characterization of the eigenvalues and policy criteria in the complex plane. Though these measures are not new, the EEA method is unique in its attempt to use them to gain qualitative intuitive understanding of the system. A significant step in this direction was first suggested by Forrester [15] with the notion that the elasticities of any links in the model (corresponding to elements of the matrix $\boldsymbol{A}$ in the linearized system (4)), can be interpreted as the sum of elasticities of all feedback loops containing that link. We have chosen to name this approach *loop eigenvalue elasticity analysis (LEEA)*.



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 8
Characterization of eigenvalues plotted in the complex plane

Kampmann [28] provided a rigorous definition of LEEA and also pointed to the fact that feedback loops are not independent. In other words, given the possibly very large number of loops in a given model (Kampmann demonstrated how the theoretical maximum number of loops grows combinatorically with the number of variables), it only makes sense to speak of individual contributions of a limited set of *independent* loops. He proved that a fully connected system (where there is a feedback loop between any pair of variables – the typical case in system dynamics models) with N links and n variables has a total of $N - n + 1$ independent loops and provided a procedure for constructing this set and calculating the loop elasticities.

Kampmann's analysis points to a fundamental issue relating to the notion of feedback loops as a way to explain

System Dynamics, Analytical Methods for Structural Dominance Analysis in, Table 2
Stabilization policy criteria and corresponding effects on eigenvalues and BDW of a policy change in a system element *g*

Policy Criterion	Description	Change in eigenvalue $\lambda = \delta \pm i\omega, \omega > 0$	Change in BDW w	Appropriate measure in time path
Damping	Increases the rate of decay of oscillation (or decreases the rate of expansion)	$\frac{\partial\delta}{\partial g}\frac{g}{\delta} < 0$	N/A	$\frac{x(t+T)}{x(t)}$
Frequency	Decreases the frequency of oscillation (or lengthens the period *T*)	$\frac{\partial\omega}{\partial g}\frac{g}{\omega} < 0$	N/A	T
Variance	Reduces the variance of a target variable (or the weighted average variances of several variables)	No simple relation	$\frac{\partial w}{\partial g}\frac{g}{w} < 0$	$\int x(t)^2\,\mathrm{d}t$
Auto-spectrum	Reduces variance of target variable(s) within a target frequency range	No simple relation	$\frac{\partial w}{\partial g}\frac{g}{w} < 0$	Filter in frequency domain
Frequency response gain	Reduces the gain (amplification) in the target frequency range for a particular combination of disturbance exogenous and output variables.	Based upon transfer function $G(i\omega)$		

System Dynamics, Analytical Methods for Structural Dominance Analysis in, Table 3

Loops and their influences in the inventory workforce model. Values are measured at time $t = 0$. The model contains three eigenvalues, $\lambda_1 = -0.250$ and $\lambda_2, \lambda_3 = -0.138 \pm i\,0.285$. The influence measure is defined as $g \cdot \partial\lambda/\partial g$. For the imaginary part, a positive influence measure means that the frequency is increased

Loop	Nodes	Gain	Influence on Re[λ_1]	Influence on Re[λ_2]	Influence on Im[λ_2]
1	ED > CED	−0.250	−0.250	0.000	0.000
2	W > HFR	−0.200	0.000	−0.100	−0.022
3	INV > IC > DP > SP > EO > P	−0.076	0.000	−0.038	0.008
4	INV > IC > DP > DW > HFR > W > NP > P	−0.100	0.000	0.000	0.176
5	INV > IC > DP > DW > HFR > W > NP > SP > EO > P	0.015	0.000	0.000	−0.027

behavior: the significance assigned to a particular loop depends upon the context (the chosen independent loop set). In other words, feedback loops are derived and relative concepts rather than fundamental independent building blocks of systems. Oliva [40] further refined the definition of independent loop sets by introducing the *Shortest independent loop set (SILS)* along with a procedure for constructing the set. Although a SILS is not generally unique, experience seems to suggest that it is easier to interpret [41]. Yet the issue remains that independent feedback loop sets are relative concepts.

In Table 3, we show how the LEEA analysis applies to the simple inventory–workforce model in Fig. 3. The model contains a total of 5 feedback loops, all of which are independent. The loops are listed in Table 3, including their constituent variables (nodes), and the gain of the loop (defined in a similar manner to the pathway participation metrics above). We see that there are three minor negative loops, related to the exponential smoothing of expected demand (loop 1) and the adjustment of workforce to desired workforce (loop 2). The minor loop 3 is the "overtime shortcut" that allows production to adjust part way to desired production immediately so one does not have to wait for the workforce to adjust. Loop 4 is the main major negative loop that adjusts inventory to desired levels via workforce adjustment. Finally, loop 5 (the only positive loop) is a fairly weak loop that moderates the effect of loop 4 by adjusting the overtime effect "back to normal" when the workforce is brought in line with desired production.

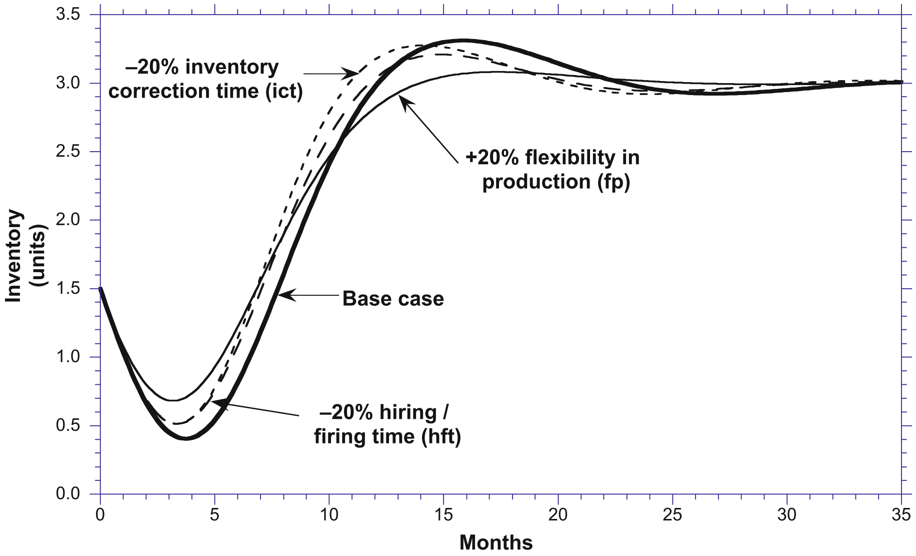
Although the model is nonlinear (due to the overtime function), the eigenvalues do not change very much over the course of its behavior. The model contains one real eigenvalue ($\lambda_1 = -0.250$) and one pair of complex conjugate eigenvalues ($\lambda_2, \lambda_3 = -0.138 \pm i\,0.285$). The first eigenvalue corresponds to the adjustment of expected demand (ED). The other pair produces a damped oscillation in inventory and workforce.

Table 3 also shows the loop influences upon the three eigenvalues. Note how there is a one-to-one correspondence between loop 1 (the adjustment of expected demand) and the first eigenvalue. This is due to fact that the ED level constitutes a single strongly connected component of the model (see Fig. 3), i. e. there is no feedback between this level and the rest of the model. We also note that the workforce adjustment and the overtime loops have a stabilizing influence upon the behavior (they make the real part of the oscillatory eigenvalues more negative and have relative little effect upon the frequency of oscillation). Conversely, the major negative loop 4 has a destabilizing influence, since strengthening it will increase the frequency of oscillation and not increase the damping. The effects of loop 5 are fairly weak.

From this analysis, one would therefore expect parameters that strengthen loop 2 (shortening hire/fire time) or loop 3 (increase overtime effect) would stabilize the system while strengthening loop 4 (shorter inventory adjustment time) will destabilize the system. Indeed this is what happens, as illustrated in the simulations in Fig. 9.

The EEA/LEEA method has been applied in a number of contexts (e. g. [1,20,22,24,29,51,52,54]), but remains a tool employed only by specialists in fundamental research, not least because it has not been incorporated into standard software packages. Thus, the potential of the method for widespread practice remains unexplored.

One might be skeptical that a method derived from linear systems theory may have any use for the nonlinear models found in system dynamics. Kampmann and Oliva [29] considered what types of models the method would be particularly suited for. They defined three categories of models, based upon the behavior they are designed to exhibit: 1) linear and quasilinear models, 2) nonlinear single-transient models, and 3) nonlinear periodic models. The first category encompasses models of oscillations, possibly combined with growth trends, with relatively stable equilibrium points, (e. g., the classical in-



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 9
Simulated behavior of inventory–workforce model, showing the effect on inventory of parameter changes for overtime (flexibility of production), inventory adjustment time (ict), and labor hiring/firing time (hft), respectively

dustrial dynamics models [11]). Nonlinearities may modify behavior (particularly responses to extreme shocks) but the instabilities and growth trends can be analyzed in terms of linear relationships. Kampmann and Oliva concluded that LEEA showed the most promise and potential for this class of models because the analytical foundations are solid and valid, and because the method has the ability to find high-elasticity loops even in large models very quickly without much intervention on the part of the analyst.

The second class is typical of scenario models like the World Model [13,33], the Urban Dynamics Model [12], or the energy transition model in [57], to name a few, that show a single transient behavior pattern, like overshoot and collapse or a turbulent transition to a new equilibrium. In these models, nonlinearities usually play an essential role in the dynamics. Yet it is possible to divide the behavior into distinct phases where certain loops tend to dominate the behavior. In this class of models LEEA also shows promise by measuring shifts in structural dominance by the change in elasticities. But it requires more input from the analyst (e. g. in defining the different phases of the transition) and it has no obvious advantage over other methods, like PPM.

The third class, nonlinear periodic models, are those that exhibit fluctuating behavior in which nonlinearities play an essential role, such as like limit cycles, quasiperiodic behavior, or chaos, (see, e. g. [48]). Here the utility of the method is much less clear and depends upon the specifics of the model in question. For example, the classic Lorenz model that exhibits limit cycles, period doubling and deterministic chaos does not lend itself to any insight using LEEA [29]. This is particularly the case in systems with strong nonlinearities such as min and max functions. In these systems, the behavior may change abruptly (eigenvalues suddenly shift) in what is called border-collision bifurcations [37,61]. In other cases, the method of breaking the behavior into phases with different dominant structures may yield significant insight from LEEA. For instance, Sterman's simple long wave model [58] lends itself well to this approach (e. g. [24,28]).

In the present paper, we add a fourth category of models or behavior for which the method has not been explored yet. We name this category nonlinear multi-modal models. These encompass the cases where one behavior mode interacts with and therefore modifies another behavior mode – something that can only happen in nonlinear systems. The most common example is mode-locking or entrainment, in which oscillations become synchronized (e. g. [25]). Another example is mode modification, where one behavior mode (growth or oscillation) affects the character of another (typically oscillation). An example of this is the interaction of the business cycle with the economic long wave, where the former tends to get more severe during long wave downturns [16]. Whether LEEA can contribute to this class of models remains to be seen.

Compared to the former two methods, the EEA/LEEA is mathematically more general and rigorous, though many of the mathematical issues in the method remain to be addressed, as we summarize below. This rigor is also the main strength of the method, since it provides an unambiguous and complete measure of the influence of the entire feedback structure on all behavior modes.

A weakness or challenge that is starting to show up is the computational intensity in calculating eigenvalues and elasticities. This is not so much an issue of computer time and memory space as of the stability of numerical methods. Kampmann and Oliva [29] found that the numerical method used sometimes proved unstable, yielding meaningless results. Clearly, there is a need to explore this issue further, possibly building upon the developments in control engineering.

A more serious weakness is the difficulty in interpreting the results: Eigenvalues do not directly relate to the observed behavior of a particular variable. The concepts of eigenvalues and elasticities are rather abstract and unintuitive [10]. There is a need for tools and methods that can translate them into visible, visceral, and salient measures. Here, the measures in Table 2 may provide a guide. In particular, it is possible to use (linear) filtering in the frequency domain to define a behavior of interest. For example, an analyst may be concerned with structures causing a typical business cycle (3–4-year oscillation) and, by specifying a filter that "picks out" that range of fluctuation, could obtain measures for structures that have elasticities in that range. Because filters are typically linear operators, all the analytical machinery of the LEEA method will also apply in this case – a significant advantage.

Using filters will also solve an issue that appears in large-scale models, namely the presence of several identical or nearly identical behavior modes. Saleh et al. [54] do consider the analytical problems associated with repeated eigenvalues, where it becomes necessary to use generalized eigenvectors, and where other behavior modes appear involving power functions of time. A filter essentially constitutes a weighted average of behavior modes and in this fashion avoids the "identity problem" of non-distinct eigenvalues.

The most serious theoretical issue, in our view, is how the results are interpreted using the feedback loop concept. As mentioned, the concept is relative (to a choice of an independent loop set). Moreover, practice reveals that the number of loops to consider is rather large and that the loops elasticities often do not have an easy or intuitive explanation. A lot of care must be taken when interpreting the results. For instance, Kampmann and Oliva [29] found that "phantom loops" – loops that cancel each other by logical necessity and are essentially artifacts of the equation formulations used in the model – could nonetheless have large elasticities and thus seriously distort the interpretation of the results. An example of "phantom loops" is found in the Bass model in Fig. 1, where loops 3 and 4 are artifacts of the way the model is formulated. If the variable *Total population* (T) was eliminated from the equations, the loops would disappear and in fact they exactly cancel each other out (since T is constant). Nonetheless, they appear on the list of loops and appear to have a separate influence on behavior. These kinds of problems may not be intractable, but their resolution will require careful mathematical analysis.

Finally, a problem with EEA and LEEA is that it only considers changes to behavior modes, not the degree to which these modes are expressed in a system variable of interest. This issue is addressed by also considering the eigen*vectors* of the system, which is the foundation for the analysis in the next section.

Eigenvectors and Dynamic Decomposition Weights (DDW)

The last set of methods, which are still in early development, we have termed the *eigenvector-based* approach (EVA). EVA attempts to improve the EEA/LEEA method by considering how much an eigenvalue or behavior mode is expressed in a particular system variable. The logic of the method and how EEA and EVA complement each other is shown in Fig. 10. As shown by Kampmann [28], in a sense there is a one-to-one correspondence between eigenvalues and loop gains whereas the eigenvectors arise from the remaining "degrees of freedom" in the system. The observed behavior of the state variables in the model is then the combined outcome of the behavior modes (from the loop gains) and the weights for each mode (from the eigenvectors) in the respective state variable.

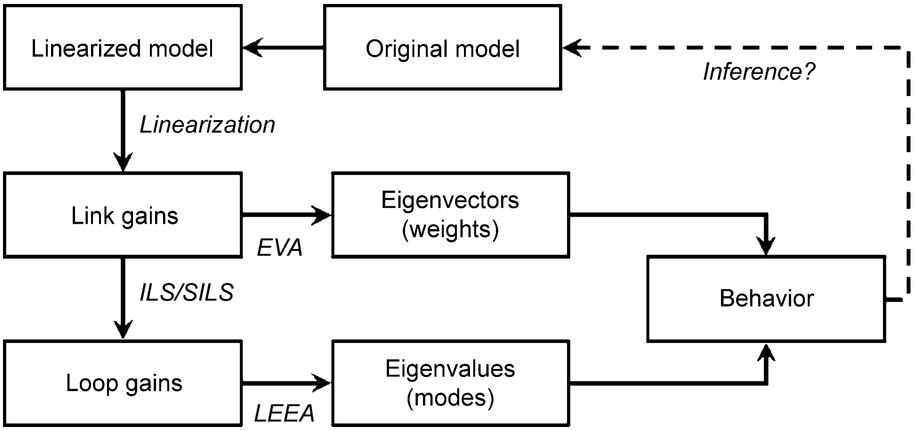
A number of researchers have attempted to develop EVA methods. Some emphasize the curvature (second time derivative) of the behavior, similar to the starting point of the PPM method [24,50,51,52]. The slope or rate of change $\dot{x}(t)$ of a given variable x in the linearized system may be written by

$$\dot{x}(t-t_0) = w_1 \exp(\lambda_1 (t-t_0)) + \cdots + w_n \exp(\lambda_n (t-t_0)) \,, \quad (10)$$

where the weights w_i are related to the eigenvectors. Then the curvature at time t_0 is

$$\ddot{x}(t_0) = w_1\lambda_1 + \cdots + w_n\lambda_n \,. \quad (11)$$

One may therefore interpret (11) has the sum of contribution from individual behavior modes. Güneralp [24]



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 10
Schematic view of eigenvalue and eigenvector analysis approach

suggested using the terms on the right-hand side of (11) as weights to combine elasticities of individual behavior modes ε_i with respect to some system element (like a link gain or a loop gain) into a weighted sum

$$\bar{\varepsilon} = \frac{\sum_{i=1}^{n} w_i \lambda_i \varepsilon_i}{\sum_{i=1}^{n} |w_i \lambda_i|}\,, \tag{12}$$

as a measure of the overall significance of that system element. He further normalized the elasticity measure by the elasticity measure for other system elements, i. e., assuming there are K such elements (loops or links), the relative importance ρ_k of the kth element is defined as

$$\rho_k = \frac{\bar{\varepsilon}_k}{\sum_{j=1}^{K} |\bar{\varepsilon}_j|}\,, \tag{13}$$

with the motivation that elasticities may vary greatly in numerical values, making comparisons at different points in time difficult, whereas ρ_k is a relative measure varying between +1 and −1. His results shed an alternative light on the behavior of these models, but the mathematical meaning, consistency and significance of the doubly normalized measure (13) remains to be clarified. It is still too early to tell what the most useful approach will be, but one may note that the emphasis on the curvature shares the basic weakness in the PPM approach in dealing with oscillations.

Other researchers have looked directly at the *dynamic decomposition weights (DDW)* w_i in (10), i. e., the relative weight of the modes for a particular variable, from a policy criterion perspective, similar to Forrester's original focus and the starting point for the EEA analysis [21,53,54].

For instance, Saleh et al. [54] look at how alternative stabilization policies affect the behavior of business cycle models, using both a simple inventory–workforce model [59], and a more extensive model based on Mass [32] and used in the LEEA analysis of Kampmann and Oliva [29]. Using the procedure in Fig. 9, they decompose the net stabilizing effect of a policy into its effect on the behavior mode itself (LEEA) and its effect on the expression of that mode in the variable of interest, measured the dynamic decomposition weights (EVA or DDW).

To illustrate the approach we perform the computations for the inventory–workforce model (Fig. 3 and Table 1). We find that the following equations describe the behavior of the state variables

$$\begin{aligned} \text{ED} &= 1 - 0.500\text{e}^{-0.250t} \\ \text{INV} &= 3 - 2.167\text{e}^{-0.250t} \\ &\quad + 1.134\text{e}^{-0.138t} \sin(2.945 + 0.285t) \\ \text{WF} &= 1 + 0.669\text{e}^{-0.250t} \\ &\quad - 1.169\text{e}^{-0.138t} \sin(1.553 - 0.285t)\ . \end{aligned} \tag{14}$$

As expected from the structure of the model, the behavior of *Expected Demand* does not have an oscillatory component and only shows a short transient exponential adjustment for the stock to match *Demand*. On the other hand, *Inventory* and *Workforce*, in addition to having the transient behavior to reach equilibrium captured by the first eigenvalue, have an oscillatory component represented by the second eigenvalue. Note that each state variable has a different *Dynamic Decomposition Weight* (w) for each

System Dynamics, Analytical Methods for Structural Dominance Analysis in, Table 4

Elasticity to parameters of weight of eigenvalue 2 (−0.138 + i0.85) on inventory and influence of parameters on eigenvalue 2 – inventory–workforce model

Parameter	w_2 on INV Elasticity	Influence on Re[$\boldsymbol{\lambda}_2$]	Influence on Im[$\boldsymbol{\lambda}_2$]
Demand	2.000	0.000	0.000
Inventory correction time	0.656	0.038	−0.157
Flexibility in production	0.364	−0.549	−0.266
Productivity	−0.353	0.000	0.000
Time to change expectations	−0.240	0.000	0.000
Normal inventory coverage	0.239	0.000	0.000
Hiring/Firing time	0.238	0.100	−0.127
Disequilibrium fraction	0.000	0.000	0.000

reference mode, i. e., each eigenvalue contributes differently to the overall behavior of each state variable.

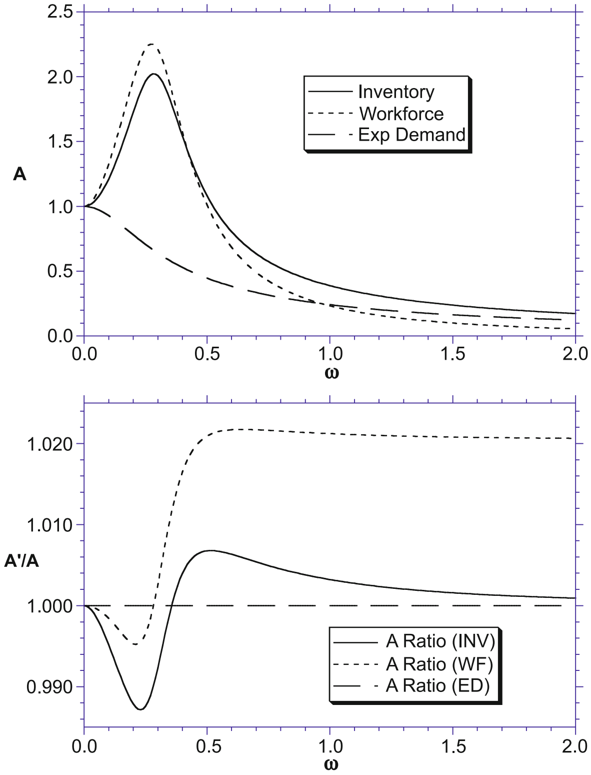
An exploration of the policy design space can be achieved by assessing the influence of model parameters on the dynamic decomposition weight. By focusing on the weights of the behavior modes for the variable of interest we can identify leverage points to increase or decrease the presence of a behavior mode in the variable. The weight elasticity column in Table 4 reports the parameter elasticity of w_2 (the weight of eigenvalue 2, the oscillatory behavior mode) on *Inventory* ($\varepsilon_w = (\mathrm{d}w/\mathrm{d}p)(p/w)$). The magnitude of the elasticity quantifies the impact that changes in the parameter value have on the weight of the oscillatory behavior model on *Inventory*. The table is sorted in descending order of absolute value of elasticity.

Changes in parameters, however, not only impact the behavior decomposition weights, but also change the eigenvalues themselves. This dual impact of parameter changes introduces a challenge in developing policy recommendations. The last two columns of Table 4 report the influence on the eigenvalue (real and imaginary part) for each parameter. These measures of influence should be interpreted in a similar way as the weight elasticities. The influence measure is defined as $\mu_\lambda = \left(\partial\lambda/\partial p\right) p$. A positive real-part measure indicates that increasing the parameter will destabilize the system by lengthening the settling time and vice-versa. A positive imaginary-part measure indicates that increasing the parameter will increase the frequency of oscillation – normally considered a destabilizing influence – and vice-versa.

Five parameters, *demand, disequilibrium fraction*, *productivity, normal inventory coverage*, and *time to change expectations*, have no influence on the oscillatory behavior mode. *Demand* and *disequilibrium fraction* are initialization constants that do not participate in any of the feedback loops in the model. *Productivity* is essentially a scaling measure having to do with the definition of units of labor and goods in the model. Redefining units should not affect the dynamics of the model. While *time to change expectations* is involved in loop 1, it does not participate in the oscillatory behavior observed in the model since, as discuss above, *Expected Demand* is in a separate strongly connected component of the model.

In accordance with LEEA, the *flexibility in production* parameter, which strengthens overtime loop 3 (cf. Fig. 3), has a strong stabilizing influence, by both increasing the damping and lowering the frequency of the oscillatory mode. Likewise, as predicted by LEEA, a shorter *hiring/firing time* will increase damping by strengthening the labor adjustment loop 5 but, again in accordance with LEEA, also increases the frequency of adjustment because it also strengthens the major loop 4. Finally, lowering the *inventory correction time* will strengthen the link from *inventory* to *desired production*, and consequently the three loops 3, 4 and 5, with the net effect that although the adjustment is a little faster (a more negative real part), the frequency is also increased significantly, i. e., it is a less effective way of stabilizing the system (cf. Fig. 9).

As an alternative approach, Fig. 11 shows what happens to the frequency response of the state variables (*Inventory* INV, *Workforce* WF, and *Expected Demand* ED) when the parameter Hiring/Firing Time (hft) is reduced by 2% from 5 to 4.9. There are a number of things to notice in the figure. First, there is no effect whatsoever on the ED variable, which should not be surprising, given that there is no feedback to this variable from the rest of the system. Second, the effect on the amplitude, like the amplitude itself, is strongly dependent upon the frequency of variation. We see that there is a significant amount of dampening on the *Inventory* fluctuation around the resonant frequencies in the range 0.1 to 0.3. On the other hand, there is a small amount of amplification of inventory in the higher frequency ranges. The effect on *Workforce* is very different: though there is a small attenuation in the reso-



System Dynamics, Analytical Methods for Structural Dominance Analysis in, Figure 11

Effect on frequency response of the inventory workforce model of reducing the parameter Hiring/Firing Time (hft) from 5.0 to 4.9. The diagram shows the gain of the base case (*upper graph*) for the three state variables, and the resulting change in the gain, measured as the ratio (A'/A) from the parameter change (*lower graph*)

nant frequencies, there is a significant increase in variance in the higher frequency range. In other words, although the LEEA analysis showed a faster hiring policy to be stabilizing (by strengthening loop 2, cf. Table 3), the DDW analysis shows that it depends – both upon the variable in question and the context (frequency of variation).

Future Directions

As mentioned above, it is not possible to construct a complete theory that will automatically provide modelers with "the" dominant structure. Given the analytical intractability of nonlinear high-order systems found in our field, the most we can hope for is a set of tools that will guide the analysis and aid the development of the modeler's intuition.

That said, however, we are left with an impression that the analytical foundation for these tools is in need of further development before one rushes into implementing them into software packages. We are quite satisfied with the current state of affairs in this regard, where code, models, and documentation are made freely to download (most of the cited papers provide a URL to their code and models). Understanding *how* and *why* the tools work the way they do is crucial, and this will require that a number of puzzles, uncertainties, and technical problems be addressed. Only then will the time come to submit the methods for wider application to test their real-world utility.

While the classical method remains a useful intuitive guide and teaching tool for graduate students, there are no signs that it may be developed further. (That said, it is possible that the classical control transfer function method may be employed in the eigensystem approaches to explore nested canonical systems, though this is purely speculative). The pathway method would benefit from a firmer mathematical foundation. In particular, it would be important to compare how its results and conclusions compare to those found in the LST. It is possible that the pathway method may eventually be merged with the LST approaches as a subset of a general analytical toolbox. We believe that there is a great deal of promise in combining the eigenvalue and eigenvector analysis in the LST approaches. This combination will yield a complete system characterization and an understanding of both how particular feedback loops are involved in generating a behavior mode, and how system elements determine the expression of that behavior mode in a particular variable. A unified LST approach along the lines suggested in Fig. 10 thus seems within reach.

It will probably be a while, however, before these methods will find their way into widely available and use-friendly software packages. Apart from the theoretical issues alluded to above, a number of technical issues related to numerical calculations, various "pathological cases" (such as non-distinct eigenvalues), and special cases of feedback loops ("figure-eight" loops, for instance), will need to be addressed.

On the more creative side, it would be interesting to explore alternative forms of visualizing the various influence measures developed. For instance, one could imagine that links between variables in a model diagram "glow" in different colors and intensities depending upon their effect on a behavior pattern in question. This is not just a question of fancy user interfaces: as mentioned in the introduction, the function of these tools will be as intuitive consistent aids to understanding, not analytical "answering machines". In this light, the visualization is as important as the analytical principles behind it. Given the power of the human eye in finding patterns in visual data, this could be a significant next step.

Article Outline

Glossary

Endogenous Generated from within. Contrasting with "exogenous," meaning generated by forces external to a system or point of view.

Feedback loop A closed path of causal influences and information, forming a circular-causal loop of information and action.

System dynamics System dynamics is a computer-aided approach to theory-building, policy analysis and strategic decision support emerging from an endogenous point of view.

Definition of the Subject

System dynamics is a computer-aided approach to theory-building, policy analysis, and strategic decision support emerging from an endogenous point of view [18,20]. It applies to dynamic problems arising in complex social, managerial, economic, or ecological systems – literally any dynamic systems characterized by interdependence, mutual interaction, information feedback, and circular causality.

Introduction

The field of system dynamics developed initially from the work of Jay W. Forrester. His seminal book *Industrial Dynamics* [7] is still a significant statement of philosophy and methodology in the field. Within ten years of its publication, the span of applications grew from corporate and industrial problems to include the management of research and development, urban stagnation and decay, commodity cycles, and the dynamics of growth in a finite world. It is now applied in economics, public policy, environmental studies, defense, theory-building in social science, and other areas, as well as its home field, management. The name industrial dynamics no longer does justice to the breadth of the field (for extensive examples, see [20,28], so it has become generalized to system dynamics. The modern name suggests links to other systems methodologies, but the links are weak and misleading. System dynamics emerges out of servomechanisms engineering, not general systems theory or cybernetics [18].

The system dynamics approach involves:

- Defining problems dynamically, in terms of graphs over time.
- Striving for an endogenous, behavioral view of the significant dynamics of a system, a focus inward on the characteristics of a system that themselves generate or exacerbate the perceived problem.
- Thinking of all concepts in the real system as continuous quantities interconnected in loops of information feedback and circular causality.
- Identifying independent stocks or accumulations (levels) in the system and their inflows and outflows (rates).
- Formulating a behavioral model capable of reproducing, by itself, the dynamic problem of concern. The model is usually a computer simulation model expressed in nonlinear equations, but is occasionally left unquantified as a diagram capturing the stock-and-flow/causal feedback structure of the system.
- Deriving understandings and applicable policy insights from the resulting model.
- Implementing changes resulting from model-based understandings and insights.

Mathematically, the basic structure of a formal system dynamics computer simulation model is a system of coupled, nonlinear, first-order differential (or integral) equations,

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{x}(t) = \mathbf{f}(\mathbf{x}, \mathbf{p}) \, ,$$

where $\mathbf{x}$ is a vector of levels (stocks or state variables), $\mathbf{p}$ is a set of parameters, and $\mathbf{f}$ is a nonlinear vector-valued function. Such a system has been variously called a *state-determined system* in the engineering literature, an *absolute system* [3], an *equifinal system* [32], and a *dynamical system* [16].

Simulation of such systems is easily accomplished by partitioning simulated time into discrete intervals of length $\mathrm{d}t$ and stepping the system through time one $\mathrm{d}t$ at a time. Each state variable is computed from its previous value and its net rate of change $x'(t)$: $x(t) = x(t - \mathrm{d}t) + \mathrm{d}t \cdot x'(t - \mathrm{d}t)$. In the earliest simulation language in the field (DYNAMO) this equation was written with time scripts K (the current moment), J (the previous moment), and JK (the interval between time J and K): $X_{\mathrm{K}} = X_{\mathrm{J}} + \mathrm{DT} \cdot \mathrm{XRATE}_{\mathrm{JK}}$ (see, e. g., [22]). The computation interval $\mathrm{d}t$ is selected small enough to have no discernible effect on the patterns of dynamic behavior exhibited by the model. In more recent simulation environments, more sophisticated integration schemes are available (although the equation written by the user may look like this simple Euler integration scheme), and time scripts may not be in evidence. Important current simulation environments include STELLA and iThink (isee Systems, http://www.iseesystems.com/), Vensim (Ventana Systems, http://www.vensim.com/), and Powersim (http://www.powersim.com/).

Forrester's original work stressed a continuous approach, but increasingly modern applications of system dynamics contain a mix of discrete difference equations and continuous differential or integral equations. Some practitioners associated with the field of system dynamics work on the mathematics of such structures, including the theory and mechanics of computer simulation, analysis and simplification of dynamic systems, policy optimization, dynamical systems theory, and complex nonlinear dynamics and deterministic chaos.

The main applied work in the field, however, focuses on understanding the dynamics of complex systems for the purpose of policy analysis and design. The conceptual tools and concepts of the field – including feedback thinking, stocks and flows, the concept of feedback loop dominance, and an endogenous point of view – are as important to the field as its simulation methods.

Feedback Thinking

Conceptually, the feedback concept is at the heart of the system dynamics approach. Diagrams of loops of information feedback and circular causality are tools for conceptualizing the structure of a complex system and for communicating model-based insights. Intuitively, a feedback loops exists when information resulting from some action travels through a system and eventually returns in some form to its point of origin, potentially influencing future action. If the tendency in the loop is to reinforce the initial action, the loop is called a *positive* or *reinforcing* feedback loop; if the tendency is to oppose the initial action, the loop is called a *negative, counteracting*, or *balancing* feedback loop. The sign of the loop is called its *po-*

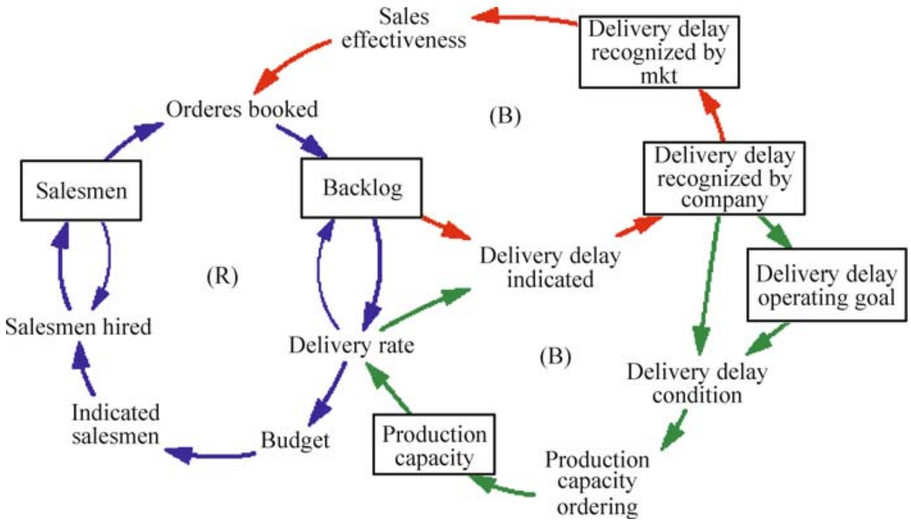
larity. Balancing loops can be variously characterized as goal-seeking, equilibrating, or stabilizing processes. They can sometimes generate oscillations, as when a pendulum seeking its equilibrium goal gathers momentum and overshoots it. Reinforcing loops are sources of growth or accelerating collapse; they are disequilibrating and destabilizing. Combined, balancing and reinforcing circular causal feedback loops can generate all manner of dynamic patterns.

Feedback loops are ubiquitous in human and natural systems and, under various names and representations, have been widely recognized in popular and scholarly literature. Feedback thought has been present implicitly or explicitly for hundreds of years in the social sciences and literally thousands of years in recorded history [9]. We have the vicious circle originating in classical logic and morphing into common usage, the bandwagon effect, the invisible hand of Adam Smith, Malthus's correct observation of population growth as a self-reinforcing process, Keynes's consumption multiplier, the investment accelerator of Hicks and Samuelson, compound interest or inflation, the biological concepts of proprioception and homeostasis, Festinger's cognitive dissonance, Myrdal's principle of cumulative causation, Venn's idea of a suicidal prophecy, Merton's related notion of a self-fulfilling prophecy, and so on. Each of these ideas can be concisely and insightfully represented as one or more loops of causal influences with positive or negative polarities. Great social scientists and feedback thinkers; great social theories are feedback thoughts. (For a full exposition of the evolution of the feedback concept see [19].)

Loop Dominance and Nonlinearity

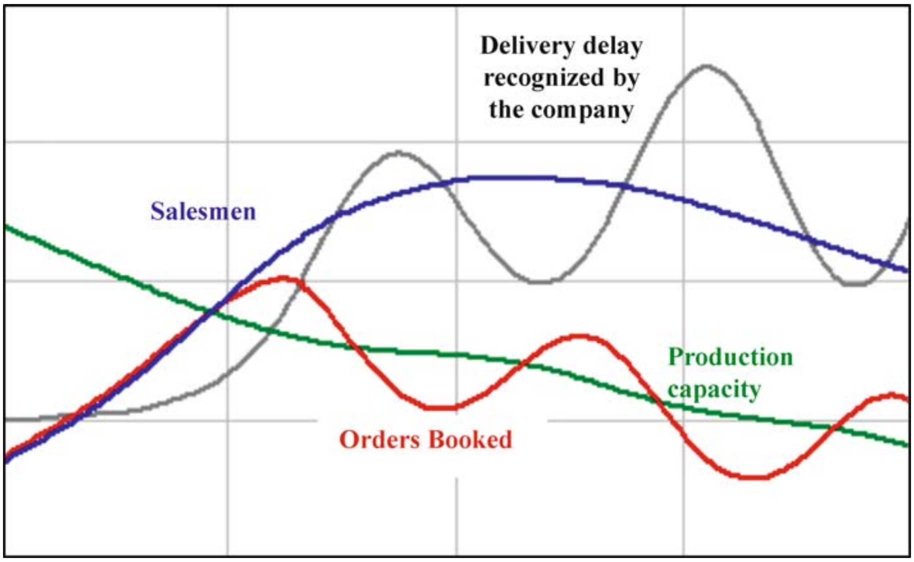
The loop concept underlying feedback and circular causality by itself is not enough, however. The explanatory power and insightfulness of feedback understandings also rest on the notions of active structure and loop dominance. Complex systems change over time. A crucial requirement for a powerful view of a dynamic system is the ability of a mental or formal model to change the strengths of influences as conditions change, that is to say, the ability to shift *active* or *dominant structure*.

In a system of equations, this ability to shift loop dominance comes about endogenously from nonlinearities in the system. For example, the S-shaped dynamic behavior of the classic logistic growth model ($\mathrm{d}P/\mathrm{d}t = aP - bP^2$) or similar structures like the Gompertz curve ($\mathrm{d}P/\mathrm{d}t = aP - bP\ln(P)$) can be seen as the consequence of a shift in loop dominance from a positive, self-reinforcing feedback loop (aP) producing exponential-like growth, to a negative feedback loop ($-bP^2$ or $-bP\ln(P)$) that brings the system to its eventual goal. The shift in loop dominance in these models comes about from the nonlinearity in the second term, which grows faster than the first term and eventually overtakes it. Only nonlinear models can endogenously alter their active or dominant structure and shift loop dominance.



System Dynamics, The Basic Elements of, Figure 1

Core structure of Forrester's market growth model [8], showing a *blue reinforcing loop* underlying the growth (or reinforcing decline) of Salesmen, Orders, and Revenue, a *red balancing loop* containing various delayed recognitions of the company's delivery delay, and a *green balancing loop* responsible for capacity ordering if the delivery delay drops too far below its operating goal



System Dynamics, The Basic Elements of, Figure 2
The dynamic behavior of the model shown in Fig. 1, illustrating an early growth phase, which turns into an oscillatory phase as the feedback loop dominance shifts to the *red balancing delivery delay loop*, and results in a long term corporate decline as the *green capacity ordering loop* responds to a sliding operating goal for the acceptable delivery delay

Real systems are perceived to change their active or dominant structure over time, often because of the build-up of internal forces. Thus from a feedback perspective, the ability of nonlinearities to generate shifts in loop dominance is the fundamental reason for advocating nonlinear models of social system behavior.

Figures 1 and 2, abstracted from an early, classic paper [8] illustrate these ideas. In Fig. 1 salesmen (in the blue reinforcing loop) book orders for the company; if enough revenue is generated, there is enough budget to hire more salesmen and corporate growth ensues. Whether salesmen (in this simplified picture) book enough orders depends on the company's delivery delay for the product, as perceived by the market (red balancing loop). The company builds production capacity according to its perceived need, as indicated by its perceived delivery delay and its target for that (green balancing loop).

Figure 2 shows the dynamics this feedback structure endogenously generates. In the early phase, salesmen grow as orders and revenue grow; the system's exponential growth behavior in that phase is generated by the reinforcing salesmen loop. But then the feedback loop dominance soon shifts to the balancing delivery delay loop, which constrains sales effectiveness and brings a halt to growth. The system moves into an oscillatory phase generated by the various monitoring and perception delays around the now dominant red balancing loop. Salesmen eventual peak and decline, as the green production capacity ordering loop fails to keep production capacity sufficient to hold the delivery delays in check.

Thus the dynamic behavior of this system is a consequence of its feedback structure and the nonlinearities that shift loop dominance endogenously over time. The particular decline scenario shown in Fig. 2 illustrates one of the deep insights of the model: the adaptive goal structure, in which the delivery delay operating goal moves slowly to accommodate changes in the company's delivery delay, weakens the green balancing loop trying to bring on capacity. The company never perceives its delivery delay is sufficiently higher than its (sliding) target, so it fails to order sufficient capacity to sustain growth. A fixed goal for the acceptable delivery delay sends a stronger signal, which can turn this corporate decline into oscillating growth [8].

Thus, nonlinearity is crucial to the system dynamics approach. However, it is crucial not merely because of its mathematical properties but because it enables the formalization of a profoundly powerful perspective on theory and policy – the *endogenous point of view*.

The Endogenous Point of View

The concept of endogenous change is fundamental to the system dynamics approach. It has both philosophical and engineering origins. A deep and lasting insight of the earliest attempts at servomechanisms control is the realization that *the attempt to control a system generates dynamics of* *its own*, complicating the dynamics trying to be controlled. A governor mechanism imposed to control the speed of a steam engine can generate oscillatory "hunting behavior," as the control system overshoots and undershoots the set point. As it becomes part of the system, the governing mechanism thus generates dynamics of its own.

The insight transfers readily, but with added significance, from engineering systems to people systems: Attempts to control complex human systems – coercing, guiding, managing, governing – generate dynamics of their own. Moreover, some of these endogenously generated dynamics are created by the control mechanisms themselves (like the governor of a steam engine) and some are created by human creative responses to the management efforts (e. g., principal-agent interactions). These natural and human forces, creating counteracting and compensating pressures in response to system control efforts, emerge as complicated circular-causal feedback structures. The often complex, difficult-to-understand dynamics of such management systems are to a great degree a consequence of their internal structures.

To capture and analyze such management complexities, one must look inward to see the ways a complex system naturally responds to system pressures. The endogenous point of view is thus central to the system dynamics approach. It dictates aspects of model formulation: exogenous disturbances are seen at most as *triggers* of system behavior (like displacing a pendulum); the *causes* are contained within the structure of the system itself (like the interaction of a pendulum's position and momentum that produces oscillations). Corrective responses are also not modeled as functions of time, but are dependent on conditions within the system. Time by itself is not seen as a cause in the endogenous point of view.

Theory building and policy analysis are significantly affected by this endogenous perspective. Taking an endogenous view exposes the natural *compensating* tendencies in social systems that conspire to defeat many policy initiatives. Feedback and circular causality are delayed, devious, and deceptive. For understanding, system dynamics practitioners strive for an *endogenous point of view*. The effort is to uncover the sources of system behavior that exist within the structure of the system itself.

System Structure

These ideas are captured almost explicitly in Forrester's [9] organizing framework for system structure:

- Closed boundary
- Feedback loops
- Levels
- Rates
- Goal
- Observed condition
- Discrepancy
- Desired action.

The *closed boundary* signals the endogenous point of view. The word *closed* here does not refer to open and closed systems in the general system sense, but rather refers to the effort to view a system as *causally* closed. The modeler's goal is to assemble a formal structure that can, *by itself*, without exogenous explanations, reproduce the essential characteristics of a dynamic problem.

The causally closed system boundary at the head of this organizing framework identifies the endogenous point of view as the feedback view pressed to an extreme. Feedback thinking can be seen as a *consequence* of the effort to capture dynamics within a closed causal boundary. Without causal loops, all variables must trace the sources of their variation ultimately outside a system. Assuming instead that the causes of all significant behavior in the system are contained within some closed causal boundary forces causal influences to feed back upon themselves, forming causal loops. Feedback loops enable the endogenous point of view and give it structure.

Levels and Rates

Stocks (accumulations, or "levels" in early system dynamics literature) and the flows ("rates") that affect them are essential components of system structure. A map of causal influences and feedback loops is not enough to determine the dynamic behavior of a system. A constant inflow yields a linearly rising stock; a linearly rising inflow yields a stock rising along a parabolic path; a stock with inflow proportional to itself grows exponentially; two stocks in a balancing loop have a tendency to generate oscillations; and so on. For example, the boxes in Fig. 1 represent accumulations in the company and its market; the three stocks in the red balancing loop (the order backlog and the two perceptions of the company's delivery delay) give that loop its tendency to generate oscillations which propagate through out the system. Accumulations are the memory of a dynamic system and contribute to its disequilibrium and dynamic behavior.

Forrester [7] placed the operating policies of a system among its rates, the inflows and outflows governing change in the system. Many of these rates of change assume the classic structure of a negative feedback loop striving to take action to reduce the discrepancy between the observed condition of the system and a goal. The simplest such rate structure results in an equation of the form

$$\text{RATE} = \frac{\text{GOAL} - \text{LEVEL}}{\text{ADJUSTMENT TIME}} ,$$

where ADJUSTMENT TIME is the time over which the level adjusts to reach the goal. This simple formulation reflects Forrester's more general statement about rates in his hierarchy of system structure (above) which can be richly thought of as

$$\text{RATE} = f(\text{DESIRED ACTION})$$

$$\begin{aligned}&\text{DESIRED ACTION}\\ &= g(\text{DESIRED CONDITION},\\ &\qquad\qquad\qquad \text{OBSERVED CONDITION})\end{aligned}$$

$$\text{OBSERVED CONDITION} = h(\text{LEVELS}) ,$$

for some functions f, g, and h representing particular system characteristics.

Operating policies in a management system can influence the *flows* of information, material, and resources, which are the only means of changing the accumulations in the system. While flows can be changed quickly, as a matter of relatively quick decision making, stocks change slowly – they rise when inflows are great than outflows, and decline when inflows are less than outflows.

The simple "tub dynamics" of stocks are clear even to children, yet can be befuddling in complex systems. The accumulation of green house gases in the atmosphere, for example, affects the *flow* of heat energy radiated from the earth. To turn around global warming, the *accumulation* of green house gases must drop far enough to raise radiant energy above the inflow of solar energy, a simple stock-and-flow insight. But to cause the accumulation of green house gases to drop, their generation must fall below their natural absorption rate (another simple stock-and-flow observation). So turning around global warming is a process involving a chain of at least two significant accumulations, and people have trouble thinking it through reliably. The accumulations can only be changed by managing their associated flows. They will change only slowly even if we manage the technical and political pitfalls involved in lowering green house gas production (see [29]).

The significance of stocks in complex systems is vivid in a resource-based view of strategy and policy. Resources that enable a corporation or government to function or flourish are stocks, usually accumulated over long periods of time with significant investment of time, energy, and money. Reputations are also stocks, built over similarly long periods of time. While inadequate by themselves to give a full picture of the dynamics of a complex system, stocks and flows are vital components of system structure, without which fundamental understandings of dynamics are impossible [33].

Behavior is a Consequence of System Structure

The importance of stocks and flows appears most clearly when one takes a *continuous* view of structure and dynamics. Although a discrete view, focusing on separate events and decisions, is entirely compatible with an endogenous feedback perspective, the system dynamics approach emphasizes a continuous view [7]. The continuous view strives to look beyond events to see the dynamic patterns underlying them: model not the appearance of a discrete new housing unit in a city, but focus instead on the rise and fall of aggregate numbers of housing units. Moreover, the continuous view focuses not on discrete decisions but on the *policy structure* underlying decisions: not why this particular apartment building was constructed but what persistent pressures exist in the urban system that produce decisions that change housing availability in the city. Events and decisions are seen as surface phenomena that ride on an underlying tide of system structure and behavior. It is that underlying tide of policy structure and continuous behavior that is the system dynamicist's focus.

There is thus a *distancing* inherent in the system dynamics approach – not so close as to be confused by discrete decisions and myriad operational details, but not so far away as to miss the critical elements of policy structure and behavior. Events are deliberately blurred into dynamic behavior. Decisions are deliberately blurred into perceived policy structures. Insights into the connections between system structure and dynamic behavior, which are the goal of the system dynamics approach, come from this particular distance of perspective.

Suggestions for Further Reading on the Core of System Dynamics

The *System Dynamics Review*, the journal of the System Dynamics Society, published by Wiley, is the best source of current activity in the field, including methodological advances and applications.

The core of a vibrant field is difficult to discern in the flow of current work. However, the works that the field itself singles out as exemplary can give some reliable hints about what is considered vital to the core. In this sense two edited volumes are noteworthy: An early, interesting collection of applications is Roberts [24]; Richardson [21] is a more recent two-volume edited collection in the same spirit, containing prize-winning work in philosophical background, dynamic decision making, applications in the private and public sectors, and techniques for modeling with management.

In addition, the following works, selected from among winners of the System Dynamics Society's *Jay Wright Forrester Award* (see www.systemdynamics.org/Society_Awards.htm), can be considered insightful although implicit exemplars of the core of system dynamics. (Publications are listed beginning with the most recent; see the bibliography for full citations):

System Dynamics in the Evolution of the Systems Approach

Markus Schwaninger
Institute of Management, University of St. Gallen,
St. Gallen, Switzerland

Article Outline

Glossary

Cybernetics The science of communication and control in complex, dynamical systems. The core objects of study are information, communication, feedback and adaptation. In the newer versions of cybernetics, the emphasis is on observation, self-organization, self-reference and learning.

Dynamical system The dynamical system concept is a mathematical formalization of time-dependent processes. Examples include the mathematical models that describe the swinging of a clock pendulum, the flow of water in a river, and the evolution of a population of fish in a lake.

Law of requisite variety Ashby's law of requisite variety says: "Only variety can destroy variety". It implies that the varieties of two interacting systems must be in balance, if stability is to be achieved.

Organizational cybernetics The science which applies cybernetic principles to organization. Synonyms are *Management Cybernetics* and *Managerial Cybernetics*.

System There are many definitions of *system*. Two examples: A portion of the world sufficiently well defined to be the subject of study; something characterized by a structure, for example, a social system (Anatol Rapoport). A system is a family of relationships between its members acting as a whole (International Society for the Systems Sciences).

System dynamics A methodology and discipline for the modeling, simulation and control of dynamic systems. The main emphasis falls on the role of structure and its relationship with the dynamic behavior of systems, which are modeled as networks of informationally closed feedback loops between stock and flow variables.

Systems approach A perspective of inquiry, education and management, which is based on system theory and cybernetics.

System theory A formal science of the structure, behavior, and development of systems. In fact there are different system theories. General system theory is a transdisciplinary framework for the description and analysis of any kind of system. System theories have been developed in many domains, e. g., mathematics, computer science, engineering, sociology, psychotherapy, biology and ecology.

Variety A technical term for *complexity* which denotes the number of (potential) states of a system.

Definition of the Subject

The purpose of this chapter is to give an overview of the role of system dynamics (SD) in the context of the evolution of the systems movement. This is necessary because SD is often erroneously taken as the systems approach as such, not as part of it. It is also requisite to show that the processes of the evolution of both SD in particular and the systems movement as a whole are intimately linked and intertwined. Finally, in view of the purpose of the chapter the actual and potential relationships between system dynamics and the other strands of the systems movement are evaluated. This way, complementarities and synergies are identified.

Introduction

The purpose of this contribution is to give an overview of the role of system dynamics in the context of the evolution of the systems movement. "Systems movement" – often referred to briefly as "systemics" – is a broad term, which takes into account the fact that there is no single system approach, but a range of different ones. The common denominator of the different system approaches in our day is that they share a worldview focused on complex dynamic systems, and an interest in describing, explaining and designing or at least influencing them. Therefore, most of the system approaches offer not only a theory but also a way of thinking ("systems thinking" or "systemic thinking") and a methodology for dealing with systemic issues or problems.

System dynamics (SD) is a discipline and a methodology for the modeling, simulation and control of complex, dynamic systems. SD was developed by MIT professor Jay W. Forrester (e. g. [20,21]) and has been propagated by his students and associates. SD has grown to a school of numerous academics and practitioners all over the world. The particular approach of SD lies in representing the issues or systems-in-focus as meshes of closed feedback loops made up of stocks and flows, in continuous time and subject to delays.

The development of the system dynamics methodology and the worldwide community that applies SD to modeling and simulation in radically different contexts suggest that it is a "systems approach" on its own. Nevertheless, taking "system dynamics" as the (one and only) synonym for "systemic thinking" would be going too far, given the other approaches to systemic thinking as well as a variety of system theories and methodologies, many of which are complementary to SD. In any case, however, the SD community has become the strongest "school" of the Systems approach, if one takes the numbers of members in organizations representing the different schools as a measure (by 2006, the System Dynamics Society had more than 1000 members).

The rationale and structure of this contribution is as follows. Starting with the emergence of the systems approach, the multiple roots and theoretical streams of systemics are outlined. Next, the common grounds and differences among different strands of the systems approach are highlighted, and the various systems methodologies are explored. Then the distinctive features of SD are analyzed. Finally comes a reflection on the relationships of SD with the rest of the systems movement as well as with potential complementarities and synergies.

In Table 1, a time-line overview of some milestones in the evolution of the systems approach in general and System Dynamics in particular is given. Elaborating on each of the sources quoted therein would reach beyond the purpose of this chapter. However, to convey a synoptic view, a diagram showing the different systems approaches and their interrelationships is provided in the Appendix "Systems Approaches – An Overview".

Emergence of the Systems Approach

The systems movement has many roots and facets, with some of its concepts going back as far as ancient Greece. What we name as "the systems approach" today materialized in the first half of the twentieth century. At least two important components should be mentioned: those proposed by von Bertalanffy and by Wiener.

Ludwig von Bertalanffy, an American biologist of Austrian origin, developed the idea that organized wholes of any kind should be describable and, to a certain extent, explainable, by means of the same categories, and ultimately by one and the same formal apparatus. His *general systems theory* triggered a whole movement which has tried to identify invariant structures and mechanisms across different kinds of organized wholes (for example, hierarchy, teleology, purposefulness, differentiation, morphogenesis, stability, ultrastability, emergence, and evolution).

In 1948 Norbert Wiener, an American mathematician at the Massachusetts Institute of Technology, published his seminal book on *Cybernetics*, building upon interdisciplinary work carried out in cooperation with Bigelow, an IBM engineer, and Rosenblueth, a physiologist. Wiener's opus became the transdisciplinary foundation for a new science of capturing as well as designing control and communication mechanisms in all kinds of dynamic systems [81]. Cyberneticists have been interested in concepts such as information, communication, complexity, autonomy, interdependence, cooperation and conflict, self-production ("autopoiesis"), self-organization, (self-) control, self-reference and (self-) transformation of complex dynamic systems.

Along the genetic line of the tradition which led to the evolution of General Systems Theory (von Bertalanffy, Boulding, Gerard, Miller, Rapoport) and Cybernetics (Wiener, McCulloch, Ashby, Powers, Pask, Beer), a number of roots can be identified, in particular:

- Mathematics (for example, Newton, Poincaré, Lyapunov, Lotka, Volterra, Rashevsky)
- Logic (for example, Epimenides, Leibniz, Boole, Russell and Whitehead, Goedel, Spencer-Brown)
- Biology, including general physiology and neurophysiology (for example, Hippocrates, Cannon, Rosenblueth, McCulloch, Rosen)
- Engineering and computer science, including the respective physical and mathematical foundations (for example, Heron, Kepler, Watt, Euler, Fourier, Maxwell, Hertz, Turing, Shannon and Weaver, von Neumann, Walsh)
- Social and human sciences, including economics (for example, Hume, Adam Smith, Adam Ferguson, John Stuart Mill, Dewey, Bateson, Merton, Simon, Piaget).

In this last-mentioned strand of the systems movement, one focus of inquiry is on the role of feedback in communication and control in (and between) organizations and society, as well as in technical systems. The other focus of interest is on the multidimensional nature and the multilevel structures of complex systems. Specific theory building, methodological developments and pertinent applications have occurred at the following levels:

- Individual and family levels (for example, systemic psychotherapy, family therapy, holistic medicine, cognitive therapy, reality therapy)
- Organizational and societal levels (for example, managerial cybernetics, organizational cybernetics, sociocybernetics, social systems design, social ecology, learning organizations)
- The level of complex (socio-)technical systems (systems engineering)

The notion of "socio-technical systems" has become widely used in the context of the design of organized wholes involving interactions of people and technology (for instance, Linstone's multi-perspectives-framework, known by way of the mnemonic TOP (*T*echnical, *O*rganizational, *P*ersonal/individual).

As can be noted from these preliminaries, different kinds of system theory and methodology have evolved over time. One of these is a theory of dynamic systems by Jay W. Forrester, which serves as a basis for the methodology of system dynamics. Two eminent titles are [20] and [21]. In SD, the main emphasis falls on the role of structure and its relationship with the dynamic behavior of systems, modeled as networks of informationally closed feedback loops between stock and flow variables. Several other mathematical systems theories have been elaborated, for example, mathematical general systems theory (Klir, Pestel, Mesarovic and Takahara), as well as a whole stream of theoretical developments which can be subsumed under the terms "dynamic systems theory" or "theories of nonlinear dynamics" (for example, catastrophe theory, chaos theory and complexity theory). Under the latter, branches such as the theory of fractals (Mandelbrot), geometry of behavior (Abraham), self-organized criticality (Bak), and network theory (Barabasi, Watts) are subsumed. In this context, the term "sciences of complexity" is used.

In addition, a number of mathematical theories, which can be called "system theories," have emerged in different application contexts, examples of which are discernible in the following fields:

- Engineering, namely information and communication theory (Shannon and Weaver), technology and computer-aided systems theory (for example, control theory, automata, cellular automata, agent-based modeling, artificial intelligence, cybernetic machines, neural nets)
- Operations research (for example, modeling theory and simulation methodologies, Markov chains, genetic algorithms, fuzzy control, orthogonal sets, rough sets)
- Social sciences, economics in particular (for example, game theory, decision theory)
- Biology (for example, Sabelli's Bios theory of creation)
- Ecology (for example, E. and H. Odum's systems ecology).

Most of these theories are transdisciplinary in nature, i. e., they can be applied across disciplines. The Bios theory, for example is applicable to clinical, social, ecological and personal settings [54]. Examples of essentially non-mathematical system theories can be found in many different areas of study, e. g.:

- Economics, namely its institutional/evolutionist strand (Veblen, Myrdal, Boulding, Dopfer)
- Sociology (for example, Parsons' and Luhmann's social system theories, Hall's cultural systems theory)
- Political sciences (for example, Easton, Deutsch, Wallerstein)
- Anthropology (for example, Levi Strauss's structuralist-functionalist anthropology, Margaret Mead)
- Semiotics (for example, general semantics (Korzybski, Hayakawa, Rapoport), cybersemiotics (Brier))
- Psychology and psychotherapy (for example, systemic intervention (Bateson, Watzlawick, F. Simon), and fractal affect logic (Ciompi))

- Ethics and epistemology (for example, Vickers, Churchman, von Foerster, van Gigch)

Several system-theoretic contributions have merged the quantitative and the qualitative in new ways. This is the case for example in Rapoport's works in game theory as well as general systems theory, Pask's conversation theory, von Foerster's cybernetics of cybernetics (second-order cybernetics), and Stafford Beer's opus in managerial cybernetics. In all four cases, mathematical expression is virtuously connected to ethical, philosophical, and epistemological reflection. Further examples are Prigogine's theory of dissipative structures, Mandelbrot's theory of fractals, complex adaptive systems (Holland et al.), Kauffman's complexity theory, and Haken's synergetics, all of which combine mathematical analysis and a strong component of qualitative interpretation.

A large number of systems methodologies, with the pertinent threads of systems practice, have emanated from these theoretical developments. Many of them are expounded in detail in specialized encyclopedias (e. g., [27] and, under a specific theme, named *Systems Science and Cybernetics*, of the Encyclopedia of Life Support Systems [18]). In this chapter, only some of these will be addressed explicitly, in order to shed light on the role of SD as part of the systems movement.

Common Grounds and Differences

Even though the spectrum of system theories and methodologies outlined in the preceding section may seem multifarious, all of them have a strong common denominator: They build on the idea of systems as organized wholes. An objectivist working definition of a system is that of a whole, the organization of which is made up by interrelationships. A subjectivist definition is that of a set of interdependent variables in the mind of an observer, or, a mental construct of a whole, an aspect that has been emphasized by the position of constructivism. *Constructivism* is a synonym for *second-order cybernetics*. While first-order cybernetics concentrates on regulation, information and feedback, second-order cybernetics focuses on observation, self-organization and self-reference. Heinz von Foerster established the distinction between 'observed systems' for the former and 'observing systems' for the latter [74].

From the standpoint of operational philosophy, a system is, as Rapoport says, "a part of the world, which is sufficiently well defined to be the object of an inquiry or also something, which is characterized by a structure, for example, a production system" [50].

In recent systems theory, the aspect of relationships has been emphasized as the main building block of a system, as one can see from a definition published by the International Society for the Systems Sciences (ISSS): "A system is a family of relationships between its members acting as a whole" [63]. Also, purpose and interaction have played an important part in reflections on systems: Systems are conceived, in the words of Forrester [21], as "wholes of elements, which cooperate towards a common goal." Purposeful behavior is driven by internal goals, while purposive behavior rests on a function assigned from the outside. Finally, the aspects of open and closed functioning have been emphasized. Open systems are characterized by the import and export of matter, energy and information. A variant of particular relevance in the case of social systems is the operationally closed system, that is, a system which is self-referential in the sense that its self-production (autopoiesis) is a function of production rules and processes by which order and identity are maintained, and which cannot be modified directly from outside. As we shall see, this concept of operational closure is very much in line with the concept of circularity used in SD.

At this point, it is worth elaborating on the specific differences between two major threads of the systems movement, which are of special interest because they are grounded in "feedback thought" [52]: The cybernetic thread, from which organizational cybernetics has emanated, and the servomechanic thread in which SD is grounded. As Richardson's detailed study shows, the strongest influence on cybernetics came from biologists and physiologists, while the thinking of economists and engineers essentially shaped the servomechanic thread. Consequently, the concepts of the former are more focused on the adaptation and control of complex systems for the purpose of maintaining stability under exogenous disturbances. Servomechanics, on the other hand, and SD in particular, take an endogenous view, being mainly interested in understanding circular causality as the principal source of a system's behavior. Cybernetics is more connected with communication theory, the general concern of which can be summarized as how to deal with randomly varying input. SD, on the other hand, shows a stronger link with engineering control theory, which is primarily concerned with behavior generated by the control system itself, and by the role of nonlinearities. Managerial cybernetics and SD both share the concern of contributing to management science, but with different emphases and with instruments that are different but in principle complementary. Finally, the mathematical foundations are generally more evident in the basic literature on SD than in the writings on organizational cybernetics, in which the formal apparatus underlying model formulation is confined to a small number of publications (e. g., [7,10]), which are less known than the qualitative treatises. The terms *management cybernetics* and *managerial cybernetics* are used as synonyms for *organizational cybernetics*.

The Variety of Systems Methodologies

The methodologies that have evolved as part of the systems movement cannot be expounded in detail here. The two epistemological strands in which they are grounded, however, can be identified – the positivist tradition and the interpretivist tradition.

Positivist tradition denotes those methodological approaches that focus on the generation of "positive knowledge," that is, a knowledge based on "positively" ascertained facts. *Interpretivist tradition* denotes those methodological approaches that emphasize the importance of subjective interpretations of phenomena. This stream goes back to Greek art and science of the interpretation and understanding of texts.

Some systems methodologies have been rooted in the positivist tradition, and others in the interpretivist tradition. The differences between the two can be described along the following set of polarities:

- An objectivist versus a subjectivist position
- A conceptual–instrumental versus a communicational/cultural/political rationality
- An inclination to quantitative versus qualitative modeling
- A structuralist versus a discursive orientation.

A positivistic methodological position tends toward the objectivistic, conceptual–instrumental, quantitative and structuralist–functionalist in its approach. An interpretive position, on the other hand, tends to emphasize the subjectivist, communicational, cultural, political, ethical and esthetic—that is, the qualitative and discursive aspects. It would be too simplistic to classify a specific methodology in itself as being "positivistic" or "interpretative". Despite the traditions they have grown out of, several methodologies have evolved and been reinterpreted or opened to new aspects (see below).

In the following, a sample of systems methodologies will be characterized and positioned in relation to these two traditions, beginning with those in the positivistic strand:

- *"Hard" OR methods*. Operations research (OR) uses a wide variety of mathematical and statistical methods and techniques—for example of optimization, queuing, dynamic programming, graph theory, time series analysis—to provide solutions for organizational and managerial problems, mainly in the operational domains of production and logistics, and in finance.
- *Living systems theory*. In his LST, James Grier Miller [44] identifies a set of 20 necessary components that can be discerned in living systems of any kind. These structural features are specified on the basis of a huge empirical study and proposed as the "critical subsystems" that "make up a living system." LST has been used as a device for diagnosis and design in the domains of engineering and the social sciences.
- *Viable system model*. To date, Stafford Beer's VSM is probably the most important product of organizational cybernetics. It specifies a set of management functions and their interrelationships as the sufficient conditions for the viability of any human or social system (see [10]). These are applicable in a recursive mode, for example, to the different levels of an organization. The VSM has been widely applied in the diagnostic mode, but also to support the design of all kinds of social systems. Specific methodologies for these purposes have been developed, for instance for use in consultancy. The term viable system diagnosis (VSD) is also used.

The methodologies and models addressed up to this point have by and large been created in the positivistic tradition of science. Other strands in this tradition do exist, e. g., systems analysis and systems engineering, which together with OR have been called "hard systems thinking" (p. 127 in [31]). Also, more recent developments such as mathematical complexity and network theories, agent-based modeling and most versions of game theory can be classified as hard systems approaches.

The respective approaches have not altogether been excluded from fertile contacts with the interpretivist strand of inquiry. In principle, all of them can be considered as instruments for supporting discourses about different interpretations of an organizational reality or alternative futures studied in concrete cases. In our time, most applications of the VSM, for example, are constructivist in nature. To put it in a nutshell, these applications are (usually collective) constructions of a (new) reality, in which observation and interpretation play a crucial part. In this process, the actors involved make sense of the system under study, i. e., the organization in focus, by mapping it on the VSM. At the same time they bring forth "multiple realities rather than striving for a fit with one reality" (p. 299 in [29]).

The second group of methodologies is part of the interpretive strand:

- *Interactive Planning*. IP is a methodology, designed by Russell Ackoff [1], and developed further by Jamshid

Gharajedaghi [28], for the purpose of dealing with "messes" and enabling actors to design their desired futures, as well as to bring them about. It is grounded in theoretical work on purposeful systems, reverts to the principles of continuous, participative and holistic planning, and centers on the idea of an "idealized design."

- *Soft Systems Methodology*. SSM is a heuristic designed by Peter Checkland [13,14] for dealing with complex situations. Checkland suggests a process of inquiry constituted by two aspects: A conceptual one, which is logic based, and a sociopolitical one, which is concerned with the cultural feasibility, desirability and implementation of change.
- *Critical Systems Heuristics*. CSH is a methodology, which Werner Ulrich [67,68] proposed for the purpose of scientifically informing planning and design in order to lead to an improvement in the human condition. The process aims at uncovering the interests that the system under study serves. The legitimacy and expertise of actors, and particularly the impacts of decisions and behaviors of the system on others – the "affected" – are elicited by means of a set of boundary questions. CSH can be seen as part of a wider movement known as the "Emancipatory Systems Approach" which embraces, e. g., Freire's Critical Pedagogy, Interpretive Systemology, and Community OR (see pp. 291ff in [31]).

All three of these methodologies (IP, SSM, and CSH) are positioned in the interpretive tradition. Other methodologies and concepts which can be subsumed under the interpretive systems approach are, e. g., Warfield's science of generic design, Churchman's social system design, Senge's soft systems thinking, Mason and Mitroff's strategic assumptions surfacing and testing (SAST), Eden and Ackermann's strategic options in development and analysis (SODA), and other methodologies of soft operational research (for details, see pp. 211ff in [31]). The interpretive methodologies were designed to deal with qualitative aspects in the analysis and design of complex systems, emphasizing the communicational, social, political and ethical dimensions of problem solving. Several authors mention explicitly that they do not preclude the use of quantitative techniques or include such techniques in their repertoire (e. g., the biocyberneticist Frederic Vester).

In an advanced understanding of system dynamics both of these traditions—positivist and interpretivist—are synthesized. The adherents of SD conceive of model building and validation as a semi-formal, relativistic, holistic social process. Validity is understood as usefulness or fitness in relation to the purpose of the model, and validation as an elaborate set of procedures – including logico-structural, heuristic, algorithmic, statistical, and also discursive components – by which the quality of and the confidence in a model are gradually improved (see [4,5,59]).

System Dynamics – Its Features, Strengths and Limitations

The features, strengths and limitations of the SD methodology are a consequence of its specific characteristics. In the context of the multiple theories and methodologies of the systems movement, some of the distinctive features of SD are (for an overview, see [52], pp. 142ff in [31]):

- *Feedback as conceptual basis*. SD model systems are high-order, multiple-loop networks of closed loops of information. Concomitantly, an interest in non-linearities, long-term patterns and internal structure rather than external disturbances is characteristic of SD (p. 31 in [40]). However, SD models are not "closed systems", as sometimes is claimed, in the sense that (a) flows can originate from outside the system's boundaries, (b) representations of exogenous factors or systems can be incorporated into any model as parameters or special modules, and (c) new information can be accommodated via changes to a model. In other words, the SD view hinges on a view of systems which are closed in a causal sense but not materially (p. 297 in [52]).
- *Focus on internally generated dynamics*. SD models are conceived as closed systems. The interest of users is in the dynamics generated inside those systems. Given the nature of closed feedback loops and the fact that delays occur within them, the dynamic behavior of these systems is essentially non-linear.
- *Emphasis on understanding*. For system dynamicists the understanding of the dynamics of a system is the first goal to be achieved by means of modeling and simulation. Conceptually, they try to understand events as embedded in patterns of behavior, which in turn are generated by underlying structures. Such understanding is enabled by SD as it "shows how present policies lead to future consequences" (Sect. VIII in [23]). Thereby, the feedback loops are "a major source of puzzling behavior and policy difficulties" (p. 300 in [52]). SD models purport to test mental models, hone intuition and improve learning (see [65]).
- *High degree of operationality*. SD relies on formal modeling. This fosters disciplined thinking; assumptions, underlying equations and quantifications must be clarified. Feedback loops and delays are visualized and formalized; therewith the causal logic inherent in a model

is made more transparent and discussable than in most other methodologies [53]. Also, a high level of realism in the models can be achieved. SD is therefore apt to support decision-making processes effectively.

- *Far-reaching requirements (and possibilities) for the combination of qualitative and quantitative aspects of modeling and simulation*. This is a consequence of the emphasis on understanding. The focus is not on point-precise prediction, but on the generation of insights into the patterns generated by the systems under study.
- *High level of generality and scale robustness*. The representation of dynamic systems in terms of stocks and flows is a generic form, which is adequate for a wide spectrum of potential applications. This spectrum is both broad as to the potential subjects under study, and deep as to the possible degrees of resolution and detail [38]. In addition, the SD methodology enables one to deal with large numbers of variables within multiple interacting feedback loops (p. 9 in [22]). SD has been applied to the most diverse subject areas, e. g., global modeling, environmental issues, social and economic policy, corporate and public management, regional planning, medicine, psychology and education in mathematics, physics and biology.

The features of SD just sketched out result in both strengths and limitations. We start with the strengths.

Strengths of SD

1. Its *specific modeling approach* makes SD particularly helpful in gaining insights into the patterns exhibited by dynamic systems, as well as the structures underlying them. Closed-loop modeling has been found most useful in fostering understanding of the dynamic functioning of complex systems. Such understanding is especially facilitated by the principle of modeling the systems or issues under study in a continuous mode and at rather high aggregation levels [20,38]. With the help of relatively small but insightful models, and by means of sensitivity analyses as well as optimization heuristics incorporated in the application software packages, decision-spaces can be thoroughly explored. Vulnerabilities and the consequences of different system designs can be examined with relative ease.
2. The *generality of the methodology* and its power to crystallize operational thinking in realistic models have triggered applications in the most varied contexts. Easy-to-use software and the features of screen-driven modeling via graphic user interfaces provide a strong lever for collaborative model-building in teams (cf. [2,69]).
3. Another strong point is the *momentum of the SD movement*. Due to the strengths commented above this point, the community of users has grown steadily, being probably the largest community within the systems movement. Lane (p. 484 in [36]) has termed SD "one of the most widely used systems approaches in the world."
4. Its specific features make SD an exceptionally effective tool for *conveying systemic thinking* to anybody. Therefore, it also has an outstanding track-record of classroom applications for which "learner-directed learning" [24] or "learner-centered learning" is advocated [25,26]. Pertinent audiences range from schoolchildren at the levels of secondary and primary schools to managers and scientists.

Given these strengths, the community of users has not only grown significantly, but has also transcended disciplinary boundaries, ranging from the formal and natural sciences to the humanities, and covering multiple uses from theory building and education to the tackling of real-world problems at almost any conceivable level. Applications to organizational, societal and ecological issues have seen a particularly strong growth. This feeds back on the availability and growth of the knowledge upon which the individual modeler can draw.

The flip side of most of the strengths outlined here embodies the limitations of SD; we concentrate on those which can be relevant to a possible complementarity of SD with other systems methodologies.

Limitations of SD

1. The main point here is that SD does not provide a framework or methodology for the *diagnosis and design* of organizational structures in the sense of interrelationships among organizational actors. This makes SD susceptible to completion from without – a completion which organizational cybernetics (OC), and the VSM in particular, but also living system theory (LST), especially can provide. The choice falls on these two approaches because of their strong heuristic power and their complementary strengths in relation to SD (cf. [57,61]).
2. Another limitation of SD is related to the *absorption of variety* (complexity) by an organization. *Variety* is a technical term for *complexity*, which denotes a (high) number of potential states or behaviors of a system (based on [3,8]). SD offers an approach to the handling of variety which allows modeling at different scales of a problem or system [47]. It focuses on the identification, at a certain resolution level or possibly several resolution levels, of the main stock variables which will be

affected by the respective flows. These, in turn, will be influenced by parameters and auxiliary variables. This approach, even though it enables thinking and modeling at different scales, does not provide a formal procedure for an organization to cope with the external complexity it faces, namely, for designing a structure which can absorb that complexity. In contrast, OC and LST offer elaborate models to enable the absorption of variety, in the case of the VSM based explicitly on Ashby's *Law of Requisite Variety*. It says "Only variety can destroy variety", which implies that the varieties of two interacting systems must be in balance, if stability is to be achieved [3]. The VSM has two salient features in this respect. Firstly, it helps design an organizational unit for viability, by enabling it to attenuate the complexity of its environment, and also to enhance its eigenvariety, so that the two are in balance. The term *variety engineering* has been used in this context [9]. Secondly, the recursive structure of the VSM ensures that an organization with several levels will develop sufficient eigenvariety along the fronts on which the complexity it faces unfolds. Similarly, LST offers the conditions for social systems to survive, by maintaining thermodynamically highly improbable energy states via continuous interaction with their environments. The difference between the two approaches is that the VSM functions more in the strategic and informational domains, while the LST model essentially focuses on the operational domain. In sum, both can make a strong contribution related to coping with the external complexity faced by organizations, and therefore can deliver a strong complement to SD.

3. Finally, the design of *modeling processes* confronts SD with specific challenges. The original SD methodology of modeling and simulation was to a large extent functionally and technically oriented. This made it strong in the domain of logical analysis, while the socio-cultural and political dimensions of the modeling process were, if not completely out of consideration, at least not a significant concern in methodological developments. The SD community – also under the influence of the soft systems approaches – has become aware of this limitation and has worked on incorporating features of the social sciences into its repertoire. The following examples, which document this effort to close the gap, stand for many. Extensive work on group model building has been achieved, which explores the potential of collaborative model building [69]. A new schema for the modeling process has been proposed, which complements logic-based analysis by cultural analysis [37]. The social dimension of system dynamics-based modeling has become subject to intensive discussion ([77]; and other contributions to the special issue of *Systems Research and Behavioral Science*, Vol. 51, No. 4, 2006). Finally, in relation to consultancy methodology, modeling has been framed as a learning process [34] and as second-order intervention [60].

As has been shown, there is a need to complement classical SD with other methodologies, when issues are at stake which it cannot handle by itself. VSM and LST are excellent choices when issues of organizational diagnosis or design are to be tackled.

The limitations addressed here call attention to other methodologies which exhibit certain features that traditionally were not incorporated, or at least not explicit, in SD methodology. One aspect concerns the features that explicitly address the subjectivity of purposes and meanings ascribed to systems. In this context, support for problem formulation, model construction and strategy design by individuals on the one hand and groups on the other are relevant issues. Also, techniques for an enhancement of creativity (e. g., the generation and the reframing of options) in both individuals and groups are a matter of concern. Two further aspects relate to methodological arrangements for coping with the specific issues of negotiation and alignment in pluralist and coercive settings.

As far as the modeling processes are concerned, group model building has proven to be a valuable complement to pure modeling and simulation. However, there are other systems methodologies which should be considered as potentially apt to enrich SD analysis, namely the soft approaches commented upon earlier, e. g., interactive planning, soft system methodology and critical system heuristics.

On the other hand, SD can be a powerful complement to other methodologies which are more abstract or more static in nature. This potential refers essentially to all systems approaches which stand in the interpretive ("soft") tradition, but also to approaches which stand in the positivist traditions, such as the VSM and LST. These should revert to the support of SD in the event that tradeoffs between different goals must be handled, or if implications of long-term decisions on short-term outcomes (and vice versa) have to be ascertained, and whenever contingencies or vulnerabilities must be assessed.

Actual and Potential Relationships

It should be clear by now that the systems movement has bred a number of theories and methodologies, none of which can be considered all-embracing or complete. All of them have their strengths and weaknesses, and their specific potentials and limitations.

Since Burrell and Morgan [12] adverted to incommensurability between different paradigms of social theory, several authors have acknowledged or even advocated methodological complementarism. They argue that there is a potential complementarity between different methods, and, one may add, models, even if they come from distinct paradigms. Among these authors are, e. g., Brocklesby [11], Jackson [30], Midgley [43], Mingers [45], Schwaninger [55] and Yolles [83]. These authors have opened up a new perspective in comparison with the non-complementaristic state-of-the-art.

In the past, the different methodologies have led to the formation of their own traditions and "schools," with boundaries across which not much dialogue has evolved. The methodologies have kept their protagonists busy testing them and developing them further. Also, the differences between different language games and epistemological traditions have often suggested incommensurability, and therewith have impaired communication. Prejudices and a lack of knowledge of the respective other side have accentuated this problem: Typically, "hard" systems scientists are suspicious of "soft" systems scientists. For example, many members of the OR community, not unlike orthodox quantitatively oriented economists, adhere to the opinion that "SD is too soft." On the other hand the protagonists of "soft" systems approaches, even though many of them have adopted feedback diagrams (causal loop diagrams) for the sake of visualization, are all too often convinced that "SD is too hard." Both of these judgments indicate a lack of knowledge, in particular of the SD validation and testing methods available, on the one hand, and the technical advancements achieved in modeling and simulation, on the other (see [5,59,66]).

In principle, both approaches are complementary. The qualitative view can enrich quantitative models, and it is connected to their philosophical, ethical and esthetical foundations. However, qualitative reasoning tends to be misleading if applied to causal network structures without being complemented by formalization and quantification of relationships and variables. Furthermore, the quantitative simulation fosters insights into qualitative patterns and principles. It is thus a most valuable device for validating and honing the intuition of decision makers, via corroboration and falsification.

Proposals that advocate mutual learning between the different "schools" have been formulated inside the SD community (e. g., [35]). The International System Dynamics Conference of 1994 in Stirling, held under the banner of "Transcending the Boundaries," was dedicated to the dialogue between different streams of the systems movement.

Also, from the 1990s onwards, there were vigorous efforts to deal with methodological challenges, which traditionally had not been an important matter of scientific interest within the SD community. Some of the progress made in these areas is documented in a special edition of *Systems Research and Behavioral Science* (Vol. 21, No. 4, July-August 2004). The main point is that much of the available potential is based on the complementarity, not the mutual exclusiveness, of the different systems approaches.

In the future, much can be gained from leveraging these complementarities. Here are two examples of methodological developments in this direction, which appear to be achievable and potentially fertile: The enhancement of qualitative components in "soft" systems methodologies in the process of knowledge elicitation and model building (cf. [69]), and the combination of cybernetics-based organizational design with SD-based modeling and simulation (cf. [61]). Potential complementarities exist not only across the qualities – quantities boundary, but also within each one of the domains. For example, with the help of advanced software, SD modeling ("top-down") and agent-based modeling ("bottom-up") can be used in combination.

From a meta-methodological stance, generalist frameworks have been elaborated which contain blueprints for combining different methodologies where this is indicated. Two examples are:

- *Total systems intervention* (TSI) is a framework proposed by Flood and Jackson [19], which furnishes a number of heuristic schemes and principles for the purpose of selecting and combining systems methods/methodologies in a customized way, according to the issue to be tackled. SD is among the recommended "tools".
- *Integrative systems methodology* (ISM) is a heuristic for providing actors in organizations with requisite variety, developed by Schwaninger [55,56]. It advocates (a) dealing with both content– and context-related issues during the process, and (b) placing a stronger emphasis on the validation of qualitative and quantitative models as well as strategies, in both dimensions of the content of the issue under study and the organizational context into which that issue is embedded. For this purpose, the tools of SD (to model content) and organizational cybernetics – the VSM (to model context) – are cogently integrated.

These are only two examples. In principle, SD could make an important contribution in the context of most of the methodological frameworks, far beyond the extent to which this has been the case. Systems methodologists and practitioners can potentially benefit enormously from including SD methodology in their repertoires.

Outlook

There have recently been calls for an eclectic "mixing and matching" of methodologies. In light of the epistemological tendencies of our time towards radical relativism, it is necessary to warn against taking a course in which "anything goes". It is most important to emphasize that the desirable methodological progress can only be achieved on the grounds of scientific rigor. This postulate of "rigor" is not to be confused with an encouragement of "rigidity." The necessary methodological principles advocated here are disciplined thinking, a permanent quest for better models (that is, thorough validation), and the highest achievable levels of transparency in the formalizations as well as of the underlying assumptions and sources used. Scientific rigor, in this context, also implies that combinations of methodologies reach beyond merely eclectic addons from different methodologies, so that genuine integration towards better adequacy to the issues at hand is achieved.

The contribution of system dynamics can come in the realms of the following:

- Fostering disciplined thinking
- Understanding dynamic behaviors of systems and the structures that generate them
- Exploring paths into the future and the concrete implications of decisions
- Assessing strategies as to their robustness and vulnerabilities, in ways precluded by other, more philosophical, and generally "soft" systems approaches

These latter streams can contribute to reflecting and tackling the meaning- and value-laden dimensions of complex human, social and ecological systems. Some of their features should and can be combined synergistically with system dynamics, particularly by being incorporated into the repertoires of system dynamicists. From the reverse perspective, incorporating system dynamics as a standard tool will be of great benefit for the broad methodological frameworks. Model formalization and dynamic simulation may even be considered necessary components for the study of the concrete dynamics of complex systems.

Finally, there are also many developments in the "hard", i. e., mathematics-, statistics-, logic-, and informatics-based methods and technologies, which are apt to enrich the system dynamics methodology, namely in terms of modeling and decision support. For example, the constantly evolving techniques of time-series analysis, filtering, neural networks and control theory can improve the design of system-dynamics-based systems of (self-)control. Also, a bridge across the divide between the top-down modeling approach of SD and the bottom-up approach of agent-based modeling appears to be feasible. Furthermore, a promising perspective for the design of genuinely "intelligent organizations" emerges if one combines SD with advanced database-management, cooperative model building software, and the qualitative features of the "soft" systems methodologies.

The approaches of integrating complementary methodologies outlined in this contribution definitely mark a new phase in the history of the systems movement.

Appendix

Milestones in the Evolution of the Systems Approach in General and System Dynamics in Particular

The table gives an overview of the systems movement's evolution, as shown in its main literature; and that overview is not exhaustive.

Systems Approaches – An Overview

Note: This diagram shows three streams of the systems approach in the context of their antecedents. The general systems thread has its origins in philosophical roots from antiquity: The term *system* derives from the old Greek *σύστημα* (systēma), while, *cybernetics* stems from the Greek *κυβερνήτης* (kybernētēs). The arrows between the threads stand for interrelationships and efforts to synthesize the connected approaches. For example, integrated systems methodology is an integrative attempt to leverage the complementarities of system dynamics and organizational cybernetics. Enumerated to the left and right of the scheme are the fields of application. The big arrows in the upper region of the diagram indicate that the roots of the systems approach continue influencing the different threads and the fields of application even if the path via general systems theory is not pursued.

The diagram is not a complete representation, but the result of an attempt to map the major threads of the systems movement and some of their interrelations. Hence, the schema does not cover all schools or protagonists of the movement. Why does the diagram show a dynamic and evolutionary systems thread and a cybernetics thread, if cybernetics is about dynamic systems? The latter embraces all the approaches that are explicitly grounded in cybernetics. The former relates to all other approaches

System Dynamics in the Evolution of the Systems Approach, Figure 1

concerned with dynamic or evolutionary systems. The simplification made it necessary to somewhat curtail logical perfection for the sake of conveying a synoptic view of the different systems approaches, in a language that uses the categories common in current scientific and professional discourse. Overlaps exist, e. g., between dynamic systems and chaos theory, cellular automata and agent-based modeling.

System Dynamics, Introduction to

Brian Dangerfield
Centre for OR & Applied Statistics, Salford Business School, University of Salford, Salford, UK

When Jay Wright Forrester published his first paper in 1958 he subtitled it *"a major breakthrough for decision-makers"*. At the time some thought this rather an exaggeration if not pompous. Now that 50 years of system dynamics (SD) has elapsed we can at least point to the achievements made and re-state continuing progress in the pages of this section. Was it a 'major breakthrough'? It certainly has the potential to raise the standards in evidence-based policy making to warrant this description and some startlingly good examples of such work will be mentioned here. But after 50 years perhaps one might expect more than has surfaced heretofore.

The key might be connected to the skills required to formulate good SD models – those which address a real-world problem with devastating simplicity and insight. It is deceptively easy to produce an SD model but there are subtleties involved in producing a really effective model for policy purposes. An uplift in modeling skills is something which a subset of the (now significant) amount of published material on SD is aimed at and this section will add to that corpus of work. In addition it will illustrate the extent to which SD applications have spread from its genesis in business to embrace health care, environmental, energy and climate issues, project management, some aspects of biological science and human physiology, governmental and public policy generally, economics (mainly macro), the diffusion of innovations and finally social and economic development. Other applications are being encountered as the power of the methodology is becoming appreciated. It has long since justified the change of title from ***Industrial*** Dynamics (1958) to ***System*** Dynamics (1970 onwards).

Richardson contributes an overview of the basics of SD modeling (see ► System Dynamics, The Basic Elements of). The underlying conceptual framework is that of the information feedback loop together with resource stocks and flows and an endogenous perspective on causation. The simplicity of the loop concept is apt to contribute to the apparent ease with which SD models can be created (along with the icon-based suites of SD software). But the novice reader should appreciate that it can take time to assimilate the modeling skills necessary to execute well an SD model-based application. Practice is essential and the references included will lead to further published material to assist the steep climb up the learning curve. So-called experts are still being confronted with the subtleties of SD modeling after years of involvement.

To place the SD methodology in context, the contribution by Schwaninger (see ► System Dynamics in the Evolution of the Systems Approach) profiles it alongside various others 'systems' based approaches which have emerged in the management and social sciences. Those professing to become experts in SD need to know about the other range of approaches which co-exist in the field of systems science. All these other methodologies have their own enthusiasts and this may even extend to the formation of societies with annual conferences. His Appendix B shows a diagram of the different systems approaches and their interrelationships.

The foundations of the SD methodology can be characterized by certain philosophical issues. Olaya's text (see ► System Dynamics Philosophical Background and Underpinnings) defines a central one as presentationalism, associated with the notion of 'mental models'. A number of other philosophical issues which relate to SD are introduced, including those of positivism and social theory.

The practice of SD when applied to real-world applications essentially involves managerial learning and will often involve an interaction with client teams rather than one individual. How best to organize such structured approaches to participative model building is described by Rouwette and Vennix (see ► Group Model Building). Client participation is required for successful modeling.

If the promotion of learning and understanding is the primary *raison d'etre* of SD, then achievement of this goal in an individual can be a significant accomplishment, especially if that person is the most senior in the client team. But there is a further goal to be pursued should the study fully reap the benefits of the SD methodology: How can we foster *organizational* learning? Maani tackles this head on (see ► System Dynamics and Organizational Learning). He defines the core capabilities of a learning organization and goes on to list the developing literature on organizational learning and, most importantly, how SD can aid the process through learning laboratories and microworlds.

Running an SD model creates a time-path of output behavior covering all the variables it is deemed necessary to include in the model. The various runs of the model are, most frequently, addressed in comparative fashion rather than taken in isolation. They can therefore be described as computer-based scenarios each of which charts a possible but not assured future. Georgantzas (see ► Scenario-Driven Planning with System Dynamics) describes environmental (traditional) scenario generation for which there is a considerable body of literature. But he emphasizes that successful strategy design involves the integration of three things: a knowledge of the business environment; the effects of unstated assumptions about change in the environment and strategy on performance; and finally the need to *compute* the effects on organizational performance. These three facets are accomplished by the process of SD modeling.

Thus far this introductory roadmap has covered all the background for contextualizing and creating an SD model. We now turn to various tasks associated with ex post modeling activities. Three such aspects are covered: model validation; analytical methods to explain behavior and determine dominant loops; and model optimization.

Schwaninger and Groesser (see ► System Dynamics Modeling: Validation for Quality Assurance) range over the various aspects of model validation, beginning with its epistemological foundations. In real-world modeling studies testing and validation is a sine qua non of the process. The range of tests made available and the attention given to the task of validation in the literature mark out SD as unique in the field of management science. Few other methodologies get near to the variety of tests which can be applied to an SD model. The authors consider the range of tests under three headings: model-related context; model structure; and model behavior.

Kampmann and Oliva deal with the behavioral analysis issue (see ► System Dynamics, Analytical Methods for Structural Dominance Analysis in). This activity tries to shed light on the model's dynamic behavior: Why does it behave as it does? What loop structures are responsible for the dominant behavior – and indeed shifts in that behavior where it occurs? In other words, they explore the link between system structure and dynamic behavior. Early methods used eigenvalue analysis but, since then, more sophisticated approaches have been put forward. A major advance will occur when one or more of these is refined enough to be included in an SD software package. This is likely to take some time although an improved user interface showing links glowing with differing degrees of intensity, reflecting their relative importance, is possible in the not-too-distant future.

Dangerfield describes the methods for improving model performance (see ► System Dynamics Models, Optimization of). The task can be categorized under two headings: calibration and policy optimization. The former relates to the determination of optimal parameter sets which deliver the best fit of the model to past time series data. Policy optimization on the other hand seeks to establish policies which deliver the 'best' performance against a suitable metric, such as minimum cost or maximum revenue. Using such an approach can accelerate the learning which comes from repeated runs of the model. Sadly, in the existing SD literature, there is scant evidence of its use in real-world studies.

The methodology of SD exists for no other reason than to offer a quantum leap in the standards of policy analysis. Therefore, any review must include a range through the landscape which defines areas of application. There are eight such areas covered in this section and the choice has been made in the knowledge that there are others which may also have been included and some new areas which are only just being opened up to the tools of SD modeling.

Business Strategy was the genesis of SD applications and rightly takes pride of place. This is the field in which the most numerous SD applications occur. Lyneis (see ► Business Policy and Strategy, System Dynamics Applications to) concentrates on the process of how SD models are used in the task of strategy formulation. He goes on to consider the various drivers of business dynamics such as oscillations in supply chains and boom and bust life cycles. Detailed references are provided for a wide range of business application case studies.

Health care is consuming a higher share of GDP in many Western industrialized countries. This is due to the age profile of the population and advances in pharmacological and medical technologies. It is unsurprising that SD methods have been applied in tackling some of the most high-profile issues in health care and the relatively recent literature is testimony to the success of SD-based analysis. Indeed, it is arguable that some of the best modeling applications have surfaced in this sector. To do justice to the field of health care two contributions were solicited, in part because of the different funding systems which exist on either side of the Atlantic: Wolstenholme surveys the work done by UK and European authors (see ► Health Care in the United Kingdom and Europe, System Dynamics Applications to), whilst Hirsch and Homer concentrate on work published by US authors (see ► Health Care in the United States, System Dynamics Applications to).

Wolstenholme describes work carried out in the UK and Continental Europe but gives particular emphasis to three areas where models have been deployed. He starts with the problem of delayed hospital discharge which generates hospital capacity problems. Epidemiology is also reviewed, in particular research on the epidemiology of HIV/AIDS. Finally, recent work on mental health reform in the UK is described.

Hirsch and Homer note that the system in the USA is comparatively difficult to manage because of its free-market approach and relative lack of regulation. They concentrate on three main areas: disease epidemiology including heart disease and diabetes; substance abuse; and health care capacity and delivery.

Along with health care, the depletion of environmental resources and its effects has consumed many thousands of column inches in printed news media. SD has been employed in the pursuit of more compelling applications in this sector and the efforts go back to the well-known *Limits to Growth* study in 1971–72. Ford charts the most notable efforts which have emerged (see ► System Dynamics Models of Environment, Energy and Climate Change). He ranges over environmental resource problems in the western USA, models for greater understanding of climate change and global warming and concludes with studies in energy, specifically two applications to the electric power industry.

The field of economics is one where SD has received a mostly hostile reception. The statistical economic modeling tool of econometrics has an extensive history and as a preferred modeling methodology seems hard to dislodge. However, there are an increasing number of heterodox economists who are prepared to embrace SD concepts and Radzicki (see ► System Dynamics and Its Contribution to Economics and Economic Modeling) describes the advances taking place. Whilst some of the literature embodies the translation of existing economic models into an SD format (which is a laudable objective) he calls for more economic dynamics models to be built from scratch embodying the best practice in SD modeling. Economic policy is too important to be informed by a single, seemingly unassailable, modeling methodology and it is to be hoped that in the future SD will become even more accepted as a viable tool for use in this field.

In a similar vein comes the contribution of Saeed (see ► Dynamics of Income Distribution in a Market Economy: Possibilities for Poverty Allevation). He takes an economic modeling perspective and describes an SD model which explains resource allocation, production and entitlements in a market economy. Its purpose is to understand better how poverty might be reduced in the context of the redistribution of income. A comprehensive listing of the model is provided in an appendix.

The application of SD to public policy generally is dealt with by Andersen, Rich and MacDonald (see ► Public Policy, System Dynamics Applications to). They emphasize how public policy issues are complex, cross organizational boundaries, involve stakeholders with widely different perspectives and evolve over time, such that longer term results may be wholly different from short-term outcomes. Detail is provided for one public policy case involving the Governor's Office of Regulatory Assistance in New York State. They conclude with coverage of studies in a range of public domains such as defense, health care, education and the environment.

One area of SD application has brought the methodology into the legal arena. Disruption and delay in the execution of complex projects invariably finds two parties in dispute. Such disputes often center upon time delays and use of resources on projects – and what might have happened if things had been managed differently. SD models have been employed by parties to such disputes to attempt to justify the occurrence of these events. Howick, Ackermann, Eden and Williams (see ► Delay and Disruption in Complex Projects) report on how cognitive mapping, cause mapping and SD can be fused into what they describe as a cascade model building process. The result is a rigorous process for explaining why a project behaved in a certain way.

New products and processes are emerging at an ever-increasing rate in modern times. We need to understand the myriad mechanisms which are the basis for their rate of adoption. Milling and Maier range over various SD models which have been created to understand and improve the management of the diffusion of innovations (see ▶ Diffusion of Innovations, System Dynamics Analysis of the). From the often-cited Bass diffusion model (1969) the authors develop a series of additional features in a modular fashion. These features include competition, network externalities, dynamic pricing and research and development. They conclude by stressing how it is not possible to offer general recommendations for strategies in dynamic and complex environments; such recommendations can only be given in the context of the specific case under scrutiny.

System Dynamics and Its Contribution to Economics and Economic Modeling

Article Outline

Glossary

Stock Stocks, which are sometimes referred to as "levels" or "states", accumulate (i. e., sum up) the information or material that flows into and out of them. Stocks are thus responsible for decoupling flows, creating delays, preserving system memory, and altering the time shape of flows.

Flow Flows of information or material enter and exit a system's stocks and, in so doing, create a system's dynamics. Stated differently, the net flow into or out of a stock is the stock's rate of change. When human decision making is represented in a system dynamics model, it appears in the system's flow equations. Mathematically, a system's flow equations are ordinary differential equations and their format determines whether or not a system is linear or nonlinear.

Feedback Feedback is the transmission and return of information about the amount of information or material that has accumulated in a system's stocks. When the return of this information reinforces a system's behavior, the loop is said to be positive. Positive loops are responsible for the exponential growth of a system over time. Negative feedback loops represent goal seeking behavior in complex systems. When a negative loop detects a gap between the amount of information or material in a system's stock and the desired amount of information or material, it initiates corrective action. If this corrective action is not significantly delayed, the system will smoothly adjust to its goal. If the corrective action is delayed, however, the system can overshoot or undershoot its goal and the system can oscillate.

Full information maximum likelihood with optimal filtering FIMLOF is a sophisticated technique for estimating the parameters of a system dynamics model, while simultaneously fitting its output to numerical data. Its intellectual origins can be traced to control engineering and the work of Fred Schwepe. David Peterson pioneered a method for adapting FIMLOF for use in system dynamics modeling.

Definition of the Subject

System dynamics is a computer modeling method that has its intellectual origins in control engineering, management science, and digital computing. It was originally created as a tool to help managers better understand and control corporate systems. Today it is applied to problems in a wide variety of academic disciplines, including economics. Of note is that system dynamics models often generate behavior that is both counterintuitive and at odds with traditional economic theory. Historically, this has caused many system dynamics models to be evaluated critically, especially by some economists. However, today economists from several schools of economic thought are beginning to use system dynamics, as they have found it useful for incorporating their nontraditional ideas into formal models.

Introduction

System dynamics is a computer simulation modeling methodology that is used to analyze complex nonlinear dynamic feedback systems for the purposes of generating insight and designing policies that will improve system performance. It was originally created in 1957 by Jay W. Forrester of the Massachusetts Institute of Technology as a method for building computer simulation models of problematic behavior within corporations. The models were used to design and test policies aimed at altering a corporation's structure so that its behavior would improve and become more robust. Today, system dynamics is applied to a large variety of problems in a multitude of academic disciplines, including economics.

System dynamics models are created by identifying and linking the relevant pieces of a system's structure and simulating the behavior generated by that structure. Through an iterative process of structure identification, mapping, and simulation a model emerges that can explain (mimic) a system's problematic behavior and serve as a vehicle for policy design and testing.

From a system dynamics perspective a system's structure consists of stocks, flows, feedback loops, and limiting factors. Stocks can be thought of as bathtubs that accumulate/de-cumulate a system's flows over time. Flows can be thought of as pipe and faucet assemblies that fill or drain the stocks. Mathematically, the process of flows accumulating/de-cumulating in stocks is called integration. The integration process creates all dynamic behavior in the world be it in a physical system, a biological system, or a socioeconomic system. Examples of stocks and flows in economic systems include a stock of inventory and its inflow of production and its outflow of sales, a stock of the book value of a firm's capital and its inflow of investment spending and its outflow of depreciation, and a stock of employed labor and its inflow of hiring and its outflow of labor separations.

Feedback is the transmission and return of information about the amount of information or material that has accumulated in a system's stocks. Information travels from a stock back to its flow(s) either directly or indirectly, and this movement of information causes the system's faucets to open more, close a bit, close all the way, or stay in the same place. Every feedback loop has to contain at least one stock so that a simultaneous equation situation can be avoided and a model's behavior can be revealed recursively. Loops with a single stock are termed minor, while loops containing more than one stock are termed major.

Two types of feedback loops exist in system dynamics modeling: positive loops and negative loops. Generally speaking, positive loops generate self-reinforcing behavior and are responsible for the growth or decline of a system. Any relationship that can be termed a virtuous or vicious circle is thus a positive feedback loop. Examples of positive loops in economic systems include path dependent processes, increasing returns, speculative bubbles, learning-by-doing, and many of the relationships found in macroeconomic growth theory. Forrester [12], Radzicki and Sterman [46], Moxnes [32], Sterman (Chap. 10 in [55]), Radzicki [44], Ryzhenkov [49], and Weber [58] describe system dynamics models of economic systems that possess dominant positive feedback processes.

Negative feedback loops generate goal-seeking behavior and are responsible for both stabilizing systems and causing them to oscillate. When a negative loop detects a gap between a stock and its goal it initiates corrective action aimed at closing the gap. When this is accomplished without a significant time delay, a system will adjust smoothly to its goal. On the other hand, if there are significant time lags in the corrective actions of a negative loop, it can overshoot or undershoot its goal and cause the system to oscillate. Examples of negative feedback processes in economic systems include equilibrating mechanisms ("auto-pilots") such as simple supply and demand relationships, stock adjustment models for inventory control, any purposeful behavior, and many of the relationships found in macroeconomic business cycle theory. Meadows [27], Mass [26], Low [23], Forrester [12], and Sterman [54] provide examples of system dynamics models that generate cyclical behavior at the macro-economic and micro-economic levels.

From a system dynamics point of view, positive and negative feedback loops fight for control of a system's behavior. The loops that are dominant at any given time determine a system's time path and, if the system is nonlinear, the dominance of the loops can change over time as the system's stocks fill and drain. From this perspective, the dynamic behavior of any economy – that is, the interactions between the trend and the cycle in an economy over time – can be explained as a fight for dominance between the economy's most significant positive and negative feedback loops.

In system dynamics modeling, stocks are usually conceptualized as having limits. That is, stocks are usually seen as being unable to exceed or fall below certain maximum and minimum levels. Indeed, an economic model that can generate, say, either an infinite and/or a negative work-

force would be seen as severely flawed by a system dynamicist. As such, when building a model system dynamicists search for factors that may limit the amount of material or information that the model's stocks can accumulate. Actual socioeconomic systems possess many limiting factors including physical limits (e. g., the number of widgets a machine can produce per unit of time), cognitive limits (e. g., the amount of information an economic agent can remember and act upon), and financial limits (e. g., the maximum balance allowed on a credit card). When limiting factors are included in a system dynamics model, the system's approach to these factors must be described. Generally speaking, this is accomplished with nonlinear relationships. Figure 1 presents a simple system dynamics model that contains examples of all of the components of system structure described above.

Types of Dynamic Simulation

From a system dynamics point of view, solving a dynamic model – any dynamic model – means determining how much material or information has accumulated in each of a system's stocks at every point in time. This can be accomplished in one of two ways – analytically or via simulation. Linear dynamic models can be solved either way. Nonlinear models, except for a few special cases, can only be solved via simulation.

Simulated solutions to dynamic systems can be attained from either a continuous (analog) computer or a discrete (digital) computer. Understanding the basic ideas behind the two approaches is necessary for understanding how economic modeling is undertaken with system dynamics.

In the real world, of course, time unfolds continuously. Yet, devising a way to mimic this process on a machine is a bit tricky. On an analog computer, the continuous flow of economic variables in and out of stocks over time is mimicked by the continuous flow of some physical substance such as electricity or water. A wonderful example of the later case is the Phillips Machine, which simulates an orthodox Keynesian economy (essentially the IS-LM model) with flows of colored water moving through pipes and accumulating in tanks. Barr [2] provides a vivid description of the history and restoration of the Phillips Machine.

On a digital computer, the continuous flow of economic variables in and out of stocks over time is approximated by specifying the initial amount of material or information in a system's stocks, breaking simulated time into small increments, inching simulated time forward by one of these small increments, calculating the amount of material or information that flowed into and out of the system's stocks during this small interval, and then repeating. The solution to the system will always be approximate because the increment of time cannot be made infinitesimally small and thus simulated time cannot be made perfectly continuous. In fact, on a digital computer a trade-off exists between round-off error and integration error. If the increment of time is made too large, the approximate solution can be poor due to integration error. If the increment of time is made too small, the approximate solution can be ruined due to round-off error.

In system dynamics modeling the "true" behavior of the underlying system is conceptualized to unfold over continuous time. As such, mathematically, a system dynamics model is an ordinary differential equation model. To approximate the solution to a continuous time ordinary differential equation model on a digital (discrete) computer, however, difference equations are used. Unlike traditional difference equation modeling in economics, in which the increment of time is chosen to match economic data (typically a quarter or a year), the increment of time in system dynamics modeling is chosen to yield a solution that is accurate enough for the problem at hand, yet avoids the problems associated with significant round-off and integration error.

The use of difference equations to approximate the underlying differential equations represented by a system dynamics model provides another interesting option when it comes to economic modeling. Since many well known dynamic economic models have been created with difference equations, they can be recast in a system dynamics format by using the difference equations in the system dynamics software literally as difference equations, and not as a tool to approximate the underlying continuous time system. Although doing this deviates from the original ideas embodied in the system dynamics paradigm, it is occasionally done when a modeler feels that analyzing a difference equation model in a system dynamics format will yield some additional insight.

Translating Existing Economic Models into a System Dynamics Format

There are three principle ways that system dynamics is used for economic modeling. The first involves translating an existing economic model into a system dynamics format, while the second involves creating an economic model from scratch by following the rules and guidelines of the system dynamics paradigm. Forrester [7], Richardson and Pugh [47], Radzicki [42], and Sterman [55] provide extensive details about these rules and guidelines. The former approach is valuable because it enables well-known economic models to be represented in a common format, which makes comparing and contrasting their as-

sumptions, concepts, structures, behaviors, etc., fairly easy. The latter approach is valuable because it usually yields models that are more realistic and that produce results that are "counterintuitive" [11] and thus thought-provoking.

The third way that system dynamics can be used for economic modeling is a "hybrid" approach in which a well known economic model is translated into a system dynamics format, critiqued, and then improved by modifying it so that it more closely adheres to the principles of system dynamics modeling. This approach attempts to blend the advantages of the first two approaches, although it is more closely related to the former.

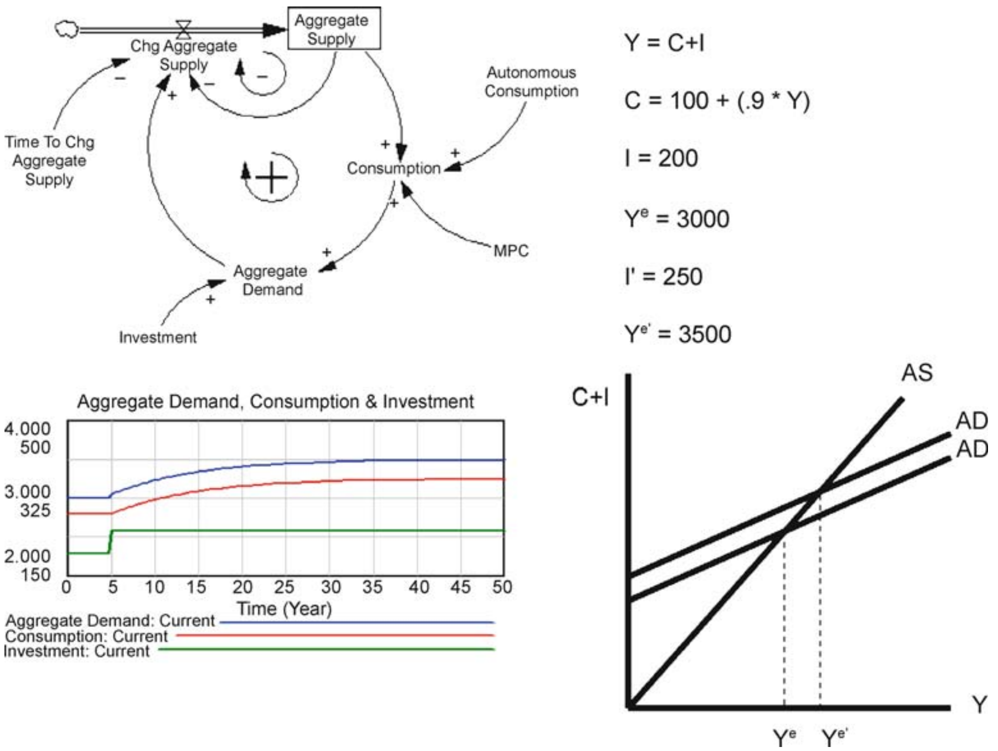
Generally speaking, existing economic models that can be translated into a system dynamics format can be divided into four categories: written, static (mathematical), difference equation, and ordinary differential equation. Existing economic models that have been created in either a difference equation or an ordinary differential equation format can be translated into system dynamics in a fairly straight-forward manner. For example, Fig. 2 presents Sir John Hicks' [21] Multiplier-Accelerator difference equation model in a system dynamics format and Fig. 3 presents the Robert Solow's [52] ordinary differential equation growth model in a system dynamics format.

Translating existing static and written economic models and theories into a system dynamics format is a more formidable task. Written models and theories are often dynamic, yet are described without mathematics. Static models and theories are often presented with mathematics, but lack equations that describe the dynamics of any adjustment processes they may undergo. As such, system dynamicists must devise equations that capture the dynamics being described by the written word or that reveal the adjustment processes that take place when a static system moves from one equilibrium point to another.

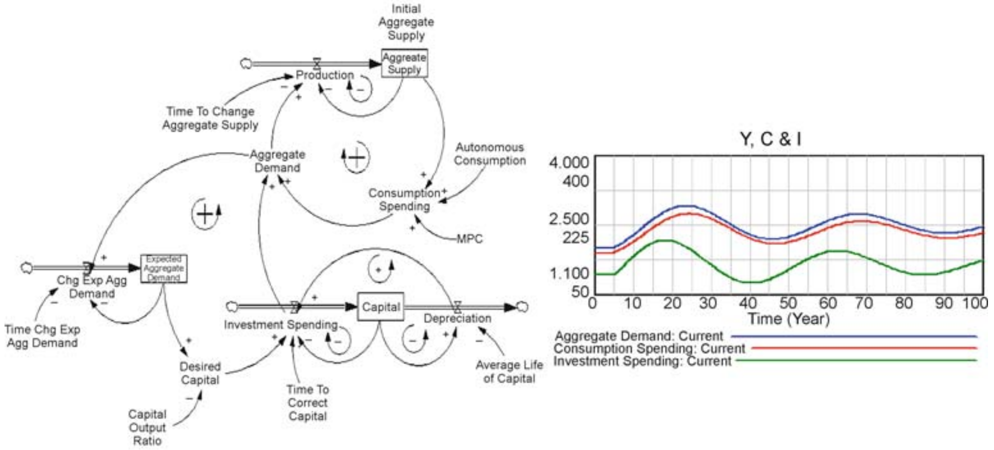
An interesting example of a system dynamics model that was created from a written economic model is Barry Richmond's [48] model of Adam Smith's *Wealth of Nations*. This model was created principally from Robert Heilbronner's [20] written description of Smith's economic system. A classic example of a static model that has been translated into a system dynamics format is a simple two sector Keynesian cross model, as is shown in Fig. 4.

Improving Existing Economic Models with System Dynamics

The simple two sector Keynesian cross model presented in Fig. 4 is an example of a well known economic model that can be improved after it has been translated into a system dynamics format. More specifically, in this example the flow of investment spending in the model does not accumulate anywhere. This violates good system dynamics modeling practice and can be fixed. Figure 5 presents the improved version of the Keynesian Cross model, which now more closely adheres to the system dynamics paradigm. Other well known examples of classic economics models that have been improved after they have been translated into a system dynamics format and made to conform more closely with good system dynamics modeling practice include the cobweb model [27], Sir John Hicks' multiplier-accelerator model [23], the IS-LM/AD-AS model [13,59], Dale Jorgenson's investment model [51], William Nordhaus' [34] DICE climate change model [4,5], and basic micro economic supply and demand mechanisms [24]. Low's improvement of Hicks' model is particularly interesting because it results



System Dynamics and Its Contribution to Economics and Economic Modeling, Figure 4
Simple two sector Keynesian cross model in a system dynamics format



System Dynamics and Its Contribution to Economics and Economic Modeling, Figure 5
Improved simple two sector Keynesian cross model

in a model that closely resembles Bill Phillips' [40] multiplier-accelerator model. Senge and Fiddaman's contributions are also very interesting because they demonstrate how the original economic models are special cases of their more general system dynamics formulations.

Creating Economic Dynamics Models from Scratch

Although translating well known economic models into a system dynamics format can arguably make them easier to understand and use, system dynamicists believe that the "proper" way to model an economic system that is experiencing a problem is to do so from scratch while following good system dynamics modeling practice. Unlike orthodox economists who generally follow a deductive, logical positivist approach to modeling, system dynamicists follow an inductive pattern modeling or case study process. More specifically, a system dynamicist approaches an economic problem like a detective who is iteratively piecing together an explanation at a crime scene. All types of data that are deemed relevant to the problem are considered including numerical, written, and mental information. The system dynamicist is guided in the pattern modeling process by the perceived facts of the case, as well as by real typologies (termed "generic structures" in system dynamics) and principles of systems. Real typologies are commonalities that have been found to exist in different pattern models and principles of systems are commonalities that have been found to exist in different real typologies. Paich [36] discusses generic structures at length and Forrester [8] lays out a set of principles of systems.

Examples of a real typologies in economics include Forrester's [9] *Urban Dynamics* model, which can reproduce the behavior of many different cities when properly parametrized for those cities, and Homer's [22] model of the diffusion of new medical technologies into the market place, which can explain the behavior of a wide variety of medical technologies when properly parametrized for those technologies. Examples of fundamental principles of systems include the principle of accumulation, which states that the dynamic behavior of any system is due to flows accumulating in stocks, and the notion of stocks and flows being components of feedback loops. The parallels for these principles in economics can be found in modern Post Keynesian economics, in which modelers try to build "stock-flow consistent models," and in institutional economics, in which the principle of "circular and cumulative causation" is deemed to be a fundamental cause of economic dynamics. Radzicki [41,43,45] lays out the case for the parallels that exist between methodological concepts in system dynamics and methodological concepts in various schools of economic thought.

The economic models that have been historically created from scratch by following the system dynamics paradigm have tended to be fairly large in scale. Forrester's [12] national economic model is a classic example, as are the macroeconomic models created by Sterman [53], the Millennium Institute [31], Radzicki [45], Wheat [59], and Yamaguchi [60]. Dangerfield [3] has developed a model of Sarawak (E. Malaysia) to analyze and plan for economic transition from a production economy to a knowledge-based one. With the exception of Radzicki [45], whose model is based on ideas from Post Keynesian and institutional economics, these models, by and large, embody orthodox economic relationships.

Model Validity

When a system dynamics model of an economic system that is experiencing a problem is built from scratch, the modeling process is typically quite different from that which is undertaken in traditional economics. As such, the question is raised as to whether or not an original system dynamics model is in any sense "valid".

System dynamicists follow a "pattern modeling" approach [41] and do not believe that models should be judged in a binary fashion as either "valid" or "invalid". Rather, they argue that confidence in models can be generated along multiple dimensions. More specifically, system dynamicists such as Peterson [38], Forrester and Senge [16] and Barlas [1] have developed a comprehensive series of tests that can be applied to a model's structure and behavior and they argue that the more tests a model can pass, the more confidence a model builder or user should place in its results. Even more fundamentally, however, Forrester [13] has argued that the real value generated through the use of system dynamics comes, not from any particular model, but from the modeling *process* itself. In other words, it is through the iterative *process* of model conceptualization, creation, simulation, and revision that true learning and insight are generated, and *not* through interaction with the resulting model.

Another issue that lies under the umbrella of model validity involves fitting models to time series data so that parameters can be estimated and confidence in model results can be raised. In orthodox economics, of course, econometric modeling is almost universally employed when doing empirical research. Orthodox economic theory dictates the structure of the econometric model and powerful statistical techniques are used to tease out parameter values from numerical data.

System dynamicists, on the other hand, have traditionally argued that it is not necessary to tightly fit models to time series data for the purposes of parameter estimation and confidence building. This is because:

1. the battery of tests that are used to build confidence in system dynamics models go well beyond basic econometric analysis;
2. the particular (measured) time path that an actual economic system happened to take is merely one of an infinite number of paths that it could have taken and is a result of the particular stream of random shocks that

happened to be historically processed by its structure. As such, it is more important for a model to mimic the basic character of the data, rather than fit it point-by-point [14];

3. utilizing the pattern modeling/case study approach enables the modeler to obtain parameter values via observation below the level of aggregation in the model, rather than via statistical analysis [18];
4. the result of a system dynamics modeling intervention is typically a set of policies that improve system performance and increase system robustness. Such policies are usually feedback-based rules (i. e., changes to institutional structure) that do not require the accurate point prediction of system variables.

Although the arguments against the need to fit models to time series data are well known in system dynamics, many system dynamicists feel that it is still a worthwhile activity because it adds credibility to a modeling study. Moreover, in modern times, advances in software technology have made this process relatively easy and inexpensive. Although several techniques for estimating the parameters of a system dynamics model from numerical data have been devised, perhaps the most interesting is David Peterson's [38,39] Full Information Maximum Likelihood with Optimal Filtering (FIMLOF). Figure 5 presents a run from the Harrod growth model, to which an adaptive expectations structure has been added, after it has been fit via FIMLOF to real GDP and labor supply data for the United States economy for the years 1929–2002. The fit is excellent and the estimated parameter values are consistent with those from more traditional econometric studies. See Radzicki [44] for a detailed description of the model and its parameter estimates.

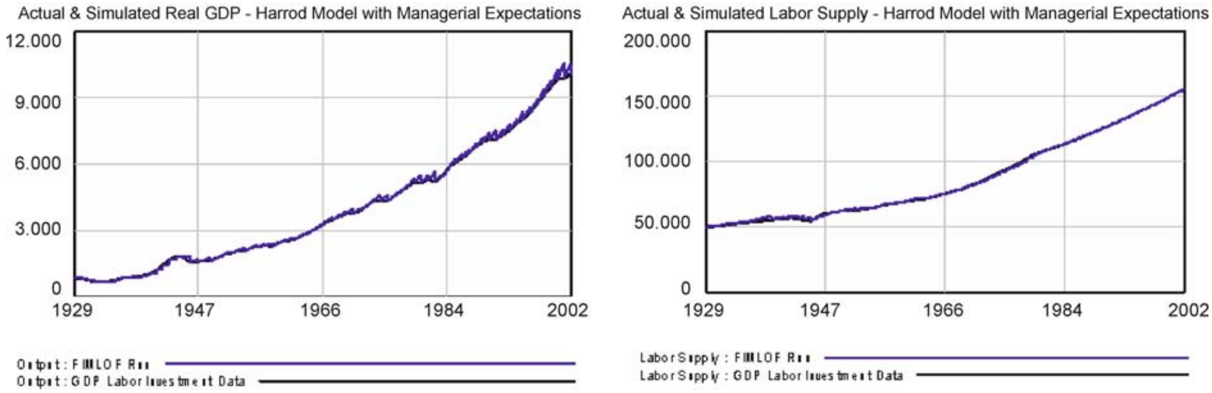
Controversies

Since system dynamics modeling is undertaken in a way that is significantly different from traditional economic modeling, it should come as no surprise that many economists have been extremely critical of some system dynamics models of economic systems. For example, Forrester's [9] *Urban Dynamics* and [10] *World Dynamics* models have come under severe attack by economists, as has (to a lesser degree) his national economic model. On the other hand, the first paper in the field of system dynamics is Forrester [6], which is essentially a critique of traditional economic modeling.

Greenberger et al. [19] present a nice overview of the controversies surrounding the *Urban Dynamics* and *World Dynamics* models. Forrester and his colleagues' replies to criticisms of the *Urban Dynamics* model are contained in Mass [25] and Schroeder et al. [50].

One of the harshest critics of the *World Dynamics* (WORLD2) model has been Nordhaus [33]. Nordhaus [35] has also very critical of the well known follow-up study to *World Dynamics* known as *The Limits to Growth* [28]. Meadows et al. [29,30] contain updates to the original *Limits to Growth* (WORLD3) model, as well as replies to the world modeling critics.

Forrester [12] presents a nice overview of his national economic model, and the critiques by Stolwijk [57] and Zellner [61] are typical of the attitude of the professional economists toward macroeconomic modeling that is undertaken by following the traditional system dynamics paradigm. The criticism of Forrester's national economic model by the economics profession has probably been less severe, relative to the criticisms of the *Urban Dynamics* and world models, because most of its details are still largely unpublished at the time of this writing.



System Dynamics and Its Contribution to Economics and Economic Modeling, Figure 6
Fit of the Harrod growth model to US macroeconomic data for the years 1929–2002

Another interesting and timely example of the sort of controversy surrounding system dynamics modeling in economics is provided by Sterman and Richardson [56]. In this paper they present a technique for testing whether Hubbert's lifecycle method or the geologic analogy method yields superior estimates of the ultimately recoverable amount of petroleum resources. This study was motivated by a disagreement with a traditionally trained economist over the proper way to conceptualize this issue. Sterman and Richardson devised a clever synthetic data experiment in which a system dynamics model serves as the "real world" with a known ultimately recoverable amount of oil. Hubbert's method and the geologic analogy method are then programmed into the model so they can "watch" the data being generated by the "real world" and provide dynamic estimates of the "known" ultimately recoverable stock of oil. The results showed that Hubbert's method was quite accurate, although it had a tendency to somewhat underestimate the ultimately recoverable amount of oil, while the geologic analogy method tended to overshoot the resource base quite substantially.

Future Directions

Historically, system dynamicists who have engaged in economic modeling have almost never been trained as professional economists. As such, they have had the advantage of being able to think about economic problems differently from those who have been trained along traditional lines, but have also suffered the cost of being seen as "amateurs" or "boy economists" [41] by members of the economics profession. The good news is that there are currently several schools of economic thought, populated by professional economists, in which system dynamics fits quite harmoniously. These include Post Keynesian economics, institutional economics, ecological economics, and behavioral economics. Historically, the economists in these schools have rejected many of the tenets of traditional economics, including most of its formal modeling methods, yet have failed to embrace alternative modeling techniques because they were all seen as inadequate for representing the concepts they felt were important. However in the modern era, with computers having become ubiquitous and simulation having become in some sense routine, system dynamics is increasingly being accepted as an appropriate tool for use in these schools of economic thought. The future of economics and system dynamics will most probably be defined by the economists who work within these schools of thought, as well as by their students. The diffusion of system dynamics models of economic systems through their translation into user-friendly interactive "learning environments" that are available over the world wide web will most likely also be of great importance (see [24,59]).

Article Outline

Glossary

Model/model system A model is a simplified representation of a real system. Models can be descriptive or prescriptive (normative). Their functions can be to enable explanation, anticipation or design. A distinction used in this contribution is between causal and non-causal models, with System Dynamics models being of the former type. The term *model system* is used to stress the systemic character of a model; this serves to identify it as an organized whole of variables and relationships on the one hand, and to distinguish it from the *real system* which is to be modeled, on the other.

Model validity A model's property of adequately reflecting the system modeled. Validity is the primary measure of model quality. It is a matter of degree, not a dichotomized property.

Model purpose The goal for which a model is designed or the function it is intended to fulfill. The model purpose is closely linked to the end-model user or model owner. Model purpose is the criterion for the choice of a model's boundary and design.

Modeling process The process involving phases such as problem articulation, boundary selection, development of a dynamic hypothesis, model formulation, model testing, policy formulation and policy evaluation [28]. The modeling process is followed by model use and implementation, i. e., the realization of actions designed or facilitated by the use of the model.

Validation process Validation is the process by which model validity is enhanced systematically. It consists in gradually building confidence in the usefulness of a model by applying validation tests as outlined in this chapter. In principle, validation pervades all phases of the modeling process, and, in addition, extends into the phases of model use and implementation.

Definition of the Subject

The present chapter addresses the question of building better models. This is crucial for coping with complexity in general, and in particular for the management of dynamic systems. Both the epistemological and the methodological-technological aspects of model validation for the achievement of high-quality models are discussed. The focus is on formal models, i. e. those formulated in a stringent, logical, and mostly mathematical language.

Introduction

The etymological root of *valid* is the Latin word *validus*, which denotes attributes such as strong, powerful and firm. A valid model, then, is well-founded and difficult to reject because it accurately represents the perceived real system which it is supposed to reflect. This system can be either one that already exists or one that is being constructed, or even anticipated, by a modeler or a group of modelers.

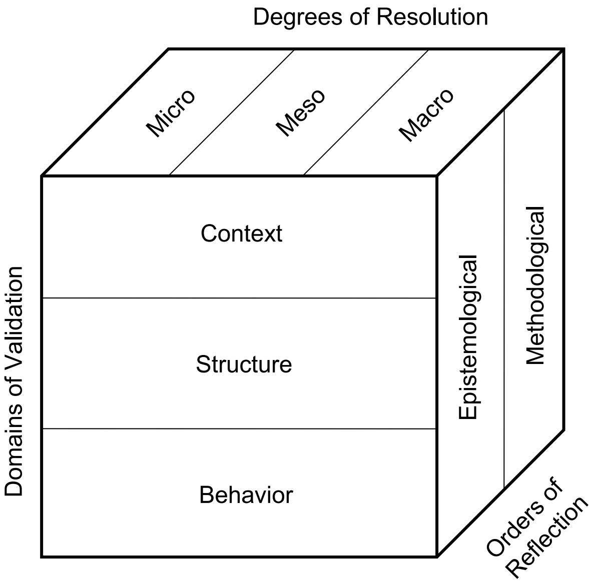
Validation standards in System Dynamics are more rigorous than those of many other methodologies. Let us distinguish between two types of mathematical models, which are fundamentally different: Causal, theory-like models and non-causal, statistical (correlational) models [4]. The former are explanatory, i. e., they embody theory about the functioning of a real system. The latter are descriptive and express observed associations among different elements of a real system. System Dynamics models are causal models.

Non-causal models are tested globally, in that the statistical fit between model and data series from the real system under study is assessed. If the fit is satisfactory, the model is considered to be accurate ("valid", "true"). In contrast, system dynamicists postulate that models be not only right, but right for the right reasons. As the models are made up of causal interdependencies, accuracy is required for each and every variable and relationship. The following principle applies: if only one component of the model is shown to be wrong, the whole model is rejected even if the overall model output fits the data [4]. This strict standard is conducive to high-quality modeling practice.

A model is an abstract version of a perceived reality. Simulation is a way of experimenting with mathematical models to gain insights and to employ these to improve the real system under study. It is often said that System Dynamics models should portray problems or issues, not systems. This statement must be interpreted in the sense that one should not try to set the boundaries of the model too widely, but rather give the model a focus by concentrating on an object in accordance with the specific purpose of the model. In a narrower definition, even an issue or problem can be conceived of as a "system", i. e., "a portion of the world sufficiently well defined to be the subject of study" [21]. Validity then consists in a stringent correspondence between model system and real system.

We will treat the issue of model validation as a means of assuring high-quality models. We interject that validity is not the only criterion of model quality, other criteria including parsimony, ease-of-use, practicality, importance, etc. [22].

In the following, the epistemological foundations of model validity are reviewed (Sect. "Epistemological Foundations"). Then, an overview of the methods for assuring model validity is given (Sect. "Validation Methods"). Further, the survey includes an overview of the validation process (Sect. "Validation Process") and our final conclusions (Sect. "Synopsis and Outlook").



System Dynamics Modeling: Validation for Quality Assurance, Figure 1

The Validation Cube – A frame of reference showing three dimensions of the validation topic

The substance of this article will be made more palpable by means of the following frame of reference. We call it the Validation Cube. The diagram in Fig. 1 shows three dimensions of the validation topic:

- *Orders of Reflection:* We distinguish between an *epistemological* and a *methodological* layer. These define the objects of the next two Sects. "Epistemological Foundations" and "Validation Methods".
- *Domains of Validation:* The three domains, *context*, *structure* and *behavior* refer to the groups of validation methods as described in Sect. "Validation Methods".
- *Degrees of Resolution:* We address the different granularities of models. *Micro* refers to the smallest building blocks of models (e. g., variables or small sets of variables), *meso* to modules which constitute a model, and *macro* to the model as a whole.

Epistemological Foundations

Epistemology is the theory that enquires into the nature and grounds of knowledge: "What can we know and how do we know it?" [13]. These questions are of utmost importance when dealing with models and their validity, because a method of validation is only as good as its epistemological basis.

We can only briefly refer to the antecedents of the epistemological perspective inherent in the idea of model validation as commonly held today in the community of system dynamicists. One could go back to Socrates who, in Plato's *Republic* (fourth century BC), addressed the problematic relationship between reality, image and knowledge. One could also refer to John Locke (seventeenth century), the first British empiricist who maintained that ideas could come only from experience, while admitting that our knowledge about external objects is uncertain. We will address the philosophical movements of the nineteenth and twentieth centuries, which are direct sources of the epistemology which is important for model validation. The reader may kindly excuse us for certain massive simplifications that we are obliged to make.

What will be said here about theories applies equally to formal models. In System Dynamics, models either embody theories or they are considered essential components of theories. In addition, processes of modeling and theory-building are of the same nature; a model, like any theory, is built and improved in a dialectic of propositions and refutations [22].

Positivism and Critique

Positivism is a scientific doctrine founded by Auguste Comte (nineteenth century) which raises the *positive* to the principle of all scientific knowledge. "Positive", in this context, is not meant to be the opposite of negative, but the given, factual, or indubitably existent. The positive is associated with features such as being real, useful, certain, and precise. Positivism confines science to the observable and manipulable, drawing on the mathematical, empirical orientation of the natural sciences as its paragon. The objectivist claim of positivism is that things exist independently of the mind and that truths are detached from human values and beliefs. This stance calls for models that approximate an objective reality.

A younger development in this vein is the school of logical positivism, also logical empiricism (with Schlick, Neurath, Hempel, etc.), which concentrates on the problem of meaning and has developed the verifiability principle: Something is meaningful only if verifiable empirically, i. e., ultimately by observation through the senses. To verify here means to show to be true [13]. For the logical positivists, the method of verification is the essence of theory-building. Tests of theories hinge on their confirmation by facts. In System Dynamics, testing models on real-world data is a core component of validation.

Positivism has been criticized for being reductionist, i. e., for its tendency to reduce concepts to simpler or empirically more accessible ones, and to conceive of learning as an accumulation of particular details. The critique has also asserted that there is no theory-independent identification of facts, and therefore different theories cannot be tested by means of the same data [6]. Another objection maintains that social facts are not merely given, but produced by human action, and that they are subject to interpretation [23]. These arguments introduce the principle of relativity, which is of crucial importance for the field of model validation: A model is a subjective construction by an observer.

Pragmatism – A Challenge to Positivism

Pragmatism, which arose in the second half of the nineteenth century, emphasizes action and the practical consequences of thinking. Its founder, Charles Sanders Peirce, was interested in the effects that the meaning of scientific concepts could have on human experience and action. He defined truth as "the opinion which is fated to be ultimately agreed to by all who investigate" [13], whereby truth is linked to consensual validation. For pragmatists, truth is in what works (Ferdinand Schiller) or satisfies us (John Dewey), and what we find believable and consistent: " 'The true' … is only the expedient in the way of our thinking", and "truth is *made* … in the course of experience." (see p. 581 and p. 583 in [11]).

Pragmatism is often erroneously disdained for supposedly being a crass variety of utilitarianism and embodying a crude instrumentalist rationality. A more accurate view considers the fact that pragmatists are not satisfied with a mere ascertainment of truth; instead they ask: "If an idea or assumption is true, does this make a concrete difference to the life of people? How can this truth be actualized?" In other words, pragmatism does not crudely equate truth and utility. It rather postulates that those truths which are useful to people ought to be put into practice [23].

Pragmatism introduces the criteria of confidence and usefulness, which are more operational as guides to the evaluation of experiments than is the notion of an absolute truth, which is unattainable in the realm of human affairs. At the same time, pragmatism triggers a crucial insight for the context of model-building: The validity of a model depends not only on the absolute quality of that model but also hinges on its suitability with respect to a purpose [7]. In the context of model validation, then, truth is a relative property; more exactly, a *truth* holds for a limited domain only.

More Challenges to Positivism

We discuss three more challenges to positivism in the twentieth century. First, Thomas Kuhn's theory of scientific revolutions [12]: Kuhn shows, by means of historical cases, that in the sphere of science, generally accepted ways of looking at the world ("paradigms") change over time through fundamental shifts. Therefore, the activities of a scientist are largely shaped by the dominant scientific worldview. Second, Willard Van Orman Quine and Wilfrid Sellars argue that knowledge creation and theory-building is a holistic, conversational process, as opposed to the reductionist and confrontational views [4].

Both of these movements contribute to our understanding of how real systems are to be modeled and validated: as organized wholes, and consciously with respect to the values and beliefs underlying a given modeling process. This approach adheres to the spirit of models themselves, by means of which the behavior of whole systems can be simulated and tested on their inherent assumptions.

A third challenge is presented by the interpretive streams of epistemology (for an overview, see [9]). Among them, a main force which expands the possibilities of scientific methodologies is the strand of hermeneutics. Derived from the Greek *hermeneuein* – to interpret or to explain – the term *hermeneutics* stands for a school, mainly associated with Hans-Georg Gadamer, which pursues the ideal of a human science of understanding. The emphasis is on interpretation in an interplay between a subject-matter and the interpreter's position. This emphasis introduces the subjective into scientific methodology. Hermeneutics denies both that a single "objective true interpretation" can transcend all individual viewpoints, and that humans are forever confined within their own ken [13]. This epistemology offers a necessary complement to a scientific stance, which exclusively hinges on "hard", quantitative methods in order supposedly to achieve absolute objectivity. The implication of hermeneutics for model validation is that it recognizes the pertinence of subjective judgment. In this connection, interpretive discourses play a crucial role in group model-building and validation. Such discourses lead beyond the subjective, entailing the creation of inter-subjective, shared realities. We will return to this factor in Sect. "Validation Process".

Critical Rationalism

Critical rationalism is a philosophical position founded by Karl R. Popper [19,20]. It grew out of positivism but rejected its verificationist stance. Critical rationalism posits that, in the social domain, theories can never be definitely proved, but can only reach greater or lesser levels of truth. Scientific proofs are confined to the realm of the formal sciences, namely logic and mathematics.

As Popper demonstrates, all theories are provisional. As a consequence, the main criterion for the assessment of a theory's truth status is *falsification* [19]. A theory holds as long as it is not refuted. Consequently, any theory can be upheld as long as it passes the test of falsification. In other words, the fertile approaches to science are not those of corroboration, but the falsificationist efforts to test if theories can be upheld. In the context of modeling this means that validation must undertake attempts to falsify a model, thereby testing its robustness.

Even Popper's theory of science is not unchallenged. For example, Kuhn has made the point that its principles are applicable only to normal science, which operates incrementally within a given paradigm, but not to anomalous science, which uncovers unsuspected phenomena in periods of scientific revolution [12]. This observation has an implication for model validation: Alternative and even multiple model designs should be assessed for their ability to account for fundamental change.

On the Meaning of Validity and Validation

One of the predominant convictions about science is the obsessive idea that proofs are the touchstone of the validity of both theories and models. We follow a different rationale, reverting to the philosophy of science as embodied in critical rationalism.

Popper's refutationist concept (as opposed to a verificationist concept) of theory-testing implies both an evolutionist perspective and an empiricist stance. The evolutionist perspective is primary because it welcomes the challenges posed to a theory, since these attempts at falsification lead to an evolutionary process: successful falsification efforts result in revisions and improvements of the theory. Correspondingly, empiricism is paramount in the social sciences, because the main source for the refutation of a theory is empirical evidence. However, falsification can also be grounded in logical arguments where empirical evidence cannot be obtained. In this sense, a structuralist approach as used in System Dynamics validation transcends the bounds of logical empiricism.

As a consequence of the evolutionist perspective, there is no such thing as absolute validity. Validity is always imperfect, but it can be improved over time. The empiricist aspect of theory-building implies that theories must be validated by means of empirical data. However, logical assay, estimation and judgment are complementary to this empiricist component (see below).

A validation process is about gradually building confidence in the model under study [2]. This is both analytical and synthetic. It is directed at the model as a whole as much as it is at the components of the model. The touchstone of validity is less whether the model is right or wrong: as Sterman states, "… all models are wrong." [28].

Some models, however, fulfill the purpose ascribed to them, i. e., they are useful. Models are inherently incomplete; they cannot claim to be true in an absolute sense, but only to be relatively true [4]. In this sense, *validation* is a *goal-oriented* activity and *validity* a *relative* concept.

Finally, the validation process often involves several people because the necessary knowledge is distributed. In these cases, the dialectics of propositions and refutations, as well as the interaction of different subjective viewpoints, and consensus-building, are integral. Validation processes, then, are semiformal, discursive social procedures with a holistic as opposed to a fragmentary orientation [ibidem].

On Objectivity

If subjective views and judgments are as prominent as alleged above, does objectivity play a role at all? Operational philosophy shows a way out of this dilemma: Rapoport defines objectivity as "invariance with respect to different observers." [21]. Popper has a similar stance in proposing that general statements must be formulated in a way that they can be criticized and, where applicable, falsified [20]. This concept of objectivity is a challenge to model validation: When defining concepts and functions, one must first of all strive for falsifiable statements. In principle, formal models meet this criterion: each variable and every function or relationship can be challenged. And they must be challenged, so that their robustness can be tested. The duty, then, is in finding the invariances that are inter-subjectively accepted as the best approximations to truth. Frequently this is best achieved in group model-building processes [30]. Finally, truth is something we search for but do not possess [20], i. e., even an accepted model cannot guarantee truth with final certainty.

Validation Methods

A considerable set of qualitative and quantitative tests has been developed for the enhancement of model validity. The state-of-the-art has been documented in seminal publications [2,4,7,8,14,17,28]. Our purpose here is to present and exemplify the different tests to encourage and help those who strive to develop high-quality System Dynamics models.

In the following, an overview of the types of tests developed for System Dynamics models is given, without any claim to completeness. Most of these tests have been documented extensively in [2,7,8,28]. The descriptions of the tests adhere closely to the specifications of these authors (mainly Forrester and Senge). In addition, we have developed a new category for tests that concentrate on the context in which the model is to be developed. High-quality models can be created only if the relevant context is taken into consideration. To facilitate orientation, we have attached an overview of all described tests in the Appendix.

In this section we describe three groups of tests: those related to model-related context, tests of model structure and tests of model behavior. Many of the tests described in the following can be utilized for explanatory analysis which aims at an understanding of the problematic behavior of the issue under study. Others are suitable for normative ends, in analyzes targeted on improvements of system performance with regard to a specified objective of the reference system. Also known as policy tests, or policy analyses, these "tests of policy implications differ from other tests in their explicit focus on comparing changes in a model and in the corresponding reality. Policy … tests attempt to verify that response of a real system to a policy change would correspond to the response predicted by the model" [8]. Policy testing can show the risk involved in adopting the model for policy making.

Tests About the Model-Related Context

These tests deal with aspects related to the situation in which the model is to be developed and embedded. They imply metalevel decisions which have to be taken in the first place, before engaging in model-building. Applied ex-post-facto, i. e., after modeling, they allow for assessing the utility of the modeling endeavor as such.

Issue Identification Test. The *raison d'être* of a System Dynamics model is its ability to adequately address an issue and to enhance stakeholders' understanding, an ability which may lead to policy insights and system improvements. The issue identification test examines whether or not the identified issue or problem is indeed meaningful. Has the "right" problem been identified? Does the problem statement address the origins of an issue or only superficial *symptoms*? Whenever complex issues are addressed by a model, different perspectives (e. g. professional, economic, political) must be integrated for accurate problem identification and modeling. This is not a "one-shot-only" test; it must be applied recurrently during the modeling procedure. By reflecting regularly on the correctness of the identified issue, the modeler can increase the likelihood of capturing the origins of suboptimal system behavior.

Adequacy of Methodology Test. Simulation models respond to the limitations of humans' mental ability to comprehend complex, dynamic feedback systems [27]. The adequacy of methodology test scrutinizes whether the

System Dynamics methodology is best-suited for dealing with the issue under study. One needs to clearly ascertain if that issue is characterized by dynamic complexity, feedback mechanisms, nonlinear interdependency of structural elements and delays between causes and effects. One needs to ask also if the issue under study could be better addressed by another methodology. For example, in a case where the question is to understand the difference in numerical outcomes between two configurations of a production system, it lets one determine whether discrete event simulation would fulfill this requirement more accurately than System Dynamics.

System Configuration Test. This test asks the fundamental question about whether the structural configuration chosen can be accepted. It challenges the assumption that the model represents the actual working of the system under study. The applicability of a different design would be suggested by its ability to capture new conditions, such as different system configurations, phenomena or rules of the game. Even revolutionary changes might be considered. Such an outlook may require a totally new model, or an alternative model designed from a different vantage point. This would at least feasibly approximate the need to take paradigmatic change into account.

System Improvement Test. The purpose of modeling is to understand a part of reality and to resolve an issue. The system improvement test can be performed only after the modeling project (an ex-post-facto test), once the insights derived from the model have already been implemented in the real system. This test reestablishes the connection between the abstract mathematical model and the real system. The system improvement test helps to evaluate whether or not model development was successful. In operational terms, any improvements of the real system under study must be compared with explicit objectives. In practice, the test might assess the impact of the modeling process or the model use either on the mental models of decision makers or on changes in organization structures. In principle, assessing the impact of a modeling endeavor is very difficult (one preliminary example is provided by Snabe and Grössler [25]).

Tests of Model Structure

Tests of model structure refer to the "nuts and bolts" of System Dynamics modeling, i. e., to the formal concepts and interrelationships which represent the real system. Model structure tests aim to increase confidence in the structure of the created theory about the behavior mode of interest. The model structure can be assessed by means of either direct or indirect inspection. Tests of model structure assess whether the logic of the model is attuned to the corresponding structure in the real world. They do not yet compare the model behavior with time series data from the real system.

Direct Structure Tests Direct structure tests assess whether or not the model structure conforms to relevant descriptive knowledge about the real system or class of systems under study. By means of direct comparison, they qualitatively assess any disparities between the original system structure and the model structure.

Structure Examination Test. Examination in this case means comparison in the sense just outlined. Qualitative or quantitative information about the real system structure can be obtained either empirically or theoretically. Empirically based tests include reviews of model assumptions about system elements and their interdependencies, e. g., reviews made by highly knowledgeable experts of the real system. Theory-based tests compare the model structure with theoretical knowledge from literature about the type of system being studied. Thereby, a preference for theoretical knowledge specific to the modeled situation over more abstract and general knowledge is usually the case.

To pass the structure examination test, a model must not contradict either the evidence or knowledge about the structure of the real system. This test ensures that the model contains only those structural elements and interconnections that are most likely extant in the real system. In this context, formal inspections of the model's equations, reviews of the syntax for the stock and flow diagram, and walkthroughs along the causal loop diagrams and their embodied causal explanations may be indicated. The experienced reader might recommend the use of statistical tests to identify and validate model structure. As Forrester and Senge [8] indicate, a long-standing discussion exists about the application of inferential statistical tests for structure examination. After a series of experiments, Forrester and Senge conclude "that conventional statistical tests of model structure are not sufficient grounds for rejecting the causal hypotheses in a system dynamics model." [8]. In the future, however, new statistical approaches might enrich the testing procedures.

Parameter Examination Test. A parameter is a quantity that characterizes a system and is held constant in a case under study, but may be varied in different cases (e. g., energy consumption per capita per day). The aim of parameter examination is to evaluate a model's parameters against evidence or knowledge about the real system. The test can utilize both empirical and theoretical information. Furthermore, the test can be conceptual or numerical. The conceptual parameter examination test is about construct validity; it identifies elements in the real system that correspond to the parameters of the model. Conceptual correspondence means that the parameters match elements of the real system's structure. Numerical parameter examination checks to see if the quantities of the conceptually confirmed parameters are estimated accurately. Techniques for the estimation of parameters are described in [9].

Direct Extreme Condition Test. Extreme conditions do not often occur in reality; they are exceptions. The validity of a model's equations under extreme conditions is evaluated by assessing the plausibility of the results generated by the model equations against the knowledge about what would happen under a similar condition in reality. Direct extreme condition testing is a mental process and does not involve computer simulation. Ideally, it is applied to each equation separately. It consists of assigning extreme values to the input variables of each equation. The values of the output variables are then interpreted in terms of what would happen in the real system under these extreme conditions. For example, if a population is zero, then neither births, deaths, nor consumption of resources can occur.

Boundary Adequacy Structure Test. Boundary adequacy is given if the model contains the relevant structural relationships that are necessary and sufficient to satisfy a model's purpose. Consequently, the boundary adequacy test inquires whether the chosen level of aggregation is appropriate and if the model includes all relevant aspects of structure. It should ensure that the model contains the concepts that are important for addressing the problem endogenously. For instance, if parameters are likely to change over time, they should be endogenized [8]. The pertinent validation question is: "Should this parameter be endogenized or not?" That question must be decided in view of the model's purpose.

The boundary adequacy test can be applied in three ways: as a structural test, as a behavioral test, and as a policy test. The names are correspondingly: boundary adequacy structure test, boundary adequacy behavior test, and boundary adequacy policy test.

As a test of model structure, the boundary adequacy test involves developing a convincing hypothesis relating the proposed model structure to the particular issue addressed by the model. The boundary adequacy behavior/policy test (explained in Subsect. "Indirect Structure Tests") continues this line of thinking.

Dimensional Consistency Test. This test checks the dimensional consistency of measurement units of the expressions on both sides of an equation. The test is performed only at the equation level. When all tests of the individual equations are passed, a large system of dimensionally consistent equations results. This test is passed only if consistency is achieved without the use of parameters that have no meaning in respect to the real world. The dimensional consistency test is a powerful test to establish the internal validity of a model.

Indirect Structure Tests Indirect structure tests assess the validity of the model structure indirectly by examining model-generated outcome behaviors. These tests require computer simulation. The comparative activities in these tests are based on logical plausibility considerations which in turn are based on the mental models of the analyst. Comparisons of model generated data and time series about the real system are not yet involved. The tests can be applied to different degrees of model completeness, i. e., to the smallest "atomic" model components, to sub-models, as well as to the entire model.

Indirect Extreme Condition Test. For this test, the modeler assigns extreme values to selected model parameters and compares the generated model behavior to the observed or expected behavior of the real system under the same extreme conditions. This test is the logical continuation of the direct extreme condition test, i. e., many of the extreme conditions mentally developed in the previous stage can now be deployed to evaluate the simulated behavioral consequences. This test can be used for the explanatory analysis phase of modeling, but also for the normative phase of policy development. In the first instance, indirect extreme conditions are used to develop a structure that can reproduce the system behavior of interest and guard against developments impossible in reality. In the latter instance, the introduction of policies aims to improve the system's performance. The indirect extreme policy test introduces extreme policies to the model and compares the simulated consequences to what would be the most likely outcome of the real system if the same extreme policies would have been implemented.

Behavior Sensitivity Test. Sensitivity analysis assesses changes of model outcome behavior given a systematic variation of input parameters. This test reveals those parameters to which the model behavior is highly sensitive, and asks if the real system would exhibit a similar sensitivity to changes in the corresponding parameters. "The behavior sensitivity test examines whether or not plausible shifts in model parameters can cause a model to fail behavior tests previously passed. To the extent that such alternative parameter values are not found, confidence in the model is enhanced." [8]. A model can be numerically sensitive, i. e., the numerical values of variables change significantly, but the behavioral patterns are conserved. It can also exhibit behavioral sensitivity, i. e., the modes of model behavior change remarkably based on systematic parameter variations (Barlas [3] defines several distinct patterns of model behavior).

As the test for indirect extreme conditions, the behavior sensitivity test can also be deployed to assess policy sensitivity. It can reveal the degree of robustness of model behavior and hence indicate to what degree model-based policy recommendations might be influenced by uncertainty in parameter values. If the same policies would be recommended regardless of parameter changes over a plausible range, risk in using the model would be lower than if two plausible sets of parameters lead to distinct policy recommendations.

Integration Error Test. Integration error is the deviation between the analytical solution of differential equations and the numerical solution of difference equations. This test ascertains whether the model behavior is sensitive to changes in either the applied integration method or the chosen integration interval (often referred to as simulation time step). Euler's method is the simplest numerical technique for solving ordinary differential and difference equations. For models that require more precise integration processes, the more elaborated Runge–Kutta integration methods can produce more accurate results, but they require more computational resources.

Boundary Adequacy Behavior Test/Boundary Adequacy Policy Test. The logic for testing boundary adequacy has already been developed under the aspect of direct structure testing in the preceding section. The indirect structure version of this test asks whether model behavior would change significantly if the boundary were extended or reduced; i. e., the test involves conceptualizing additional structure or canceling unnecessary structure with regard to the purpose of the study. As one example of expanding the model boundary, this version of the test allows one to detail the treatment of model assumptions considered as unrealistically simple but still important for the model's purpose. On the other hand, simplifying the model is also a way to reduce the model boundary. The loop-knockout analysis is a useful method to implement this two-sided test. Knockout analysis checks behavior changes induced by the connection and disconnection of a portion of the model structure, and helps the modeler to evaluate the usefulness of those changes with respect to the model's purpose.

The other version of this test is the boundary adequacy policy test. It examines whether policy recommendations would change significantly if the boundary were extended (or restricted): That is, what would happen if the boundary assumptions were relaxed (or confined)?

Loop Dominance Test. Loop dominance analysis studies the internal mechanisms of a dynamic model and their temporal, relative contribution to the outcome behavior of the model. The relative contribution of a mechanism is a complex quantitative statement that explains the fraction of the analyzed behavior mode caused by the mechanism considered in ► System Dynamics, Analytical Methods for Structural Dominance Analysis in. The analysis reveals the relative strengths of the feedback loops in the model. The loop dominance test compares these results with the modeler's or client's assumption about which are the dominant feedback loops in the real system. Since the results are analytical statements, interpretation and comparison with the real system requires profound knowledge about the system under study.

Loop dominance analysis reveals insights about a model on a different level of analysis than the other validation tests discussed so far: It works not on the level of individual concepts or behaviors of variables but on the level of causal structure, and compares the temporal significance of the different structures to each other. The use of this test for model validation is a novelty. If the relative loop dominances of the model map the relative loop dominances of the real system, confidence in the model is enhanced. If the relative loop dominances of the real system are not known, it is still possible to evaluate whether or not the loop dominance logic in the model is reasonable.

Tests of Model Behavior

Tests of model behavior are empirical and compare simulation outcomes with data from the real system under study. On that basis, inferences about the adequacy of the model can be made. The empirical data can either be historical or refer to reasonable expectations about possible future developments.

Behavior Reproduction Tests The family of behavior reproduction tests examines how well model-generated behavior matches the observed historical behavior of the real system. As a principle, models should be tested against data not only from periods of stability but also from unstable phases. Policies should not be designed or tested on the premise of normality, but rather should be validated with a view toward robustness and adaptiveness.

Symptom Generation Test. This test indicates whether or not a model produces the symptom of difficulty that motivated the construction of the model. To pass the symptom generation test is a prerequisite for considering policy changes, because "unless one can show how internal policies and structures cause the symptoms, one is in a poor position to alter those causes" [8].

Summary statistics, which measure and enable the interpretation of quantitative deviations, provide the means to operationalize the symptom generation test.

One known example is Theil inequality statistics, which measures the mean square-error (MSE) between the model-generated behavior and the historical time series data. It breaks down the deviation into three sources of error: Bias (U_m), unequal variation (U_s), and unequal covariation (U_c) [26].

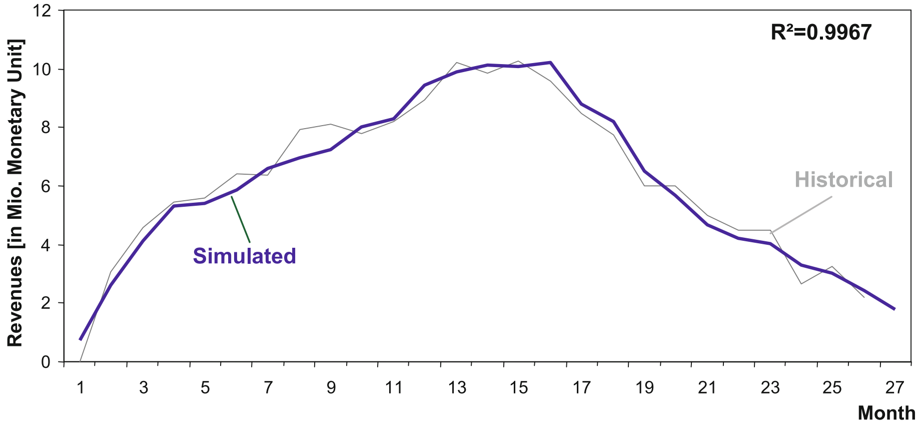
An example taken from Schwaninger and Groesser [22] illustrates the interpretation of the error sources.

This example from an industrial firm concerns the design of a model that replicates the observed, historical product life-cycle pattern with high accuracy (Fig. 2). "Product Revenue" is the main variable of interest and specifies the symptom (growth phase followed by rapid decay). The mean square-error for revenues is 0.35. The individual components of the inequality statistics are: $U_m = 0.01, U_s = 0.01, U_c = 0.98$. The break down of the statistics shows that the major part of the error is in the U_c component, while the other two sourees of error are small. This signifies that the point-by-point values of the simulated and historical data do not match, even though the model captures the dominant trend and the average values in the historical data. Such a situation indicates that a major part of the error is probably unsystematic, and therefore the model should not be rejected for failing to match the noise component of the data. The residuals of the historic and simulated time series show no significant trend. This strengthens the assessment that the model comprises a structure that captures the fundamental dynamics of the issue under consideration.

Frequency Generation and Phase Relationship Tests. These tests focus on the frequencies of time series and phase relationships between variables. An example is the pattern of investment cycles in an industry. These tests are superior to point-by-point comparisons between model-generated and observed behavior (cf. [7]).

Frequency refers to periodicities of fluctuation in a time series. Phase relationship is the relationship between the time series of at least two variables. In principle, three phase relations are possible: Preceding, simultaneous, and successive. The frequency generation test evaluates whether or not the periodicity of a variable is in accordance with the real system. The phase relationship test assesses the phase shifts of at least two variables by comparing their trajectories.

If the phase shift between the selected simulation variables contradicts the phase shift between the same variables as observed or expected in the real system, a structural flaw in the model might be diagnosed. The test can



System Dynamics Modeling: Validation for Quality Assurance, Figure 2
An example comparison of historical and simulated time series for product revenues. The explained variance is close to 100% ($R^2 = 0.9967$)

uncover failures in the model, but offers only little guidance as to where the erroneous part of the model might be. The autocorrelation function test is one way to operationalize the frequency generation test [1]. The function test consists in comparing the autocorrelation functions of the observed and the model-generated behavior outputs, and can detect if significant errors between them exist.

Modified Behavior Test. Modified behavior can arise from a modified model structure or changes in parameter values. This test concerns changes in the model structure. It can be performed if data about the behavior of a structurally modified version of the real system are available. "The model passes this test if it can generate similar modified behavior, when simulated with structural modifications that reflect the structure of the "modified" real system" [2]. The applicability of this test is rather limited since it requires specific data about the modified real system which must be similar in kind to the original real system. Only under this condition can additional insights into the suitability of the original model structure be obtained. If the modified real system deviates strongly from the original real system, the test does not result in any additional insights, because no stringent conclusions about the validity of the original system can be derived from a model that is dissimilar in its structure.

Multiple Modes Test. A mode is a pattern of observed behavior. The multiple mode test considers whether a model is able to generate more than one mode of observed behavior, for instance, if a model about the production sector of an economy generates distinct patterns of fluctuations for the short-term (production, employment, inventories, and prices) and for the long term (investment, capital stock) [15]. " A model able to generate two distinct periodicities of fluctuation observed in a real system provides the possibility for studying possible interaction of the modes and how policies differentially affect each mode" [8].

Behavior Characteristic Test. Characteristics of a behavior are features of historical data that are clearly distinguishable, e. g., the peculiar shape of an oscillating time series, sharp peaks, long troughs, or such unusual events as an oil crisis. Since System Dynamics modeling is not about point prediction, the behavior characteristic test evaluates whether or not the model can generate the circumstances and behavior leading to the event. The creation of the exact time of the behavior is not part of the test.

Behavior Anticipation Tests System Dynamics models do not strive to forecast future states of system variables. Nevertheless, given that the fundamental system structure is not subject to rapid and fundamental change, dynamic models might provide insights about the possible range of future behaviors. Hence, behavior anticipation tests are similar to behavior reproduction tests but possess a higher level of uncertainty.

Pattern Anticipation Test. This test examines whether a model generates patterns of future behavior which are assumed to be qualitatively correct. The limits of anticipation reside in the fact that that the structure of the system may change over time. The pattern anticipation test entails evaluation of periods, phase relationships, shape, or other characteristics of behavior anticipated by the model. One possibility for implementing this test is to split the historical time series into two data sets and introduce an artificial present time at the end of the first data series. The first set is then used for model development and calibration. The second data series is employed to perform the behavior anticipation test, i. e., to evaluate whether the model is able to anticipate possible future behavior.

This test can also be used for policy considerations, in which case it is called "Changed Behavior Anticipation Test". It determines whether the model correctly anticipates how the behavior of the real system will change if a governing policy is altered.

Event Anticipation Test. In respect to System Dynamics, the anticipation of events does not imply knowing the exact time at which the events occur; it rather means understanding the dynamic nature of events and being able to identify the antecedents leading to them. For instance, the event anticipation test is passed if a model has the ability to anticipate a steep peak in food prices based on the development of the conditioning factors.

Behavior Anomaly Test In constructing and analyzing a System Dynamics model, one strives to make it behave like the real system under study. However, the analyst may detect anomalous features of the model's behavior which conflict with the behavior of the real system. Once the behavioral anomaly is traced to components of the model structure responsible for the anomaly, one often finds flaws in model assumptions. The test for recognizing behavioral anomalies is sporadically applied throughout the modeling process.

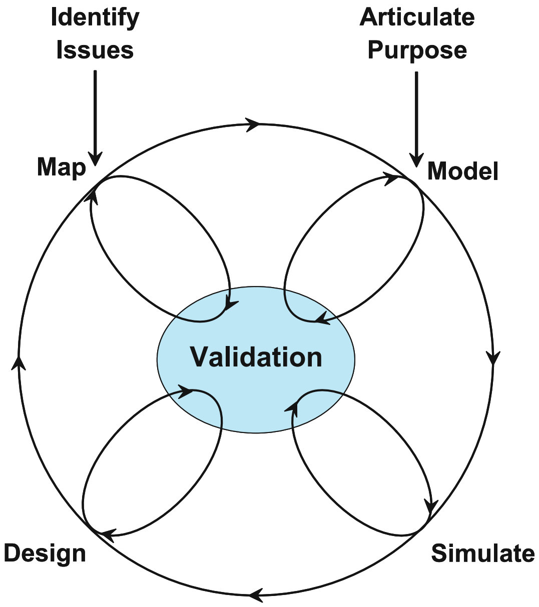
Family Member Test A System Dynamics model often represents a family of social systems. Whenever possible, a model should be a general representation of the class of that system to which the particular case belongs. One should ask if the model can generate the behavior in other instances of the same class. "The family-member test permits a repeat of the other tests of the model in the context of different special cases that fall within the general theory covered by the model. The general theory is embodied in the structure of the model. The special cases are embodied in the parameters. To perform this test, one uses the particular member of the general family for picking parameter values. Then one examines the newly parametrized model in terms of the various model tests to see if the model has withstood transplantation to the special case" [8]. The model should be calibrated so as to be applicable to the widest range of related systems. For the family member test, only the parameter values of the model are subject to alterations; changes in the model structure are part of the modified behavior test, as discussed in the preceding section.

Surprise Behavior Test A surprising model behavior is a behavior that is not expected by the analysts. When such an unexpected behavior appears, the model analysts must first understand the causes of the unexpected behavior within the model. They then compare the behavior and its causes with those of the real system. In many cases, the surprising behavior turns out to be due to a formulation flaw in the model. However, if this procedure leads to the identification of behavior previously unrecognized in the real system, the confidence in the model's usefulness is strongly enhanced. Such a situation may signify a model-based identification of a counter-intuitive behavior in a social system.

Turing Test The Turing test is a qualitative test which uses the intuitive knowledge of system experts to evaluate model behavior. Experts are presented with a shuffled collection of real and simulated output behavior patterns. They are asked if they can distinguish between these two types of patterns. If they are unable to discern which pattern belongs to the real system and which to the simulation output, the Turing test is passed. Similar to the phase relationship test, the Turing test is powerful in its ability to indicate structural flaws, but offers only little guidance for locating them in the model.

Validation Process

The validation process pervades all phases of model-building and reaches even beyond, into the phases of model implementation and use. The diagram in Fig. 3 visualizes the function of validation in the process of model-building.



System Dynamics Modeling: Validation for Quality Assurance, Figure 3
Validation in the context of the System Dynamics modeling procedure

For the purposes of this contribution, validation is placed at the center of the scheme. From there it is dispersed through all steps of the modeling process, Map (high-level model creation), Model (build the formal model), Simulate (explore scenarios, etc.) and Design (articulation of policies). We have limited the differentiation of these steps in order to highlight the structure of the process – a recursive structure drawn as a nested loop line. After the initial identification of issues and the articulation of model purpose, the simplified diagram denotes the four phases, of mapping to modeling to simulation and design. The small loops symbolize micro-processes in which, for example, a model is submitted to validation, e. g., a direct structure test, which may lead to its modification (two small arrows). The larger loops illustrate more comprehensive processes. For example, an indirect structure test of the model is carried out, in which the behavior is tested by means of simulation. Or a policy test by simulation leads to implications for design (large loop), and the design is validated in detail thereafter (small loop).

Now, we should note that the process scheme reminds us of a further aspect which is quite fundamental. If the results of the model's operation, e. g., a "prediction", diverge from the results of a test, then either the model is wrong or the test is inadequate (see p. 168 in [24]). This meta-perspective lets us keep an eye on the adequacy of the tests:

is the logic of the test flawless? Are the data sources in order? (see adequacy of methodology test in Sect. "Validation Methods").

Model-building is a process of knowledge-creation, and model validation is an integral part of it. As the model is validated using the methods described in the former chapter, insights emerge, and a better understanding of the system under study keeps growing. But model-building is also a construction of a reality in the minds of observers [31,32] concerned with an issue. In this procedure, validation is supposed to be a "guarantor" for the realism of the model, a control function for preventing gross aberrations in individual and collective perceptions. Validation should encompass precautions against cognitive limitations and modeler blindness. The set of tests presented above is a system of heuristic devices for enhancing such provisions. A question not yet answered is how these tests should be ordered along the timeline. We have fleshed out three structural principles, which are illustrated in Fig. 4:

1. *Validation is a parallel process:* Validation in all three domains – context, structure and behavior – is carried out in a synchronized fashion, as shown in Fig. 4. Context validation is continuous, while the other two components show alternations.
2. *Parts of the validation process have a sequential structure:* This refers to the alternations between the components of structure and behavior validation. In principle, they occur alternately, with structural validation taking the lead and behavior validation following. After that, one might revert to structural validation again and so forth.
3. *Validation processes are polyrhythmic:* The length and accentuation of validation activities vary among the three levels. This fact is symbolized by the frequency of the vertical lines in the blocks of the chronogram.

A further important factor affecting the validation process is the degree of resolution: micro, meso or macro (as visualized in Fig. 1). The focus of validation is primarily on micro-objects, the smallest building blocks of a model, for example, a stock or a subsystem containing a stock with its flows. One could call them metaphorically *atoms* or *molecules*. Each building-block should be validated individually, before it is integrated into the overall model structure. The reason is that at this atomic level disfunctionalities or errors of thinking are discovered immediately, while at higher levels of resolution the identification of structural flaws is more difficult and cumbersome. The same holds for the relation between modules (meso) and the whole model (macro). Before adding a module, it should be validated in itself. This way, errors at the level of the whole system can be minimized and, it is very important to add, counterintuitive behavior of the model can be understood with more ease.

Until now we have examined what occurs in a validation process and how the process is structured. Finally, we raise the issue of who the actors are and why. In this context, we will concentrate on group processes in model validation.

System Dynamics Modeling: Validation for Quality Assurance, Figure 4
The interplay of validation activities

Different observers associate diverse contents with a system, and they might even conceive the system distinctly, as far as its boundaries, goals and structures are concerned. They might also succumb to erroneous inferences and therefore adhere to defective propositions. Consequently, error-correcting devices are needed. A powerful mechanism for this purpose is the practice of model-building and validation in groups. We have already referred to that concept in respect to several of the methods discussed in Sect. "Validation Methods", and now we will briefly expand on it.

Group Model-building (GMB) is a methodology to facilitate team learning with the help of System Dynamics [30]. The methodology consists of a set of methods and instruments as well as heuristic principles. These are meant to facilitate the elicitation of knowledge, the negotiation of meanings, the creation of a shared understanding of a problem in a team, as well as the joint construction and validation of models. The process of GMB is essentially a dialog in which different interpretations of the real system under study are exposed, transformed, aligned and translated into the concepts and relationships which make up the model system. This is mainly a matter of structural validation, of qualitative mapping and the elaboration of the formal model.

Given its transdisciplinary approach, GMB enables an integration of different perspectives into one shared image of the system-in-focus. GMB is an important provision for attaining higher model quality: it can broaden the available knowledge base, inhibit errors and show itself to be a cohesive force in the quest for consensual model validation. The opportunity for validation inheres in the broad knowledge base normally available in a modeling group. Much of this knowledge can be leveraged for validation purposes. Most validation tests are carried out in coordination with model-building activities. Often the tests become a task to be accomplished between workshops. However, the members of the model-building group can, in principle, be made available for knowledge input into and monitoring of validation activities.

A functioning GMB process requires a number of necessary elements [18]: commitment of key players (e. g., attendance of workshops), impartial facilitation, on-the-spot modeling at conversational pace, with continuous display of the developing model as well as an interactive and iterative group process.

Let us not forget that there are many situations in which one single person is in charge of building and validating a model. In these cases the modeler must constantly challenge his or her own position. Normally, it is preferred that one should also call for external judgment in reviews, walkthroughs and the like. The same holds for knowledge supply. One-person modelers can find a lot of material in the media, libraries, the internet, etc., but it is also usually beneficial to find experienced persons from whom to elicit relevant knowledge, or even persons who join the modeling and validation venture.

Synopsis and Outlook

Models should be relevant for coping with the complexity of the real world. At the same time, the methods by which they are constructed must be rigorous; otherwise the quality of the model suffers. Rigor and relevance are not entirely dichotomous, but given resource constraints they are in competition to a certain extent. Lack of rigor in building a model is often worse than limitations to the model's relevance. One may say, *cum grano salis*: incomplete validation entails complete irrelevance. Modelers must find a way to ensure both rigor and relevance, as both are necessary conditions for achieving the model purpose. Neither alone is sufficient, but one may assume that, taken together, rigor and relevance are sufficient conditions. The relative importance of these two dimensions of model building may vary over time as a function of the model quality achieved. At the beginning, relevance might be more important, while at high levels of model accomplishment rigor might become prevalent.

Investing in high model quality is indeed both worthwhile and imperative. It is impressive to register the fact that model validation has achieved higher levels of rigor not only in the academic field but also in the world of affairs: According to Coyle and Exelby, the need for orientating decisions about "real-world" affairs has also fueled strong efforts among commercial modelers and consultants for ensuring model validity [5].

We have discussed two essential aspects of model validation, the epistemological foundations and methodological procedures for ensuring model validity. The main conclusion we have reached on epistemology is that crude positivism has been superseded by newer philosophical orientations that provide guidance for an adequate concept of validation in System Dynamics. Validation has been defined as a rich and well-defined process by which the confidence in a model is gradually enhanced. Validity, then, is always a matter of degree, never an absolute property.

Well-defined here is not meant in the sense of a rigid algorithm, but as the rigorous application of a battery of validation methods which we have described in some detail. We have included a number of new validation tests by which modelers' understanding of the relevant context can be scrutinized. These additional tests are rightly supposed to prevent wrong methodological choices. They should also trigger innovative approaches to the issues under study and foster the ability to think in terms of contingencies. Finally, they should liberate modelers from tunnel vision and open avenues to creativity. The imperative here is to cultivate a "sense of the possible" (Robert Musil's *Möglichkeitssinn*) and a skepticism against the supposedly impossible (see also [29]).

Simulation based on formal dynamic models is likely to become ever more important for both private and public organizations. It will continue to support managers at all levels in decision-making and policy design. The more that models are relied upon, the greater the importance of their high quality. Therefore, model validation is one of the big issues lying ahead in System Dynamics modeling.

Appendix: Overview of the Tests Described in This Chapter

1. **Tests of the Model-Related Context**
    - 1.1 Issue Identification Test
    - 1.2 Adequacy of Methodology Test
    - 1.3 System Configuration Test
    - 1.4 System Improvement Test
2. **Tests of Model Structure**
    - 2.1 Direct Structure Tests
        - 2.1.1 Structure Examination Test
        - 2.1.2 Parameter Examination Test
        - 2.1.3 Direct Extreme Condition Test
        - 2.1.4 Boundary Adequacy Structure Test
        - 2.1.5 Dimensional Consistency Test
    - 2.2 Indirect Structure Tests
        - 2.2.1 Indirect Extreme Condition Test
        - 2.2.2 Behavior Sensitivity Test
        - 2.2.3 Integration Error Test
        - 2.2.4 Boundary Adequacy Behavior Test/Boundary Adequacy Policy Test
        - 2.2.5 Loop Dominance Test
3. **Tests of Model Behavior**
    - 3.1 Behavior Reproduction Tests
        - 3.1.1 Symptom Generation Test
        - 3.1.2 Frequency Generation and Phase Relationship Test
        - 3.1.3 Modified Behavior Test
        - 3.1.4 Multiple Modes Test
        - 3.1.5 Behavior Characteristic Test
    - 3.2 Behavior Anticipation Tests
        - 3.2.1 Pattern Anticipation Test
        - 3.2.2 Event Anticipation Test
    - 3.3 Behavior Anomaly Test
    - 3.4 Family Member Test
    - 3.5 Surprise Behavior Test
    - 3.6 Turing Test

Washington State University, Pullman, Washington, USA

Article Outline

Glossary

CO_2 Carbon dioxide is the predominant greenhouse gas. Anthropogenic CO_2 emissions are created largely by the combustion of fossil fuels.

CGCM Coupled general circulation model, a climate model which combines the atmospheric and oceanic systems.

GCM General circulation model, a term commonly used to describe climate models maintained at large research centers.

GHG GHG is a greenhouse gas such as CO_2 and methane. These gases contribute to global warming by capturing some of the outgoing infrared radiation before it leaves the atmosphere.

GT Gigaton, a common measure of carbon storage in the global carbon cycle. A GT is a billion metric tons.

IPCC The Intergovernmental Panel on Climate Change was formed in 1988 by the World Meteorological Organization and the United Nations Environmental Program. It reports research on climate change. Their assessments are closely watched because of the requirement for unanimous approval by all participating delegates.

Definition of the Subject

System dynamics is a methodology for studying and managing complex systems which change over time. The method uses computer modeling to focus our attention on the information feedback loops that give rise to the dynamic behavior. Computer simulation is particularly useful when it helps us understand the impact of time delays and nonlinearities in the system. A variety of modeling methods can aid the manager of complex systems. Coyle (p. 2 in [3]) puts the system dynamics approach in perspective when he describes it as that “branch of control theory which deals with socio-economic systems, and that branch of management science which deals with problems of controllability." The emphasis on controllability can be traced to the early work of Jay Forrester [9] and his background in control engineering [10]. Coyle highlighted controllability again in the following, highly pragmatic definition:

> *System dynamics is a method of analyzing problems in which time is an important factor, and which involve the study of how a system can be defended against, or made to benefit from, the shocks which fall upon it from the out-side world.*

The emphasis on controllability is important as it directs our attention to understanding and managing the system, not to the goal of forecasting the future state of the system. Making point predictions is the objective of some modeling methods, but system dynamics models are used to improve our understanding of the general patterns of dynamic behavior. System dynamics has been widely used in business, public policy and energy and environmental policy making. This article describes applications to energy and environmental systems.

Introduction

System dynamics has been used extensively in the study of environmental and energy systems. This article describes some of these applications, paying particular attention to the problem of global climate change. The applications were selected to illustrate the power of the method in promoting an interdisciplinary understanding of complex problems.

The applications to environmental and energy systems are similar to applications to other systems described in this encyclopedia. They usually begin with the recognition of a dynamic pattern that represents a problem. System dynamics is based on the premise that we can improve our understanding of the dynamic behavior by the construction and testing of computer simulation models. The models are especially helpful when they illuminate the key feedbacks that give rise to the problematic behavior.

System dynamics is explained in the core article in this volume, in the early texts by Forrester [9], Coyle [3] and Richardson [18] and in more recent texts on strategy by Warren [22] and by Morecroft [17]. The most comprehensive explanation is provided in the text on business dynamics by Sterman [19]. Applications to environmental systems are explained in the text by Ford [7]. The most widely read application to the environment is undoubtedly *The Limits to Growth* [16]. Collections of environmental applications appear in special issues of the *System Dynamics Review* [11,20].

The models are normally implemented with visual software such as Stella (http://www.iseesystems.com), Vensim (http://www.vensim.com/) or Powersim (http://www.powersim.com/). These programs use stock and flow icons to help one see where the accumulations of the system take place. They also help one to see the information feedback in the simulated system. The programs use numerical methods to show the dynamic behavior of the simulated system. The examples selected for this article make use of the Stella and Vensim software.

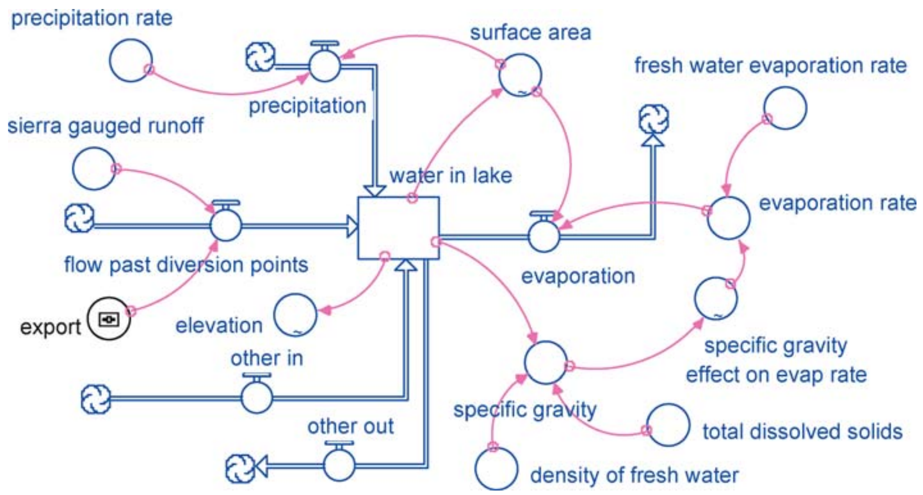
This article begins with textbook examples of environmental resources in the western US. The management of water levels at Mono Lake in Northern California is the first example. It shows a hydrological model to simulate the decline in lake levels due to water exported out of the basin. The second example involves the declining salmon population in the Tucannon River in Eastern Washington. These examples demonstrate the clarity of the approach, and they illustrate the potential for interdisciplinary modeling.

The article then turns to the topic of climate change and global warming. The focus is on the global carbon cycle and the growing concentration of carbon dioxide (CO_2) in the atmosphere. A wide variety of models have been used to improve our understanding of the climate system and the importance of anthropogenic CO_2 emissions. Examples of system dynamics models are presented to show how they can improve our understanding and provide a platform for interdisciplinary analysis.

System dynamics has also been widely applied in the study of energy problems, especially problems in the electric power industry. The final section describes two applications to electric power. The first involved the financial problems of regulated electric utilities in the US during the 1970s. It demonstrates the usefulness of the method in promoting an interdisciplinary understanding of the utilities' financial problems. The second study dealt with the CO_2 emissions in the large electricity system in the Western USA and Canada. It demonstrated how the power industry could lead the way in reducing CO_2 emissions in the decades following the implementation of a market in carbon allowances.

The Model of Mono Lake

Mono Lake is an ancient inland sea on the east side of the Sierra Nevada Mountains in California. Microscopic algae thrive in its saline waters, and the algae support huge populations of brine flies and brine shrimp which can,



System Dynamics Models of Environment, Energy and Climate Change, Figure 1
Stella diagram of the model of Mono Lake

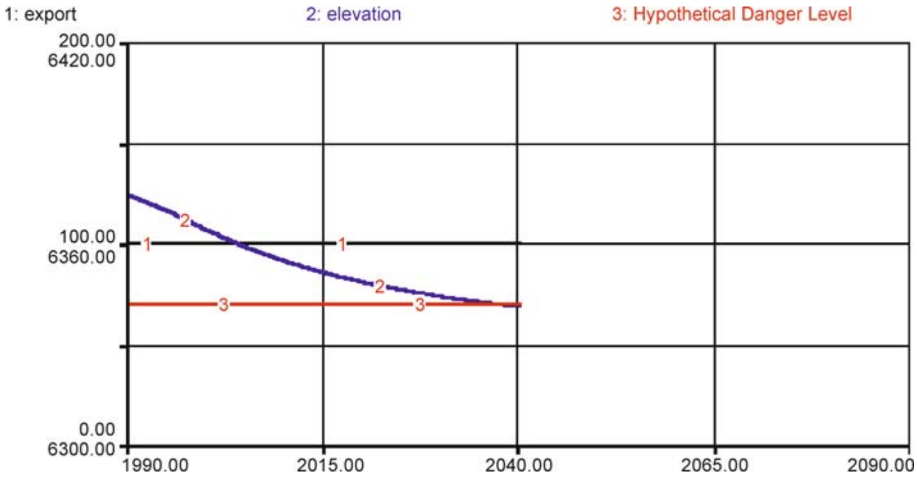
under the right conditions, provide a virtually limitless food supply for migratory and nesting birds. Starting in 1941, stream flows toward Mono Lake were diverted into the aqueduct for export to Los Angeles. The large export deprived the lake of the historical flows, and the volume shrunk over the next four decades. By 1980, the lake's volume was cut approximately in half, and its salinity nearly doubled. Higher salinity levels posed risks to the ecosystem, and environmental scientists feared for the future of the lake ecosystem. Various groups filed suit in the 1970s to limit exports, and the California Supreme Court ruled in 1983 that public trust doctrine mandated a reconsideration of the management of the waters of the Mono Basin. That reconsideration led to a long-term plan to limit exports until the lake's elevation would return to safer levels.

Figure 1 shows a system dynamics model to simulate water flows and storage in the Mono Basin. The goal was to understand the pattern of decline over four decades and to study the responsiveness of the lake to a change in export policy. The model is implemented with the Stella software, and Fig. 1 shows how the model appears when using the software. A single stock variable is used to represent the storage in the basin. The main flow into the lake is the flow from gauged streams that bring runoff from the Sierra to the lake. The aqueduct system diverts a portion of this flow south to Los Angeles, and the flow allowed past the diversion points is the main flow into the lake. The main outflow is the evaporation. It depends on the surface area of the lake and the evaporation rate. The surface area depends in a nonlinear way on the volume of water in the lake. Figure 1 shows that this model follows the standard, system dynamics practice of using familiar names to convey the meaning of the variables in the model. (These particular names match the terms used by water managers and hydrological models of the basin.)

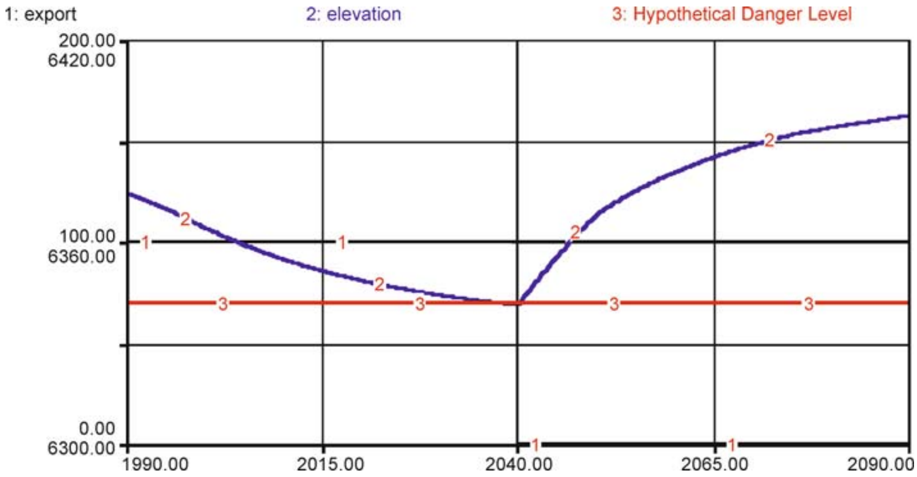
Figure 2 shows the simulated decline in the lake if exports were allowed to continue at high levels for 50 years. The lake would decline from 6374 to around 6342 feet above sea level, a value which is designated as a hypothetical danger level for this simulation. The long, gradual decline is a match of projections by the other hydrological models used in the management plan for the basin. The lake will continue to fall until the area has been reduced sufficiently to create an evaporation which will lead to a balance of the flows in and out of the basin.

Figure 3 shows the simulated responsiveness of the lake to a change in export. The export is cut to zero midway through the simulation, and the elevation increases rapidly in the ensuing decade. The simulation reveals an immediate and rapid response, indicating that there is little downward momentum associated with the hydrology of the basin. This responsiveness is highly relevant to the management plan. When the lake falls to a dangerous level, the export could be reduced, and the lake would climb to higher elevations within a few years after the change in policy. This rapid response supports the "wait and see" argument by those who advocated waiting for full signs of a dangerous salinity before changing export policy.[1] But there is far more than hydrology at work in this system. The waters of Mono Lake support a com-

[1] "Wait and see" may be supported by an analysis of the hydrology of the basin, but it does not necessarily make sense when considering the long delays in the political and managerial process to change water export.



System Dynamics Models of Environment, Energy and Climate Change, Figure 2
Simulated decline in Mono Lake elevation if historical export were allowed to continue until the year 2040

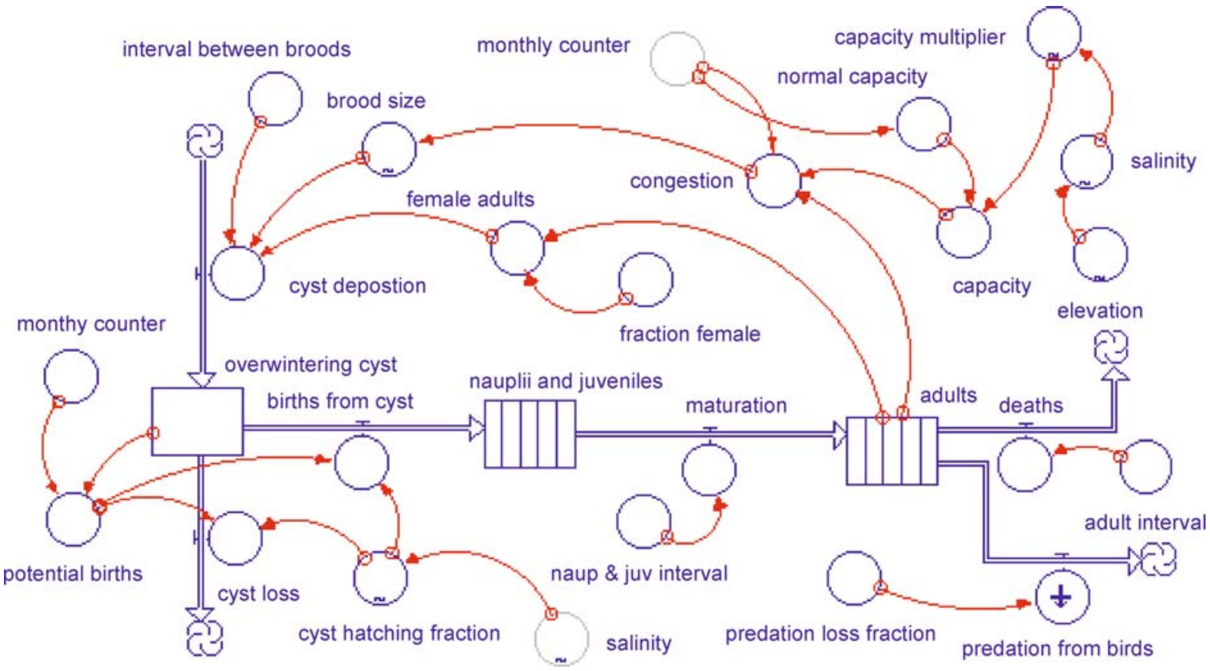


System Dynamics Models of Environment, Energy and Climate Change, Figure 3
Simulated recovery of Mono Lake elevation if export is set to zero for the second half of the simulation

plex ecosystem which may or may not recover as quickly as the lake elevation. To explore the larger system requires an interdisciplinary model, one that looks at both hydrology and population biology.

Figure 4 shows a model of the population of brine shrimp that live in Mono Lake. The life cycle begins when the adult females deposit cysts in the summer. A stock is assigned to the over wintering cysts. The nauplii and juvenile phases are combined into a second stock, and the maturation leads to a new population of adults in the following summer. The model operates in months and is simulated over a long time interval to show the population response to long-term changes in elevation and in salinity. The model shows the population's response to changes in lake elevation, so one can learn about the delays in the population's response to the changes in lake elevation. Since the shrimp life cycle is 12 months, one would expect the population to rebound rapidly after the increase in elevation and the reduction in salinity. The model confirms that the shrimp population would increase rapidly in the years following the elimination of water export from the basin.

The Mono Lake models are textbook models [7]. They demonstrate the clarity that the system dynamics approach brings to the modeling of environmental systems. The stock and flow icons help one see the structure of the system, and the long variable names help one appreciate the individual relationships. The simulation results help one understand the downward momentum in the system. In this particular case, there is no significant down-



System Dynamics Models of Environment, Energy and Climate Change, Figure 4
Stella model of the brine shrimp population of Mono Lake

ward momentum associated with either the hydrological dynamics or the population dynamics.

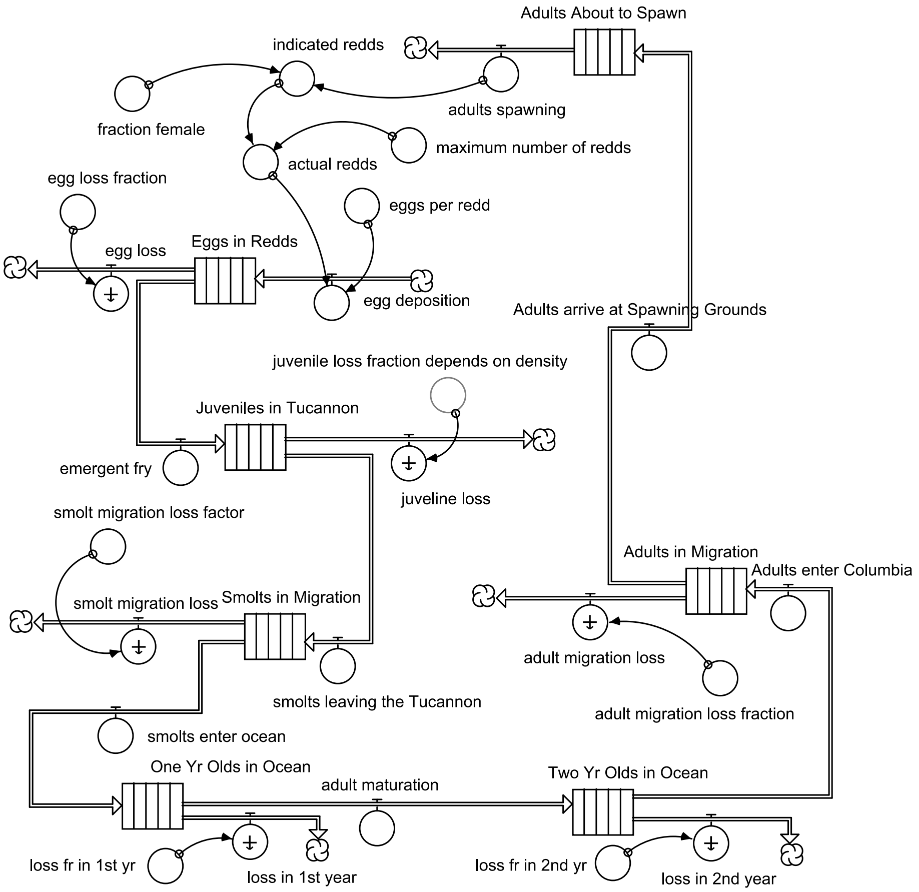
The model in Fig. 1 allows for a system dynamics portrayal of the type of calculations commonly performed by hydrologists. Compared to the previous methods in hydrology, system dynamics adds clarity and ease of experimentation. The population model in Fig. 4 is a system dynamics version of the type of modeling commonly performed by population biologists. System dynamics adds clarity and ease of experimentation in this discipline as well.

The main theme of this article is that system dynamics offers the opportunity for interdisciplinary modeling and exploration. The Mono Lake case illustrates this opportunity with the combination of the hydrological and biological models that allows one to simulate management policies that control export based on the size of the brine shrimp population. The new model is no longer strictly hydrology nor strictly population biology; it is an interdisciplinary combination of both. And by using stock and flow symbols that are easily recognized by experts from many fields of study, the system dynamics enables quick transfer of knowledge. The ability to combine perspectives from different disciplines is one of the most useful aspects of the system dynamics approach to environmental and energy systems. This point is illustrated further with each of the remaining examples in the article.

The Model of the Salmon in the Tucannon River

The next example involves the decline in salmon populations in the Snake and Columbia River system of the Pacific Northwest. By the end of the 1990s, the salmon had disappeared from 40% of their historical breeding ranges despite a public and private investment of more than $1 billion. The annual salmon and steelhead runs had dwindled to less than a quarter of the runs from one hundred years ago. Figure 5 shows a system dynamics model one of the salmon runs, the population of Spring Chinook that spawn in the Tucannon River. The river rises in the Blue Mountains of Oregon and flows 50 miles toward the Snake River in Eastern Washington. It is estimated that the river originally supported runs of 20 thousand adults. But the number of returning adults has declined substantially due to many changes in the past sixty years. These changes include agricultural development in the Tucannon watershed, hydro-electric development on the Snake and Columbia, and harvesting in the ocean.

Each of the stocks in Fig. 5 correspond to a different phase in the salmon life cycle (see Table 1), with a total lifecycle of 48 months. The parameters represent predevelopment conditions, the conditions prior to agricultural development in the Tucannon watershed and hydro-electric development on the Snake and Columbia. Each of these parameters is fixed regardless of the size of the salmon



System Dynamics Models of Environment, Energy and Climate Change, Figure 5
Stella diagram of the model of the salmon life cycle

populations. One of the most important variables is the "juvenile loss fraction depends on density." It can be as low as 50% when there are only a few emergent fry each spring. With higher densities, however, juvenile survival becomes more difficult due to crowding in the cool and safe portions of the river.

Figure 6 shows the model results over a 480 month period with the population parameters in Table 1. The simulation begins with a small number to see if the population will grow to the 20 thousand adults that were thought to have returned to the river in earlier times. The time graph shows a rapid rise to around 20 thousand adults within the first 120 months of the simulation. The remainder of the simulation tests the population response to variability in environmental conditions, as represented by random variations in the smolt migration loss fraction. (This loss tends to be high in years with low runoff and low in years with high runoff.) Figure 6 confirms that the model simulates the major swings in returning adults due to environmental variability. The runs can vary from a low of ten thousand to a high of thirty thousand.

System dynamics models are especially useful when they help us to understand the key feedbacks in the system. Positive feedback loops are essential to our under-

System Dynamics Models of Environment, Energy and Climate Change, Table 1
Inputs to simulate the salmon population under pre-development conditions

Months in each phase		Population parameters	
Adults ready to spawn	1	fraction female	50%
eggs in redds	6	eggs per redd	3,900
juveniles in Tucannon	12	egg loss fraction	50%
smolts in migration	1	smolt migration loss factor	90%
one yr olds in ocean	12	loss fr for first yr	35%
two yr olds in ocean	12	loss fr for second yr	10%
adults in migration	4	adult migration loss fraction	25%

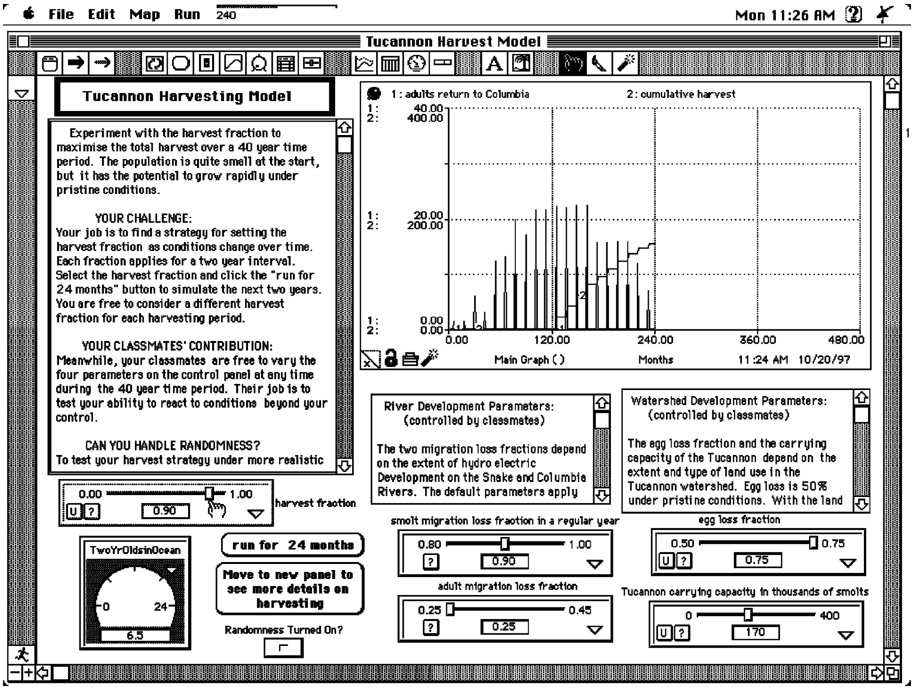
Key feedback loops in the salmon model

standing of rapid, exponential growth; negative feedbacks are essential to our understanding of the controllability of the system. Causal loop diagrams are often used to depict the feedback loops at work in the simulated system. Figure 7 shows an example by emphasizing the most important feedback loops in the salmon model.

Most readers will immediately recognize the importance of the outer loop which is highlighted by bold arrows in the diagram. Starting near the top, imagine that there are more spawning adults and more eggs in redds. We would then expect to see more emergent fry, more juveniles, more smolts in migration, more salmon in the ocean, more adults entering the Columbia, and a subsequent increase in the number of spawning adults. This is the positive feedback loop that gives the salmon population the opportunity to grow rapidly under favorable conditions.

An equally important feedback works its way around the inner loop in the diagram. If we begin at the top with more spawners, we would expect to see more eggs, more fry and a greater juvenile loss fraction as the fry compete for space in the river. With a higher loss fraction, we expect to see fewer juveniles survive to be smolts, fewer smolts in migration, and fewer adults in the ocean. This means we would see fewer returning adults and less egg deposition. This “density dependent feedback” becomes increasingly strong with larger populations, and it turns out to be crucial to the eventual size of the population. Simulating density dependent feedback is also essential to our understanding of the recovery potential of the salmon population. Suppose, for example, that the salmon experience high losses during the adult migration, This will mean that fewer adults reach the spawning grounds. There will be less egg deposition and fewer emergent fry in the following spring. The new cohort of juveniles will then experience more favorable conditions, and a larger fraction will survive the juvenile stage and migrate to the ocean. The density dependent feedback is crucial to the population’s ability to withstand shocks from external conditions.[2]

[2] The shocks could take the form of changes in ocean mortalities, changes in harvesting and changes in the migration mortalities. These



Tucannon Harvesting Model

Experiment with the harvest fraction to maximise the total harvest over a 40 year time period. The population is quite small at the start, but it has the potential to grow rapidly under pristine conditions.

YOUR CHALLENGE:
Your job is to find a strategy for setting the harvest fraction as conditions change over time. Each fraction applies for a two year interval. Select the harvest fraction and click the "run for 24 months" button to simulate the next two years. You are free to consider a different harvest fraction for each harvesting period.

YOUR CLASSMATES' CONTRIBUTION:
Meanwhile, your classmates are free to vary the four parameters on the control panel at any time during the 40 year time period. Their job is to test your ability to react to conditions beyond your control.

CAN YOU HANDLE RANDOMNESS?
To test your harvest strategy under more realistic

River Development Parameters:
(controlled by classmates)

The two migration loss fractions depend on the extent of hydro electric Development on the Snake and Columbia Rivers. The default parameters apply

Watershed Development Parameters:
(controlled by classmates)

The egg loss fraction and the carrying capacity of the Tucannon depend on the extent and type of land use in the Tucannon watershed. Egg loss is 50% under pristine conditions. With the land

System Dynamics Models of Environment, Energy and Climate Change, Figure 8
Salmon harvesting model to encourage student experimentation

Figure 8 shows a version of the model to encourage student experimentation with harvesting policies. The information fields instruct the students to work in groups of three with one student playing the role of "the harvest manager". The harvest manager's goal is to achieve a large, sustainable harvest through control of the harvest fraction. The other students are given control of the parameters that describe conditions on the Snake and Columbia and in the Tucannon watershed. These students are encouraged to make major and unpredictable changes to test the instincts of the harvest manager.

Models designed for highly interactive simulations of this kind are sometimes called "management flight simulators" because they serve the same function as actual flight simulators. With a pilot simulator, the trainee takes the controls of an electro-mechanical model and tests his instincts for managing the simulated airplane under difficult conditions. The Tucannon harvesting model provides a similar opportunity for environmental students. They can learn the challenge of managing open access fisheries that are vulnerable to over harvesting and the tragedy of the commons [12]. In this particular exercise, students learn that they can achieve a sustainable harvest under a wide variety of difficult and unpredictable conditions. The key to sustainability is harvest manager's freedom to change the harvest fraction in response to recent trends in number of returning adults. This is an important finding for fishery management because it reveals that the population dynamics are not the main obstacle to sustainability. Rather, unsustainable harvesting is more likely to occur when the managers find it difficult to change the harvest fraction in response to recent trends. This is the fundamental challenge of an open-access fishery.

The salmon model is a system dynamics version of the type of modeling commonly performed by population biologists. System dynamics adds clarity and ease of experimentation compared to these models. It also provides a launching point for model expansions that can go beyond population biology. Figure 9 shows an example. This is a student expansion to change the carrying capacity from a user input to a variable that responds to the user's river restoration strategy. The student was trained in geomorphology and was an expert on restoring degraded rivers in the west. The Tucannon began the simulation with 25 miles of river in degraded condition and the remaining 25 miles in a mature, fully restored river with a much higher carrying capacity. The new model per-

shocks are external to the boundary of this model, so one is reminded of Coyle's definition of system dynamics. That is, the model helps us understand how the salmon population could withstand the shocks which fall upon it from the out-side world.

mits one to experiment with the timing of river restoration spending and to learn the impact on the management of the salmon fishery.

The student's model provides another example of interdisciplinary modeling that aids our understanding of environmental systems. In this particular case, the modeling of river restoration is normally the domain of the geomorphologist. The model of the salmon population is the domain of the population biologist. Their work is often conducted separately, and their models are seldom connected. This is unfortunate as the experts working in their separate domains miss out on the insights that arise when two perspectives are combined within a single model. In the student's case, surprising insights emerged when the combined model was used to study the economic value of the harvesting that could be sustained in the decades following the restoration of the river. To the student's surprise, the new harvesting could "pay back" the entire cost of the river restoration in less than a decade.

Models of Climate Change

Scientists use a variety of models to keep track of the greenhouse gasses and their impact on the climate. Some of the models combine simulations of the atmosphere, soils, biomass and ocean response to anthropogenic emissions. The more developed models include CO_2, methane, nitrous oxides and other greenhouse gas (GHG) emissions and their changing concentrations in the atmosphere. Claussen [2] classifies climate models as simple, intermediate and comprehensive. The simple models are sometimes called "box models" since they represent the storage in the system by highly aggregated stocks. The parameters are usually selected to match the results from more complicated models. The simple models can be simulated faster on the computer, and the results are easier to interpret. This makes them valuable for sensitivity studies and in scenario analysis [13].

The comprehensive models are maintained by large research centers, such as the Hadley Center in the UK. The term "comprehensive" refers to the goal of capturing all the important processes and simulating them in a highly detailed manner. The models are sometimes called GCMs (general circulation models). They can be used to describe circulation in the atmosphere or the ocean. Some simulate both the ocean and atmospheric circulation in a simultaneous, interacting fashion. They are said to be coupled general circulation models (CGCMs) and are considered to be the "most comprehensive" of the models available [2]. They are particularly useful when a high spatial resolution is required. However, a disadvantage of the CGCMs is that only a limited number of multi-decadal experiments can be performed even when using the most powerful computers.

Intermediate models help scientists bridge the gap between the simple and the comprehensive models. Claussen [2] describes eleven models of intermediate complexity. These models aim to "preserve the geographic integrity of the Earth system" while still providing the opportunity for multiple simulations to "explore the parameter space with some completeness. Thus, they are more suitable for assessing uncertainty". Figure 10 characterizes the different categories of models based on their relative emphasis on:

- number of processes (right axis)
- detailed treatment of the each process (left axis), and the
- extent of integration among the different processes (top axis).

Regardless of the methodology, climate modeling teams must make some judgments on where to concentrate their attention. No model can achieve maximum performance along all three dimensions. (Figure 10 uses the dashed lines to draw our attention to the impossible task of doing every thing within a single model.)

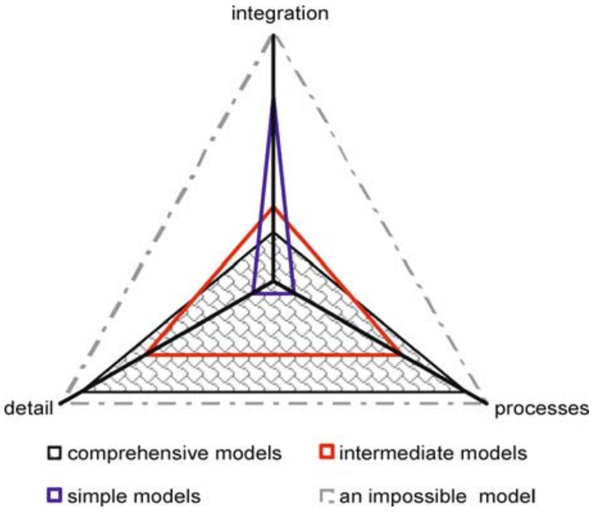
The comprehensive models strive to simulate as many processes as possible with a high degree of detail. This approach provides greater realism, but the models often fail to simulate the key feedback loops the link that atmospheric system with the terrestrial and oceanic systems. (An example is the feedback between CO_2 emissions, temperatures and the decomposition of soil carbon. If higher temperatures lead to accelerated decomposition, the soils could change from a net sink to a net source of carbon [15].) The simple models sacrifice detail and the number of processes in order to focus on the feedback effects between the processes. Using Claussen's terminology, one would say that such models aim for a high degree of "integration". However, the increased integration is achieved by limiting the number of processes and the degree of detail in representing each of the processes.

System dynamics has been used in a few applications to climate change. These applications fit in the category of simple models whose goal is to provide a highly integrated representation of the system. Two examples are described here; both deal with the complexities of the global carbon cycle.

System Dynamics Models of the Carbon Cycle

Figures 11 and 12 depict the global carbon cycle. Figure 11 shows the carbon flows in a visual manner. Figure 12 uses the Vensim stock and flow icons to summarize carbon storage and flux in the current system. The storage is measured in GT, gigatons of carbon, (where carbon is the C in CO_2). The flows are in GT/year of carbon with values rounded off for clarity.

The left side of Fig. 12 shows the flows to the terrestrial system. The primary production removes 121 GT/yr from the atmosphere. This outflow exceeds the return flows by 1 GT/year. This imbalance suggests that around 1 GT of carbon is added to the stocks of biomass and soil each year. So the carbon stored in the terrestrial system would grow over time (perhaps due to extensive reforestation of previously cleared land.) The right side of Fig. 12 shows the flows from the atmosphere to the ocean. The CO_2 dissolved in the ocean each year exceeds the annual release back to the atmosphere by 2 GT. The total, net-flow out of the atmosphere is 3 GT/year which means that natural processes are acting to negate approximately half of the current anthropogenic load.



System Dynamics Models of Environment, Energy and Climate Change, Figure 10
Classification of climate models

As the use of fossil fuels grows over time, the anthropogenic load will increase. But scientists do not think that natural processes can continue to negate 50% of an ever increasing anthropogenic load. On the terrestrial side of the system, there are limits on the net flow associated with reforestation of previously cleared land. And there are limits to the carbon sequestration in plants and soils due to nitrogen constraints. On the ocean side of the system, the current absorption of 2 GT/year is already sufficiently high to disrupt the chemistry of the ocean's upper layer. Higher CO_2 can reduce the concentration of carbonate, the ocean's main buffering agent, thus affecting the ocean's ability to absorb CO_2 over long time periods.

Almost of the intermediate and comprehensive climate models may be used to estimate CO_2 accumulation in the atmosphere in the future. For this article, it is useful to draw on the mean estimate published in *Climatic Change* by Webster [23]. He used the climate model developed at the Massachusetts Institute of Technology, one of the eleven models of "intermediate complexity" in the

review by Claussen [2]. The model began the simulation in the year 2000 with an atmospheric CO_2 concentration of 350 parts per million (ppm). (This concentration corresponds to around 750 GT of carbon in the atmosphere.) The mean projection assumed that anthropogenic emissions would grow to around 19 GT/year by 2100. The mean projection of atmospheric CO_2 was around 700 ppm by 2100. The amount of CO_2 in the atmosphere would be twice as high at the end of the century.

Figure 13 shows the simplest possible model to explain the doubling of atmospheric CO_2. The stock accumulates the effect of three flows, each of which is specified by the

Net Removal to Biomass & Soils Could Grow from 1 to 2 GT/yr during next 50 yrs
Net Removal to Oceans Could Remain Constant at 2 GT/yr

System Dynamics Models of Environment, Energy and Climate Change, Figure 13
Simple model to understand accumulation of CO_2 in the atmosphere

user. Anthropogenic emissions are set to match Webster's assumption. They grow to 19 GT/year by the end of the century. Net removal to oceans is assumed to remain constant at 2 GT/year for the reasons given previously. Net removal to biomass and soils is then subject to experimentation to allow this simple model to match Webster's results. A close match is provided if the net removal increases from 1 to 2 GT/year during the first half of the century and then remains at 2 GT/year for the next fifty years. With these assumptions, the CO_2 in the atmosphere would double from 750 to 1500 GT during the century. This means that the atmospheric concentration would double from 350 to 700 ppm, the same result published by Webster [23].

The model in Fig. 13 is no more than an accumulator. This is the simplest of possible models to add insight on the dynamics of CO_2 accumulation in the atmosphere. It includes a single stock and only three flows, with all of the flows specified by the user. There are no feedback relationships which are normally at the core of system dynamics models. This extreme simplification is intended to make the point that simple models may provide perspective on the dynamics of a system. In this case, a simple accumulator can teach one about the sluggish response of atmospheric CO_2 in the wake of reductions in the anthropogenic emissions. As an example, suppose carbon policies were to succeed in cutting global emissions dramatically in the year 2050. By this year, emissions would have reached 10 GT/yr, so the supposed policy would reduce emissions to 5 GT/yr. What might then happen to CO_2 concentrations in the atmosphere for the remainder of the century? Experiments with highly educated adults [21] suggest that some subjects would answer this question with "pattern matching" reasoning. For example, if emissions are cut in half, it might make sense that CO_2 concentrations would be cut in half as well. But pattern matching leads one astray since the accumulation of CO_2 in the atmosphere responds to the total effect of the flows in Fig. 13. Were anthropogenic emissions to be reduced to 5 GT/year and net removals were to remain at 4 GT/year, the CO_2 concentration would continue to grow, and atmospheric CO_2 would reach 470 ppm by the end of the century.

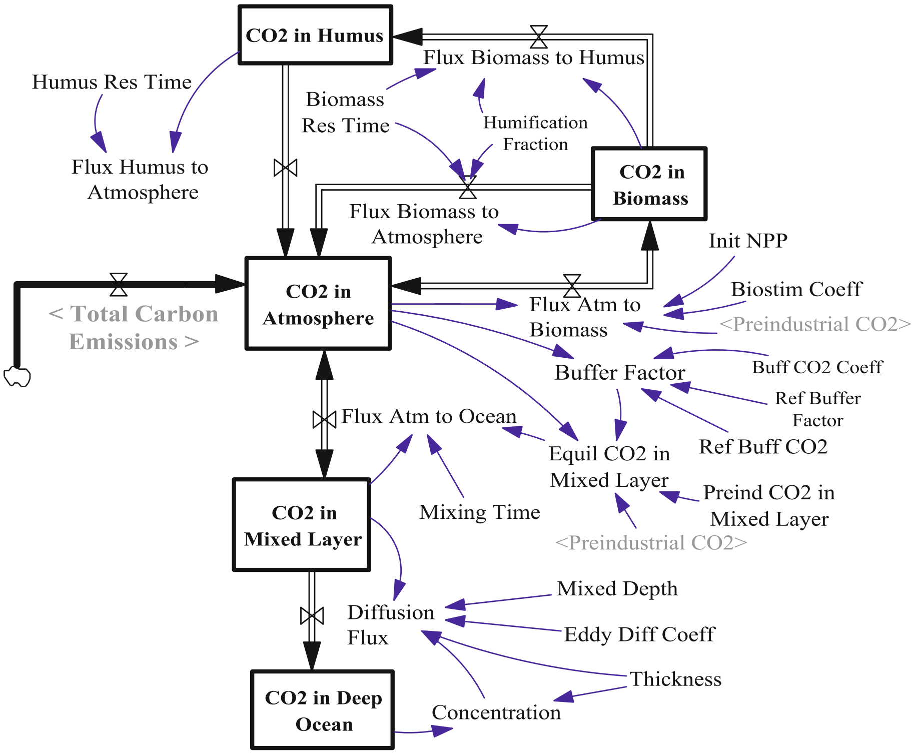
The model in Fig. 13 is an extreme example to make a point about the usefulness of simple models. The next example is by Fiddaman [6]. It was selected as illustrative of the type of model that would emerge after a system dynamics study. Figure 14 shows the view of the carbon cycle, one of 30 views in the model. The model simulates the climate system within a larger system that includes growth in human population, growth in the economy, and changes in the production of energy. The model was organized conceptually as nine interacting sectors with a high degree of coupling between the energy, economic and the climate sectors.

Fiddaman focused on policy making, particularly the best way to put a price on carbon. In the current debate, this question comes down to a choice between a carbon tax and a carbon market. His simulations add support to those who argue that the carbon tax is the preferred method of putting a price on carbon. The simulations also provide another example of the usefulness of system dynamics models that cross disciplinary boundaries. By representing the economy, the energy system and the climate system within a single, tightly coupled model, he provides another example of the power of system dynamics to promote interdisciplinary exploration of complex problems.

System dynamics has also been applied to a wide variety of energy problems [1,7]. Indeed, a key word frequency count in 2004 revealed nearly 400 energy entries in the System dynamics bibliography [11]. Many of these applications deal with the electric power industry, and I have selected two electric studies to illustrate the usefulness of the approach. The first involves the regulatory and financial challenges of the investor owned electric utilities in the United States.

Lessons from the Regulated Power Industry in the 1970s

The 1970s was a difficult decade for the regulated power companies in the United States. The price of oil and gas was increasing rapidly, and the power companies were frequently calling on their regulators to increase retail rates to cover the growing cost of fuel. The demand for electricity had been growing rapidly during previous decades, often at 7 %/year. At this rate, the demand doubled every decade, and the power companies faced the challenge of doubling the amount of generating capacity to ensure that demand would be satisfied. The power companies dealt with this challenge in previous decades by building ever



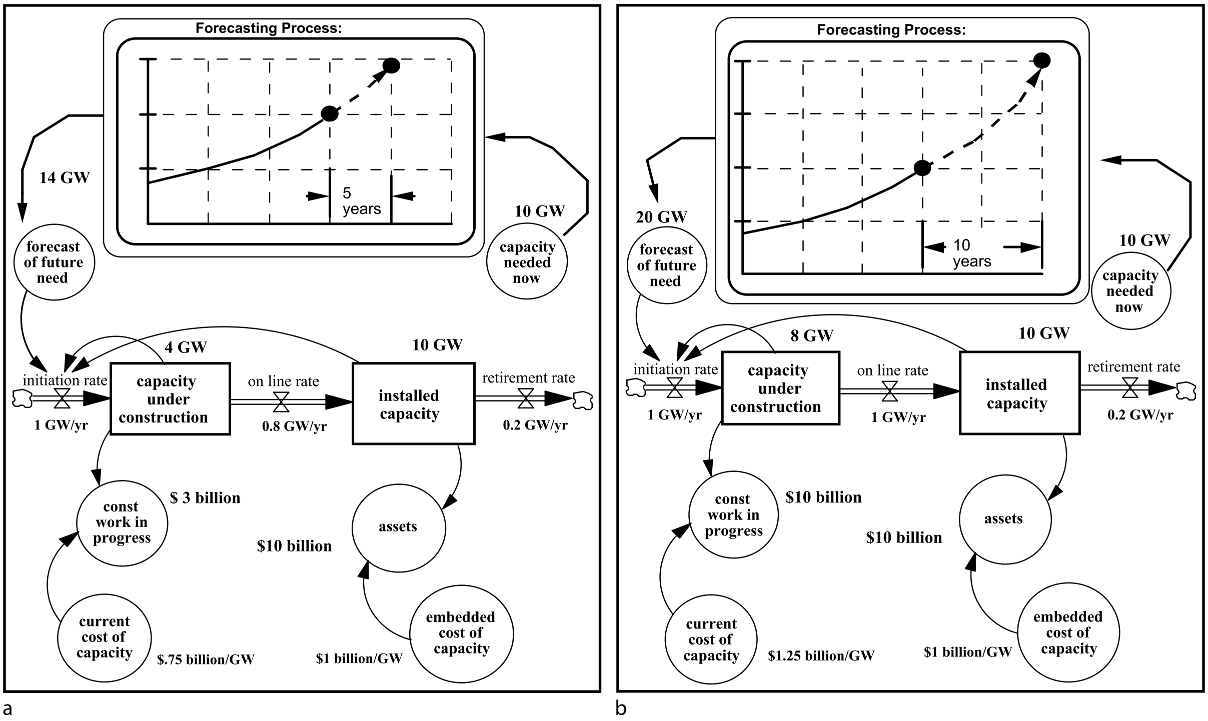
System Dynamics Models of Environment, Energy and Climate Change, Figure 14
Representation of the carbon cycle in the model by Fiddaman [6]

larger power plants (whose unit construction costs declined due to economies of scale). But the economies of scale were exhausted by the 1970s, and the power companies found themselves with less internal funds and poor financial indicators. Utilities worried that the construction of new power plants would not keep pace with demand, and the newspapers warned of curtailments and blackouts.

Figure 15 puts the financial problems in perspective by showing the forecasting, planning and construction processes. The side by side charts allows one to compare the difficult conditions of the 1970s with conditions in previous decades. Figure 15a shows the situation in the 1950s and 1960s. Construction lead times were around 5 years, so forecasts would extend 5 years into the future. Given the costs at the time, the power company would need to finance $3 billion in construction. This was a substantial, but manageable task for a company with $10 billion in assets.

Figure 15b shows the dramatic change in the 1970s. Construction lead times had grown to around 10 years, and construction costs had increased as well. The power company faced the challenge of financing $10 billion in construction with an asset base of $10 billion. The utility executives turned to the regulators for help. They asked for higher electricity rates in order to increase annual revenues and improve their ability to attract external financing. The regulators responded with substantial rate increases, but they began to wonder whether further rate increases would pose a problem with consumer demand. If consumers were to lower electricity consumption, the utility would have less sales and less revenues. The executives might then be forced to request another round of rate increases. Regulators wondered if they were setting loose a "death spiral" of ever increasing rates, declining sales and inadequate financing.

Figure 16 puts the problem in perspective by showing the consumer response to higher electricity rates along side of the other key feedback loops in the system. Higher electricity rates do pose the problem which came to be called "the death spiral". But the death spiral does not act in isolation. Figure 16 reminds us that higher rates lead to lower consumption and to a subsequent reduction in the demand forecast and in construction. After delays for the new power plants to come on line, the power companies experiences a reduction in its "rate base" and the "allowed revenues". When the causal relationships are traced around the outer loop, one sees a negative feedback loop that could act to stabilize the situation. The prob-



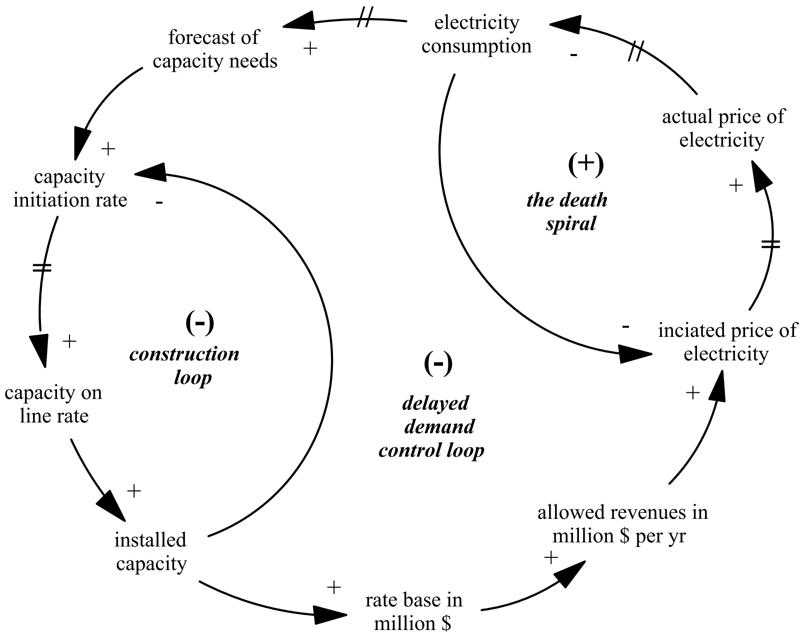
System Dynamics Models of Environment, Energy and Climate Change, Figure 15
a The electric utility's financial challenge during the 1950s and 1960s. b The electric utility's financial challenge during the 1970s

lem, however, is that the delays around the outer loop are substantially longer than the delay for the death spiral.

The utility companies financial challenge was the subject of several system dynamics studies in the 1970s and 1980s [7]. The studies revealed that the downward spiral could pose difficult problems, especially if consumers reacted quickly while utilities were stuck with long-lead time, capital intensive power plants under construction. The studies showed that utility executives needed to do more than rely on regulators to grant rate increases; they needed to take steps on their own to soften the impact of the death spiral. The best strategy was to shift the investments to technologies with shorter lead times. (As an example, a power company in coal region would do better to switch from large to smaller coal plants because of the small plants' shorter lead time.) The studies also revealed that the company's financial situation would improve markedly with slower growth in demand. By the late 1970s and early 1980s, many power companies began to provide direct financial incentives to their customers to slow the growth in demand. System dynamics studies showed that the company-sponsored efficiency programs would be beneficial to the both the customers (lower electric bills) and to the power companies (improved financial performance).

An essential feature of the utility modeling was the inclusion of power operations along side of consumer behavior, company forecasting, power plant construction, regulatory decision making and company financing. This interdisciplinary approach is common within the system dynamics community because practitioners believe that insights will emerge from simulating the key feedback loops. (This belief leads one to follow the cause and effect connections around the key loops regardless of the disciplinary boundaries that are crossed along the way.) This approach contrasts strongly with the customary modeling framework of large power companies who were not familiar with system dynamics. Their approach was to assign models to different departments (i. e., operations, accounting and forecasting) and string the models together to provide a view of the entire corporation over the long-term planning interval.

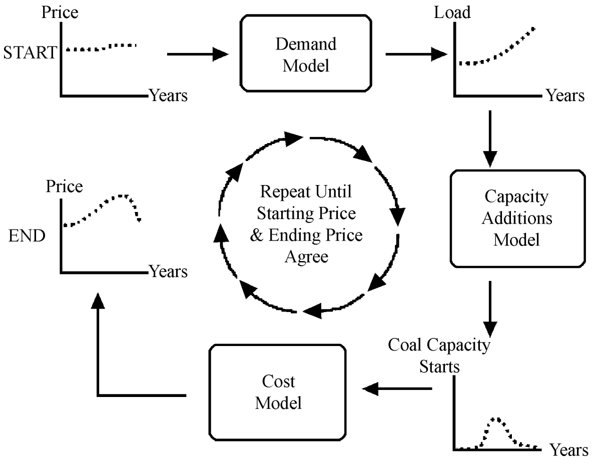
Figure 17 shows what can happen when models within separate departments are strung together. A large corporation might use 30 models, but this diagram makes the point by describing three models. The analysis would begin with an assumption on future electricity prices over the



System Dynamics Models of Environment, Energy and Climate Change, Figure 16
Key feedbacks and delays faced by power companies in the 1970s

20-year interval. These are needed to prepare a forecast of the growth in electricity load. The forecast is then given to the planning department which may run a variety of models to select the number power plants to construct in the future. The construction results are then handed to the accounting and rate making departments to prepare a forecast of electricity prices. When the company finally completes the many calculations, the prices that emerge may not agree with the prices that were assumed at the start. The company must then choose whether to ignore the contradiction or to repeat the entire process with a new estimate of the prices at the top of the diagram. This was not an easy choice. Ignoring the price discrepancy was problematic because it was equivalent to ignoring the "death spiral," one of the foremost problems of the 1970s. Repeating the analysis was also problematic. The new round of calculations would be time consuming, and there was no guarantee that consistent results would be obtained at the end of the next iteration.

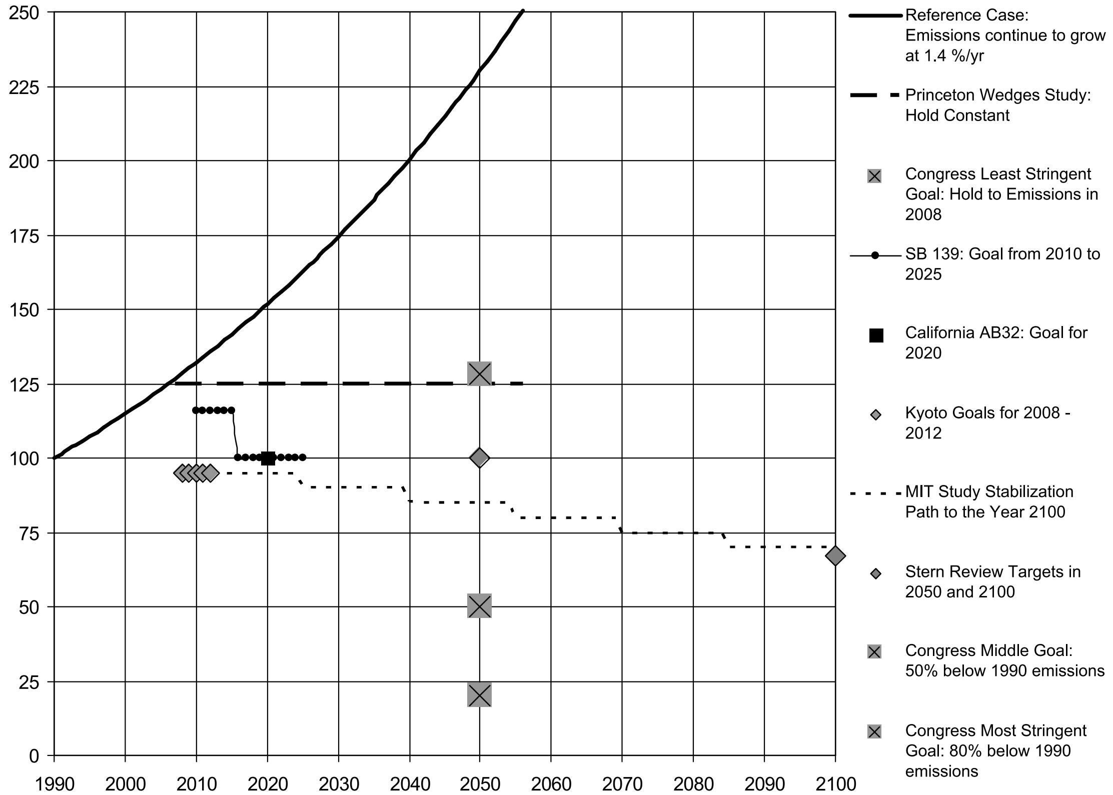
The power companies' dilemma from the 1970s is described here to make an important point about the usefulness of system dynamics. System dynamics modeling is ideally suited for the analysis of dynamic problems that require a feedback perspective. The method allows one to "close the loop", as long as one is willing to cross the necessarily disciplinary boundaries. In contrast, other modeling methods are likely to be extremely time consuming or fall short in simulating the key feedbacks that tie the system together.



System Dynamics Models of Environment, Energy and Climate Change, Figure 17
The iterative approach often used by large power companies in the 1970s

Simulating the Power Industry Response to a Carbon Market

The world is getting warmer, both in the atmosphere and in the oceans. The clearest and most emphatic description

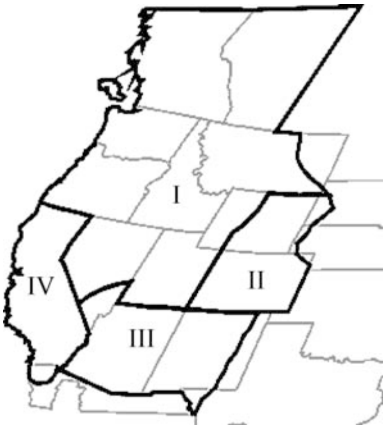


System Dynamics Models of Environment, Energy and Climate Change, Figure 18
Comparison of goals for emissions (100 on the vertical axis represent emissions in the year 1990)

of global warming was issued by the intergovernmental panel on climate change (IPCC) in February of 2007. Their summary for policymakers (p. 4 in [14]) reported that the "Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice and rising global mean sea level". The IPCC concluded that "most of the observed increase is very likely due to the observed increase in anthropogenic greenhouse gas concentrations". As a consequence of the IPCC and other warnings, policymakers around the world are calling for massive reductions in CO_2 and other greenhouse gas (GHG) emissions to reduce the risks of global warming.

Figure 18 summarizes some of the targets for emission reductions that have been adopted or proposed around the world. In many cases, the targets are specified relative to a country's emissions in the year 1990. So, for ease of comparison, the chart uses 100 to denote emissions in the year 1990. Emissions have been growing at around 1.4%/year. The upward curve shows the future emissions if this trend continues: emissions would reach 200 by 2040 and 400 by 2090. The chart shows the great differences in the stringency of the targets. Some call for holding emissions constant; others call for dramatic reductions over time. Some targets apply to the next two decades; many extend to the year 2050; and some extend to the year 2100. However, when compared to the upward trend, all targets require major reductions relative to business as usual.

The targets from the Kyoto treaty are probably the best known of the goals in Fig. 18. The treaty became effective in February of 2005 and called for the Annex I countries to reduce emissions, on average, by 5% below 1990 emissions by the year 2008 and to maintain this limit through 2012. The extension of the Kyoto protocol beyond 2012 is the subject of ongoing discussions. The solid line from 2010 to 2050 represents the "stabilization path" used in the climate modeling by Webster [23]. The limit on emissions was imposed in modeling calculations designed to stabilize atmospheric CO_2 at 550 ppmv or lower. The scenario assumed that the Kyoto emissions caps are adopted by all countries by 2010. The policy assumed that the caps would be extended and then further lowered by 5% every 15 years. By the end of the century, the emissions would be 35% below the value in 1990.



System Dynamics Models of Environment, Energy and Climate Change, Figure 19
Map of the western electricity system

This article concentrates on Senate Bill 139, The Climate Stewardship Act of 2003. Figure 19 shows the S139 targets over the interval from 2010 to 2025. The bill called for an initial cap on emissions from 2010 to 2016. The cap would be reduced to a more challenging level in 2016, when the goal was to limit emissions to no more than the emissions from 1990. S139 was introduced by Senators McCain and Lieberman in January of 2003. It did not pass, but it was the subject of several studies including a highly detailed study by the Energy Information Administration [5]. The EIA used a wide variety of models to search for the carbon market prices that would induce industries to lower emissions to come into compliance with the cap. The carbon prices were estimated at $22 per metric ton of CO_2 when the market was to open in 2010. They were projected to grow to $60 by the year 2025.

The EIA study showed that the electric power sector would lead the way in reducing emissions. By the year 2025, power sector emissions would be reduced 75% below the reference case. This reduction was far beyond the reductions to be achieved by other sectors of the economy. This dramatic response was possible given the large use of coal in power generation and the power industry's wide range of choices for cleaner generation.

A system dynamics study of S139 was conducted at Washington State University (WSU) to learn if S139 could lead to similar reductions in the west. Electricity generation in the western system is provided in a large, interconnected power system shown in Fig. 19. This region has considerably more hydro resources, and it makes less use of coal-fired generation than the nation as a whole. The goal was to learn if dramatic reductions in CO_2 emissions could be possible in the west and to learn if they could be achieved with generating technologies that are commercially available today.

The opening view of the WSU model is shown in Fig. 20. The model deals with generation, transmission and distribution to end use customers, with price feedback on the demand for electricity. The model is much larger than the textbook models described earlier in this article. Fifty

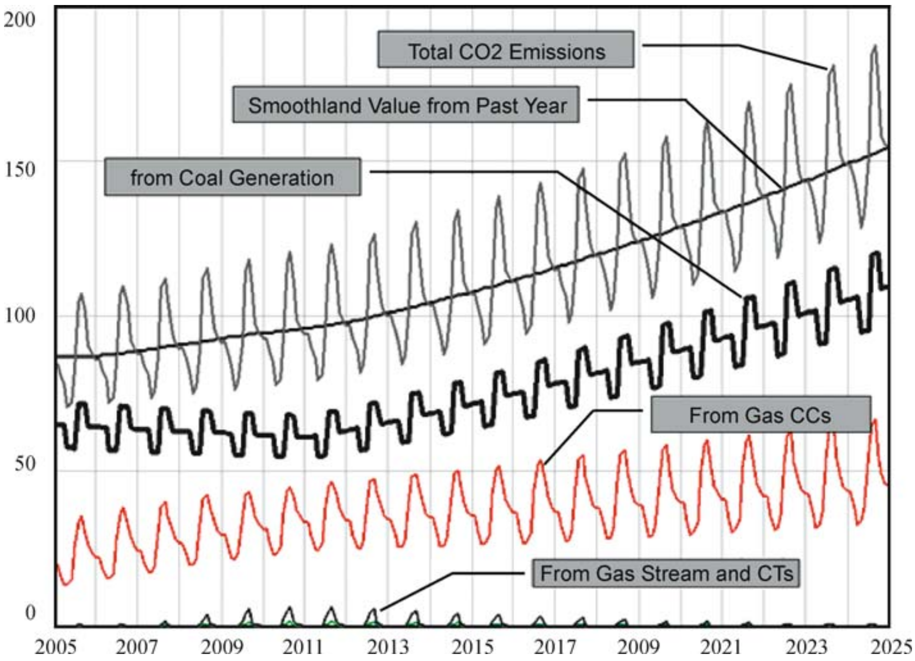
System Dynamics Models of Environment, Energy and Climate Change, Figure 20
Opening view of the model of the western electricity system



System Dynamics Models of Environment, Energy and Climate Change, Figure 21
Annual emissions in a base case simulation (annual emissions are in million metric tons of carbon)

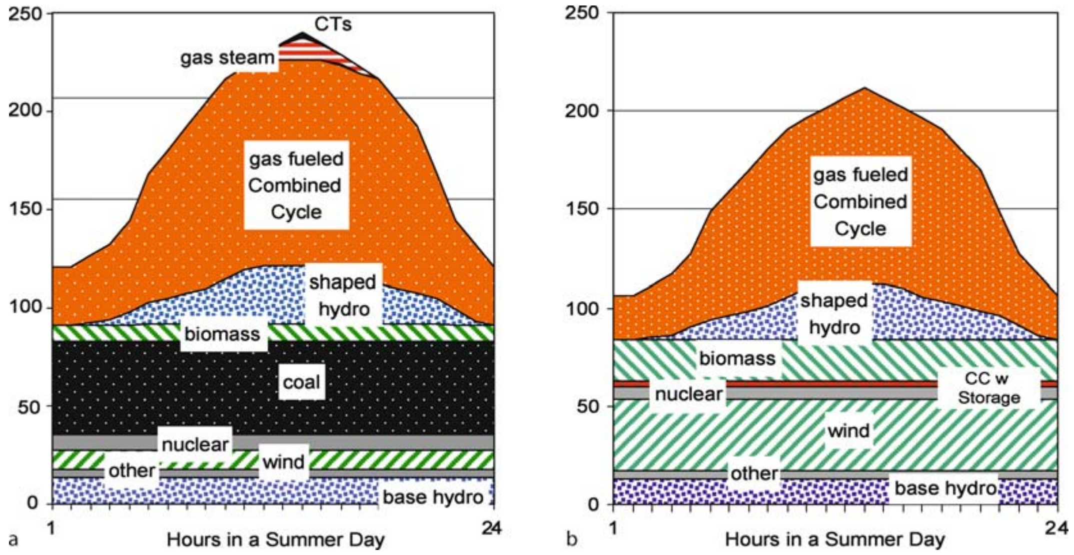
views are required to show the all the diagrams and the simulation results. The opening view serves as a central hub to connect with all the other views.

The opening view uses Vensim's comment icons to draw attention to the CO_2 emissions in the model. The emissions arise mainly from coal-fired power plants, as shown in Fig. 21. A smaller, but still significant fraction of the emissions is caused by burning natural gas in combined cycle power plants. Total emissions vary with the seasons of the year, with the peak normally appearing in the summer when almost all of the fossil-fueled plants are needed to satisfy peak demand. The base case shows annual emissions growing by over 75% by the year 2025.

A major challenge for the system dynamics model is representing power flows across a transmission grid. Finding the flows on each transmission line and the prices in each area is difficult with the standard tools of system dynamics. It simply doesn't make sense to represent the power flows with a combination of stocks, flows and feedback processes to explain the flows. It makes more sense to calculate the flows and prices using traditional power systems methods, as explained by Dimitrovski [4]. The power flows were estimated using an algebraic approach which power engineers label as a reduced version of a direct-current optimal power flow calculation. The solution to the algebraic constraints were developed with the Matlab software and then transferred to user-defined functions to operate within the Vensim software. The Vensim simulations were set to run over twenty years with time in months. (A typical simulation required 240 months with changes during a typical day handled by carrying along separate calculations for each of 24 h in a typical day.) These are extensive calculations compared to many system dynamics models, so there was concern that we would lose the rapid simulation speed that helps to promote interactive exploration and model testing. The important methodological accomplishment of this project was the inclusion of network and hourly results within a long-term model without losing the rapid simulation response that encourages users to experiment with the model.

One of the model experiments called for a new simulation with carbon prices set to follow the $20 to $60 trajectory projected by the EIA for S139. These prices were specified as a user input, and the model responded with a change in both short-term operations and long-term investments. The important result was a 75% reduction in CO_2 emissions by the end of the simulation. This dramatic reduction corresponds almost exactly to the EIA estimate of CO_2 reduction for the power industry in the entire US.

Figure 22 helps one understand how CO_2 emissions could be reduced by such a large amount. These diagrams show the operation of generating units across the Western US and Canada for a typical day in the summer of the final year of the simulation. Figure 22a shows the reference



System Dynamics Models of Environment, Energy and Climate Change, Figure 22

a Projected generation for a peak summer day in 2024 in the reference case. b Projected generation for a peak summer day in 2024 in the S139 case

case; Figure 22b shows the case with S139. The side by side comparison helps one visualize the change in system operation. A comparison of the peak loads shows that the demand for electricity would be reduced. The reduction is 9%, which is due entirely to the consumers' reaction to higher retail electric prices over time.

Figure 22b shows large contributions from wind and biomass generation. Wind generation is carbon free, and biomass generation is judged to be carbon neutral, so these generating units make an important contribution by the end of the simulation. Both of these generating technologies are competitive with today's fuel prices and tax credits. The model includes combined cycle gas generation equipped with carbon capture and storage, a technology that is not commercially available today. The model assumes that advances in carbon sequestration over the next two decades would allow this technology to capture a small share of investment near the end of the simulation. By the year 2025, the combined cycle plants with sequestration equipment would provide 2% of the generation.

The most important observation from Fig. 22 is the complete elimination of coal-fired generation in the S139 case. Coal-fired units are shown to operate in a base load mode in the reference simulation. They provide around 28% of the annual generation, but they account for around two/thirds of the CO_2 emissions in the western system. The carbon prices from S139 make investment in new coal-fired capacity unprofitable at the very start of the simulated market in 2010. As the carbon prices increase, utilities to cut back on coal-fired generation and compensate with increased generation from gas-fired CC capacity. In the simulations reported here, this fuel switching would push the coal units into the difficult position of operating fewer and fewer hours in a day. Eventually this short duration operation is no longer feasible, and coal generation is eliminated completely by the end of the simulation.

The WSU study of the western electric system was selected as the concluding example because of its novel treatment of network flows inside a system dynamics model [4]. The model is also interesting for its treatment of daily price changes within a long-term model. (Such changes are important to the simulation of revenues in the wholesale market.) From a policy perspective, the study confirms previous modeling of the pivotal role of the electric power industry in responding to carbon markets. The study indicated that the western electricity system could achieve dramatic reductions in CO_2 emissions within 15 years after the opening of a carbon market, and it could do so with technologies that are commercially available today [8].

Conditions for Effective Interdisciplinary Modeling

All of the applications demonstrate the usefulness of system dynamics in promoting interdisciplinary modeling. The article concludes with comments on the level of effort and the conditions needed for effective, interdisciplinary modeling.

The examples in this article differ substantially in the level of effort required, from several weeks for the classroom examples to several years for the energy studies. The textbook examples involved student expansions of models of Mono Lake and the Tucannon salmon. The expansions were completed by undergraduate students in projects lasting two or three weeks. The key was the students' previous education (classes from many different departments) and their receptiveness to an interdisciplinary approach.

Fiddaman's model of the climate and energy system [6] was a more ambitious exercise, requiring several years of effort as part of his doctoral research. Bringing multi-year interdisciplinary modeling projects to a successful conclusion requires one to invest the time to master several disciplines and to maintain a belief that there are potential insights at the end of the effort.

The electric power industry examples were also ambitious projects that required several years of effort. The modeling of the western electricity system was a four-year project with support from the National Science Foundation. The long research period was crucial for it allowed the researchers from power systems engineering, system dynamics and environmental science to take the time to learn from one another. The modeling of the electric company problems in the 1970s was also spread over several years of effort. The success of this modeling was aided by utility planners, managers and modelers who were looking for a systems view of their agency and its problems. They saw system dynamics as a way to tie existing ideas together within an integrated portrayal of their system. Their existing ideas were implemented in models maintained by separate functional areas (i. e., forecasting, accounting, operations). The existing models often provided a foundation for the system dynamics models (i. e., in the same way that the comprehensive climate models in Fig. 11 provide support for the development of the more integrated models). The key to effective, interdisciplinary modeling within such large organizations is support from a client with a strong interest in learning and with managerial responsibility for the larger system.

Future Directions

This article concludes with future directions for system dynamics applications to climate change. People often talk of mitigation and adaptation. Mitigation refers to the challenge of lowering greenhouse gas emissions to avoid dangerous anthropogenic interference with the climate system. Adaptation refers to the challenge of living in a changing world.

Mitigation: The challenge of lowering CO_2 and other GHG emissions is the fundamental challenge of the coming century. The next two decades will probably see various forms of carbon markets, and system dynamics can aid in learning about market design. It is important that we learn how to make these markets work well. And if they don't work well, it's important to speed the transition to a carbon tax policy with better prospects for success. System dynamics can aid in learning about markets, especially if it is coupled with simulating gaming to allow market participants and regulators to "experience" and better understand market dynamics.

Adaptation: The world will continue to warm, and sea levels will continue to rise. These trends will dominate the first half of this century even with major reductions in CO_2 emissions. These and other climate changes will bring a wide variety of problems for management of water resource, public health planning, control of invasive species, preservation of endangered species, control of wildfire, and coastal zone management, just to name a few. Our understanding of the adaptation challenges can be improved through system dynamics modeling. The prospects for insight are best if the models provide an interdisciplinary perspective on adapting to a changing world.

Article Outline

Glossary

Econometrics A statistical approach to economic modeling in which all the parameters in the structural equations are estimated according to a 'best fit' to historical data.

Maximum likelihood A statistical concept which underpins calibration optimization and which generates the most likely parameter values; it is equivalent to the parameter set which minimizes the chi-square value.

Objective function See **Payoff** below.

Optimization The process of improving a model's results in terms of either an aspect of its performance or by calibrating it to fit reported time series data.

Payoff A formula which expresses the objective, say, maximization of profits, minimization of costs or minimization of the differences between a model variable and historical data on that variable.

Zero-one parameter A parameter which is used as a multiplier in a policy equation and serves the effect of bringing in or removing a particular influence in determining the optimal policy.

Definition of the Subject

The term 'optimization' when related to system dynamics (SD) models has a special significance. It relates to the mechanism used to improve the model vis-à-vis a criterion. This collapses into two fundamentally different intentions. Firstly one may wish to improve the model in terms of its performance. For instance, it may be desired to minimize overall costs of inventory whilst still offering a satisfactory level of service to the downstream customer. So the criterion here is cost, and this would be minimized after searching the parameter space related to service level. The direction of need may be reversed and maximization may be desired as, for instance, if one had a model of a firm and wished to maximize profit subject to an acceptable level of payroll and advertising costs. Here the parameter space being explored would involve both payroll and advertising parameters. This type of optimization might be described generically as *policy optimization*.

Optimization of performance is also the *raison d'etre* of other management science tools, most notably mathematical programming. But such tools are usually static: they offer the 'optimum' resource allocation given a set of constraints and a performance function to either maximize or minimize. These models normally relate to a single time point and may then need to be re-run on a weekly or monthly basis to determine a new optimal resource allocation. In addition, these models are often linear (certainly so in the case of linear programming), whereas SD models are usually non-linear. So the essential differences are that SD model optimization for performance involves both a dynamic and a non-linear model.

A separate improvement to the model may be sought where it is required to fit the model to past time series data. Optimization here involves minimizing a statistical function which expresses how well the model fits a time-series of data pertaining to an important model variable. In other words a vector of parameters are explored with a view to determining the particular parameter combination which offers the best fit between the chosen important model variable and a past time series data set of this variable. This type of optimization might be generically termed *model calibration*. If *all* the parameters in the SD model are determined in this fashion then the process is equivalent to the technique of econometric modeling. A good comparison between system dynamics and econometric modeling can be found in Meadows and Robinson [12].

Optimization as Calibration

In these circumstances we wish to determine optimal parameters, those which, following a search of the parameter space, offer the best fit of a particular model variable to a time series dataset on that variable taken from real world reporting.

As an example consider a variation of the one of the epidemic models which are made available with the Vensim™ software. The stock-flow diagram is presented as Fig. 1.

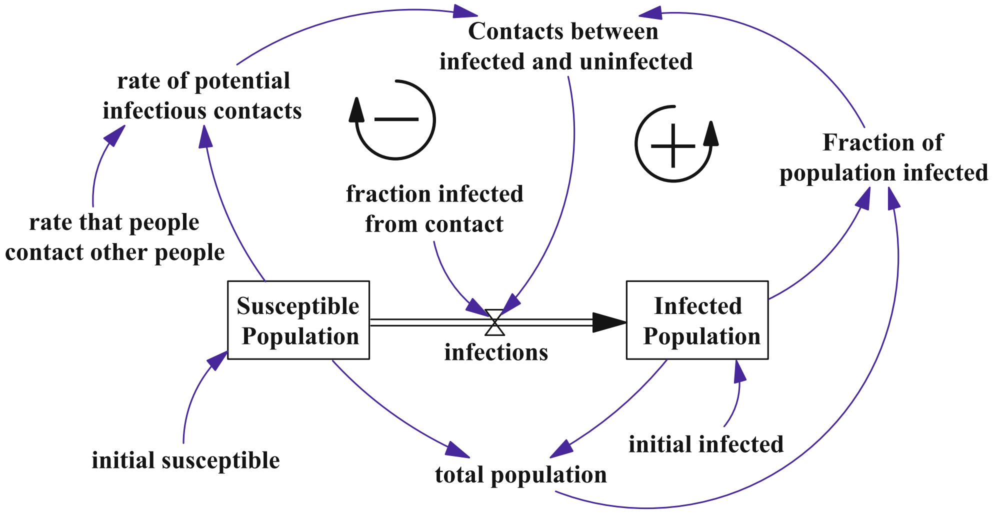
In this epidemiological system members of a susceptible population become infected and join the infected population. Epidemiologists call this an S–I model. It is a simpler variation of the S–I–R model which includes recovered (R) individuals.

Suppose some data on new infections (at intervals of five days) are available covering 25 days of a real-world epidemic. The model is set with a time horizon of 50 days which is consistent with, say, a flu epidemic or an infectious outbreak of dysentery in a closed population such as a cruise ship. The 'current' run of the model is shown in Fig. 2, with the real-world data included for comparison.

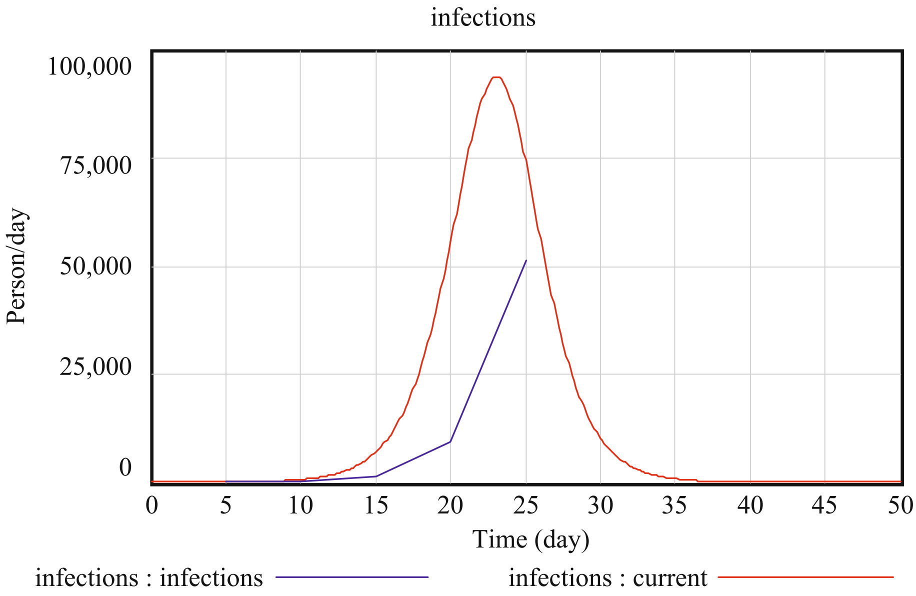
Clearly there is not a very good correspondence between the actual data and the model variable for the infection rate (infections). We wish to achieve a better calibration, and so there is a need to select relevant parameters through which the calibration optimization can be performed over. Referring back to Fig. 1, we can see that the *fraction infected from contact* and the *rate that people contact other people* are two possible parameters to consider. The initial infected and initial susceptible are also parameters of the model in the strict sense of the term, but we will ignore them on this occasion. In this model the *initial infected* is 10 persons and *initial susceptibles* number 750,000 persons.

The chosen value for the *fraction infected from contact* is 0.1, while that for the *rate that people contact other people* is 5.0. The former is a dimensionless number while the latter is measured as a fraction per day (1/day). This is obtained from consideration of the *rate of potential infectious contacts* (persons/day) as a proportion of the *susceptible population* (persons).

The optimization process for calibration involves reading into the model the time series data, in this case on new infections, and, secondly, determining the range for the search in parameter space. There is usually some basic background knowledge which allows a sensible range to be entered. For instance, a probability can only be specified between 0 and 1.0. In this case we have chosen to specify



System Dynamics Models, Optimization of, Figure 1
Stock-flow diagram for a simple epidemic model



System Dynamics Models, Optimization of, Figure 2
Current (base) run of the model and reported data on infections

the ranges as follows:

$$0.03 \leq \text{fraction infected from contact} \leq 0.7$$

$$2 \leq \text{rate that people contact other people} \leq 10\,.$$

A word of warning is necessary in respect of optimizing delay parameters. Because there is a risk of mathematical instability in the model if the value of DT (the TIME STEP) is too large relative to the smallest first-order delay constant, it is important to ensure the TIME STEP employed in the model is sufficiently small to cope with delay constant values which may be reached during the search of the delay parameter space. In other words ensure the minimum number for the search range on the delay parameter is at least double the value of the TIME STEP.

Maximum Likelihood Estimation and the Payoff Function

The optimization process involves a determination of what are termed statistically as maximum likelihood estimates. In Vensim™ this is achieved by maximizing a payoff function. Initially this is negative and the optimization process should ensure this becomes less negative. An ideal payoff value, after optimization, would be zero. A weighting is needed in the payoff function too, but for calibration optimization this is normally 1.0. Driving the payoff value to be larger by making it less negative has parallels with the operation with the simplex algorithm common in linear programming. This algorithm was conceived initially for problems where the objective function was to be minimized. Its use on maximization problems is achieved by minimizing the negative of the objective function.

During the calibration search, Vensim™ takes the difference between the model variable and the data value, multiplies it by the weight, squares it and adds it to the error sum. This error sum is minimized. Usually data points will not exist at every time point in the model. Here the model TIME STEP is 0.125 (1/8th), but let us assume that reported data on new infections have been made available only at times $t = 5, 10, 15, 20$ and 25 so the sum of squares operation is performed only at these five time points.

The data are shown as Table 1.

System Dynamics Models, Optimization of, Table 1
Data used for calibration experiment

Time	5	10	15	20	25
Infections	30	230	1400	9500	51 400

The Recording Point for Reported Data

System dynamics models differentiate between stock and flow variables and the software used for simulating such models advances by a small constant TIME STEP (also known as DT). This has implications for the task of fitting real-world reported data to each type of system dynamics model variable. The following is the issue: at what point in a continuum of time steps should the reported data be recorded at? This is important because the reported data has to be read into the model to be compared with the simulated data. The answer will be different for stock and flow variables.

Where the reported data relate to a stock variable the appropriate time point for recording will be known. If it is recorded at the end of the day (say a closing bank balance) then the appropriate point for data entry in the model will be the beginning of the next day. Thus the first data point above is at time $t = 5$ (5.00) and would, if it were a stock, correspond to a record taken at the very end of time period 4.

However, if the data relate to a flow variable, as in the case of new infections here, the number is the total new infections which have occurred over the entire time unit (day, week, month etc.) and so there is a decision to be reached as to which time point the data are entered at. This is because the TIME STEP (DT) is hardly ever as large as the basic time unit which the model is calibrated in. The use of 5 (10, 15 etc.) above implies that the data on new infections over the period of time $t = 0$ to $t = 5$ are compared with the corresponding model variable at time $5 + 1 * \mathrm{DT}$ (and the new infections over the period $t = 5$ to $t = 10$ at time $10 + 1 * \mathrm{DT}$ etc.). A more appropriate selection might be towards the end of the 5-day time period. Following the example above using a TIME STEP $= 0.125$, this might be at time $4 + 7 * \mathrm{DT}$ (that is at 4.875).

Calibration Optimization Results

Based upon the data on new infections shown above and the chosen ranges for the parameter search, the following output is obtained (Table 2). After 114 simulations the optimized values for our two parameters are shown to be 0.08 and 5.12 and the payoff is over 2500 times larger (less negative). Replacing the original parameters with the optimized values reveals the result shown in Fig. 3. To take things further we may wish to put confidence intervals on the estimated parameters. One way of accomplishing this is by profiling the likelihood and is described in Dangerfield and Roberts [3].

System Dynamics Models, Optimization of, Table 2
Results from the calibration optimization

```
Initial point of search
fraction infected from contact = 0.1
rate that people contact other people = 5
Simulations = 1
Pass = 0
Payoff = −2.67655e + 009
---------------------------------------------
Maximum payoff found at:
fraction infected from contact = 0.0794332
*rate that people contact other people = 5.11568
Simulations = 114
Pass = 6
Payoff = −1.06161e + 006
```

Avoid Cumulated Data

There might be a temptation to optimize parameters against cumulated data when the data are reported essentially as a flow, as is the case here. Were the data to be cumulated we would obtain as shown in Table 3.

The results from this optimization are shown in Table 4. The ranges for the parameter space search are kept the same but the payoff function now involves a comparison of the model variable *infected population* with the corresponding cumulated data. Figure 4 shows the resultant fit to infected population is good, but that is manifestly not borne out when we consider the plot of infections obtained from the same optimization run (Fig. 5).

The reason for this is rooted in statistics. The maximum likelihood estimator is equivalent to the chi-squared statistic. This is turn assumes that each expected data value is independent. A cumulated data series would not exhibit this property of independence.

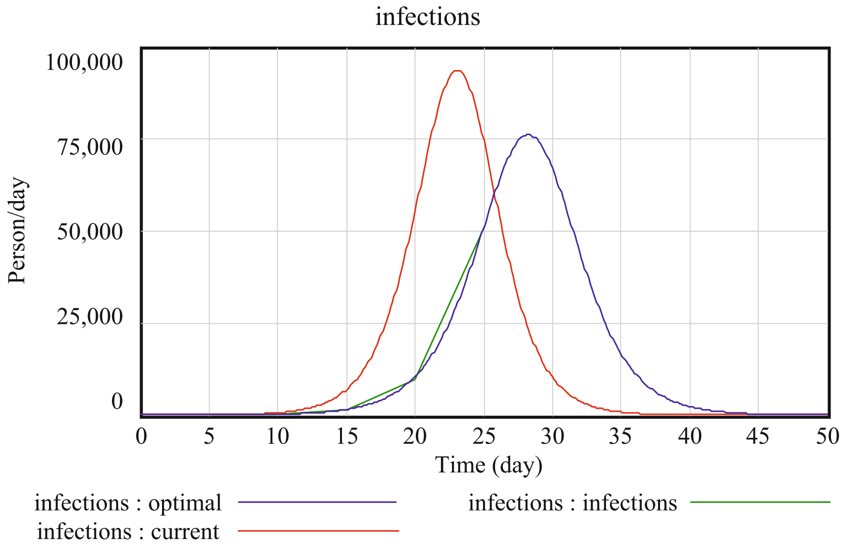
As an aside it is worth pointing out that this model, with suitable changes to the variable names and the time constants involved, could equally represent the diffusion

System Dynamics Models, Optimization of, Table 3
Cumulated reported data for the infected population

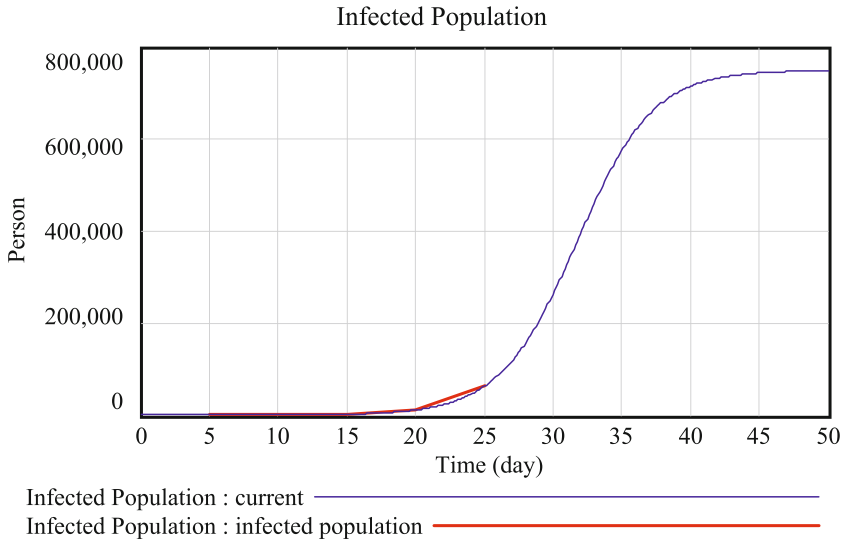
Time	5	10	15	20	25
Infected population	30	260	1660	11 160	62 560

System Dynamics Models, Optimization of, Table 4
Results from the calibration using cumulated data

```
Initial point of search
fraction infected from contact = 0.1
rate that people contact other people = 5
Simulations = 1
Pass = 0
Payoff = −2.48206e + 011
---------------------------------------------
Maximum payoff found at:
fraction infected from contact = 0.0726811
*rate that people contact other people = 4.96546
Simulations = 145
Pass = 6
Payoff = −212 645
The final payoff is −212 645
```



System Dynamics Models, Optimization of, Figure 3
Reported data on infections and optimized (calibrated) model; the base case (current) is reproduced for reference

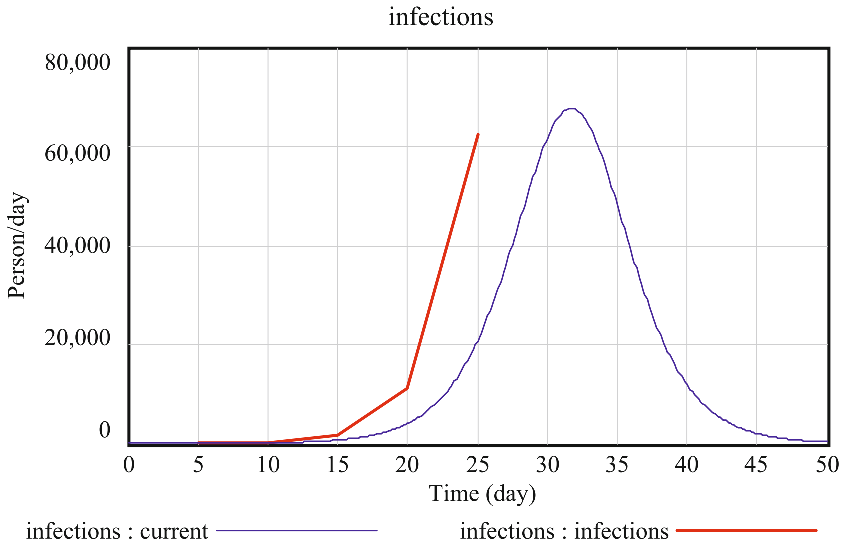


System Dynamics Models, Optimization of, Figure 4
The cumulative model variable (infected population) together with reported data

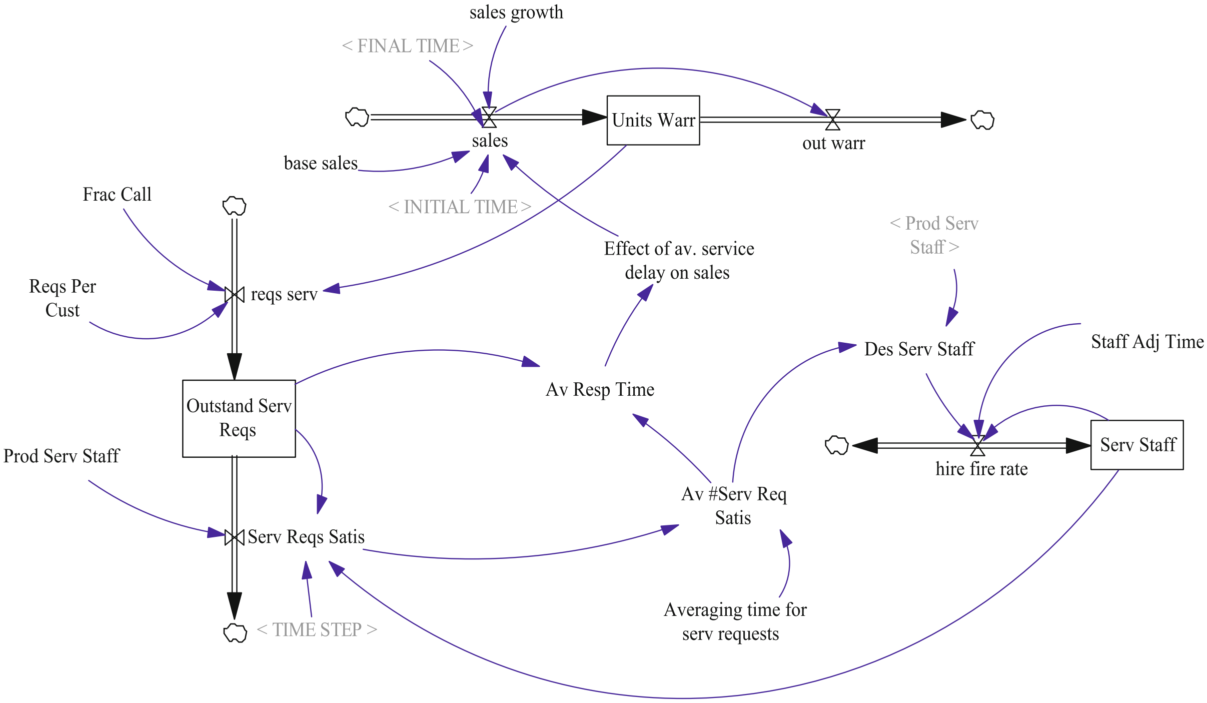
of a new product into a virgin market. In systems terms the structures are equivalent. The *fraction infected from contact* is the same as, say, the fraction reached by word of mouth or advertising and the *rate that people contact other people* is a measure of the potential interactions at which new products might be mentioned amongst the members of the relevant market segment. An *infected population* is equivalent to a customer base, the number of adopters of the relevant product. So it is possible to shed light on important real-world marketing parameters through a calibration optimization of models of this general structure.

Optimization of Performance (Policy Optimization)

An example model is to be used to illustrate the process of optimization to improve the performance of the system, and this is illustrated in Fig. 6. It concerns the service re-



System Dynamics Models, Optimization of, Figure 5
The corresponding fit to infections is poor



System Dynamics Models, Optimization of, Figure 6
Model of service delays for durable goods under warranty

quirements which can arise following the sale of a durable good. These items are typically sold with a 12-month warranty and during this time the vendor is obliged to offer service if a customer calls for it. In this particular case the vendor is not being responsive in terms of staffing the service section. The result is that as sales grow the increasing number of service requests is putting pressure on the service personnel. The delay in responding to service calls also increases and the effect of this is that future sales are depressed because of the vendor's acquired reputation for poor service response. The basic behavior mode is overshoot and collapse.

In the model depicted in Fig. 6, the growth process is achieved by a RAMP function which causes sales of the good to increase linearly by 20 units per month from a base of 500 units per month.

The payoff function is restricted to the variable *Sales*. However, this need not be the case. Where a number of variables might be options in a payoff function, it is possible to assign weights to each such that the sum of the weights is 1.0 (or 100). The optimization process will then proceed with the software accumulating a weighted payoff which it will attempt to maximize. Weights are positive when more is better and negative when less is better.

Policy Experiment No. 1

Here it is decided to try to improve the productivity of the service staff. Currently they manage, on average, to respond to 120 calls per operative per month. It may be an option to improve their productivity by, say, providing them with hand-held devices which direct each operative from one call to the next – calls which may have arisen since setting out from their base. In this way their call routing is improved.

The optimization parameter is *Prod Serv Staff*, and we select an upper limit for the search range of 240 calls per person per month. The chosen performance variable is *Sales*, since we wish to maximize this – or at least not have it overly depressed by poor response times. The results are shown in Table 5. We see that the payoff is increased and that the optimum productivity is a modest increase of 2.6 requests per month, on average. This should be easily achievable and perhaps without expenditure on high-tech devices. The graphical output for sales is shown in Fig. 7.

For comparison, the effect of increasing the productivity to as high as 150 calls per month, on average, is also shown. This would represent an increase of 25% and would be much more difficult to accomplish. Here the benefit of optimization is highlighted. A modest increase in productivity returns a visibly improved sales performance (although the basic behavior mode is unchanged), whilst a much greater productivity increase offers little extra benefit for the effort and cost involved in improving productivity.

System Dynamics Models, Optimization of, Table 5
Optimization results for the productivity of the service staff

Initial point of search
Prod Serv Staff = 120
Simulations = 1
Pass = 0
Payoff = 27 743.5

Maximum payoff found at:
*Prod Serv Staff = 122.647
Simulations = 27
Pass = 3
Payoff = 29 915

Policy Experiment No. 2

Another approach to policy optimization involves the use of a zero-one parameter which has the effect of either including or excluding an influence on policy. Suppose it was thought that the quantity of product units in warranty should exert an influence on the numbers of service personnel hired (or fired). The equation for the desired number of service staff (*Des Serv Staff*) can be expressed as:

Des Serv Staff = "Av #Serv Req Satis"/Prod Serv Staff ∗ trigger + ("Av #Serv Req Satis"/Prod Serv Staff)∗(Units Warr/initial units in warranty)∗(1-trigger). (Units: Persons).

The *trigger* variable is initially set to 1.0 and so the more sophisticated policy is not active. The optimization run results are shown in Table 6. Clearly there is benefit from including the more sophisticated policy which takes into account the current numbers of product units in warranty.

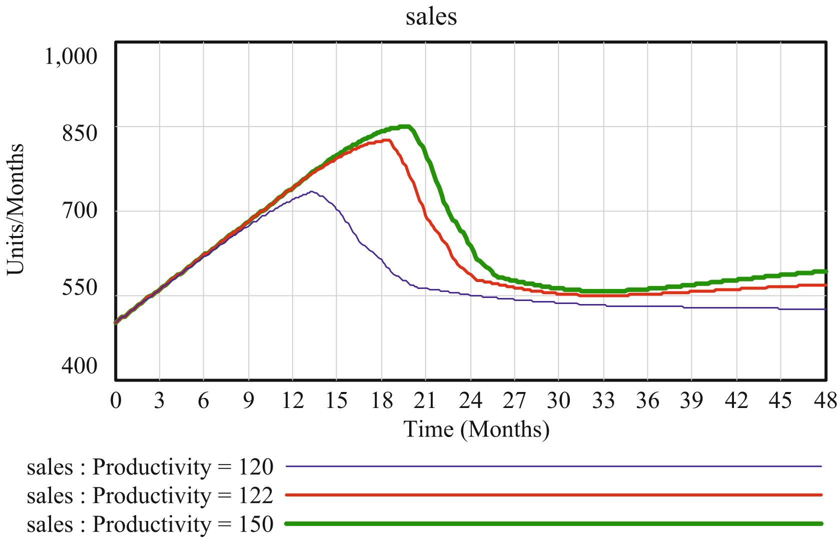
The graphical output is unequivocal (Fig. 8). Sales are continuously increasing when the recruitment policy for service personnel takes into account the number of product units in warranty. The depressive effect on sales of poor service performance is non-existent.

Whilst this might seem an obvious policy, it is surprising how easily the naïve alternative might be accepted without question. The number of calls a typical operative can manage each month is well known along with the (his-

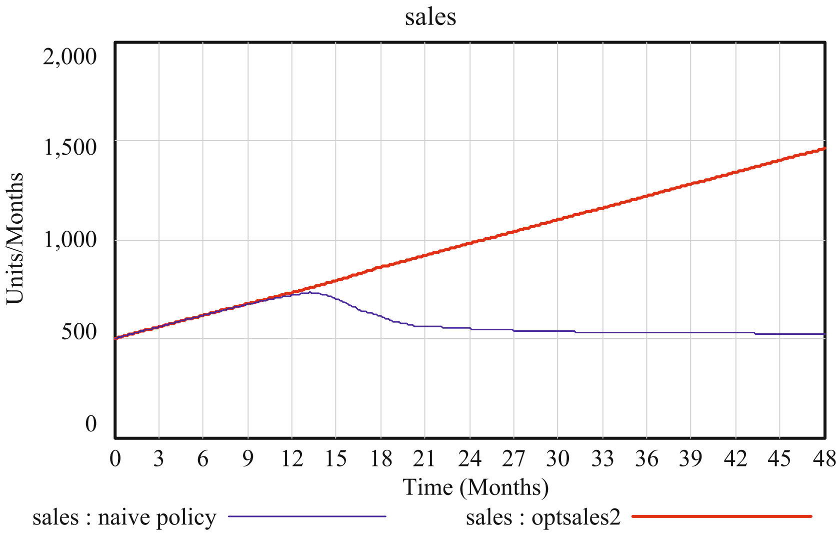
System Dynamics Models, Optimization of, Table 6
Optimization results from selection of policy drivers

Initial point of search
trigger = 1
Simulations = 1
Pass = 0
Payoff = 27 743.5

Maximum payoff found at:
∗trigger = 0
Simulations = 13
Pass = 3
Payoff = 47 090.9



System Dynamics Models, Optimization of, Figure 7
Plots of sales achieved for differing productivities



System Dynamics Models, Optimization of, Figure 8
Comparison of sales from two different policy drivers

torical) number of service requests satisfied. Hence, the desired number of staff is more or less fixed. This comes undone when there is a growth in the number of products sold. In this different environment such a simplistic policy can, as shown, lead to overshoot and collapse. Notice needs to be taken of the changing number of product units in warranty in order that a more effective system performance is achieved.

The above experiments are illustrative only, and there is no intention of over-working a simple teaching model in order to uncover an ideal policy. In the case of policy optimization a wide range of possible alternatives exists. Indeed, a process of learning naturally arises through carrying out repeated optimization experiments with the model [1].

Examples of SD Optimization Reported in the Literature

Amongst the earliest work in this area the writings of Keloharju are worthy of mention. He contributed a number of papers on the topic in the pages of *Dynamica*. See, for example, Keloharju [9]. His work brought the concept to prominence but he did not employ the method on anything other than problems described in text books or postulated by himself. For instance, an application of optimization to the project model contained in Richardson and Pugh's [13] text is contained in Keloharju and Wolstenholme [11]. A statement of the method together with some textbook examples is also available [10]. Additionally, an overview of the methods and their deployment on textbook examples has been contributed by the current author [3]. Finally, there is an example of optimization applied to defence analysis. Again though it is a standard defence model – the armored advance model – rather than any real-world study [14].

Retaining the emphasis on textbook problems for the moment, Duggan [6] employs Coyle's model [1] of the *Domestic Manufacturing Company* to illustrate the methods of multi-objective optimization – an advance over standard SD optimization with its single objective function. The concept of multiple objectives arises from multi-criteria decision-making where a situation can be judged on more than one performance metric. While a multi-objective payoff function can be formulated using a set of weights, it is argued that the selection of the weights is very individual-specific. The multi-objective approach – underpinned by the methods of genetic algorithms – rests upon determining a Pareto-optimal situation, defined as one where no improvement is possible without making some other aspect worse. In other words the method strives for an optimal solution which is not dominated by any other solution. The author demonstrates the approach combining two objectives in the model: one for the differences between desired stock and actual and another between desired backlog and actual.

In terms of applications to real-world problems, the current author has also used the methods of optimization in research conducted in connection with modeling the epidemiology of HIV/AIDS. Fitting a model of AIDS spread to data was carried out for a number of European countries [2,4]. The optimized parameters furnished support for some of the features of AIDS epidemiology which, at the time, were being uncovered by other branches of science. For example, the optimized output revealed that a U-shaped profile of infectiousness in a host was necessary in order to achieve a best fit to data on new AIDS cases. This infectiousness profile was also evidenced by virologists who had analyzed patients' blood and other secretions on a longitudinal basis.

Within this strand of research, a much more complex optimization was performed using American data on transfusion-associated AIDS cases [5]. The purpose here was to estimate the parameters for a number of plausible statistical HIV incubation distributions. Given the nature of the data, the point of infection could be quite accurately determined, but two difficulties were evident: the data were right-censored and the number receiving infected transfusions in each quarter was unknown. However, the SD optimization could estimate this number as part of the process, in addition to estimating parameters of the incubation distribution. The best fit was found to be a three stage distribution similar to the gamma and one which accorded with the high-low-high U-shaped infectiousness profile which was receiving support from a number of sources.

In the marketing domain Graham and Ariza [8] carried out an optimization on a system dynamics model which was designed to shed light on the allocations to make from a marketing budget in a high-tech client firm. Assuming the budget was fixed, the task was to optimize the allocations across more than 90 'buckets' – combinations of product lines, marketing channels and types of marketing. However, these were not discrete: advertising on one product line might have crossover effects on another and the impacts could propagate over a period of time. One major conclusion for this firm was that the advertising allocation should be increased markedly. In general intuitive allocations were shown to fall short of the ideal: they were directionally correct but magnitudes fell short often by factors of three or four.

Future Directions

A primary aim must be to see more published work which describes optimization studies carried out on real-world SD applications. There may be frequent use of optimization in consulting assignments but such activities are rarely published. The references herein suggest that, thus far, outside of unpublished work, the number may be three at most. Whilst software requirements may have inhibited use of SD optimization in the past, there are now no computational barriers to its use and it is to be hoped that in future this quite powerful analytical tool in SD will feature in more application studies.

An advance in the methodology itself has been developed by Duggan [7] and this is a promising pointer for the future. Based on genetic algorithms, it is best suited to the class of SD problems that are agent-based and this highlights a slight limitation. Traditional optimization takes the policy equations as given and explores the parameter space to determine an optimal policy. Instead he has offered an approach which searches over both parameter space and policy (strategy). Theoretically there is no limit to the number of strategies which can be evaluated in this approach, although the user has to define a set in advance of the runs. Under a conventional optimization approach a limited tilt at this is possible using the zero-one parameter method suggested above, although this would restrict the enumerated strategies to two only. Duggan demonstrates the new approach using a classic SD problem: the four agent beer-game. We await its use in a real-world application.

Article Outline

Glossary

Stock In system dynamics stock is a concept representing accumulation and the state of a variable, such as, assets, inventory, capacity, reputation, morale etc. Stock can be measured at any point of time. In mathematical terms, stock is the sum over time (integral) of one or more flows.

Flow Flow or rate represents change or movement in a stock such as, buying assets, building inventories, adding capacity, losing reputation or morale, etc. Flow is measured as "per unit of time" like hiring rate (employees hired per year, production rate (units made per day), or rainfall (inches of rain per month).

Causal loops Causal loops (model) are visual maps that connect a group of variables with known or hypothesized cause and effect relationships. A causal loop can be open or closed. Causal loops can be used for complex problem solving/decision making, consensus building, conflict resolution, priority setting and group learning.

Feedback In a cause and effect chain (system), feedback is a signal from the effect/s to cause/s as to its/their influence on downstream effect/s. Feedback can be information, decision or action. For example, if X causes or changes Y, Y in turn could influence or change X directly or through other intervening variables. This creates a *closed* "causal loop" with either a positive or amplifying feedback (Reinforcing – R) or a negative feedback with damping, counteracting or (Balancing – B) effect.

Delay Cause and effect relationships are often not close in time or space. The lapse time between a cause and its effect is called a systems delay or simply delay. Because some delays in physical, natural and social systems are rather long they mask the underlying or earlier causes when effects become evident. This provides confusion and unintended consequences, especially in social systems, such as economics, education, immigration, judicial systems, etc.

Reference Mode Reference mode is the actual/observed pattern of a key variable of interest to decision makers or policy analysts. It represents the actual behavior of a variable over time which is used to compare with the simulated pattern of the same variable generated by a simulation model to validate the accuracy of the model.

Simulation A computer tool and methodology for modeling complex situations and challenging problems where mathematical tools fail to operate.

Microworld Microworlds are simulation models of real systems such as a firm, a hospital, a market, or a production system. They provide a "virtual" world where decision makers can test and experiment their policies and strategies in a laboratory environment before implementation. Microworlds are constructed using system dynamic software with user friendly interfaces.

Leverage Leverage refers to decisions and actions for change and intervention which have the highest likelihood of lasting and sustainable outcomes. Leverage decisions are best reached by open discussion after the group develops a deep understanding of system dynamics through a causal loop or stock & flow modeling process.

Systems thinking Systems thinking is a paradigm for viewing reality based on the primacy of the whole and relationships. It is one of the key capabilities (disciplines) for organizational learning [30]. Systems Thinking consists of a series of conceptual and modeling tools such as behavior over time, causal loop diagrams and systems archetypes. These tools reveal cause and effect dynamics over time and assist understanding of complex, non-linear, and counter-intuitive behaviors in all systems – physical, natural and social.

Definition of the Subject

System dynamics (SD) is "a methodology for studying and managing complex feedback systems… While the word system has been applied to all sorts of situations, feedback is the differentiating descriptor here. Feedback refers to the situation of *X* affecting *Y* and *Y* in turn affecting *X* perhaps through a chain of causes and effects… Only the study of the whole system as a feedback system will lead to correct results." [36]

Sterman ([35], p 4) defines System Dynamics as "a method to enhance learning in complex systems". "System dynamics is fundamentally interdisciplinary… It is grounded in the theory of nonlinear dynamics and feedback control developed in mathematics, physics, and engineering. Because we apply these tools to the behavior of human as well as physical and technical systems, system dynamics draws on cognitive and social psychology, economics, and other social sciences."

Wolstenholme's [40] offers the following description for system dynamics and its scope:

> A rigorous way to help thinking, visualizing, sharing, and communication of the future evolution of complex organizations and issues over time; for the purpose of solving problems and creating more robust designs, which minimize the likelihood of unpleasant surprises and unintended consequences; by creating operational maps and simulation models which externalize mental models and capture the interrelationships of physical and behavioral processes, organizational boundaries, policies, information feedback and time delays; and by using these architectures to test the holistic outcomes of alternative plans and ideas; within a framework which respects and fosters the needs and values of awareness, openness, responsibility and equality of individuals and teams.

Organizational Learning

Organizational learning is the ability of organizations to enhance their collective capacity to learn and to act, harmoniously. According to Senge [30] "Real learning gets to the heart of what it means to be human. Through learning we re-create ourselves. Through learning we become able to do something we never were able to do. Through learning we re-perceive the world and our relationship to it. Through learning we extend our capacity to create, to be part of the generative process of life. There is within each of us a deep hunger for this type of learning." Organizational learning extends this learning to the organization and its members.

Introduction

History of System Dynamics

(This section is due to US Department of Energy website) "System dynamics was created during the mid-1950s by Professor Jay W. Forrester of the Massachusetts Institute of Technology. Forrester arrived at MIT in 1939 for graduate study in electrical engineering. His first research assistantship put him under the tutelage of Professor Gordon

Brown, the founder of MIT's Servomechanism Laboratory. Members of the MIT Servomechanism Laboratory, at the time, conducted pioneering research in feedback control mechanisms for military equipment. Forrester's work for the Laboratory included traveling to the Pacific Theatre during World War II to repair a hydraulically controlled radar system installed aboard the aircraft carrier Lexington. The Lexington was torpedoed while Forrester was on board, but not sunk.

At the end of World War II, Jay Forrester turned his attention to the creation of an aircraft flight simulator for the US Navy. The design of the simulator was cast around the idea, untested at the time, of a digital computer. As the brainstorming surrounding the digital aircraft simulator proceeded, however, it became apparent that a better application of the emerging technology was the testing of computerized combat information systems. In 1947, the MIT Digital Computer Laboratory was founded and placed under the direction of Jay Forrester. The Laboratory's first task was the creation of WHIRLWIND I, MIT's first general-purpose digital computer, and an environment for testing whether digital computers could be effectively used for the control of combat information systems. As part of the WHIRLWIND I project, Forrester invented and patented coincident-current random-access magnetic computer memory. This became the industry standard for computer memory for approximately twenty years. The WHIRLWIND I project also motivated Forrester to create the technology that first facilitated the practical digital control of machine tools.

After the WHIRLWIND I project, Forrester agreed to lead a division of MIT's Lincoln Laboratory in its efforts to create computers for the North American SAGE (Semi-Automatic Ground Environment) air defense system. The computers created by Forrester's team during the SAGE project were installed in the late 1950s, remained in service for approximately twenty-five years, and had a remarkable "up time" of 99.8%.

Forrester's seminal book Industrial Dynamics [11] "is still a significant statement of philosophy and methodology in the field. Since its publication, the span of applications has grown extensively and now encompasses work in

- corporate planning and policy design
- public management and policy
- biological and medical modeling
- energy and the environment
- theory development in the natural and social sciences
- dynamic decision making
- complex nonlinear dynamics" [36]

Systems Thinking and Modeling Methodology

System Dynamics is one of the five phases of systems thinking and modeling intervention methodology [6,21]. These distinct but related phases are as follows:

1. Problem structuring;
2. Causal loop modeling;
3. System dynamics modeling;
4. Scenario planning and modeling;
5. Implementation and organizational learning (learning lab).

These phases follow a process, each involving a number of steps, as outlined in Table 1. This process does not require all phases to be undertaken, nor does each phase require all the steps listed. Which phases and steps are included in a particular project or intervention depends on the issues or problems that have generated the systems enquiry and the degree of effort that the organization is prepared to commit to.

System Dynamics Modeling

This phase follows the causal modeling phase. Although it is possible to go into this phase directly after problem structuring, performing the causal modeling phase first will enhance the conceptual rigor and learning power of the systems approach. The completeness and wider insights of systems thinking is generally absent from other simulation modeling approaches, where causal modeling does not play a part. The following steps are generally followed in the system dynamics modeling phase.

1. Develop a high-level map or systems diagram showing the main sectors of a potential simulation model, or a 'rich picture' of the main variables and issues involved in the system of interest.
2. Define variable types (e. g. stocks, flows, converters, etc.) and construct stock flow diagrams for different sectors of the model.
3. Collect detailed, relevant data including media reports, historical and statistical records, policy documents, previous studies, and stakeholder interviews.
4. Construct a computer simulation model based on the causal loop diagrams or stock-flow diagrams. Identify the initial values for the stocks (levels), parameter values for the relationships, and the structural relationships between the variables using constants, graphical relationships and mathematical functions where appropriate. This stage involves using specialized computer packages like STELLA, *ithink*, VENSIM, POWERSIM, DYSMAP, COSMIC and Consideo.

System Dynamics and Organizational Learning, Table 1
The five phase process of systems thinking and modeling (Source: [6])

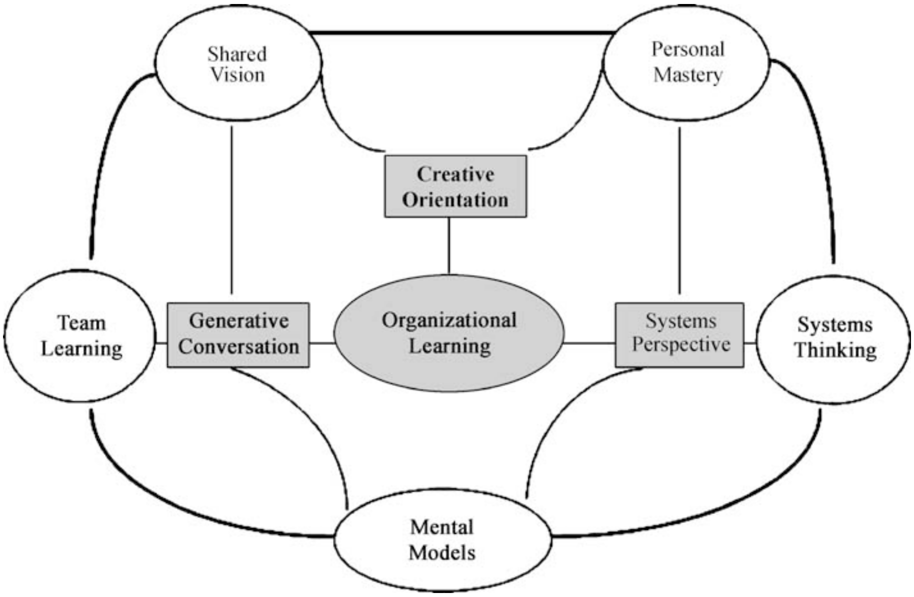
Phases	Steps	
1	Problem structuring	Identify problems or issues of concern to management, Collect preliminary information and data
2	Causal loop modeling	Identify main variables, Prepare behavior over time graphs (reference mode), Develop causal loop diagram (influence diagram), Analyze loop behavior over time and identify loop types, Identify system archetypes, Identify key leverage points, Develop intervention strategies
3	**System dynamic modeling**	Develop a systems map or rich picture, Define variable types and construct stock-flow diagrams, Collect detailed information and data, Develop a simulation model, Simulate steady -state/stability conditions, Reproduce reference mode behavior (base case), Validate the model, Perform sensitivity analysis, Design and analyze policies, Develop and test strategies
4	Scenario planning and modeling	Plan general scope of scenarios, Identify key drivers of change and keynote uncertainties, Construct forced and learning scenarios, Simulate scenarios with the model, Evaluate robustness of the policies and strategies
5	Implementation and organizational learning	Prepare a report and presentation to management team, Communicate results and insights of proposed intervention to stakeholders, Develop a microworld and learning lab based on the simulation model, Use learning lab to examine mental models and facilitate

5. Simulate the model over time. Select the initial value for the beginning of the simulation run, specify the unit of time for the simulation (e. g. hour, day, week, month, year, etc.). Select the simulation interval (DT) (e. g. 0.25, 0.5, 1.0) and the time horizon for the simulation run (i. e. the length of the simulation). Simulate model stability by generating steady state conditions.
6. Produce graphical and tabular output for the base case of the model. This can be produced using any of the computer packages mentioned above. Compare model behavior with historical trends or hypothesized reference modes (behavior over time charts).
7. Verify model equations, parameters and boundaries, and validate the model's behavior over time. Carefully inspect the graphical and tabular output generated by the model.
8. Perform sensitivity tests to gauge the sensitivity of model parameters and initial values. Identify areas of greatest improvement (key leverage points) in the system.
9. Design and test policies with the model to address the issues of concern to management and to look for system improvement.
10. Develop and test strategies (i. e. combinations of functional policies, for example operations, marketing, finance, human resources, etc.).

Organizational Learning

(This section is adapted from [21])
Peter Senge, who popularized the concept through his seminal book: The Fifth Discipline [30], describes a learning organization as one 'which is continually expanding its ability to create its future'. He identifies five core capabilities (disciplines) of the learning organization that are derived from three "higher orientations": creative orientation; generative conversation; and systems perspective. "The reality each of us sees and understands depend on what we believe is there. By learning the principles of the five disciplines, teams begin to understand how they can think and inquire that reality, so that they can collaborate in discussions and in working together create the results that matter [to them]."

As Fig. 1 shows the learning organization capabilities are dynamically interrelated, and collectively they lead to organizational learning.



System Dynamics and Organizational Learning, Figure 1
The core capabilities of a learning organization (Source: [19])

Senge maintains that *Creative orientation* is the source of a genuine desire to excel. It is the source of an intrinsic motivation and drive to achieve. It relinquishes personal gains in favor of the common good. *Generative conversation* refers to a deep and meaningful dialog to create unity of thought and action. *Systems perspective* is the ability to see things holistically by understanding the interconnectedness of the parts. The foregoing elements give rise to the five core capabilities of learning organizations, namely: personal mastery; shared vision; mental models; team learning and dialog; and systems thinking. These five disciplines are described below. Figure 1 below shows the core capabilities and their relationships.

Personal Mastery

Senge [30] describes that personal mastery is the cornerstone and 'spiritual' foundation of the learning organization. It is born out of a creative orientation and systemic perspective. Personal mastery instils a genuine desire to do well and to serve a noble purpose. People exhibiting high levels of personal mastery focus "on the desired result itself, not the process or the means they assume necessary to achieve that result" [30]. These people can "successfully focus on their ultimate intrinsic desires, not on secondary goals. This is a cornerstone of Personal Mastery". Personal mastery also requires a commitment to truth, which means to continually challenge "theories of why things are the way they are". Without committing to the truth, people all too quickly revert to old communication routines which can distort reality and prevent them from knowing where they really stand.

Shared Vision

It is commonly assumed that in contemporary organizations senior management can develop a vision which employees will follow with genuine commitment. This is a fallacy. Simply promoting a 'vision statement' could result in a sense of apathy, complacency and resentment. Instead, there needs to be a genuine endeavor to understand what people will commit to. The overriding vision of the group must build on the personal visions of its members. Shared vision should align diverse views and feelings into a unified focus.

This is emphasized by Arie de Geus [9] when he describes what makes a truly extraordinary organization. "The feeling of belonging to an organization and identifying with its achievements is often dismissed as soft. But case histories repeatedly show that a sense of community is essential for long term survival". For example, when Apple Corporation challenged IBM, it was in its 'adolescent' years, characterized by creativity, confidence and even defiance. This is similar to the spirit in Team New Zealand when it competed against the bigger-budget syndicates! Within these organizations there is a real passion for the outcome; a common vision for success [19].

Creating a shared vision is the most fundamental job of a leader [26]. By creating a vision, the leader provides a vehicle for people to develop commitment, a common goal around which people can rally, and a way for people to *feel* successful. The leader must appeal to people's emotions if they are to be energized towards achieving the goal. Emotional acceptance of, and belief in, a vision is far more powerful in energizing team members than is intellectual recognition that the vision is simply a 'good idea'. One of the most powerful ways of communicating a vision is through a leader's personal example and actions, demonstrating behavior that symbolizes and furthers that vision.

Mental Model and Leadership

Mental models reflect beliefs, assumptions and feelings that shape one's world views and actions. They are formed through family, education, professional and social learning based, on the most part, on cultural and social norms. Mental models, however, can be altered and aligned.

Organizations are often constrained by deep-seated belief systems, resulting in preconceived ideas on how things ought to perform. Goodstein and Burke ([14] p. 10), pioneers in the field of social psychology of organizations, observed that 'the first step in any change process is to unfreeze the present patterns of behavior as a way of managing resistance to change'. The leader has a pivotal role in dismantling negative mental models and shaping new ones.

In order to get people to engage in open discussions of issues that affect the organization, a leader must appeal to their emotions and must get beyond the superficial level of communication. In the 1970s Shell Oil undertook major changes in its leadership approach and communications style. According to a manager at Shell, "When I tried to talk personally about an issue rather than say 'here's the answer', it was powerful. It caused me to engage in dialog with others that resulted in mutual learning on all sides" ([7] p. 71).

The leader is a 'designer', and part of that role is designing the governing ideas of purpose and core values by which people will live [30,31]. In this role, the leader must propose and model the manner in which the group has to operate internally. This provides ample opportunities for leaders to examine their deeply held assumptions about the task, the means to accomplish it, the uniqueness of the people and the kinds of relationship that should be fostered among the people. Only after people have observed and *experienced* the organizational values in practice would these values become the basis for prolonged group behavior. These values should be manifested first and should be most visible in the leader's own behavior.

Leadership, especially in knowledge-based organizations, must be distributed and shared to a far greater extent than it was in the past. For example, in the Chicago Bulls basketball team, Michael Jordan changed his role: it became not only that of an individually brilliant player but *also* that of a leader whose job it was to raise the level of play of other team members. After this transition, the Bulls began their record run of championship seasons [7].

Team Learning and Dialog

The word 'dialog' comes from the Greek words *dia* and *logos*. It implies that when people engage in dialog, the meaning *moves through* them – Thus, it enables them to 'see through words' [16]. Dialog is an essential requirement for organizational learning. It results from generative conversation, shared vision, and transparent mental models. Dialog creates a deep sense of listening and suspending one's own views. Feedback is an integral aspect of dialog.

Communication routines in organizations are generally anti-learning and promote mediocrity. They include 'defensive routines' [2] – statement that can stifle dialog and innovative thinking. Exposing and unlearning such routines, and understanding the powerful detrimental impact they have on learning, are serious challenges many organizations face if they are to create effective learning environments.

Many leaders are charismatic and are highly eloquent when it comes to presenting their ideas; that's often why they get to the top of the organization. However, many appear to lack the ability to extract the very best from employees in a non-threatening manner. Without this ability, leaders may miss many good ideas, or might act on many bad ones.

In a group context, encouragement from the leader and mutual encouragement among group members is essential. Furthermore, personal differences must be put aside in order for effective dialog to ensue.

How Organizations Learn

(This section is edited from Wikipedia: http://en.wikipedia.org/wiki/Organizational_learning)

"Argyris and Schon were the first to propose concepts and models that facilitate organizational learning, the following literatures have followed in the tradition of their work:

- March and Olsen [23] attempt to link up individual and organizational learning. In their model, individual beliefs lead to individual action, which in turn may lead to an organizational action and a response from the environment which may induce improved individual beliefs and the cycle then repeats over and over. Learning occurs as better beliefs produce better actions.

- Argyris and Schon [3] distinguish between single-loop and double-loop learning, related to Gregory Bateson's concepts of first and second order learning. In single-loop learning, individuals, groups, or organizations modify their actions according to the difference between expected and obtained outcomes. In double-loop learning, the entities (individuals, groups or organization) question the values, assumptions and policies that led to the actions in the first place; if they are able to view and modify those, then second-order or double-loop learning has taken place. Double loop learning is the learning about single-loop learning.
- Kim [17], as well, in an article titled "The link between individual and organizational learning", integrates Argyris, March and Olsen and another model by Kofman into a single comprehensive model; Further, he analyzes all the possible breakdowns in the information flows in the model, leading to failures in organizational learning; For instance, what happens if an individual action is rejected by the organization for political or other reasons and therefore no organizational action takes place?
- Nonaka and Takeuchi [27] developed a four stage spiral model of organizational learning. They started by differentiating Polanyi's concept of "tacit knowledge" from "explicit knowledge" and describe a process of alternating between the two. Tacit knowledge is personal, context specific, subjective knowledge, whereas explicit knowledge is codified, systematic, formal, and easy to communicate. The tacit knowledge of key personnel within the organization can be made explicit, codified in manuals, and incorporated into new products and processes. This process they called "externalization". The reverse process (from explicit to implicit) they call "internalization" because it involves employees internalizing an organization's formal rules, procedures, and other forms of explicit knowledge. They also use the term "socialization" to denote the sharing of tacit knowledge, and the term "combination" to denote the dissemination of codified knowledge. According to this model, knowledge creation and organizational learning take a path of socialization, externalization, combination, internalization, socialization, externalization, combination… etc. in an infinite spiral.
- Flood [10] discusses the concept of organizational learning from Peter Senge and the origins of the theory from Argyris and Schon. The author aims to "re-think" Senge's *The Fifth Discipline* through systems theory. The author develops the concepts by integrating them with key theorists such as Bertalanffy, Churchman, Beer, Checkland and Ackoff. Conceptualizing organizational learning in terms of structure, process, meaning, ideology and knowledge, the author provides insights into Senge within the context of the philosophy of science and the way in which systems theorists were influenced by twentieth-century advances from the classical assumptions of science.
- Nick Bontis et al. [4] empirically tested a model of organizational learning that encompassed both stocks and flows of knowledge across three levels of analysis: individual, team and organization. Results showed a negative and statistically significant relationship between the misalignment of stocks and flows and organizational performance.
- Imants [15] provides theory development for organizational learning in schools within the context of teachers' professional communities as learning communities, which is compared and contrasted to teaching communities of practice. Detailed with an analysis of the paradoxes for organizational learning in schools, two mechanisms for professional development and organizational learning, (1) steering information about teaching and learning and (2) encouraging interaction among teachers and workers, are defined as critical for effective organizational learning.
- Common [8] discusses the concept of organizational learning in a political environment to improve public policy-making. The author details the initial uncontroversial reception of organizational learning in the public sector and the development of the concept with the learning organization. Definitional problems in applying the concept to public policy are addressed, noting research in UK local government that concludes on the obstacles for organizational learning in the public sector: (1) overemphasis of the individual, (2) resistance to change and politics, (3) social learning is self-limiting, i. e. individualism, and (4) political "blame culture". The concepts of *policy learning* and *policy transfer* are then defined with detail on the conditions for realizing organizational learning in the public sector."

Modeling for Organizational Learning

In general, the *process* of model building can be an effective conduit for collective learning. System Dynamics modeling, in particular, can be used to enhance organizational learning [35] through rapid feedback and experimentation and its facility to test assumptions and mental models. As we have discussed, dealing effectively with mental models is one of the core competencies for organizational learning

Ackoff [1] likens complex problems to "messes". "Messy problems are defined as situations in which there are large differences of opinion about the problem or even on the question of whether there is a problem. Messy situations make it difficult for a management team to reach agreement. System Dynamics modeling with groups known as Group Model Building (GMB) is a powerful tool for dealing with these. SD and GMB are especially effective in dealing with semi-structured and ill-structured decision situations."

GMB offers an opportunity to align and share piecemeal mental models and create the possibility of assimilating and integrating partial mental models into a holistic system description [38,39]. GMB and SD can help uncover 'illusions' that may occur due to the fact that the definition of a problem may be a socially constructed phenomenon that has not been put to test ([18] p. 84).

Learning Laboratory

(This section is adapted from [21], Chapter 6)
Learning laboratory is a setting as well as a process in which a group can learn together. The purpose of the learning lab is to enable managers to test their long held assumptions and to experiment and 'see' the consequences of their actions, policies and strategies. This often results in finding inconsistencies and the discovery of *unintended* consequences of actions and decisions, *before* they are implemented. System Dynamics models known as Microworlds or Management Flight Simulators (MFS) are the 'engine' behind the learning lab. "Just as an airline uses flight simulators to help pilots learn, system dynamics is, partly, a method for developing management flight simulators, often computer simulation models, to help us learn about dynamic complexity, understand the sources of policy resistance, and design more effective policies." ([35], p. 4)

A learning lab is distinct from so-called management games. In management games, the players are required to compete – design the 'best' strategy and 'beat' other players or teams. The competitive nature of management games often encourages aggressive and individualistic behavior with scant regard for group learning and gaining deep insights. The learning lab, in contrast, aims to enhance *learning*: To test individual and group mental models and to provide deeper understanding and insights into why systems behave the way they do. This will help the participants to test their theories and discover inconsistencies and 'blind spots' in policies and strategies *before* they are implemented.

A significant benefit of the learning lab stems from the process in which participants examine, reveal and test their mental models and those of their organization. The learning lab can also help participants

- To align strategic thinking with operational decisions;
- To connect short-term and long-term measures;
- To facilitate integration within and outside the organization;
- To undertake experimentation and learning;
- To balance competition with collaboration.

Managerial Practice Field

Team and teamwork are parts of the lexicons of numerous organizations today. Company after company has reorganized work around a variety of team concepts. From factories to hospitals, *titles* like 'manager' and 'supervisor' have been replaced by *roles* such as 'facilitator' and 'team leader'. Despite this level of attention to team and teamwork the expected benefits have been marginal at best.

But when we examine real teams, such as sporting teams, orchestras or ballet companies more closely, they all share one key characteristic. That is they *practice* a lot more than they 'perform'. Practice involves allowing time and space to experiment with new ways, try different approaches and most importantly, make mistakes without the fear of failure. In fact, making mistakes is indispensable to learning. One cannot learn from doing things right all the time! Yet a great deal of organizational energy and attention is devoted to the prevention and masking of mistakes.

But, what is the *practice field* for management teams? The fact is that the practice field is, by and large, absent from the managerial world. In other words, there is no time and no space for management to 'practice' in the true sense of the word – to experiment, make mistakes and learn together. In this era of restructuring and downsizing, lack of time is the greatest impediment to managerial and organizational learning. As a recent advertisement by IBM reads, "Innovative Thinking! We don't even have time for bad thinking". The pace in the modern work environment is so unrelenting that there is virtually no room for managers to slow down, to practice, to reflect and learn. The consequence of this lack of practice and learning space is grave, in that most organizations only achieve a small fraction of their potential – about 5%, according to Jay Forrester, the father of System Dynamics [13].

In order to fill this gap, the concept of learning laboratory has been developed to provide practice fields for managers. The learning lab allows learning to become an integral part of managerial work and helps learning to become institutionalized [17].

Aligning Mental Models Through the Learning Laboratory

Mental models are formed throughout one's life. Family, school, culture, religion, profession and social norms play important roles in this formation. Therefore, modifying one's mental model is not a small matter. The most effective way to check one's mental models is to *experience* alternative realities at first hand and see their implications with a new 'lens' [5].

There are rarely any opportunities in the course of a manager's daily work for him/her to engage in lengthy, drawn-out experimentation. Learning in a 'laboratory' setting is a viable and powerful alternative. Fortunately, advanced computers and sophisticated system dynamics software have enabled the creation of managerial learning labs where managers can experiment, test their theories and learn rapidly. Thus, learning labs can play a significant role in clarifying and changing mental models. Learning lab deals with mental models at three levels [33], as described below.

- *Mapping* mental models. This step begins at the conceptualization phase. Here, the learning lab participants articulate and clarify their assumptions, views, opinions, and biases regarding the issue at hand.
- *Challenging* mental models. The participants identify and discuss inconsistencies and contradictions in their assumptions. This step will begin at the conceptualizations phase and will continue to the experimentation phase.
- *Improving* mental models. Having conducted experimentation and testing, the participants reflect on the outcomes. This may cause them to alter, adjust, improve and harmonize their mental models.

The laboratory setting provides a neutral and 'safe' space for the participants to create a shared understanding of complex and endemic issues. The following characteristics of the learning lab provide a powerful catalyst for alignment of divergent mental models in the organization.

- The laboratory environment is neutral and non-threatening. The emphasis is on learning and theory building (what we *don't* know), not on winning or display of knowledge.
- Lack of hierarchy. Managers and staff are equal in this environment. The traditional hierarchy is minimized in the laboratory setting.
- The response time is fast. Hence, the feedback cycle is short, which leads to rapid learning.
- There is no cost or 'loss of face' attached to failure. Hence, it is safe to make mistakes. In fact, mistakes provide opportunities for learning.
- People can see the consequences of their actions first hand. No one attempts to convince or teach anyone else or force his or her preconceived views on others. People learn by themselves and through group interactions.

Implications for Management

The practice field and the learning lab concepts offer fresh and challenging implications for managers and their role. They suggest that a leader/manager should think as a *scientist*, be open to and welcome hard questions, experiment with new ideas, and be prepared to be *wrong*. This requires managers to learn systems thinking skills and use them not just for 'solving' problems but as powerful tools for communication, team building and organizational learning. This means that an effective leader should be the 'designer' of the ship and not its captain [31]. Once they have designed a new structure, strategy, policy or procedure then the managers/leaders should allow (i. e. create a practice field for) the staff to experience the new design, and experiment with it and learn for themselves – the desired outcome is shared understanding leading to alignment of thoughts and actions. This is the essence of organizational learning.

Future Directions

Agent-Based Modeling (ABM)

Agent based modeling (ABM) is an emerging modeling technology which draws its theories and techniques from complexity science [29]. While System Dynamics and Agent-Based Modeling (ABM) use different modeling philosophies and approaches, they can be used complementarily and synergistically.

System Dynamics focuses on modeling structures (i. e. relationships, policies, strategies) that underlie behavior of systems. This may be viewed as a weakness of system dynamics approach in that behavior is assumed to be solely a function of structure (model relationships defined a priori). In contrast, in ABM, organizations are modeled as a system of semi-autonomous decision-making elements – purposeful individuals called *agents*. Each agent individually assesses its situation and makes decisions based upon value hierarchies representing goals, preferences, and standards for behavior. Thus, macro-behavior is not modeled separately but *emerges* from the micro-decisions of individual agents. In other words, in agent based modeling; "emergent" behavior is expected as a result of agents' interactions. This is a key difference between the two approaches.

While system dynamics acknowledges the critical role of individual and organizational mental models (e. g., motivations, values, norms, biases, etc.) it does not explicitly model them. SD utilizes factual data or "cold knowledge" and does not take into account decision makers 'mood'. In contrast, ABM attempts to capture "warm knowledge", representing emotional and human context of decision-making.

Recent advances in video game technology allow the development of multi-agent, artificial 'society' simulators with capabilities for modeling physiology, stress and emotion in decision-making [34]. At the simplest level, an agent-based model consists of a system of agents and their relationships. This new approach enables superior understanding of the complexity in organizations and their relevant business environments. This in turn provides an opportunity for new sophistications in game-play that enhances decision-making. Experience with agent-based modeling shows that even a simple agent-based model can exhibit complex behavior patterns and provide valuable information about the dynamics of the real world system that emulates them.

Despite their differences, SD and ABM can be used in a complementary fashion. Both ABM and SD are powerful tools for transforming information into knowledge and understanding leading to individual and group learning. However, the transition from knowledge to understanding may not be immediate or transparent. This requires a deep shift in mental models through experimentation and group learning.

Systems Thinking and Sustainability

Systems Thinking has a natural affinity with sustainability modeling and management. Sustainability issues are complex; cut across several disciplines; involve multiple stakeholders and require a long term integrated approach. Thus, the systems paradigm and tools have direct and powerful applications in sustainability issues and management.

The applications of system dynamics in sustainability go back to the early 1970s with Jay Forrester's "World2 and World3 analyzes against 30 years of history", followed by "World Dynamics" and "Limits to Growth" [24] and "Beyond the Limits" [25]. "The politics of the environment has also evolved dramatically since 1970. Public awareness of the reality of the environmental challenge has risen; Ministries of Environment have become commonplace" ([28] p. 220). As an example today concern over carbon emissions has already become an international currency. As a result, sustainability has brought a fresh challenge for governments, business and industry, scientists, farmers and all the citizens of the world collectively to find systemic solutions that are mutually and globally agreeable. Systems Thinking and System dynamics can make real and valuable contributions to addressing this challenge.

Books and Reviews

(This section is due to M. Anjali Sastry and John D. Sterman, "An Annotated Survey of the Essential System Dynamics Literature System Dynamics Group", Sloan School of Management, MIT)

Industrial and Economic Dynamics: The Foundations

Forrester JW (1961) Industrial dynamics. Productivity Press, Cambridge (Presents dynamic analysis of a business problem through a model of a production-distribution system that shows oscillatory behavior. Policies to improve system performance are discussed, and numerous policy experiments are demonstrated. Includes full equation listing.)

Forrester JW (1968) Principles of systems. Productivity Press, Cambridge (System structure and behavior are differentiated, with examples showing how structure determines behavior. Rates and levels are described. Inventory model shows effects of delivery delay and resulting production cycles.)

Forrester JW (1975) Collected papers of Jay W. Forrester. Productivity Press, Cambridge (Includes many seminal papers, such as Industrial Dynamics: A Major Breakthrough for Decision Makers; Common Foundations Underlying Engineering and Management; A New Corporate Design; Market Growth as Influenced by Capital Investment; and Counterintuitive Behavior of Social Systems.)

Forrester JW (1989) The beginnings of system dynamics (Working Paper No. D-4165). System Dynamics Group, Sloan School of Management, MIT, Cambridge (A personal history beginning on the high plains of western Nebraska. Describes the early projects that shaped the field.)

Mass NJ (1975) Economic cycles: An analysis of underlying causes. Productivity Press, Cambridge (Shows how production scheduling and work force management policies generate the 3–5 year business cycle. Economic cycles, in turn, are caused by capital investment policies that fail to account for delays in acquiring long-lead time plant and equipment.)

Meadows DL (1970) Dynamics of commodity production cycles. Productivity Press, Cambridge (Develops a simple generic model of commodity supply and demand with explicit production capacity and delays, prices and markets. Applies the model to hogs, chicken and cattle.)

Urban and Public Policy Dynamics

Alfeld LE, Graham AK (1976) Introduction to urban dynamics. Productivity Press, Cambridge (A very readable introductory text. Uses the urban system as an example to teach general points about modeling methods, formulation and analysis.)

Forrester JW (1969) Urban dynamics. Productivity Press, Cambridge (Seminal model of urban growth and decay, controversial then and vindicated now. Chapter 6 describes general characteristics of complex systems such as compensating feedback and shifting the burden to the intervener.)

Mass NJ (ed) (1974) Readings in urban dynamics, vol I. Productivity Press, Cambridge (Extensions, modification, and responses to criticisms of the Urban Dynamics model.)

Schroeder WW, III, Sweeney RE, Alfeld LE (eds) (1975) Readings in urban dynamics, vol II. Productivity Press, Cambridge (Further extends and explores the Urban Dynamics model.)

Limits to Growth and Other Global Models

Forrester JW (1973) World Dynamics, 2nd edn. Productivity Press, Cambridge (The first global model, on which Limits to Growth was based. The extreme simplicity of the model allowed it to be presented to a wide audience.)

Meadows DL, Meadows DH (eds) (1974) Toward global equilibrium: Collected papers. Productivity Press, Cambridge (Describes and explores, through system dynamics models, policies for sustainability designed to avoid the collapse shown in the 'business as usual' WORLD3 scenarios.)

Meadows DH, Meadows DL, Randers J, Behrens WW III (1972) The limits to growth: A report for the club of Rome's project on the predicament of mankind. Universe Books, New York (Classic controversial study of the human future. Nontechnical presentation of structure, assumptions, and results of the WORLD3 model. Concluded that present policies were unsustainable; shows how alternate policies could stabilize population at a high standard of living.)

Meadows DL, Behrens WW III, Meadows DH, Naill RF, Randers J, Zahn EKO (1974) Dynamics of growth in a finite world. Productivity Press, Cambridge (Full documentation and data for the WORLD3 model used in the Limits to Growth. Describes the structure and assumptions; includes all data needed for complete replication of all runs in the popular book. Formulations described here may be useful to all system dynamics modelers.)

Meadows D, Richardson J, Bruckmann G (1982) Groping in the dark. Wiley, New York (Describes a range of global models built under different approaches and discusses the strengths, weaknesses, and implications of each. Presented in an engaging, personal style.)

Meadows DH, Meadows DL Randers J (1992) Beyond the limits: Confronting global collapse, envisioning a sustainable future. Chelsea Green, Post Mills (Follows up on Limits to Growth. Shows that many problems described in 1972 have worsened, as predicted by the model. Argues for a shift in values necessary to create a sustainable and equitable future.)

SD for Management: Firm and Market Models

Coyle RG (1977) Management System Dynamics. Wiley, New York (Text emphasizing managerial modeling, with a focus on operations and examples including discrete elements.)

Hall RI (1976) A system pathology of an organization: The rise and fall of the Old Saturday Evening Post. Adm Sci Q 21(2):185–211 (A case-study using a system dynamics model to explain how failure to understand the feedbacks among policies governing ad rates, ad and editorial pages, marketing, and pricing lead to the failure of the Post just as circulation reached an all-time high.)

Lyneis JM (1980) Corporate planning and policy design. Productivity Press, Cambridge (Begins with a simple model of inventory management in a manufacturing firm and gradually extends the model to one of the entire firm.)

Merten PP (1991) Loop-based strategic decision support systems. Strat Manag J 12:371–382 (Describes a model of a multinational firm establishing new markets in less-developed countries. Captures qualitative shifts in firm structure and organization endogenously as the firm evolves.)

Morecroft JDW (1984) Strategy support models. Strat Manag J 5(3):215–229 (Describes the use of models as participants in the ongoing dialogue among managers regarding strategy formation and evaluation. Emphasizes the processes for model development and use that enhance the utility of modeling in design of high-level corporate strategy.)

Morecroft JDW, Lane DC, Viita PS (1991) Modelling growth strategy in a biotechnology startup firm. Syst Dyn Rev 7(2):93–116 (Describes a case-study of a start-up in which system dynamics modeling helps to define a desirable growth strategy for the firm. The integrated model generated strategies that allowed different parts of the firm to choose consistent approaches.)

Roberts EB (ed) (1978) Managerial applications of system dynamics. Productivity Press, Cambridge (Extensive collection of early corporate models, including history and commentary by practitioners. Covers R&D management, production and operations, human resources, and other applications areas.)

Economic Models

Forrester JW (1989) The system dynamics national model: Macrobehavior from microstructure. In: Milling PM, Zahn EOK (eds) Computer-based management of complex systems: International System Dynamics Conference. Springer, Berlin (Provides an overview of the national modeling project in which both micro- and macro-economic factors are included. Model generates business cycles, inflation, stagflation, the economic long wave, and growth.)

Saeed K (1986) The dynamics of economic growth and political instability in the developing countries. Syst Dyn Rev 2(1):20–35 (Shows how rapid economic development can generate social and political instability through a model that links socio-political factors to economic development.)

Sterman JD (1985) A behavioral model of the economic long wave. J Econ Behav Organ 6(1):17–53 (Proposes and tests a simple model of the long wave. The intended rationality of each decision rule is tested and the long wave is explained as the unintended result of the interaction of locally rational decision processes. The model is the basis for the STRATAGEM-2 game, and can exhibit chaos.)

Sterman JD (1989) Deterministic chaos in an experimental economic system. J Econ Behav Organ 12:1–28 (Sterman's 1985 model of the long wave is converted into a management flight simulator and used as an experiment in which subjects make the capital investment decision. Simple decision rules capturing subject's policies are estimated and explain their behavior well. Simulation of these rules yields deterministic chaos for about 25% of the subjects.)

Sterman JD (1986) The economic long wave: Theory and evidence. Syst Dyn Rev 2(2):87–125 (Comprehensive overview of the theory of long waves arising from the System Dynamics National Model. Reviews the feedback structures responsible for the long wave and empirical evidence supporting the dynamic hypotheses. Discusses the role of innovation and political value change.)

Conceptualizing, Formulating and Validating Models

Barlas Y (1989) Multiple tests for validation of system dynamics type of simulation models. Europ J Operat Res 42(1):59–87 (Discusses a variety of tests to validate SD models, including structural and statistical tests.)

Barlas Y, Carpenter S (1990) Philosophical roots of model validation: Two paradigms. Syst Dyn Rev 6(2):148–166 (Contrasts the system dynamics approach to validity with the traditional, logical empiricist view of science. Finds that the relativist philosophy is consistent with SD and discusses the practical implications for modelers and their critics.)

Forrester JW (1980) Information sources for modeling the national economy. J Am Stat Assoc 75(371):555–574 (Argues that modeling the dynamics of firms, industries, or the economy requires use of multiple data sources, not just numerical data and statistical techniques. Stresses the role of the mental and descriptive data base; emphasizes the need for first-hand field study of decision making.)

Forrester JW (1985) The model versus a modeling process. Syst Dyn Rev 1(1):133–134 (The value of a model lies not in its predictive ability alone but primarily in the learning generated during the modeling process.)

Forrester JW (1987) Fourteen 'Obvious Truths'. Syst Dyn Rev 3(2):156–159 (The core of the system dynamics paradigm, as seen by the founder of the field.)

Forrester JW (1987) Nonlinearity in high-order models of social systems. Europ J Operat Res 30(2):104–109 (Nonlinearity is pervasive, unavoidable, and essential to the functioning of natural and human systems. Modeling methods must embrace nonlinearity to yield realistic and useful models. Linear and nearly-linear methods are likely to obscure understanding or lead to erroneous conclusions.)

Homer JB (1983) Partial-model testing as a validation tool for system dynamics. In: International System Dynamics Conference, pp 920–932 (How model validity can be improved through partial model testing when data for the full model are lacking.)

Legasto AA Jr, Forrester JW, Lyneis JM (eds) (1980) System dynamics. In: TIMS studies in the management sciences, vol 14. North-Holland, Amsterdam (Collection of papers focused on methodology. Includes Forrester and Senge on Tests for Building Confidence in System Dynamics Models and Gardiner & Ford's discussion on Which Policy Run is Best, and Who Says So?)

Mass N (1991) Diagnosing surprise model behavior: A tool for evolving behavioral and policy insights. Syst Dyn Rev 7(1):68–86 (Guidelines for learning from surprise model behavior with tests to resolve anomalous behavior.)

Morecroft JDW (1982) A critical review of diagramming tools for conceptualizing feedback system models. Dynamica 8(1):20–29 (Critiques causal-loop diagrams and proposes subsystem and policy structure diagrams as superior tools for representing the structure of decisions in feedback models.)

Randers J (ed) (1980) Elements of the system dynamics method. Productivity Press, Cambridge (Includes Mass on Stock and Flow Variables and the Dynamics of Supply and Demand; Mass & Senge on Alternative Tests for Selecting Model Variables; and Randers' very useful Guidelines for Model Conceptualization.)

Richardson GP (1986) Problems with causal-loop diagrams. Syst Dyn Rev 2(2):158–170 (Causal-loop diagrams cannot show stock-and-flow structure explicitly and can obscure important dynamics. Offers guidelines for proper use and interpretation of CLDs.)

Richardson GP, Pugh AL III (1981) Introduction to system dynamics modeling with DYNAMO. Productivity Press, Cambridge (Introductory text with excellent treatment of conceptualization, stocks and flows, formulation, and analysis. A good way to learn the DYNAMO simulation language as well.)

Roberts N, Andersen DF, Deal RM, Grant MS, Shaffer WA (1983) Introduction to computer simulation: A system dynamics modeling approach. Addison-Wesley, Reading (Easy-to-understand introductory text, complete with exercises.)

Sterman JD (1984) Appropriate Summary Statistics for Evaluating the Historical Fit of System Dynamics Models. Dynamica 10(2):51–66 (Describes the use of rigorous statistical tools for establishing model validity. Shows how Theil statistics can be used to assess goodness-of-fit in dynamic models.)

Wolstenholme EF (1990) System enquiry – A system dynamics approach. Wiley, Chichester (Describes a research methodology for building a system dynamics analysis. Emphasizes causal-loop diagramming, mapping of mental models, and other tools for qualitative system dynamics.)

Modeling for Learning: Systems Thinking and Organizational Learning

Kim D (1989) Learning laboratories: Designing a reflective learning environment. In: Milling PM, Zahn EOK (eds) Computer-based management of complex systems: International system dynamics conference. Springer, Berlin (A case-study of a process designed to convey dynamic insights to participants in a workshop setting designed around a management flight simulator game.)

Morecroft JDW (1988) System dynamics and microworlds for policymakers. Europ J Operat Res 35(3):301–320 (Describes the model-building tools available to managers and policymakers.)

Morecroft JDW, Sterman JD (eds) (1992) Modelling for Learning. Eur J Operat Res Special Issue 59(1) (17 papers describing models and methods to enhance learning, both for individuals and organizations. Covers elicitation and group process techniques, management flight simulators, and tools for capturing, representing, and simulating mental and formal models.)

Richmond B (1990) Systems thinking: A critical set of critical thinking skills for the 90's and beyond. In: Andersen DF, Richardson GP, Sterman JD (eds) International System Dynamics Conference, 1990 (Proposes a process and skill set to teach systems thinking. The process relies on learner-directed learning. The skill set includes general scientific reasoning and SD, supported by simulation.)

Senge PM (1990) Catalyzing systems thinking within organizations. In: Masarik F (ed) Advances in organization development. Ablex, Norwood (Presents a case study in which the use of system dynamics generated insights into a chronic business problem. Steps in generating, testing and disseminating a system dynamics model are described.)

Senge PM (1990) The fifth discipline: The art and practice of the learning organization. Doubleday Currency, New York (Introduces systems thinking as part of a wider approach to organizational learning. Conveys basic system structures to a non-technical business audience by means of anecdotes and archetypes.)

Decision Making

Morecroft JDW (1983) System dynamics: Portraying bounded rationality. Omega 11(2):131–142 (SD models represent decision making as boundedly rational. Reviews and contrasts the concept of bounded rationality as developed by Herbert Simon. Uses Forrester's Market Growth model to show how locally rational decision rules can interact to yield globally dysfunctional outcomes.)

Morecroft JDW (1985) Rationality in the Analysis of Behavioral Simulation Models. Manag Sci 31(7):900–916 (Shows how the intended rationality of decision rules in SD models can be assessed, and how one analyzes a simulation model and output to understand the assumed bounds on rationality in dynamic models. A model of salesforce effort allocation is used to illustrate.)

Sterman JD (1987) Expectation formation in behavioral simulation models. Behav Sci 32:190–211 (Proposes and tests a simple dynamic model of expectation formation in dynamic models (the TREND function). Shows how the TREND function explains a forty year history of inflation forecasts and several different types of long-term energy demand forecasts.)

Sterman JD (1989) Misperceptions of feedback in dynamic decision making. Organ Behav Hum Decis Process 43(3):301–335 (Describes an experiment with a simple economic system in which subjects systematically generate costly oscillations. Estimates decision rules to characterize subject behavior. Finds that people systematically ignore feedbacks, time delays, accumulations, and nonlinearities. These misperceptions of feedback lead to poor quality decisions when dynamic complexity is high.)

Sterman JD (1989) Modeling managerial behavior: Misperceptions of feedback in a dynamic decision making experiment. Manag Sci 35(3):321–339 (Analyzes the results of the Beer Distribution Game. Misperceptions of feedback are found to cause poor performance in the beer game, as in other experiments. Estimates of the subjects' decision rules show they ignore time delays, accumulations, feedbacks, and nonlinearities.)

Selected Applications of SD

Abdel-Hamid TK, Madnick SE (1991) Software project dynamics: An integrated approach. Prentice Hall, Englewood Cliffs (Integrated SD model of the software development process. The model covers design, coding, reviewing, and quality assurance; these are integrated with resource planning, scheduling, and management of software projects. Includes full documentation, validation, and policy tests.)

Cooper KG (1980) Naval ship production: A claim settled and a framework built. Interfaces 10(6) (An SD model was used to quantify the causes of cost overruns in a large military shipbuilding project. One of the first and most successful applications of system dynamics to large-scale project management; initiated a long line of related project modeling work.)

Ford A, Bull M (1989) Using system dynamics for conservation policy analysis in the pacific northwest. Syst Dyn Rev 5(1):1–15 (Describes the use of an extensive SD model of electric power generation with endogenous demand. The model is used to evaluate strategies for conservation and new generation capacity. Includes discussion of implementation and integration of the SD model with other existing planning tools.)

Gardiner LK, Shreckengost RC (1987) A system dynamics model for estimating heroin imports into the United States. Syst Dyn Rev 3(1):8–27 (Describes how the CIA used SD to estimate the illegal importation of drugs to the US.)

Homer JB (1985) Worker burnout: A dynamic model with implications for prevention and control. Syst Dyn Rev 1(1):42–62 (Explains how knowledge workers can experience cycles of burnout through a simple system dynamics model. Avoiding burnout requires that one work at less than maximum capacity.)

Homer JB (1987) A diffusion model with application to evolving medical technologies. Technol Forecast Soc Chang 31(3):197–218 (Presents a generic model of the diffusion of new medical technologies. Case studies of the cardiac pacemaker and an antibiotic illustrate how the same model can explain the different diffusion dynamics of successful and unsuccessful technologies.)

Homer JB (1993) A system dynamics model of national cocaine prevalence. Syst Dyn Rev 9(1):49–78 (An excellent model of the interacting dynamics of addiction, policy-setting, and enforcement.)

Jensen KS, Mosekilde E, Holstein-Rathlou N (1985) Self-sustained oscillations and chaotic behaviour in kidney pressure regulation. In: Prigogine I, Sanglier M (eds) Laws of nature and human conduct. Taskforce of Research Information and Study on Science, Brussels (Presents a system dynamics model of the dynamics of rat kidneys. Experimental data show previously unexplained oscillations, sometimes chaotic. The model explains how these fluctuations arise. Excellent example of SD applied to physiology.)

Levin G, Hirsch GB, Roberts EB (1975) The persistent poppy: A computer-aided search for heroin policy. Ballinger, Cambridge (Examines the interactions within a community among drug users, the police and justice system, treatment agencies, and the citizens. Analyzes policies designed to restore the community's health.)

Levin G, Roberts EB, Hirsch GB, Kligler DS, Roberts N, Wilder JF (1976) The Dynamics of Human Service Delivery. Ballinger, Cambridge (Presents a generic theory of human service delivery, with case studies and examples drawn from mental health care, dental planning, elementary education, and outpatient care.)

Naill RF (1992) A system dynamics model for national energy policy planning. Syst Dyn Rev 8(1):1–19

Naill RF, Belanger S, Klinger A, Peterson E (1992) An analysis of the cost effectiveness of US energy policies to mitigate global warming. Syst Dyn Rev 8(2):111–128 (Reviews the 20 year history of the SD energy models used by the US Dept. of Energy to forecast and analyze policy options for national energy security, including the impact of US policies on global climate change.)

Sklar Reichelt K (1990) Halter marine: A case study of the dangers of litigation. (Working Paper No. D-4179). System Dynamics Group, Sloan School of Management, MIT, Cambridge (A case-study illustrating the use of system dynamics in litigation. Suitable for classroom teaching.)

Sturis J, Polonsky KS, Mosekilde E, Van Cauter E (1991) Computer model for mechanisms underlying ultradian oscillations of insulin and glucose. Am J Physiol 260(Endocrinol. Metab. 23):E801–E809 (New experimental data show that the human glucose/insulin system is inherently oscillatory. An SD model explains these dynamics. The model is validated against detailed physiological data.)

Cross-Fertilization and Comparative Methodology

Allen PM (1988) Dynamic models of evolving systems. Syst Dyn Rev 4(1–2):109–130 (Reviews approaches to nonlinear dynamics, self-organization, and evolution developed in the Brussels school by Prigogine, Allen, and others. Provides illustrations and examples.)

Kim DH (1990) Toward learning organizations: Integrating total quality control and systems thinking. (Working Paper No. D-4036). System Dynamics Group, Sloan School of Management, MIT, Cambridge (Argues that SD and Total Quality Management are complementary approaches to improvement and organizational learning. Systems thinking and modeling are needed to speed the improvement cycle for processes with long time delays.)

Meadows DH, Robinson JM (1985) The electronic oracle: Computer models and social decisions. Wiley (Comparative assessment of the underlying assumptions, boundary, limitations, and uses of different models, including optimization, simulation, and econometrics. Offers guidelines for assessing model assumptions, including ways to recognize the implicit biases of each modeling paradigm.)

Powers WT (1990) Control theory: A model of organisms. Syst Dyn

Rev 6(1):1–20 (An explicit feedback control perspective on perception and decision making in living organisms. Argues the behaviorist and cognitive paradigms have fundamentally misunderstood the concept of feedback. For Powers, feedback allows organisms to control perceptions by altering behavior.)

Radzicki MJ (1990) Methodologia oeconomiae et systematis dynamis. Syst Dyn Rev 6(2):123–147 (Surveys the institutionalist paradigm in economics and argues that system dynamics is compatible with the institutionalist perspective. The SD approach offers a means by which institutional theories can be formalized and tested.)

Sterman JD (1985) The growth of knowledge: Testing a theory of scientific revolutions with a formal model. Technol Forecast Soc Chang 28(2):93–122 (Presents a formal dynamic model of TS Kuhn's theory of scientific revolutions.)

Sterman JD (1988) A skeptic's guide to computer models. In: Grant L, Lanham MD (eds) Foresight and national decisions. University Press of America (Reviews different modeling methods and their underlying assumptions in nontechnical language. Provides a list of questions model users should ask to assess whether a model or method are appropriate to the problem.)

Other Themes: Pulling the Threads Together

Cooper K, Steinhurst W (eds) (1992) The system dynamics society bibliography. System Dynamics Society. Available from Julie Pugh, 49 Bedford Rd., Lincoln MA, USA 01773. (Lists over 3,000 system dynamics journal articles, books, conference proceedings and working papers. Available in computer-readable format and compatible with bibliographic software)

Meadows DH (1989) System dynamics meets the press. Syst Dyn Rev 5(1):68–80 (Reviews the history of encounters between SD and the media. Offers guidelines for effective communication to the public at large. Stresses the importance of communicating even the simplest system concepts.)

Meadows DH (1991) The global citizen. Island Press, Washington (A collection of Dana's syndicated newspaper columns applying system dynamics principles to problems of everyday life, from organic farming to the fall of the Soviet Union. Emphasizes environmental issues.)

Richardson GP (1991) Feedback thought in social science. University of Pennsylvania Press (Traces the history of the concept of feedback in the social sciences through two threads of thought – the cybernetic and feedback threads. System dynamics is placed in context in a readable and scholarly manner.)

Software

DYNAMO. Pugh-Roberts Associates, Cambridge MA. (The first widely-used computer language developed to simulate system dynamics models, DYNAMO is still in use, available for mainframes and PCs. Many of the models in the system dynamics literature were simulated in DYNAMO)

DYSMAP. University of Salford, UK (PC-based simulation language with syntax similar to DYNAMO. Includes optimization capability based on hill-climbing.)

Microworld Creator and S^4. Microworlds Inc., Cambridge MA (Easy to use environment for simulation and gaming. S^4, the 'industrial strength' version, supports arrays and includes diagnostics for analyzing behavior. Both Creator and S^4 support user-defined information displays and facilitate rapid development of management flight simulators.)

STELLA and ithink. High Performance Systems, Hanover NH. (User-friendly modeling software with full graphical interface. Models are entered graphically, at the level of the stock and flow diagram. Widely used in education from elementary school up; also used in research and practice.)

Vensim. Ventana Systems, Harvard MA. (Powerful simulation environment for SD models. Runs on workstations and PCs. Includes array capability and a wide range of features for analyzing model behavior.)

System Dynamics Philosophical Background and Underpinnings

Camilo Olaya
Universidad de Los Andes, Bogotá, Colombia

Article Outline

Glossary

Philosophy The reflection and study of our most basic assumptions – or the assumptions themselves.

Mental model A mental image of selected concepts and relationships of the world around us which we consider relevant for explaining the behavior of a particular system.

Presentationalism Synonymous of idealism. The view that material objects or external realities do not exist apart from our knowledge or consciousness of them.

Definition of the Subject

We all tend to take things for granted. Indeed it is a common place to judge formal models exclusively based on the technical grounds and on the logic with which those models were built without a proper reflection on the assumptions underlying those models. This omission is even more pressing in complexity and system science, since these areas represent a novel challenge for philosophers of science – e. g. see an overview in [34].

What is the idea of reality with which we work? What do we assume about human nature? What kind of knowledge do we pursue? What kind of knowledge do we obtain?

What is the scope of rational inquiry? What are the basis and the implications of our own reasoning methods? The identification of how philosophy has shaped the work of scientists – on a conscious or unconscious level – is essential for comprehending the implications, the limitations, and the scope of our very scientific practice. The lack of concern by scientists for these issues may explain many of their failures which has produced just a sort of inertial blindness that is easy to recognize in current scientific debates.

One of the strengths of system dynamics (abbreviated, SD) is that it leads us to make explicit our assumptions about the systems we deal with. This attitude, i. e. the importance of reflection upon our own assumptions, is also fundamental for the very development and practice of system dynamics. Many of the debates on different issues of every day scientific practice such as model conceptualization, formal model building, validation, policy design, etc. are informed and can be enlightened by the reflection on the philosophical background behind those processes. There are also various fundamental aspects of SD that are yet to be demarcated, e. g. the characterization of SD explanations. Furthermore, the ambiguity of the discussions found in large part of related literature, characterized by superficiality, confusion of terms, misdirected arguments, etc. only adds noise and it complicates the advance of a discipline. This article sketches and overview on some basic assumptions regarding the development and the practice of system dynamics. Various suggestions that help to integrate various debates are introduced and important clarifications are also indicated.

Introduction

The philosophical background and underpinnings of a discipline should have to do with its most basic universal assumptions. Such a discussion becomes difficult if we bear in mind that those assumptions are not necessarily shared by practitioners and researchers. Nevertheless, central premises can be identified which in turn can be related to important questions regarding philosophical concerns such as reality and knowledge.

The article is organized as follows. After this short introduction, the second sections develops an overview of the origins of system dynamics underlining fundamental aspects that formed what can be called the core of the discipline. This historical review highlights the initial interest, purposes and initial assumptions around the foundation of SD. With these elements the following sections introduce various philosophical issues that can be identified underlying system dynamics. Perhaps the central aspect is presentationalism, a stance associated with the notion of "mental models" which is central in SD; this is the topic of the fourth section. The following section makes a clarification on the controversial issue of positivism and relates presentationalism with knowledge. The sixth section summarizes the position of system dynamics regarding social theory. The seventh section presents the inquiry of explanation clarifying that in spite that SD involves causal models the nature of its kind of explanation can be found in the notion of mechanism. The eighth section introduces the implication of the use of computer simulation as a distinctive epistemology which is different from the traditional discourse in philosophy of science. The ninth section outlines future directions.

Before starting, a brief warning should be made: given the scope of this review and the limited space for covering very wide subjects then this article should be viewed as a broad introductory overview of the different topics. The cited literature has been selected as possible starting points for further inquiry.

System Dynamics

In order to address a "philosophical background" the first question naturally would be: What is system dynamics? Already this inquiry can be a matter of debate, e. g. [102]. Indeed SD has been labeled as a theory [23,49], a method [18,56,63,98,108], a methodology [81], a field of study [17,78], a tool [61], a paradigm, among other nouns. A natural starting point is the work of Jay Forrester, the founder of system dynamics. A brief historical review should help to grasp the very core we are looking for since it can show the initial motivations, assumptions, and purposes behind the development of SD.

Genesis of System Dynamics

Jay W. Forrester, member of the Sloan School of Management at MIT, was looking for linkages between engineering and management education given his background in feedback control systems and computers [28]. In 1956 he wrote a "note" to the Faculty Research Seminar, the first ever MIT "D-memo"; in this communication he sketched the worldview of what would be known as "system dynamics" [32].

He started with a strong criticism of economic models. The following were the central aspects: (i) their failure to reflect adequately the loop structures that make up economic systems; in particular this neglect leads to exclude inherent properties of closed loops such as resistance to change, accumulations and delays; (ii) The incapacity for including flows of goods, money, information, and labor, in one single interrelated model; (iii) The exclusion of changing mental attitudes that affect and explain economic processes; (iv) The use of linear equations for describing systems; (v) The restriction of building models constrained by the capacity for manipulating numerical data and solving the equations; (vi) The overconfidence in multiple regression analysis for obtaining coefficients for equations that define economic behavior; (vii) The lack of reflection and discussion on the very assumptions underlying every model preferring an emphasis on the logic with which the model is developed.

After delineating these points, Forrester then proceeded in the same note to highlight techniques that were largely underused at that time: servomechanisms, differential equations, and what he called "the art of simulation". Anchored on the mentioned assessment and on these developments Forrester conceived "a new avenue of attack for understanding the firm and the economy" ([28] p. 336) envisaging *a new kind of models* that would include aspects such as:

Dynamic structure: Detailed attention to the *sequences of actions* which occur in the system being studied and to the *forces* which trigger or temper such actions, with a particular concern on the controlling influences of lags and delays.

Information flows: Explicit recognition of information flow channels and information transformation with time and transmission.

Decision criteria: Re-examination of the proper decision criteria which must not be defined as depending only on current values of gross economic variables; instead, such criteria must be traced to the motivations, hopes, objectives and optimism of the people involved, including as well what he calls business man's intuition which "represents a disordered accumulation of basic insights into how people and social systems react. The hope for the future lies in generating an orderly arrangement of basic insights" ([28] p. 342).

Non-linear systems: Economic systems present most – if not all – of the time highly non-linear characteristics.

Differential equations: The behavior of economic systems should be better described by non-linear differential equations since they have been developed to describe delays, momentum, elasticity, reservoirs, and accelerations, which are better suited quantities for describing the economic world. In practice these equations would be handled as incremental difference equations in order to obtain numerical solutions.

Incremental changes in variables: To prefer the formulation of a model in terms of the motivations that cause incremental changes in a variable since the new value of a variable "can be found by solving the equations for its incremental change and then adding the change to the preceding full value of the variable" ([28] p. 344).

Model complexity: Much complex and complete models can be developed with these techniques.

Empirical solutions: It is useless to look for explicit unique or "correct" solutions; instead, these models provide diverse solutions according to the different assumptions about the model structure and the initial values of the variables.

Symbolism and correspondence with real counterparts: The possibility of having a pictorial representation – a flow diagram – whose processes of information, money, goods, and people, are moved, i. e. simulated, time-step-by-time-step from place to place.

Structure over coefficient accuracy: To prefer a structure in which we have confidence using intuitively estimated coefficients instead of using unlikely structures with accurately derived coefficients from statistical data.

A subsequent advance came in 1958 with an article entitled "Industrial Dynamics: A Major Breakthrough for Decision Makers" published in the *Harvard Business Review* [27]. In this article Forrester shaped the previous ideas with the concern that management should evolve from a highly fragmentized art to a profession capable of recognizing unified systems given that the task of management is to interrelate the flows of information, materials, labor, money, and capital equipment. He again emphasized features such as electronic data processing, decision making, simulation, feedback control, and information flows. These elements were presented as the cornerstones of the innovative industrial dynamics program at MIT.

Industrial Dynamics

The definitive breakthrough came in 1961 with his *magnus opus* "Industrial Dynamics" [24]. The main motivation behind was the development of a *science* for designing and controlling industrial systems, the quest for a management science. In particular he conceived it as "a method of system analysis for management." (p. 9). He stated:

> Industrial dynamics is the study of the information-feedback characteristics of industrial activity to show how organizational structure, amplification (in policies), and time delays (in decisions and actions) interact to influence the success of the enterprise (p. 13).

Forrester underlined four pillars for this new science: information-feedback control theory anchored on the concept of servomechanisms, the study of decision-making processes, an experimental approach to system analysis based on simulation, and the use of computers.

Coming from engineering, he had in mind models that deal with nonlinear dynamic systems whose purpose is to *design* new systems – as opposed to just *explain* systems; the models should show how changes in policies or structure will produce better or worse behavior. In order to accomplish this aim Forrester indicated that we should focus on understanding the characteristics of the system in hands (instead of looking for specific predictions) and on our assumptions about them. "We then have a means for tracing the implications of our assumptions" ([24] p. 55).

What should be included in a model? Forrester underlined that "there will be no such thing as *the* model of a social system, any more than there is *the* model of an aircraft ... the factors that must be included arise directly from the questions that are to be answered" ([24] p. 60). It is expected that these factors will include closed-loop information-feedback structures that give rise to so much of the interesting behavior. An important aspect of this new kind of models is symbolism and pictorial representations by means of flow diagrams with a special emphasis on correspondence: the model variables should correspond to those in the system being represented. In this book Forrester also demarcated the network structure of this new kind of models as made of four basic components: accumulations (levels), flows (rates), decision functions, and information channels; these networks trace cause-effect relationships which are described via mathematical formalization. He also discussed in detail how to represent delays and how to model decision processes which are particularly defined by general policies, i. e. rules that state how operation decisions are made converting information into action; this study of general policies explains the importance for SD of the examination of human decision-making processes. Another fundamental characteristics are continuous flows and aggregation: "grouping of individual events into classes ... Our interest in the model ... is from the viewpoint above the separate individual transactions" ([24] p. 65); it is assumed that different individual items are controlled by the same identical decision-function; this notion leads to aggregation which is a distinctive aspect of SD: "items controlled by sufficiently similar policies that depend on sufficiently equivalent information sources may be combined into a single channel" ([24] p. 109); the central criterion for such aggregation is the purpose of the model. Finally, model significance (or validity) rests on its suitability for a particular purpose which is motivated by the design of improved industrial and economic systems.

Principles of System Dynamics

The main concern in these initial steps were business operations. However, Forrester sketched a glance to a broader view in the final part of his book; there, he speaks of "system" dynamics since "the study of systems can provide a framework to unite subjects ... The dynamic model represents a system as broad as one chooses to describe" ([24] pp. 344, 346). Indeed, looking for a more general view he presents a section of "principles of systems structure":

> The principles to be discussed here all arise in the context of information-feedback systems. They are systems principles. They are not the principles of the management art such as have been taught in organization, production, and human relations courses. Because the principles apply to systems behavior, they do not fall into neat separate packages ... The concept of a system implies interaction and interdependence. In attempting to identify factors that are common to all systems, we must keep the essential indivisibility in mind ([24] pp. 347, 348).

Indeed, Forrester reaffirmed this general *systems* view in a follow-up book entitled *Principles of Systems* [25] published in 1968. He gives a basic definition of system as "a grouping of parts that operate together for a common purpose" ([25] p. 1-1). Moreover, he suggests that the way to organize knowledge is with this idea of system which are represented by the models we develop:

> A structure (theory) is essential if we are to effectively interrelate and interpret our observations in any field of knowledge ... Without an organizing structure, knowledge is a mere collection of observations, practices and conflicting incidents ... A model is s substitute for an object or system ... Any set of rules and relationships that describe something is a model of that thing. In this sense, all of our thinking depends on models. Our mental processes use concepts which we manipulate into new arrangements. These concepts are not, in fact, the real system that they represent. The mental concepts are abstractions based on our experience. This experience has been filtered and modified by our individual perception and organization processes to produce our mental models that represent the world around us ([25] pp. 1-2, 3-1).

The previous statement summarizes core assumptions for SD. It points at the central notion of *mental model* and it emphasizes that these models are models of *systems*. In fact, in an article published in 1968 in *Management*

Science, Forrester [28] underlined that this application of feedback concepts to social systems was evolving toward a theory of structure in systems with a particular goal of policy design. Specifically, "industrial dynamics is a philosophy of structure in systems. It is also gradually becoming a body of principles that relate structure to behavior" ([28] p. 141). Two fundamental variables are identified: levels and rates, and the basic structural element is the feedback loop: "every decision is responsive to the existing condition of the system and influences that condition" ([28] p. 143). And, as stated above, the structure is an aid to organize knowledge in a particular situation given a particular purpose which is motivated by the pursue of explanation and policy design.

This historical review has accentuated central aspects of the foundation of SD. As a summary, this science initially envisaged by Forrester for designing systems is known nowadays as system dynamics. The models developed in SD have distinctive characteristics: dynamic structures, information flows, study of decision criteria, non-linearity, difference equations, symbolism and correspondence, and emphasis on confidence based on the structure of the model. The practice of this science is anchored on: the concept of servomechanism, the study of decision-making processes, the embrace of an experimental approach, and the use of computers for building formal models. These models are models of systems and the main goal is to help to organize our knowledge – which can be seen as arranged in mental models – so as to enhance learning processes and systems design on concrete settings and under specific purposes.

With these elements in mind, it is now possible to proceed with a brief discussion on important aspects regarding assumptions on reality and knowledge that can be recognized behind these premises and the practice of SD.

"Real" World and Presentationalism

The traditional distinctions of *ontology*, *epistemology*, and *methodology*, form the habitual framework to drive a philosophical discussion. But the isolation of these issues may not be the most adequate or clear strategy. Given the interrelated nature of such categories and the misleading discussion on those terms which is present in a large part of organization and management science literature – part of this confusion will be exposed and clarified below – then a different plan will be used to develop the rest of this article. An instinctive option is to pick up significant issues and to relate them with what we can identify as part of the core of SD.

Where to start? Assumptions concerning a "real" world can be a first step to take since the traditional debate developed through the years around the claim of building models of "social systems" has fueled part of the discussions in systems science. As most of examinations on philosophical matters the debate has been permeated by a confusion originated in terms and words without the proper examination of the topic. However, this short revision is useful for opening the assessment of the premises of SD regarding a real world.

A prominent example is the criticism made by influential commentators who state that SD models represent an assumed "objective" real world [49]. This kind of critique usually labels SD as a "hard" approach, e. g. [48], meaning with such a term models of an assumed objective machine-like world – and habitually including and inverting the meaning of the term "positivism" – a mistaken assessment that still can be seen nowadays, e. g. [16]. This type of comments can be illustrated with the following quote from the work of Flood and Jackson [23]:

> System dynamics models still center on capturing the structure of the "real world" … the underlying assumption of SD that there is an external world made up of systems the structure of which can be grasped using models built upon feedback processes … Because intentions derive from inside social systems, from the conscious human actors which constitute them, many possible appreciations of the nature and purpose of particular social systems are possible. SD simply does not deal with the innate subjectivity of human beings … In essence the argument is that social systems cannot be studied, in the way of system dynamics, objectively from the outside (pp. 78, 79–80).

However, that is not what SD looks for. The mentioned emphasis on the examination of human decision-making processes and on the assumptions behind, the notion of mental model, the fact that model significance rests on its suitability for a particular purpose, among other aspects, should suffice to illustrate the point. Already Forrester in 1961 [24] emphasized: "a model can be useful if it represents only what we *believe* to be the nature of the system under study … we are forced to commit ourselves on what we believe is the relative importance of various factors. We shall discover inconsistencies in our basic assumptions … Thorough any of these we learn" (pp. 57–58, emphasis original). This should be enough to discard the assessment made by Flood and Jackson, and similar critics, who mistakenly placed SD in the terrain of a sort of naive realism as depicted in the quote above; this point is extensively clarified by Lane [55,56]. More importantly, this argument is helpful to introduce the discussion about the nature of SD models, the assumptions behind these models, and their relation with a "reality". The notion that drives these matters has been labeled in SD literature as "mental model" and even though this concept is not free of debate [21] it is placed at the core of the discipline.

The idea of mental model was already addressed by Forrester, as it has been indicated; he demarcated it in 1970 as the mental image of selected concepts and relationships of the world around us that we carry in our heads [26]; furthermore, "the mental model is fuzzy. It is incomplete. It is imprecisely stated … [It] changes with time" (p. 213). Doyle and Ford [22], looking for a consensus on this subject, propose as a definition: "a relatively enduring and accessible [conscious], but limited, internal conceptual representation of an external system (historical, existing or projected) whose structure is analogous to the perceived structure of that system" (p. 411). Sterman [98] summarizes what the expression "mental model" refers to: "our beliefs about the networks of causes and effects that describe how a system operates, along with the boundary of the model (which variables are included and which are excluded) and the time horizon we consider relevant … Most of us do not appreciate the ubiquity and invisibility of mental models, instead believing naively that our senses reveal the world as it is. On the contrary, our world is actively constructed (modeled) by our senses and brain" (p. 16–17). It should be noticed that these mental models may refer as well to planned or desired systems existing in the mind of the modeler [54]. The ultimate goal of system dynamics is to enhance our learning processes by testing and improving our mental models in a way that becomes consistent with the complexity of the systems that we face and design everyday [98].

Then, what is a SD model as related to some "real" world? Or how is it related to the notion of mental models? The usual option to answer these questions is to frame the discussion in the debate realism/anti-realism. This examination is even more relevant considering that some criticism labels SD as anchored on "realism". A brief clarification follows.

Realism? Anti-Realism?

Typical of latest debates in history of science concerns the dispute between the so-called *realism*, i. e. theories are true *or* false as descriptions of the world, and *instrumentalism*, i. e. theories are more or less adequate. This latter position is closer to pragmatism: theories are just instruments to systematize – and for many philosophers predict – observations, but theories are not claims about the world; or they can be also subjected to linguistic frameworks but still always truth-value-less. An overview of this debate is made by Leplin [60]. Yet, here it should be clarified that both positions and those definitions – habitually taken by historians of science – are two sides of the same coin. In short, both are forms of idealism. This assessment will be commented next.

On the one hand, scientific "realism" is usually defended using the method of abduction as source of knowledge, i. e. inference to the best explanation, which is just a form of induction and hence it is confirmationist, ultimately relativistic. It is not realism at all; it is exactly the opposite, i. e. idealism. For instance, take the influential ideas of Sellars [91] who defends an illustrative traditional position of scientific realism holding the source of knowledge on observation and relying on justification by induction for building theoretical frameworks; he emphasizes: "Laws in question are stipulated to be inductively established in the observation framework" (p. 313), the theories are then refined by empirical generalizations and what he calls further "injections" of images of the theory into the observational framework, in a typical process of instructional correction. A further refined and formal model of such a framework (proposed by Friedmann, holding a model–submodel relation) is commented by Morrison [66] who still holds, nevertheless, the search for truth and justification as support for his criticism and the necessity of confirmation [67]; see also for example the paper of Kukla [52] with a criticism to the ideas of Friedmann, yet also supported also on confirmation. In short, this "realism" is just idealism as we know it. Similar "realist" positions abound on the literature of the history of science. E.g. Smith [95] postulates a realist stance based on "common sense" but, since for him "science begins with observations" (p. 53), his realism ends up, indeed, trapped in sensations, i. e. idealism. Quantum mechanics does not escape the debate, e. g. arguing in favor of realism within the subjective theory of probability (the Copenhagen interpretation, Bohr, Heisenberg, etc.), Dickson [20] stands on the verification criterion for discussing on what he calls "quantum realism"; naturally such base can not succeed, which is anyway best self-explanatorily reflected in the first part of the title of his paper "An Empirical Reply to Empiricism"; simply there is no such reply. Another case is the criticism of Brown [13] to the deterministic notion of "realism" that Cherniak discards (who supports it on computer simulation of finite agents); the criticism of Brown shows a Galilean notion of realism, i. e. achievable true descriptions of the world via laws, but in a very "complex world" and thus, for him, inaccessible to agents with limited cognitive capacity; this Galilean view is found in large part of complexity science. In other attempts, for instance Schlagel [90] defends "contextualistic realism" which ends up in relativism: elements of the world have a conditional status relative to contexts and conditions, the existents are real relative to the particular structures and contexts on which they depend; his proposal is just idealism and can be better described as a sort of multi-phenomenalism, indeed relativism. The diverse "realist" positions *actually rooted on non-negotiable empiricism* seem endless; e. g. further examples are found in [1,59,75], and in most papers with the expression "scientific realism" in the abstract.

On the other hand, let us consider a supposedly opposite position, for instance instrumentalism. Instrumentalism actually ends up in relativism as well, e. g. with respect to the points of view where instruments can be applied; at the end the notions of "applicability" or "adequacy" become reference frameworks for establishing partial truths. Newton-Smith [68] proposes a conciliatory position, he calls it "modest realism" which ends up indeed in a sort of "moderate" relativism; a catalog of various scientific realisms can be found in that paper too, all of them addressing still the question of how such truths about a real world can be sustained (justified). In short, instrumentalists declare the dependence on observations, i. e. idealism, and thus this position is in fact sharing assumptions with the alleged "realists". Leplin [60] summarizes: "some theory can be reduced to observation by defining or translating theoretical terms into terms that describe observable conditions. The remainder must be construed instrumentally" (p. 394).

The "realism" vs. instrumentalism debate is futile and yet it is perhaps one of the core discussions in philosophy of science. But unlike these influential historians of science, the presented dispute tends to be dismissed by several professional philosophers who see it as self-serving and unsophisticated; Fuller [33] underlines this assessment though he also illustrates the consequences of leaving such pointlessness discussions to endure. In this case, two seemingly unaware idealist factions argue about the best way to establish positive knowledge, e. g. either with a supposedly "true" description of the world (more precisely: *phenomena*, subjectivism) or by pragmatism (and again: *phenomena*, relativism). This shared *idealism* is the matter of the next section.

Presentationalism

A broader debate can be assessed framed in the opposition between *realism* and *idealism*, see e. g. [72] and [77]. It will be shown that SD rests on the broad stance known as idealism, i. e. presentationalism – this latter term is preferred here just for clarity [10].

Firstly, it should be commented the widely inverted and misleading use of both terms. And there is good company. Blackmore [10] shows various celebrities that became misusers of the expressions in question such as the former president of the American History of Science Society and prominent Harvard University professor, Erwin Hiebert, and Sir Russell Brain, outstanding neurologist and former president of the British Association for the Advancement of Science. Add the seemingly customary tendency to quote references in second hand without inspecting direct sources and a few decades later we have the terms used in exactly their opposite original sense in journals and books. Blackmore pictures the situation:

> Like-minded 'empiricists' have restricted what they understand by the term to what idealistic philosophers of science *have wanted them to understand by it*. And since the term 'realism' sounds good to 'tough-minded empiricists' and since idealistic philosophers such as Hume, Comte, Schuppe, and Mach and their recent successors *scarcely if ever have admitted their idealism*, many scientists and historians of science have let themselves be seduced into reversing the normal epistemological definitions of 'realism' and 'idealism'. Even worse, respected scholars such as Stillman Drake, perhaps our most outstanding authority on the manuscripts of Galileo, and Larry Laudan, a young, energetic, and much published commentator on Mach and 'empiricism', have allowed themselves to become advocates of hopelessly naive 'non-philosophical' positions. Drake is sure that Galileo held no philosophical position, or that if he did, it had no effect on his scientific work. Laudan is equally positive on the basis of Mach's written comments that his phenomenalistic epistemology had no influence on Mach's 'empirical' methodology of science. The simplicity of their views can party be explained by their tendency to understand by the term 'philosophy', not one's most basic universal assumptions, *but expressed talk about speculative matters*. Similarly, many 'materialists' who feel sure that the physical world is directly given in experience, and who accept the idealist Kant's distinction between 'science' and 'metaphysics', are convinced that anyone who identifies the physical world with what is *beyond* immediate experience is an 'idealist' and 'metaphysician' and (following Wittgenstein) 'is merely uttering nonsense' (p. 131 in [10]).

In order to clarify, it is appropriate to underscore the attitude behind an empiricist epistemology. A major defining posture is what has been labeled as *idealism*, given the natural disbelief of a world beyond senses, which is the pillar of an empiricist epistemology. The term "idealism" comes from the "idea" of Bishop Berkeley, who took physical objects as "ideas" which included sensations and thoughts: "It is evident to any one who takes a survey of the objects of human knowledge, that they are either ideas actually imprinted on the senses, or else such as are perceived by attending to the passions and operations of the mind, or lastly ideas formed by help of memory and imagination, either compounding, dividing, or barely representing those originally perceived in the aforesaid ways." [8]. This idealism relies entirely on senses and mind-dependent worlds since consequently sense-data were the only things of whose existence our perceptions could assure us, and that to be known is to be 'in' a mind, and therefore to be mental. Berkeley, therefore, concluded that nothing can ever be known except what is in some mind, and that whatever is known without being in my mind must be in some other mind [85]. Hunter [47] summarizes:

> As a result of their constraints on knowledge and meaning, empiricists tend to be skeptical of necessary truths that are independent of mind and language, and of putative eternal abstract entities (p. 110).

This idealism can be equally identified with terms such as 'phenomenalism', 'neutral monism', or 'subjective idealism' (e. g. [10]), or presentationalism. In other words, "anything in time or space, anything than can be known by the human mind, is phenomenal" (p. 146 in [15]).

Taking this posture to the context of science, Bartley [4] provides the implications: "Presentationalists see the subject matter of science not as an external reality independent of sensation. The subject matter of science is our sensory perceptions. The collectivity of these sensations is renamed 'nature' … The aim of science is seen not as the description and explanation of that independent external reality but as the efficient computation of perceptions … [It] became the dominant twentieth-century *philosophy* of physics" (p. 11, 16, emphasis original). In general this position is the pillar of the prevalent conception of science which has been fueled by physics (for instance in the interpretation of quantum mechanics of Bohr and Heisenberg) and backed by influential names like Mach, Russell, Wittgenstein, Ayer, Lewis, Carnap, etc.

To appreciate the contrast, a standard definition of *realism* can be:

> 'Realism' … is used for the view that material objects exist externally to us and independently of our sense experience. Realism is thus opposed to idealism, which holds that no such material objects or external realities exist apart from our knowledge or consciousness of them, the whole universe thus being dependent on the mind or in some sense mental. It also clashes with phenomenalism, which, while avoiding much idealist metaphysics, would deny that material objects exist except as groups or sequences of sensa, actual and possible (p. 126 in [10]).

Apart from the particular emphasis on material objects (as opposed to Berkeley's *ideas*), another point is that realism defends a cosmocentric thesis opposed to the anthropocentric view in the discussions of the alleged "realists" of science presented earlier; in the latter case the observer-centered learning process is fundamental, and it is carried on via induction looking for acquiring positive, verifiable, and true knowledge – or justified true belief. Moreover, let us recall that historians of science denote with the term "realism" just the concern with supposed true descriptions of the world. But in fact *realism* does not imply that knowledge is achievable, it does not imply that the world is a perfect clock, it does not imply determinism, it does not imply that there can be correspondence between theories and such real world; these are different affirmations that unfortunately seem to be muddled inside the same bag. One thing is to assume a real world beyond senses. But a different inquiry is the character we ascribe to it. Another different issue is the role we assume for our senses. Another very different concern is the question of knowability, etc. Rescher [77] illustrates typical examples of the confusing use of terms in literature: "The three positions to the effect that real things just exactly are things as *philosophy* or as *science* or as '*commonsense*' takes them to be – positions generally designated as *scholastic*, *scientific* and *naive* realism, respectively – are in fact versions of epistemic idealism exactly because they see reals as inherently knowable and do not contemplate mind-transcendence for the real" (p. 187).

Coming back to presentationalism, this position then assumes that we are imprinted by the environment, and we call to this *impressions* "knowledge". Given the limitation of our senses then presentationalism postulates that nothing more can be known; and thus, such assumption is used to construct the world in our minds: for a presentationalist, strictly speaking, the world is not re-presented since we do not have access to it, the world is just what is *presented* to our senses: the world as we experience it happens to be the world itself; and, since anything that can be known by the human mind is, then, phenomenal (sensations, etc.), therefore knowledge strictly depends on – and is source in – what is sensed, e. g. observed. Hence knowledge needs to be justified in order to avoid error; and yet, the only existent knowledge is the imperfect evidence sourced in sensation and, nevertheless, a foundation that can be justified is pursued. This is the popular plan we have come up with, so far, to try to avoid the destruction of empiricism made by Hume. The picture can be summarized:

> Almost all traditional epistemologies are Lamarckian in their accounts of the growth of knowledge. This is conspicuously true of presentationalism, almost all adherents to which maintain an inductivist, justificationalist account of knowledge growth, according to which knowledge is constructed out of sensations (as building blocks or elements) by a relative passive process of combination, accumulation, repetition, and induction (p. 25 in [4]).

This position is identified with *idealism* and most popularly associated with *epistemological empiricism*, with all its assumptions and its consequent scientific method.

The last point to underline is that this epistemology has subordinated ontology. A remarkable illustration of this type of problems was already made by Bowman [11]: "The result … is the more or less deliberate abnegation of a genuine epistemology and the substitution for it of a highly formal logic. Hence the paradox illustrated equally in the case of Plato and, recently, of Mr Russell, of a radical empiricism (expressed in Plato's Protagorean theory of sensation and in Russell's subjectivism) subsisting side by side with the extremist rationalism. Such a dualistic position is the despair of philosophy, and indicates a failure in the synthetic work of thought" (p. 485). This despair is easy to recognize in current science which presents a contradictory ontological position whose difficulty is found in its subsumption under a radical epistemology. Indeed extreme empiricism, i. e. presentationalism, has become the metaphysics, i. e. the theory of reality, of our science. The debates on "scientific realism" presented earlier picture this failure. On this particular subject the different use of terms in literature is a source of confusion; but here the terms have been inverted by historians of science and scientists; and beyond a semantic confusion this has brought a narrow conception and a very restricted examination of epistemological assumptions. In short, the subjectivism of Descartes and Kant – or more precisely, Kantian idealism – is what now is labeled as "realism", e. g. *everything* has become "phenomena". As a matter of fact common expressions like "objective phenomena" or "real phenomena" uncover an idealistic position where the "objective" or "real" are just *phenomena*. Indeed, the so-called scientific "realism" commented above is nothing more than *a sort of empiricism* driven by Hume and Kant. This "realism" is just ontology overlapped by epistemology (*idealism*). More precisely, regarding Kant, let us recall his "Transcendental Idealism" which was the common answer of Kant when he was accused of idealist, e. g. see [93], denying to be a "dogmatic idealist" (in the Berkeley sense; see e. g. [101]); a full discussion of this failed defence of Kant is made by Guyer [37]. In particular Turbayne [101] defends Kant when he was accused of having misinterpreted (or even completely having misunderstood) Berkeley's idealism; yet, Turbayne's conclusion summarizes the Kantian idealism (and its ambiguity) unmistakably: "The Kantian antidote to this is not the a priori nature of space, but *its reality or subjectivity*, which assimilates space and its contents into the realm of ideas, and thus *prevents* illusion" (p. 243, emphases added). Regarding consequences, perhaps the best summary is the radical idealist position of Mach – who denied even the existence of atoms since they cannot be observed. Kant seems to be taken for granted without a proper reflection on his position.

These few points were commented since this debate is the major informer of the method and the assumptions of management science, organization science, and social science in general, places where SD has its roots. More important, by making this clarifications then a clear ground for SD can be envisaged. It can be affirmed that SD has been mistakenly labeled as "realist" by many commentators alluding the alleged aim of building "true" descriptive theories of the world, and using the misleading definitions of historians of science. But also from the discussion above it should be clear that SD safely rests on presentationalism. Moreover, the identified presentationalist stance known as "instrumentalism", and in general the so-called anti-realists positions (independent of the inverted use of the term), fit to the SD worldview: the abstractions from our experience are arranged in mental models which form knowledge that we want to improve in order to make better decisions. The SD models built for achieving this goal are judged against their adequacy and suitability for a particular purpose; these models are not claims about the world but instruments for systematizing observations and for boosting learning processes using experimentation via simulation.

The Discussions on Positivism: Presentationalism and Knowledge

An issue previously mentioned which is closely connected with presentationalism is relativism and positivism. Since positivism usually – and mistakenly – is pejoratively associated with a supposed objective representation of reality, then an important clarification is needed. In short: positivism is consistent with presentationalism and with relativism as well.

Presentationalism Brings Positivism

Blackmore [10] reminds that strictly speaking neither "rationalism" nor "empiricism" are properly epistemological terms at all; the entrenched idealism has led just to this narrowed identification. For instance, usually the term "empiricism" is synonymous of knowledge sourced in observation, i. e. in a restricted epistemological context, but such popular narrowness is inaccurate. Blackmore remarks: "Granted, that if one *means* by 'empiricism' not just an extensive and careful concern with empirical evidence but *restricting* reference or knowledge or both to sensory appearances, then there are indeed epistemological implications. One has become an epistemological phenomenalist or subjective idealist, or if you will, a positivist" (p. 130, emphases original). This clarification is needed for two reasons; on the one hand, as it was stated, SD has been labeled as "positivist" but the critics take this term as a sort of naive realism; the confusion is patent once we realize that positivism actually is a consequence of idealism, the opposite doctrine of realism. On the other hand, since SD is better identified with idealism then a sort of positivism can be also associated with it, but not the sort of "positivism" that the critics have in mind but the authentic positivism; and yet we will see that with the use of simulation positivism does not necessarily fit either.

The case of management science is a good example regarding the discussion on relativism and positivism. Let us consider the traditional and unfortunate sharp division between "hard vs. soft" which also takes the form "quantitative vs. qualitative". However, this discussion is misleading as well. It is not difficult to find researchers that claim to be anti-positivists but being themselves grounded on positivism (e. g. empirical observation, verification, induction, etc.) without noticing the contradiction. A good example is the claimed opposition between positivism and phenomenology. Yet, phenomenology is authentic positivism when is committed to evidence – Husserl himself underlines this aspect – see e. g. [94]. Indeed it is easy to appreciate an inverted use of the term "positivism" in literature; in management science this is a favored and widespread practice where so-called anti-positivists do not notice their positivism. The fact is that anthropocentrism is the ground in our most influential epistemologies that recognize the obvious imperfections of our sensorial apparatus but, nevertheless, rely knowledge on sensation (observation, etc.), that is, positivism, which is nothing more that our anxiety to confirm and validate, i. e. justify, our "imperfect" knowledge, e. g. empirically. This is a simplification of highly loaded terms; clarifications and further discussions can be found elsewhere, e. g. regarding positivism see [9,97,100].

Positivism is Anchored on Justification

Within a presentationalist worldview the search for confirmation and verification is nothing less than the search for justification of knowledge where the intellectual authority lies in sense experience. From a presentationalist account it is straightforward to have a justificationist approach for confirming and verifying theories. Following Bartley [4]:

> Preoccupied with the avoidance of error, they suppose that, in order to avoid error, they must make no utterances that cannot be justified by – i. e., derived from – the evidence available. Yet sense perception seems to be the only available evidence … The claim that there is an external world *in addition* to the evidence is a claim going *beyond* the evidence. Hence, claims about such realms are unjustifiable. Crucial to the presentationalist argument are, then, two things: the desire to give a firm foundation or justification to the tenets of science, and the construal of sense experience as the incorrigible source of all knowledge (pp. 12–13, emphases original).

In fact justification philosophy taken as the search for epistemic 'authorities' has been the dominant style of western philosophy looking for "well-grounded" knowledge. For instance in the customary view of knowledge as *justified true belief*, e. g. in the sense of Russell [86]) – as the result of systematic analysis "of our sensory experience of a knowable external reality" (p. 47 in [96]). Within this popular position the central problem of epistemology – as succinctly formulated by Radnitzky [76] – becomes:

> "When is it rational or, so to speak consistent with one's intellectual integrity, to *accept* a particular position?" The formulation suggests the direction in which the answer is to be sought: "When concerned with a statement, a theory, etc., accept those and only those statements, theories, etc., which not only are true but whose truth has been established" (p. 282, emphasis original).

The goal of justification is usually entrenched within the method of induction where every new repeated observation is a confirmation that validates – justifies – the theoretical statement. Even with weaker conditions the way of reasoning is the same, for instance within the ideas of Ayer where strict verifiability is seen as a too rigid criterion – he introduces *confirmability to some degree*, instead of complete and conclusive verifiability (see [88]); justification is still pursued. The appeal of justification can be explained because it looks for avoiding relativism (inherently attached to presentationalism) since not all positions are equally good or bad and it suggests to look for something beyond blind belief [76]. Though it is not the only option, nevertheless, it is the most common view of science; the concerns on validation, justification, verification, confirmation, and generalization, are part of this popular and influential view. Here the observer is the fixed point of reference. In short, within a justificationist logic, it is rational to accept only those positions that have been justified according to the rational authority which in the case of presentationalism is sense experience, consistent then with the highly influential ideas of Locke, Berkeley, Hume, Mach, Carnap that have shaped our prevalent view of science [4].

Justification in System Dynamics

Turning back to SD, it must be recalled the role of mental models whose characteristic nature of "abstractions based on experience" can be better assessed within a presentationalist stance. Here justification has also a place. How is this knowledge justified? Already Forrester [24] emphasized, within the debate of model validation, that, "knowledge of all forms can be brought to bear on forming an opinion of whether or not a model is suitable to its particular purpose" (p. 129). Therefore, Forrester [25] also emphasized that "we can never prove that any model is an exact representation of 'reality' … Models are then to be judged, not on an absolute scale that condemns them for failure to be perfect, but on a relative scale that approves them if they succeed in clarifying our knowledge" (p. 3–4). This sort of relativism will be addressed next.

With the aim of placing this stance within the discussion of history of science, Barlas and Carpenter [3] addressed the "philosophical roots of model validation" associating SD with what they called a "relativist philosophy of science". In this view justification is pursued: such a knowledge is seen as socially, culturally and historically dependent and it becomes socially justified belief. Here "a valid model is assumed to be only one of many possible ways of describing a real situation … for every model carries in it the modeler's world view … validation is a matter of social conversation" (p. 157). Hence, confirmation and verification are pursued through a social process relative to a frame of reference. This sort of moderate relativism was later criticized by Vásquez, Liz and Aracil [103] for whom such relativism is unacceptable in spite of their recognition that there is no privileged single model (or set of models); since they are also concerned with epistemological justification these authors present Putnam's internal "realism" as a more adequate way to conceptualize the type of knowledge consistent with the assumptions about reality held by SD practitioners; in short, these authors underline that mental models are the source of knowledge – and its justification – helping to select the structures that must be assumed as working in real systems; here knowledge is taken as internal to the conceptual scheme of SD. Since there can be many models for a given situation, the authors argue that this framework gives the possibility of convergence as a result of "the strong interactive character of mental models" (p. 34) recognizing that in any case SD modeling is a process of revision and adjustment. With this proposal these authors seek to achieve justification and some realistic representational content in spite of the plurality of alternative SD models available for a specific situation. It is easy to see that this proposal is still relativistic, in this case knowledge is relative to the mental models and the conceptual scheme – though the mentioned authors would not agree since for them there is a "reality" given by the internal representational schema, in this case the mental models of the modelers.

The fail to recognize presentationalism as the epistemology which is driving ontology is at the root of the presented discussions. This is a distinctive trait present in large part of the philosophy of science literature. However, the characteristic problem of mistaking positivism with a sort of supposed "objectivism" is also present in this discussion – in fact, Barlas and Carpenter, following the misdirecting literature on the subject, argue that the relativist philosophy that they defend rejects positivism; Vásquez, Liz and Aracil also follow the same inertia. However, these theses, which seek for confirmation, verification, justification, reflect the search for *positive* knowledge within an idealist epistemology. In the first case, knowledge is confirmed and accepted through social interaction and it is relative to a context. In the second case, knowledge is justified on mental models. To appreciate a genuine contrasting position see an anti-justificationist approach to validation in computer simulation in [51]; the core of anti-justificationism can be found in the work of Popper, e. g. [73,74].

System Dynamics as Presentationalist

It should be clear that the assumptions on SD reject naive realism; the models are not supposed to be accurate and corresponding descriptions of an external true reality – and furthermore, this is not what the term "positivism" refers to. In any case validation in SD does not mean a supposed "positive proof" or to assess the development of "true models" of the world. On the contrary, SD aims at enhancing our ways of reasoning, it emphasizes a process of learning so as to consistently improve our mental models which are product of our experience and the operations of our mind. Hence SD is closer to presentationalism. Knowledge can be socially justified and our mental models can be enhanced. Moreover, a particular emphasis on the modeling *process* is also underlined – see e. g. [29,44,89] and it will be commented in the eight section devoted to simulation.

A Brief Note Regarding Social Theory

Another important discussion is related to the theories about the "social world" that are supposedly held in SD, i. e. the social theory behind SD if any. Part of the misguided debate is explained by the widespread use of the traditional framework of Burrell and Morgan [14] whose oversimplification of social science in four paradigms has deviated major issues covering important topics under a too practical and inadequate schema – e. g. see a criticism in Deetz [19]. Jackson [49] provides a summary of such usual misconstruction:

> System dynamics … is essentially functionalist in nature. It sees system structure as the determining force behind system behavior … If humans are free to construct social systems as they wish, what determining influence does system structure have? … This tension between determinism and free will is unresolved (p. 39).

It should suffice to recall from the discussion above that the *aggregate* approach of SD is not a theory of human behavior; SD is not concerned with *individual* action. Furthermore, it does not assume that a structure, of any kind, determines human behavior either, i. e. the sort of determinism that Burrell and Morgan [14] oppose to "free will" and in the lines of the already vague term known as "structuralism" – see an early clarification of the problems of such type of oversimplification in [84]. In any case, this sort of criticism has been answered and clarified by Lane [56] who has underlined the main point: SD is concerned with aggregate social phenomena and not with individual meaningful actions [55]. Moreover, system dynamics does not propose invariant causal laws, as Lane [56] also concludes: "The only universal law/theory on offer is a grand methodological, or structural theory, associated with a representation scheme … it does not attract the determinism-related criticisms attached to grand theory in the sense of Parsons and Mills" (p. 111). In [57] Lane proposes to link system dynamics with a different framework: agency/structure theories.

Servomechanism

Part of the confusion is because of the misunderstanding by various commentators of the notion of feedback that underlies SD. This point has been also a source of misconception given the use of feedback in theories of control applied to social systems, e. g. cybernetics. Consider for example the following comment by Flood and Jackson [23]:

> The attempt of SD thinkers to model external reality is misguided … The emphasis placed on "structure" as the means of revealing knowledge about the optimal behavior of systems cannot be accepted … SD modelers using feedforward control appear to believe that there are optimal future states that we should steer systems towards" (pp. 80, 81).

Such criticism apparently is associated with the notion of feedback used in cybernetics. However SD does not pursue optimization, let alone by studying "knowledge revealing" structures in order to achieve supposed optimal behavior patterns. Instead, the goal is to have a better understanding of feedback structures in order to enhance decision-making and policy design. This point has been also addressed by Lane [53,55]. The central clarification of this issue has been made by Richardson [78] who distinguishes two different threads in the development of the concept of feedback in the social sciences: the cybernetics thread and the servomechanisms thread. The failure in noticing these two different lines of thought has produced various misconceptions regarding the notion of feedback in SD, a concept that has been shown as one of its building blocks. On the one hand, the cybernetic conception of feedback is defined in terms of input and output, it is limited only to loops of negative polarity which in turn are conceived as the mechanisms of control – and hence there is a particular interest in goal seeking and goal formulation given the concern in cybernetics for achieving adaptive behavior via directed processes and homeostatic mechanisms; feedback mechanisms guide this pursue of viable behavior which is carried by goal-seeking processes. On the other hand, in SD, coming from the servomechanisms thread, feedback loops are taken as intrinsic parts of the system (and not just as mechanisms of control), it includes also loops of positive polarity, and such feedback structures are seen as responsible for counterintuitive behaviors and policy resistance in social systems; here the analysis is directed toward policy design.

Explanation and Mechanism

The next interesting question would be how we can achieve better understanding and better policy design by enhancing our mental models. How can we characterize this type of knowledge?

A solid account of *explanation* should be placed at the heart of any scientific activity. The general inquiry about [scientific] explanation has to do with "learning how the process of doing science facilitates understanding, and what type(s) of understanding science provides" ([7] p. 307). In a very intuitive way, a first approach to explanation might be associated plainly with removing puzzlement [6]. It is also common to affirm that an explanation aims to answer queries of *why* in order to provide understanding [87]. Yet, to characterize such idea is a major and open unresolved question in philosophy of science [69]. The notion of causality has traditionally played a central role; this view has pervaded most of scientific research where theory development and explanations are essentially conceived as the search for causes, e. g. [50,87]. However, several explanations are not essentially based on simple causal relations but on other approaches such as identification, models, analogies, formal linguistics, laws of association, laws of co-existence, variational principles, among others [83]. Berger [7] underlines the prominence of this question when attempting to characterize the explanations provided by nonlinear dynamical modeling:

> Mathematical modeling [is recognized] as one of the central activities of science, and it is reasonable to say that modeling explanations dramatically increase our understanding of the world. But the modeling explanations found in contemporary scientific research show that the interesting claims of causal accounts are untenable … An adequate account of scientific explanation must accommodate modeling explanations, because they are simply too central to ignore (pp. 329–330).

The main goal of this section is to explore the position and the characterization of the kind of explanation pursued in system dynamics. This characterization fits with the presented core of SD and the presentationalist stance. And again various clarifications will be needed along the way.

Causality

The difficult issue of causality can be treated in several senses. In the first place, a possible relationship associated with the term "determinism" on human behavior is dismissed with a previous argument: SD causal models does not point at supposed laws of causality governing human action [55,56]. What is more interesting is to investigate the concept of causality as such in SD models; after all, a large part of SD modeling relies on what are known as "causal"-loop diagrams. Forrester emphasized the term *interrelationships* [24] where feedback loops are understood as closed informational paths connecting in a sequence decisions that control actions [25]; he labeled it as a "circular cause-and-effect structure" (p. 1–9). In fact the development of *causal*-loop diagrams has become important in SD practice; in particular, flow diagrams were initially recognized as useful pictorial representations that help to formulate and communicate the structure of a dynamic model [24]. These models are ultimately theories of behavior, surely causal theories of behavior. But consistent with presentationalism, these theories are sourced in the mental models of the modeler, there is no direct connection to an alleged causation in a real world. Sterman summarizes a definition: "a causal diagram consists of variables connected by arrows denoting the causal influences among the variables" [98]; here, every link represents *what the modeler believes is* a causal relationship between two variables; this causal attribution is seen as a central feature of mental models, as Sterman also stresses "we all create and update cognitive maps of causal connections among entities and actors … Within a causal field, people use various cues to causality including temporal and spatial proximity of cause and effect, temporal precedence of causes, covariation, and similarity of cause and effect" [98]. Again, the core of the discussion should be driven by the concept of mental model in order to deliver a clear discussion on this view of causality held in SD. This section outlines a framework.

Most of the time we seem to hold a strong causal view of the world. In particular, the causal relationship – whatever that could be – tends to be the source of explanatory power, i. e. the *explanans*, and one usual source of validity, that is, *for having a relevant valid explanation we must have a causal relationship*. That is the usual principle, and it is usually associated to the term "determinism". Recalling the discussion on presentationalism, one should note that – as Hesslow [42] underlines – if we are going to retain a Humean view of the world, i. e. consistent with idealism, then it seems that we have two different paths, probabilistic or deterministic. The latter one is of interest here (for the probability account of causation see e. g. [43]). Within a deterministic approach, a cause is always sufficient condition or a part of a sufficient condition for the effect, that is, if A_t is a nonsufficient cause of $B_{t'}$, then there must be some auxiliary condition $C_{t''}$, [with $t'' < t'$], such that A_t in combination with $C_{t''}$ is sufficient for $B_{t'}$. Hesslow clarifies this "sufficiency principle" [42]:

> The deterministic approach has been something of a received view of causation. This view, which we may call the 'sufficiency principle' is also common among scientists. The sufficiency principle is not in itself strictly deterministic. It does not mean that every event has a sufficient cause, only that if an event has a cause, then it has a sufficient one. However, it seems that the popularity of the sufficiency principle is a reflection of a widely spread, though usually implicit, commitment to the stronger thesis, that every event has a sufficient cause (p. 592).

The cited paper of Hesslow aims to show that the deterministic approach is superior to the probabilistic one, that is, the idea that the probabilistic account presupposes determinism. Indeed what is happening is the trap of Hume – so to speak. The issue in hands is illustrated with the *Humean fork*: based on observation of constant conjunction of events – altogether with temporal priority, i. e. the cause is observed prior to its effect – we *suppose* a causal connection between them – see summaries in e. g. [46,70] and the original work of Hume [45]. These *suppositions* are arranged in our mental models, that is, in our theories about what we assume as the relevant causal connections that we suppose so as to explain the world.

With this framework in mind, the network of causal connections that the SD modeler believes to be relevant indicates a sort of "sufficiency principle", but of a special kind. It is sufficient relative to the purpose of the model, as it has been indicated above. And it is sourced in the mental model since SD is seen as a vehicle for learning and not as a device for operating a "real world". How are these causal relationships portrayed? In a generic form, a feedback loop based stance is based on the fact that decisions in a time t affect the environment which affects again the future assessment of the situation in a time $t'(t' > t)$ which usually is the base for new upcoming decisions and actions taken in a time t'' $(t'' > t')$ and so on. These relationships are not necessarily close in space or time. Furthermore, a related issue is what can be labeled as "multiple causality". The complexity of social systems is a current concern for social scientists; the multiple interactions among several agents, actors, or entities, is what has been distinguished as the key to study and to understand complex systems because of the recognition of our inability to deal with them based on traditional incomplete simple-causality thinking – the assumption that explanation of phenomena can be satisfactory or even sufficient based in simple unidirectional causal relationships between variables or constructs. What is more, feedback loops have important implications associated with counterintuitive behavior that usually we do not consider easily or that we misunderstand; they have a key role in complex settings; in fact they are, to a large extent, responsible for the arising of complex behaviors; this is a central affirmation in SD [26,98]. The simplest example might be the tendency that we have to infer linear growth from single first order positive feedback loops. But the behavior here actually is exponential. Let S be the state of a system and g the constant fractional growth rate, the linear first order positive loop and its solution are:

$$\frac{\mathrm{d}S}{\mathrm{d}T} = gS$$

and it has as solution:

$$S = S_0 \mathrm{e}^{gt} .$$

The central question is: are these causal theories, portrayed in system dynamics, claims about the world? i. e. Are these models assumed true descriptions of the world? Clearly no. From the presentationalist stance of SD, the causal-loop diagram is essentially what the modeler *believes* is the relevant causal network for the problem in hands. It constitutes his theory about it. The source of knowledge is the mental model and causality is only a supposition of the modeler and a way to arrange knowledge, it is not an affirmation of truth about a supposed causal world. And furthermore, causation as such is not the source of explanation provided by SD. In order to clarify this we should take a look to the notion of explanation held in system dynamics.

Mechanism

System dynamics aims to answer *why* questions. This is done generally via the development of *dynamic hypotheses*. A core premise of SD has always been to enhance learning and to provide understanding [30]. This aim has been stated from the very beginning; for instance Forrester asserted in *Industrial Dynamics*: "Our objective is to enhance understanding and to clarify our thinking about the system" p. 57 in [24]).

How is this goal pursued? A SD model should be able to account for a specific problematic behavior which is explained in terms of the structure of the model; here the term "structure" refers to the stock and flow organization, the feedback loops and the rules of interaction [98]. This approach to explanation is known as a dynamic hypothesis and is the core concept in order to provide understanding from a system dynamics point of view; its endogenous character is the chief feature that makes it intelligible; for instance: "One key task in this search for insightful, system level understanding is the telling of 'system stories' – coherent, dynamically correct explanations of how influential pieces of system structure give rise to important patterns of system behavior" (p. 1 in [65]). In fact this task represents one of the more significant research lines [79].

How can we characterize this particular kind of explanation? As a first point, the notion of organized social complexity helps to drive this discussion. A quote borrowed from Hayek illustrates it:

> Where we have to deal with such social wholes we cannot, as we do in the natural sciences, start from the observation of a number of instances which we recognize spontaneously by their common sense attributes as instances of 'societies' or 'economies' ... What we group together as instances of the same collective or whole are different complexes of individual events, in themselves perhaps quite dissimilar, but believed by us to be related to each other in a similar manner: they are classifications or selections of certain elements of a complex picture on the basis of a theory about their coherence (p. 43 in [40]).

Based on the quote above of Hayek, he suggests conceiving the *explanation* as modeling [104], and for social sciences he rejects the usual prediction and control aspirations and asks the reader to focus more on models to explain typical processes [64], he depicts it with biology: "It deals with pattern-building forces, the knowledge of which is useful for creating conditions favorable to the production of certain kinds of results, while it will only in comparatively few cases be possible to control all the relevant circumstances" (as cited in p. 202 in [104]). Hayek calls it "explanation of the principle". Essentially he means the explanation of a *kind* of phenomena instead of particular events. As another example consider mathematics: "A set of equations which shows merely the form of a system of relationships but does not give the values of the constants contained in it, is perhaps the best general illustration of an explanation merely of the principle on which any phenomenon is produced" (p. 291 in [39]). This analogy illustrates the notion of abstract relations that would build an "explanation of the principle" which can be associated with *mechanism* as the source of explanatory power – instead of causality.

Again, a clarification is needed given the widespread identification of the term "mechanism" with ontic commitments. Fundamentally mechanism is a kind of *explanation*. It should be noticed that "mechanism" refers to *epistemological* issues. However, the term is habitually associated with assumptions about reality. But Hogben already clarified in 1930:

> In any discussion between the two [mechanist and holist or vitalist], the combatants are generally at cross purposes. The mechanist is primarily concerned with an epistemological issue. His critic has always an ontological axe to grind. The mechanist is concerned with how to proceed to a construction which will represent as much about the universe as human beings with their limited range of receptor organs can agree to accept. The vitalist or holist has an incorrigible urge to get behind the limitations of our receptor organs and discover what the universe is really like (1930, p. 100, as cited in [12], p. 347).

The explanatory notion of mechanism is well underlined by Grene: "Let us look for a mechanism which might underlie the phenomena we hope to understand, seeking wherever we may relevant sources from which to derive ... an analogue of a possible mechanism ... [Such an explanation is of value because it tells us] *how in fact those phenomena are produced*" (as cited in [12], p. 346, emphasis original).

However, there is still no agreement about what a mechanism is and how it appears to succeed in science as a way to provide understanding. Perhaps the most complete account is the one of Tabery [99] who proposes integrating two complementary points of view. These two aspects are (i) the interactions among several parts and, (ii) the activities associated with these interactions. Both characteristic are taken as necessary for having a mechanism-based explanation.

On the one hand there is the emphasis on interactions, a thesis supported by Glennan [36] with a central concern on the nature of *complex systems* since the role of parts and its interactions are conceived as indispensable. The work of Bechtel and Richardson [5] develops the association of mechanism and complex systems (in biology and psychology) and emphasizes the tasks of decomposition and localization as the heuristics in order to uncover mechanisms. This position replies to the conventional view of a mechanism as merely the interactions between causal processes as the essential *explanans*; Glennan [36] stresses: "A mechanism for a behavior is a complex system that produces that behavior by the interaction of a number of parts, where the interactions between parts can be characterized by direct, invariant, change-relating generalizations" (p. 344). Glennan clarifies also that he avoids using the term "causal-law" and instead uses "change-relating generalizations" because these relations are not exception-less as traditionally a law is understood. In addition, he emphasizes the very different character of such account which is in opposition to the traditional causal view in which mechanisms are sequences or chains of events leading up to a particular event – which is often associated in systems theory literature with "linear thinking".

On the other hand we have activities. Machamer, Darden and Craver [62] emphasize this aspect adding that mechanisms are not only inter-connected entities but also activities producing regular changes from initial to finish conditions; they call themselves dualists since for them both notions – entities and activities – are necessary to constitute a mechanism: "The organization of these entities and activities determines the ways in which they produce the phenomenon. Entities often must be appropriately located, structured, and oriented, and the activities in which they engage must have a temporal order, rate, and duration" (p. 3). It is important to underline their critique to Glennan's view arguing that the concept of *activity* is fundamental to understand the changes produced (because of the activities) through the process and not only as the black-box view of change of states or change of properties of the inter-connected entities; they picture it clearly with the following statement: "it is not the penicillin that causes the pneumonia to disappear, but what the penicillin does" (p. 6). Furthermore, in order to account for a mechanism they emphasize three distinctions: set-up conditions (as *part* of the mechanism, not as a sort of input; this includes relevant entities and their properties and initial states), intermediate activities (including also relevant entities, properties, and an intelligible account of the activities that link them) and termination conditions (such as privileged endpoints, equilibrium states or the final stage of some unitary integral process). They also draw attention to the fact that mechanisms take place in nested multi-level hierarchies and that they usually are not full pictures but truncated abstract accounts – *a mechanism schema* – depending on the required level of detail or aggregation.

System dynamics modeling is perhaps one of the best ways to picture this kind of explanation. One can distinguish two main components in the structure of SD models: the physical and institutional assumptions – including the chosen parts/variables and the interconnections between them, and the decision rules of the agents [98]. The interplay between the physical structure and the associated decision rules as the explanation for behavior is a foundational aspect. Indeed the interconnections and the activities needed to account for a mechanism are included in these system dynamic models structures. Specifically, the activities producing change can be referenced in the links of the models and the decision rules describe how the interactions produce certain activities. The whole set of initial and final conditions and the inter-connected parts engaged in producing activities characterize a mechanism. For example, the simplest mechanism is perhaps a single feedback loop. The set-up conditions are the initial values of the variables involved, the termination condition is the endpoint of the loop which can be accounted in a mechanism as "the final stage of what is identified as a unitary, integral process" (p. 12 in [62]). The intermediate activities are depicted by the links and the application of the decision rules. For instance, a simple positive first order loop can produce exponential behavior beyond the particular values of the variables involved. More intricate structures are the source of different behaviors, i. e. the change in the values or patterns of variables through time.

This stance fits an explanation of an abstract principle in the sense of Hayek. The structure is the source of explanation of patterns of behavior, i. e. the change in the values or patterns of variables of interest through time. This is known in SD as a dynamic hypothesis [98]. With this focus on aggregate patterns – instead of individual events – as consequence of the structure, it can be said that the "causal" mechanism is indeed the loop structure of the system, or the particular and relevant feedback substructures of the model that may explain the behavior; for instance Richardson [78] illustrates it in this way: "The 'cause' of an arms race is viewed not as a given event or even a given sequence of events, but as a feedback structure dominated by self-reinforcing positive loops, within which events take place" (p. 338). These types of explanations are based on *mechanisms* as explanatory power and not in simple causal relationships as the source of explanation, even less in (substantivalist) causality, i. e. change in singular properties/entities. Furthermore, these hypotheses are developed for each problem consistent with the mental models of the modelers. This is why system dynamics is not committed to specific theories and only to the explanation of problematic behaviors in terms of structure of the model in order to enhance learning and decision-making.

A particular remark must be made. It can be noticed a natural link between mechanism and the idea of "generic structure". This latter expression has been used in different senses in SD literature. Lane and Smart [58] trace the evolution of this concept – see also [71], they identify three different interpretations. One of these view cannot be connected with mechanism, the one popularized by Senge, e. g. [92,109,110], usually known under the expression "system archetypes". The lack of computer simulation within this interpretation points at a problem of validity in its scope and claims, as Lane and Smart discuss [58], e. g. since this perspective skips the possibility of formal computer model building then the relation between structure and behavior is weak and the mentioned approach becomes just a hasty shortcut from problematic behavior to insights and principles, and without the experimental spirit of SD for enhancing learning. But two other notions are relevant. On the one hand, generic structures can be conceived as general models (theories of behavior) of a class of systems that are associated with a domain of application, e. g. urban development, supply chain, economic growth. Lane and Smart label these structures as "canonical situation models". On the other hand, a generic structure may refer to theories of mathematical structures (feedback loops, levels, rate equations, etc.) that generate corresponding dynamic behaviors, i. e. "systems belong to the same class if they can be represented by the same structure … This dynamic structure when abstracted from any application domain data defines the class of system" (p. 93 in [58]); therefore they offer transferability of structure across diverse domains. These models can be labeled as "abstracted micro-structures", e. g. patterns of exponential growth, goal seeking, oscillation, etc. [58,98]. Both interpretations look for establishing a general class of models that formally link structure with behavior and they constitute an important line of research. These developments contribute to different aspects of SD practice; in particular they directly fuel the processes of conceptualization and formal model construction (e. g. see [31,58,98]), and more important, they enhance understanding and the improvement of our mental models as long as we can exploit the powerful idea of having general classes of models, either within a domain of application or across different domains by transferring structures across them.

Consequently, system dynamics explanations can be characterized as *mechanisms*, since there can be found the source of explanatory power. In spite of its causal diagrams, the *explanans*, i. e. that which does the explaining, is based on mechanisms – dynamic hypotheses based on structures; and the problematic behavior is the *explanandum*, i. e. that which is explained. Following Glymour: "Remains, however, a considerable bit of science that sounds very much like explaining, and which perhaps has causal implications, but which does not seem to derive its point, its force, or its interest from the fact that it has something to do with causal relations (or their absence)" (as cited in [p. 212 in 83]). The theories built with SD are essentially structure-based and not content-based (substantivalist) explanations i. e. they are not associated with intrinsic properties of objects or entities but with the consequences of processes and activities entrenched in relevant parts of the structure of the model. Recalling Hayek who identifies explanation with modeling, it is interesting to notice the range of his thought expressed half a century ago and that accurately illustrates SD explanations:

> Any model defines a certain range of phenomena which can be produced by the type of situation which it represents. We may not be able directly to confirm that the causal mechanism determining the phenomenon in question is the same as that of the model. But we know that, if the mechanism is the same, the observed structures must be capable of showing some kinds of action and unable to show others (p. 221 in [38]).

A further reminder follows. Since SD was previously identified with instrumentalism, then a mechanism is not to be taken as a description; here a mechanism is an instrument for arranging observations. It should be kept in mind that mechanism is a kind of explanation which refers to epistemological issues.

The popularity of simple causality as the way to characterize the explanation of phenomena contrasts with the assumptions made in SD: structures that generate processes responsible for behavior. This is consistent with the purpose of system dynamics simulation which might be oriented to activities such as theoretical-representations building, articulation and testing in order to learn in and about complex systems [98]. System dynamics uses simulation as a method which is different from the traditional inductive logic of research that deals with single instances which attempts to confirm theories via repeated observation. However, SD does not dismiss presentationalism as it was shown. This should be highlighted as an important and distinctive characteristic of SD. Though there is a commitment with a real world, justification is rooted in social processes and on mental models, and it is also relative to the purpose of the model. Furthermore, the goal is to enhance our decision-making processes by improving our mental models. How can we characterize such method? A short comment follows.

Simulation and Method

In a plain sense "simulation means driving a model of a system with suitable inputs and observing the corresponding outputs" (p. 23 in [2]). But simulation actually is not just a matter of number crunching. Its scope is broader. And it represents another challenge for philosophy of science. Winsberg [107] illustrates it:

> Typically, to a philosopher of science, epistemological issues arise when we try to justify high level the-

> oretical claims based on low level data or specific observational reports. But simulation is about starting with theory and working your way down. This kind of epistemology is, to the philosopher of science, a curious beast. It is an epistemology that is concerned with justifying inferences from a theory to its application – an inference that most philosophy of science has assumed is deductive and consequently not in need of justification (p. S447).

What is simulation in SD? It can be affirmed that it is a technique able to represent and test theoretical concepts and not only – in a narrow sense – a tool to just solve mathematical problems. Besides, the emphasis on processes, on patterns of collective action and on the relations between components and its dynamic consequences can be better addressed with simulation because of its capacities to represent these issues with fewer restrictions than other approaches [35]. But there is more. Simulation reflects a very different attitude. This way of inquiry suggests a whole different and new scientific methodology [82,106,107]. Winsberg emphasizes that "simulation represents an entirely new mode of scientific activity – one that lies between theory and experiment ... a form of theory articulation or 'model building' (pp. 117, 119 in [106]). Axelrod [2] indeed suggests "a third way" of doing science:

> Simulation as a way of doing science can be contrasted with the two standard methods of induction and deduction ... Simulation is a third way of doing science. Like deduction, it starts with a set of explicit assumptions. But unlike deduction, it does not prove theorems. Instead, a simulation generates data that can be analyzed inductively. Unlike typical induction, however, the simulated data comes from a rigorously specified set of rules rather than direct measurement of the real world (p. 24).

Moreover, its strength rests on the capacity for conducting *experiments* [82]. This emphasis on experimentation is the key to understand why this approach is different. Our mental models are nothing more than theoretical models that attribute properties and relations to the systems they represent; the relevance of these theoretical models depends on the purpose of the model. And computer simulation simply permits experiments of these (theoretical) models. This is where the novelty and the power of this methodology are to be found, in the very iterative process of model building and experimentation via simulation. This position contrasts with the traditional prominence of assumed representational capacities of *theories* and *models* where usually the emphasis has been placed, see [107]. But computer simulation has a distinct epistemology [105] that emphasizes *the process of modeling*. The method was demarcated by Forrester [24] in *Industrial Dynamics*:

> Simulation consists of tracing through, step by step, the actual flows of orders, goods, and information, and observing the series of new decisions that take place ... This is the counterpart of trying a new policy or organizational structure in the real system... After a simulation run comes interpretation of the results. Did it turn out as expected? If not, why? As the experiment is examined, new questions arise ... This is a process of invention and trial ... Each simulation result teaches, and it also prompts additional questions ... Such experimentation will yield new insights into the characteristics of the system that the model represents (pp. 23, 44–45, 55).

Hence, the method of simulation through continued experimentation is aimed at providing better understanding of the modeled system. As it was mentioned, the method calls attention to the *process* – see also [44,89]. Indeed SD aims at developing a *modeling* culture (consistent with [80]) that gives emphasis to model building as an ongoing dialectic between stakeholders instead of a mapping exercise concerned on the efficacy of the model itself.

Why is fundamental the use of the computer? Perhaps the best answer is provided again by Forrester [26]:

> We stress the importance of being explicit about assumptions and interrelating them in a computer model ... The most important difference between the properly conceived computer model and the mental model is in the ability to determine the dynamic consequences when the assumptions within the model interact with one another. The human mind is not adapted to sensing correctly the consequences of a mental model ... The computer model ... is a statement of system structure. It contains the assumptions being made about the system ... Generally, the consequences are unexpected (pp. 213–215).

The shortcomings of our mental models coupled with the complexity of the systems we model lead to the use of the computer. Sterman [101] summarizes these drawback with aspects such our flawed cognitive maps and our erroneous inferences about dynamics. As it was shown, the strength of explanation and understanding in SD is not in the causal models as such; the heart lies in the development of dynamic hypotheses with the use of simulation in order to enhance our understanding and our decision-making processes. Explanations are posed under the notion of mechanism; but this is an iterative process that seeks a central aim: to improve our own theories about the world.

Future Directions

There are several aspects to develop based on this reflection on various assumptions behind system dynamics. The central argument was built around the position known as presentationalism. This stance integrates and informs many of the debates on related subjects, e. g. validation, and it characterizes the initial purposes and assumptions held in the field. However, there are a number of lines to emphasize and to develop.

We have focused on the role of the idea of "mental model" for the practice of SD. Yet, it can be seen utilization of SD models under assumptions which are closer to a naive realism that seem to ignore the purposes of enhancing understanding and learning processes. This article should help to underscore that system dynamics is less naive – and hence more powerful – when we recognize a presentationalist stance which means that our theories about the world are just that, *theories* based on our experience and on the operations of our own mind. We can improve these theories with the use of system dynamics, that is, making our assumptions about systems explicit and using simulation as a method for enhancing understanding and for developing explanations that guide our processes of systems design. This recognition includes the relative nature of justification of knowledge held in SD and the emphasis on mechanism as a powerful way to develop explanations about complex systems.

It has been introduced mechanism as the way to characterize the particular type of explanation pursued in SD. The explanatory force does not rest on causal relations as such but on the structures – physical and decision rules aspects – and on the dynamic processes and activities that explain change. The idea of mechanism is shaped in SD under the expression "generic structure". The focus on understanding behavior in terms of abstract structures is a central line of inquiry. This article underlines the importance of developing such a line of research since it has been located at the core of the kind of knowledge that SD provides. The issue of unification to provide understanding of diverse phenomena is a definitive step in the way to assert that the field progresses as long as broader range of phenomena may be explained with the same mechanism. Should be the advance of system dynamics assessed by the progress in this type of study? Behind this discussion there are major and provocative issues that arise to be developed.

The long debate of qualitative and quantitative modeling is informed by this characterization. It is clear that the issue of explanation compels theorists and practitioners to ask themselves what is the kind of explanation they are pursuing and if such explanations are enough and satisfying; it is worthy to ask for qualitative modeling what kind of understanding it gives and how it can be characterized, in other words, to give an account of *explanans* and *explanandum*. Another line to develop might be oriented around the following question: what would be *essential* criteria for comparing different arranges or modes of organization in order to identifying them as belonging to the same type of mechanism? The identification and search of mechanisms becomes a powerful heuristic for guiding the modeling process.

There are promising suggestions for philosophy of science as well. SD offers guidelines, e. g. can the ways in which system dynamicists work provide meaningful insights, or even concrete accounts, for the philosophical unresolved issue of explanation? The mechanism depicted in system dynamics proposes a kind of explanation that goes beyond the received view based on causation. A related question is whether explanation must always follow a deductive path; the classic models of Hempel, e. g. [41], emphasized the condition of deduction and general laws for having an explanation; however, the explanation in SD is not framed under a deductive schema from universal covering laws, instead it can be conceived as a sort of abductive reasoning based on the understanding of the dynamics of the model as a way to understand the actual behavior it accounts for. A further issue is that in spite of the lack of universality, i. e. no universal laws, SD models aim to provide understanding for a diverse range of phenomena that might share relevant influential structures and similar associated behaviors, that is, it accounts for regularities in order to unify them in a certain kind of explanation under the same explanation. This situation insinuates a flavor of paradox because of the traditional rigid association of universal laws with the explanation of regularities, but in SD there are no general laws though the aim is to explain general regularities. The study of *models* and computer simulation – instead of abstract theories and traditional methodologies – is an additional indication that SD suggests for philosophy of science, including the emphasis on the modeling process.

Glossary

Exosystem A dynamical system modeling the set of all exogenous inputs (command/disturbances) affecting a controlled plant.

Internal model A model of the exogenous inputs (command/disturbances) affecting a controlled plant, embedded in the interior of the controller.

Generalized tracking problem The problem of designing a controller able to asymptotically track/reject any exogenous command/disturbance in a fixed set of functions.

Observer A device designed to asymptotically track the state of a dynamical system on the basis of measured observations.

Steady state A family of behaviors, in a dynamical system, that are asymptotically approached, as actual time tends to infinity or as initial time tends to minus infinity.

Definition

A central problem in control theory is the design of feedback controllers so as to have certain outputs of a given plant *to track* prescribed reference trajectories. In any realistic scenario, this control goal has to be achieved in spite of a good number of phenomena which would cause the system to behave differently than expected. These phenomena could be endogenous, for instance parameter variations, or exogenous, such as additional undesired inputs affecting the behavior of the plant. In numerous design problems, exogenous inputs are not available for measurement, nor are known ahead of time, but rather can only be seen as unspecified members of a given family of functions. Embedding a suitable "internal model" of such a family in the controller is a design strategy that has proven to be quite successful in handling uncertainties in the controlled plant as well as in the exogenous inputs.

Introduction

The problem of controlling the output of a system so as to achieve asymptotic tracking of prescribed trajectories and/or asymptotic rejection of disturbances is a central problem in control theory. There are essentially three different possibilities to approach the problem: tracking by dynamic inversion, adaptive tracking, tracking via internal models. Tracking by *dynamic inversion* consists in computing a precise initial state and a precise control input (or equivalently a reference trajectory of the state), such that, if the system is accordingly initialized and driven, its output exactly reproduces the reference signal. The computation of such control input, however, requires "perfect knowledge" of the entire trajectory which is to be tracked as well as "perfect knowledge" of the model of the plant to be controlled. Thus, this type of approach is not suitable in the presence of large uncertainties on plant parameters as well as on the reference signal. *Adaptive* tracking consists in tuning the parameters of a control input computed via dynamic inversion in such a way as to guarantee asymptotic convergence to zero of a tracking error. This method can successfully handle parameter uncertainties, but still presupposes the knowledge of the entire trajectory which is to be tracked (to be used in the design of the adaptation algorithm) and therefore an approach of this kind is not suited to the problem of tracking unknown trajectories. Of course, one might consider the problem of tracking a slowly varying reference trajectory as a stabilization problem in the presence of a slowly varying unknown parameter, but this would, in most cases, yield a very conservative solution.

In most cases of practical interest, the trajectory to be tracked (or the disturbance to be rejected) is not available for measurement. Rather, it is only known that this trajectory is simply an (undefined) member in a set of functions, for instance the set of all possible solutions of an ordinary differential equation. These cases include the classical problem of the set point control, the problem of active suppression of harmonic disturbances of unknown amplitude, phase and even frequency, the synchronization of nonlinear oscillations, and similar others. It is in these cases that *tracking via internal models* proves particularly efficient, in its ability to handle simultaneously uncertainties in plant parameters as well as in the trajectory which is to be tracked.

For linear multivariable systems, tracking problems of this kind (those in which the exogenous commands and/or disturbances are only known to be members in the set of solutions of a given ordinary differential equations) have been addressed in very elegant geometric terms by Davison, Francis, Wonham [8,10,11] and others. In particular, one of the most relevant contributions of [11] was a clear delineation of what is known as *internal model principle*, i. e. the fact that the property of perfect tracking is insensitive to plant parameter variations "only if the controller utilizes feedback of the regulated variable, and incorporates in the feedback path a suitably reduplicated model of the dynamic structure of the exogenous signals which the regulator is required to process". Conversely, in a stable-closed loop system, if the controller utilizes feedback of the regulated variable and incorporates an internal model of the exogenous signals, the output regulation property is insensitive to plant parameter variations.

A nonlinear enhancement of this theory, which uses a combination of geometry and nonlinear dynamical systems theory, was initiated in [15,16,19] in the context of solving the problem near an equilibrium, in the presence of exogenous signals which were produced by a Poisson stable system. In particular, in [19] it was shown how the use center manifold theory near an equilibrium determines the necessity of the existence of an internal model whenever one can solve an output regulation problem in spite of (small) parameter uncertainties (see also [3]). Since these pioneering contributions, the theory has experienced a tremendous growth, culminating in the development of design methods able to handle the case of parametric uncertainties affecting the autonomous (linear) system which generates the exogenous signals (such as in [9,23]), the case of nonlinear exogenous systems (such as in [5]), or a combination thereof (as in [22]). The purpose of these notes is to present a self-contained exposition of the fundamentals of these design methods.

The Generalized Tracking Problem

In this article, we address tracking problems that can be cast in the following terms. Consider a finite-dimensional, time-invariant, nonlinear system described by equations of the form

$$\begin{aligned}\dot{x} &= f(w,x,u)\\ e &= h(w,x)\\ y &= k(w,x)\,,\end{aligned} \tag{1}$$

in which $x \in \mathbb{R}^n$ is a vector of state variables, $u \in \mathbb{R}^m$ is a vector of inputs used for *control* purposes, $w \in \mathbb{R}^s$ is a vector of inputs which cannot be controlled and include *exogenous* commands, exogenous disturbances and model uncertainties, $e \in \mathbb{R}^p$ is a vector of *regulated* outputs which include tracking errors and any other variable that needs to be steered to 0, $y \in \mathbb{R}^q$ is a vector of outputs that are available for *measurement* and hence used to feed the device that supplies the control action. The problem is to design a controller, which receives $y(t)$ as input and produces $u(t)$ as output, able to guarantee that, in the resulting closed-loop system, $x(t)$ remains bounded and

$$\lim_{t\to\infty} e(t) = 0\,, \tag{2}$$

regardless of what the exogenous input $w(t)$ actually is.

The ability to successfully address this problem very much depends on how much the controller is allowed to know about the exogenous disturbance $w(t)$. In the ideal situation in which $w(t)$ is available to the controller in real-time, the design problem indeed looks much simpler. This is, though, only an extremely optimistic situation which does not represent, in any circumstance, a realistic scenario. The other extreme situation is the one in which nothing is known about $w(t)$. In this, pessimistic, scenario the best result one could hope for is the fulfillment of some prescribed ultimate bound for $|e(t)|$, but certainly not a sharp goal such as (2). A more comfortable, intermediate, situation is the one in which $w(t)$ is only known *to belong to a fixed family* of functions of time, for instance the family of all solutions obtained from a fixed ordinary differential equation of the form

$$\dot{w} = s(w) \tag{3}$$

as the corresponding initial condition $w(0)$ is allowed to vary on a prescribed set. This situation is in fact sufficiently distant from the ideal but unrealistic case of perfect knowledge of $w(t)$ and from the realistic but conservative case of totally unknown $w(t)$. But, above all, this way of thinking at the exogenous inputs covers a number of cases of major practical relevance. There is, in fact, abundance of design problems in which parameter uncertainties, reference commands and/or exogenous disturbances can be modeled as functions of time that satisfy an ordinary differential equation.

The control law is to be provided by a system modeled by equations of the form

$$\begin{aligned} \dot{\xi} &= \varphi(\xi, y) \\ u &= \gamma(\xi, y) \end{aligned} \tag{4}$$

with state $\xi \in \mathbb{R}^\nu$. The initial conditions $x(0)$ of the *plant* (1), $w(0)$ of the *exosystem* (3) and $\xi(0)$ of the *controller* (4) are allowed to range over fixed *compact* sets $X \subset \mathbb{R}^n$, $W \subset \mathbb{R}^s$ and, respectively, $\Xi \subset \mathbb{R}^\nu$. All maps characterizing the model of the controlled plant, of the exosystem and of the controller are assumed to be sufficiently differentiable.

The problem which will be studied, known as the *generalized tracking problem* (or *problem of output regulation* or also *generalized servomechanism problem*) is to design a feedback controller of the form (4) so as to obtain a closed loop system in which all trajectories are bounded and the regulated output $e(t)$ asymptotically decays to 0 as $t \to \infty$. More precisely, it is required that the composition of (1), (3) and (4), that is the *autonomous* system

$$\begin{aligned} \dot{w} &= s(w) \\ \dot{x} &= f(w, x, \gamma(\xi, k(w, x))) \\ \dot{\xi} &= \varphi(\xi, k(w, x)) \end{aligned} \tag{5}$$

with output

$$e = h(w, x)\,,$$

be such that:

- The positive orbit of $W \times X \times \Xi$ is bounded, i. e. there exists a bounded subset S of $\mathbb{R}^s \times \mathbb{R}^n \times \mathbb{R}^\nu$ such that, for any $(w_0, x_0, \xi_0) \in W \times X \times \Xi$, the integral curve $(w(t), x(t), \xi(t))$ of (5) passing through (w_0, x_0, ξ_0) at time $t = 0$ remains in S for all $t \geq 0$.
- $\lim_{t\to\infty} e(t) = 0$, uniformly in the initial condition, i. e., for every $\varepsilon > 0$ there exists a time $\bar{t}$, depending only on ε and *not on* (w_0, x_0, ξ_0), such that the integral curve $(w(t), x(t), \xi(t))$ of (5) passing through (w_0, x_0, ξ_0) at time $t = 0$ satisfies $\|e(t)\| \leq \varepsilon$ for all $t \geq \bar{t}$.

The Steady-State Behavior of a System

Limit Sets

The generalized tracking problem can be seen as the problem of forcing in the plant, by means of an appropriate control input $u(t)$, a response $x(t)$ that asymptotically compensates the effect, on the regulated variable $e(t)$, of the exogenous input $w(t)$. The classical way in which the problem is addressed for linear, time-invariant systems, when the exosystem is a neutrally stable linear system, is to seek a controller forcing in the associated closed-loop system (5) a (stable) "steady state" behavior entirely contained in the kernel of the map defining the tracking error e. Thus, it is natural to expect that a similar tool should also be effective in the more general setting considered here. It appears, though, that a rigorous investigation of the concept of "steady state", beyond the classical domain of linear system theory, had never been fully pursued.

Motivated by the current practice in linear system theory, the "steady state" behavior of a dynamical system can be viewed as a kind *limit* behavior, approached either as the *actual* time t tends to $+\infty$ or, alternatively, as the *initial* time t_0 tends to $-\infty$. Relevant, in this regard, are certain concepts introduced by G.D. Birkhoff in his classical

1927 essay, where he asserts that “with an arbitrary dynamical system ... there is associated always a closed set of ‘central motions’ which do possess this property of regional recurrence, towards which all other motions of the system in general tend asymptotically” (see p. 190 in [2]). In particular, a fundamental role is played by the concept of ω-limit set of a given point, which is defined as follows. Consider an *autonomous* ordinary differential equation

$$\dot{x} = f(x) \tag{6}$$

with $x \in \mathbb{R}^n$, $t \in \mathbb{R}$. It is well known that, if $f\colon \mathbb{R}^n \to \mathbb{R}^n$ is locally Lipschitz, for any $x_0 \in \mathbb{R}^n$, the solution of (6) with initial condition $x(0) = x_0$, denoted by $x(t, x_0)$, exists on some open interval of the point $t = 0$ and is unique.

Assume, in particular, that $x(t, x_0)$ is defined for all $t \geq 0$. A point x is said to be an ω-limit *point* of the motion $x(t, x_0)$ if there exists a sequence of times $\{t_k\}$, with $\lim_{k\to\infty} t_k = \infty$, such that

$$\lim_{k\to\infty} x(t_k, x_0) = x\,.$$

The ω-limit *set* of a point x_0, denoted $\omega(x_0)$, is *the union* of all ω-limit points of the motion $x(t, x_0)$.

It is obvious from this definition that an ω-limit point *is not* necessarily a limit of $x(t, x_0)$ as $t \to \infty$, as the solution in question may not admit any limit as $t \to \infty$. It happens though, that if the motion $x(t, x_0)$ is *bounded*, then $x(t, x_0)$ asymptotically approaches *the set* $\omega(x_0)$. This property is precisely described in what follows [2].

Lemma 1 *Suppose there is a number M such that $\|x(t, x_0)\| \leq M$ for all $t \geq 0$. Then, $\omega(x_0)$ is a nonempty compact connected set, invariant under (6). Moreover, the distance of $x(t, x_0)$ from $\omega(x_0)$ tends to 0 as $t \to \infty$.*

One of the remarkable features of $\omega(x_0)$, as indicated in this Lemma, is the fact that this set is *invariant* for (6). Invariance means that for any initial condition $\bar{x}_0 \in \omega(x_0)$ the solution $x(t, \bar{x}_0)$ of (6) exists *for all* $t \in (-\infty, +\infty)$ and that $x(t, \bar{x}_0) \in \omega(x_0)$ for all such t. Put in different terms, the set $\omega(x_0)$ is filled by motions of (6) which are bounded backward and forward in time. The other remarkable feature is that $x(t, x_0)$ *approaches* $\omega(x_0)$ as $t \to \infty$, in the sense that the distance *of the point* $x(t, x_0)$ (the value at time t of the solution of (6) starting in x_0 at time $t = 0$) *from the set* $\omega(x_0)$ tends to 0 as $t \to \infty$.

Since any motion $x(t, x_0)$ which is bounded in positive time asymptotically approaches the ω-limit set $\omega(x_0)$ as $t \to \infty$, one may be tempted to look, for a system (6) in which *all* motions are bounded in positive time, at the *union* of the limit sets of all points x_0, i. e. at the set

$$\Omega = \bigcup_{x_0 \in \mathbb{R}^n} \omega(x_0)$$

and to say that the system is in steady state if its state $x(t)$ evolves in the (invariant) set Ω. There is a major drawback, though, in taking this as definition of “steady state” behavior of a nonlinear system: the convergence of $x(t, x_0)$ to Ω is not guaranteed to be *uniform* in x_0, even if the latter ranges over a compact set (see, e. g [7]).

One of the main motivations for looking into the concept of steady state is the aim *to shape* the steady state response of a system to a given (or to a given family of) forcing inputs. But this motivation looses much of its meaning if the time needed to get within an ε-distance from the steady state may grow unbounded as the initial state changes (even when the latter is picked within a fixed *bounded* set). In other words, *uniform* convergence to the steady state (which is automatically guaranteed in the case of linear systems) is an indispensable feature to be required in a nonlinear version of this notion. The set Ω, the union of all ω-limit points of all points in the state space does not have this property of uniform convergence, but there is a larger set which does have this property. This larger set, known as the ω limit set *of a set*, is precisely defined as follows.

Consider again system (6), let B be a subset of $\mathbb{R}^n$ and suppose $x(t, x_0)$ is defined for all $t \geq 0$ and all $x_0 \in B$. The ω-limit set of B, denoted $\omega(B)$, is the set of all points x for which there exists a sequence of pairs $\{x_k, t_k\}$, with $x_k \in B$ and $\lim_{k\to\infty} t_k = \infty$ such that

$$\lim_{k\to\infty} x(t_k, x_k) = x\,.$$

It is clear from the definition that if B consists of only one single point x_0, all x_k’s in the definition above are necessarily equal to x_0 and the definition in question reduces to the definition of ω-limit set of a point, given earlier. It is also clear form this definition that, if for some $x_0 \in B$ the set $\omega(x_0)$ is nonempty, all points of $\omega(x_0)$ are points of $\omega(B)$. In fact, all such points have the property indicated in the definition, if all the x_k’s are taken equal to x_0. Thus, in particular, if all motions with $x_0 \in B$ are bounded in positive time,

$$\bigcup_{x_0 \in B} \omega(x_0) \subset \omega(B)\,.$$

However, the converse inclusion is not true in general.

The relevant properties of the ω-limit set of a set, which extend those presented earlier in Lemma 1, can be summarized as follows [14].

Lemma 2 *Let B be a nonempty bounded subset of $\mathbb{R}^n$ and suppose there is a number M such that $\|x(t, x_0)\| \leq M$ for all $t \geq 0$ and all $x_0 \in B$. Then $\omega(B)$ is a nonempty compact* *set, invariant under (6). Moreover, the distance of $x(t, x_0)$ from $\omega(B)$ tends to 0 as $t \to \infty$, uniformly in $x_0 \in B$. If B is connected, so is $\omega(B)$.*

Thus, as it is the case for the ω-limit set of a point, we see that the ω-limit set of a bounded set, being compact and invariant, is filled with motions which exist for all $t \in (-\infty, +\infty)$ and are bounded backward and forward in time. But, above all, we see that the set in question is *uniformly* approached by motions with initial state $x_0 \in B$, a property that the set Ω does not have. Note also that the set of all such trajectories is a "behavior", in the sense of J.C. Willems [25].

The set $\omega(B)$, as shown in the previous Lemma, asymptotically attracts, as $t \to \infty$, all motions that start in B. Since the convergence to $\omega(B)$ is uniform in x_0, it is also true that, whenever $\omega(B)$ is contained in the interior of B, the set $\omega(B)$ is *asymptotically stable*, in the sense of Lyapunov (see [14]).

The Steady State Behavior of a Nonlinear System

Consider now again system (6), with initial conditions in a closed subset $X \subset \mathbb{R}^n$. Suppose the set X is *positively invariant*, which means that for any initial condition $x_0 \in X$, the solution $x(t, x_0)$ exists for all $t \geq 0$ and $x(t, x_0) \in X$ for all $t \geq 0$. The motions of this system are said to be *ultimately bounded* if there is a bounded subset B with the property that, for every compact subset X_0 of X, there is a time $T > 0$ such that $\|x(t, x_0)\| \in B$ for all $t \geq T$ and all $x_0 \in X_0$. In other words, if the motions of the system are ultimately bounded, every motion eventually enters and remains in the bounded set B.

Suppose the motions of (6) are ultimately bounded and let $B' \neq B$ be any other bounded subset with the property that, for every compact subset X_0 of X, there is a time $T > 0$ such that $\|x(t, x_0)\| \in B'$ for all $t \geq T$ and all $x_0 \in X_0$. Then, it is easy to check that $\omega(B') = \omega(B)$. Thus, in view of the properties described in Lemma 2 above, the following definition can be adopted (see [7]).

Definition Suppose the motions of system (6), with initial conditions in a closed and positively invariant set X, are ultimately bounded. A *steady state* motion is any motion with initial condition $x(0) \in \omega(B)$. The set $\omega(B)$ is the *steady state locus* of (6) and the *restriction* of (6) to $\omega(B)$ is the *steady state behavior* of (6).

The notion introduced in this way recaptures the classical notion of steady state for linear systems and provides a new powerful tool to deal with similar issues in the case of nonlinear systems.

Example In order to see how this notion includes the classical viewpoint, consider an n-dimensional, single-input, *asymptotically stable* linear system

$$\dot{z} = Fz + Gu \tag{7}$$

forced by the harmonic input $u(t) = u_0 \sin(\omega t + \phi_0)$. A simple method to determine the periodic motion of (7) consists in viewing the forcing input $u(t)$ as provided by an autonomous "signal generator" of the form

$$\dot{w} = Sw \qquad u = Qw$$

in which

$$S = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix} \qquad Q = \begin{pmatrix} 1 & 0 \end{pmatrix}$$

and in analyzing the state state behavior of the associated "augmented" system

$$\begin{aligned} \dot{w} &= Sw \\ \dot{z} &= Fz + GQw\,. \end{aligned} \tag{8}$$

As a matter of fact, let Π be the unique solution of the Sylvester equation $\Pi S = F\Pi + GQ$ and observe that the graph of the linear map

$$\begin{aligned} \pi : \mathbb{R}^2 &\to \mathbb{R}^n \\ w &\mapsto \Pi w \end{aligned}$$

is an invariant subspace for the system (8). Since all trajectories of (8) approach this subspace as $t \to \infty$, the limit behavior of (8) is determined by the restriction of its motion to this invariant subspace.

Revisiting this analysis from the viewpoint of the more general notion of steady state introduce above, let $W \subset \mathbb{R}^2$ be a set of the form

$$W = \{w \in \mathbb{R}^2 \colon \|w\| \leq c\} \tag{9}$$

in which c is a fixed number, and suppose the set of initial conditions for (8) is $W \times \mathbb{R}^n$. This is in fact the case when the problem of evaluating the periodic response of (7) to harmonic inputs whose amplitude does not exceed a fixed number c is addressed. The set W is compact and invariant for the upper subsystem of (8) and, as it is easy to check, the ω-limit set of W under the motion of the upper subsystem of (8) is the subset W itself.

The set $W \times \mathbb{R}^n$ is closed and positively invariant for the full system (8) and, moreover, since the lower subsystem of (8) is a linear asymptotically stable system driven by a bounded input, it is immediate to check that the motions of system (8), with initial conditions taken in $W \times \mathbb{R}^n$, are ultimately bounded. As a matter of fact, any bounded set B of the form

$$B = \{(w, z) \in \mathbb{R}^2 \times \mathbb{R}^n : w \in W, \|z - \Pi w\| \le d\}$$

in which d is any positive number, has the property indicated in the definition of ultimate boundedness. It is easy to check that

$$\omega(B) = \{(w, z) \in \mathbb{R}^2 \times \mathbb{R}^n : w \in W, z = \Pi w\} ,$$

i. e. $\omega(B)$ is the graph of the restriction of the map π to the set W. The restriction of (8) to the invariant set $\omega(B)$ characterizes the steady state behavior of (7) under the family of all harmonic inputs of fixed angular frequency ω, and amplitude not exceeding c.

Example A similar result, namely the fact that the *steady state locus* is the *graph* of a map, can be reached if the "signal generator" is any nonlinear system, with initial conditions chosen in a compact invariant set W. More precisely, consider an augmented system of the form

$$\begin{aligned} \dot{w} &= s(w) \\ \dot{z} &= Fz + Gq(w) , \end{aligned} \tag{10}$$

in which $w \in W \subset \mathbb{R}^r$, $x \in \mathbb{R}^n$, and assume that: (i) all eigenvalues of F have negative real part, (ii) the set W is a compact set, invariant for the the upper subsystem of (10).

As in the previous example, the ω-limit set of W under the motion of the upper subsystem of (10) is the subset W itself. Moreover, since the lower subsystem of (10) is a linear asymptotically stable system driven by the bounded input $u(t) = q(w(t, w_0))$, the motions of system (10), with initial conditions taken in $W \times \mathbb{R}^n$, are ultimately bounded.

It is easy to check that the steady state locus of (10) is the graph of the map

$$\begin{aligned} \pi : W &\to \mathbb{R}^n \\ w &\mapsto \pi(w) , \end{aligned}$$

defined by

$$\pi(w) = \lim_{T\to\infty} \int_{-T}^{0} \mathrm{e}^{-F\tau} Gq(w(\tau, w))\,\mathrm{d}\tau . \tag{11}$$

To see why this is the case, pick any initial condition (w_0, z_0) for (10) on the graph of π and compute the solution $z(t)$ of the lower equation of (10) by means of the classical variation of constants formula, to obtain

$$z(t) = \mathrm{e}^{Ft} z_0 + \int_0^t \mathrm{e}^{F(t-\tau)} Gq(w(\tau, w_0))\,\mathrm{d}\tau$$

Since by hypothesis $z_0 = \pi(w_0)$, using (10) one obtains

$$\begin{aligned} z(t) =& \mathrm{e}^{Ft} \int_{-\infty}^{0} \mathrm{e}^{-F\tau} Gq(w(\tau, w_0))\,\mathrm{d}\tau \\ &+ \int_0^t \mathrm{e}^{F(t-\tau)} Gq(w(\tau, w_0))\,\mathrm{d}\tau \\ =& \int_{-\infty}^{t} \mathrm{e}^{F(t-\tau)} Gq(w(\tau, w_0))\,\mathrm{d}\tau \\ =& \int_{-\infty}^{0} \mathrm{e}^{-F\theta} Gq(w(\theta + t, w_0))\,\mathrm{d}\theta \\ =& \int_{-\infty}^{0} \mathrm{e}^{-F\theta} Gq(w(\theta, w(t, w_0)))\,\mathrm{d}\theta \\ =& \pi(w(t, w_0)) = \pi(w(t)) \end{aligned}$$

which proves the invariance of the graph of π for (10). It is deduced from this that that any point of the graph of π is necessarily a point of the steady state locus of (10). To complete the proof of the claim it remains to show that no other point of $W \times \mathbb{R}^n$ can be a point of the steady state locus. But this is a straightforward consequence of the fact that F has eigenvalues with negative real part.

There are various ways in which the result discussed in the previous example can be generalized. For instance, it can be extended to describe the steady state response of a nonlinear system

$$\dot{z} = f(z, u) \tag{12}$$

in the neighborhood of a locally exponentially stable equilibrium point. To this end, suppose that $f(0, 0) = 0$ and that the matrix

$$F = \left[\frac{\partial f}{\partial z}\right](0, 0)$$

has all eigenvalues with negative real part. Then, it is well known (see e. g. p. 275 [13]) that it is always possible to find a compact subset $Z \subset \mathbb{R}^n$, which contains $z = 0$ in its interior and a number $\sigma > 0$ such that, if $\|z_0\| \in Z$ and $\|u(t)\| \le \sigma$ for all $t \ge 0$, the solution of (12) with initial condition $z(0) = z_0$ satisfies $\|z(t)\| \in Z$ for all $t \ge 0$. Suppose that the input u to (12) is produced, as before, by a signal generator of the form

$$\begin{aligned} \dot{w} &= s(w) \\ u &= q(w) \end{aligned} \tag{13}$$

with initial conditions chosen in a compact invariant set W and, moreover, suppose that, $\|q(w)\| \le \sigma$ for all $w \in W$. If this is the case, the set $W \times Z$ is positively invariant for

$$\begin{aligned} \dot{w} &= s(w) \\ \dot{z} &= f(z, q(w)) , \end{aligned} \tag{14}$$

and the motions of the latter are ultimately bounded, with $B = W \times Z$. The set $\omega(B)$ may have a complicated structure but it is possible to show, by means arguments similar to those which are used in the proof of the Center Manifold theorem, that if Z and B are small enough the set in question can still be expressed as the graph of a map $z = \pi(w)$. In particular, the graph in question is precisely the center manifold of (14) at $(0, 0)$ if $s(0) = 0$ and the matrix

$$S = \left[\frac{\partial s}{\partial w}\right](0)$$

has all eigenvalues on the imaginary axis.

A common feature of the examples discussed above is the fact that the steady state locus of a system of the form (14) can be expressed as the graph of a map $z = \pi(w)$. This means that, so long as this is the case, a system of this form has a *unique* well defined *steady state response* to the input $u(t) = q(w(t))$. As a matter of fact, the response in question is precisely $z(t) = \pi(w(t))$. Of course, this may not always be the case and *multiple* steady state responses to a given input may occur. In general, the following property holds.

Lemma 3 *Let W be a compact set, invariant under the flow of (13). Let Z be a closed set and suppose that the motions of (14) with initial conditions in $W \times Z$ are ultimately bounded. Then, the steady state locus of (14) is the graph of a set-valued map defined on the whole of W.*

Necessary Conditions for Output Regulation

Taking advantage of the notions introduced in the previous section, we are now in a position to highlight some general properties that any controller that solves a problem of output regulation must necessarily have. Recall that, as defined earlier, the problem of output regulation is solved if, in the composite system (5):

- the positive orbit of $W \times X \times \Xi$ is bounded,
- $\lim_{t\to\infty} e(t) = 0$, uniformly in the initial condition.

The notions introduced in the previous section are instrumental to prove the following, elementary – but fundamental – result, which is a nonlinear enhancement of a Lemma of [10] on which all the theory of output regulation for linear systems is based.

Lemma 4 *Suppose the positive orbit of $W \times X \times \Xi$ is bounded. Then*

$$\lim_{t\to\infty} e(t) = 0$$

if and only if

$$\omega(W \times X \times \Xi) \subset \{(w, x, \xi) \colon h(w, x) = 0\}. \qquad (15)$$

It is seen from this simple result that the problem of output regulation can be simply cast as the problem of *shaping the steady state locus of the closed loop system*, in such a way that property (15) holds.

To proceed with the analysis in a more concrete fashion, we consider from now on the special case in which the controlled plant (4) is modeled by equations *in normal form*

$$\begin{aligned}
\dot z &= f_0(w, z) + f_1(w, z, e_1)e_1\\
\dot e_1 &= e_2\\
&\vdots\\
\dot e_{r-1} &= e_r\\
\dot e_r &= q(w, z, e_1, \ldots, e_r) + b(w, z, e_1, \ldots, e_r)u\\
e &= e_1\\
y &= col(e_1, \ldots, e_r)\,,
\end{aligned} \qquad (16)$$

with state $(z, e_1, \ldots, e_r) \in \mathbb{R}^{n-r} \times \mathbb{R}^r$, control input $u \in \mathbb{R}$, regulated output $e \in \mathbb{R}$, measured output $y \in \mathbb{R}^r$. The functions $f_0(\cdot)$, $f_1(\cdot)$, $q(\cdot)$, $b(\cdot)$, $s(\cdot)$ in (16) and (3) are assumed to be at least continuously differentiable. It is also assumed that

$$b(w, z, e_1, \ldots, e_r) \neq 0 \qquad \forall (w, z, e_1, \ldots, e_r)\,.$$

The initial conditions of (16) range on a set $Z \times E$, in which Z is a fixed *compact* subset of $\mathbb{R}^{n-r}$ and $E = \{(e_1, \ldots, e_r) \in \mathbb{R}^r \colon |e_i| \leq c\}$, with c a fixed number.

Suppose that a controller of the form (4) solves the problem of output regulation. Then Lemma 4 applies and, since $e = e_1$, we deduce that the steady state locus of the closed loop system (5) is necessarily a subset of the set of all states in which $e_1 = 0$. This being the case, it is seen from the form of the equations (16) that, when the closed loop system (5) is in steady state, necessarily also

$$e_2 = e_3 = \cdots = e_r = 0\,.$$

As a consequence, the following conclusions hold:

- *The steady state locus $\omega(W \times Z \times E \times \Xi)$ of the closed-loop system is a subset of the set $\mathbb{R}^s \times \mathbb{R}^{n-r} \times \{0\} \times \mathbb{R}^\nu$.*
- *The restriction of the closed-loop system to its steady state locus $\omega(W \times Z \times E \times \Xi)$ reduces to*

$$\begin{aligned}
\dot w &= s(w)\\
\dot z &= f_0(w, z)\\
\dot \xi &= \varphi(\xi, 0)\,.
\end{aligned} \qquad (17)$$

- *For each* $(w, z, 0, \ldots, 0, \xi) \in \omega(W \times Z \times E \times \Xi)$

$$0 = q(w, z, 0, \ldots, 0) + b(w, z, 0, \ldots, 0)\gamma(\xi, 0)\,. \quad (18)$$

The prior analysis implicitly assumes that the positive orbit of W under the flow of exosystem is bounded, i. e. that the motions of the exosystem asymptotically approach the its own steady state locus $\omega(W)$. In principle, $\omega(W)$ may differ from W but there is no loss of generality in assuming from the very beginning that the two sets coincide. After all, the problem in question is a problem concerning how the closed-loop system behaves in steady state and there is no special interest in considering exosystems that are not "in steady state". We make this assumption precise as follows.

Assumption (i) *The compact set W is invariant for (3).*

With this in mind we observe that, by Lemma 3, if the positive orbit of $W \times Z \times E \times \Xi$ under the flow of (5) is bounded, then $\omega(W \times Z \times E \times \Xi)$ is the graph of a (possibly set-valued) map defined on the whole of W. Consider now the set

$$\mathcal{A}_{\mathrm{ss}} = \{(w, z)\colon (w, z, 0, \ldots, 0, \xi) \in \omega(W \times Z \times E \times \Xi), \\ \text{for some } \xi \in \mathbb{R}\}$$

and define the map

$$u_{\mathrm{ss}} : \mathcal{A}_{\mathrm{ss}} \to \mathbb{R}$$
$$(w, z) \mapsto -\frac{q(w, z, 0, \ldots, 0)}{b(w, z, 0, \ldots, 0)}\,.$$

By construction, the set $\mathcal{A}_{\mathrm{ss}}$ is the graph of a (possibly set-valued) map defined on the whole of W, which is invariant for the dynamics of

$$\begin{aligned} \dot{w} &= s(w) \\ \dot{z} &= f_0(w, z)\,, \end{aligned} \quad (19)$$

that are precisely *the zero dynamics of the "augmented system"* (3)–(16), while the map $u_{\mathrm{ss}}(\cdot)$ is the control that forces the motion of (3) –(16) to evolve on $\mathcal{A}_{\mathrm{ss}}$.

With this in mind, the conclusions reached above can be rephrased in the following terms. Suppose that a controller of the form (4) solves the problem of output regulation for (16) with exosystem (3). Then, there exists a (possibly set-valued) map defined on the whole of W whose graph $\mathcal{A}_{\mathrm{ss}}$ is invariant for the autonomous system (19). Moreover, for each $(w_0, z_0) \in \mathcal{A}_{\mathrm{ss}}$ there is a point $\xi_0 \in \mathbb{R}^\nu$ such that the integral curve of (19) issued from (w_0, z_0) and the integral curve of

$$\dot{\xi} = \varphi(\xi, 0)$$

issued from ξ_0 satisfy

$$u_{\mathrm{ss}}(w(t), z(t)) = \gamma(\xi(t))\,, \qquad \forall t \in \mathbb{R}\,.$$

This is a nonlinear version of the celebrated *internal model principle* of [11].

Sufficient Conditions for Output Regulation

The Control Structure

On the basis of the ideas presented in the previous section we proceed now with the construction of a controller that solves the problem of output regulation. The "steady state" features of this controller are those identified at the end of the section, namely this controller has to be able to "generate" all controls of the form $u_{\mathrm{ss}}(w(t), z(t))$ for any "steady state" trajectory $w(t), z(t)$ of (19). The controller should incorporate a device that generates all such trajectories (the *internal model*), thus making sure that the "appropriate" state-state behavior takes place, and a device guaranteeing that convergence to this specific steady state behavior occurs. It is here that additional assumptions are needed.

Note that, since W is invariant for $\dot{w} = s(w)$, the closed cylinder

$$C := W \times \mathbb{R}^{n-r}$$

is locally invariant for (19). Hence, it is natural regard (19) as a system defined on C and endow the latter with the subset topology.

Assumption (ii) *There exists a bounded subset B of C which contains the positive orbit of the set W × Z under the flow of (19) and the resulting omega-limit set*

$$\mathcal{A} := \omega(W \times Z)$$

satisfies

$$(w, z) \in C\,, \quad |(w, z)|_{\mathcal{A}} \le d_0 \quad \Rightarrow \quad z \in Z \qquad (20)$$

where d_0 is a positive number.

While in the analysis of the necessity we have only identified the existence of a compact set (actually, the graph of a map defined on W) which is invariant for (19), the new assumption (ii) implies, in its first part, the existence of a compact set $\mathcal{A}$ (still the graph of a map defined on W) which is not only invariant but also uniformly attractive of all trajectories of (19) issued from points of $W \times Z$. The second part of the assumption, in turn, guarantees that this set is also stable in the sense of Lyapunov. In the next assumption we strengthen this property by also requiring the set $\mathcal{A}$ to be locally exponentially stable (this assumption is useful to straighten the subsequent analysis, but is not essential).

Assumption (iii) *There exist $M \geq 1$, $\lambda > 0$ such that*

$$\begin{gathered}(w_0, z_0) \in C\,, \quad |(w_0, z_0)|_{\mathcal{A}} \leq d_0 \quad \Rightarrow \\ |(w(t), z(t))|_{\mathcal{A}} \leq M e^{-\lambda t} |(w_0, z_0)|_{\mathcal{A}}\,, \qquad \forall t \geq 0\end{gathered}$$

in which $(w(t), z(t))$ denotes the solution of (19) passing through (w_0, z_0) at time $t = 0$.

To simplify the exposition, we address the special case in which the controlled system (16) has relative degree 1, and in which the coefficient $b(w, z, e_1)$ is identically equal to 1. In other words, we consider a system modeled by equations of the form

$$\begin{aligned}\dot{z} &= f_0(w, z) + f_1(w, z, e)e \\ \dot{e} &= q(w, z, e) + u \\ y &= e\,.\end{aligned} \tag{21}$$

There is no loss of generality in considering a system having this simple form (21) because, as shown for instance in [9,22], the case of a more general system of the form (16) can easily be reduced, by appropriate manipulations, to this one.

For convenience, rewrite the augmented system (3)–(21) as

$$\begin{aligned}\dot{z} &= f_0(z) + f_1(z, e)e \\ \dot{e} &= q_0(z) + q_1(z, e)e + u\end{aligned} \tag{22}$$

having set $z = (w, z)$. Consistently let $Z := W \times Z$ denote the compact set where the initial condition $z(0)$ is supposed to range. In these notations, assumptions (i) – (ii) - (iii) express the property that, in the autonomous system

$$\dot{z} = f_0(z)\,, \tag{23}$$

the set $\mathcal{A}$ is asymptotically and locally exponentially stable, with a domain of attraction that contains the set Z.

Suppose now that the control u is chosen as $u = -ke$. The closed-loop system thus obtained can be regarded as a feedback interconnection of

$$\dot{z} = f_0(z) + f_1(z, e)e \tag{24}$$

viewed as a system with input e and state z, and

$$\dot{e} = q_0(z) + q_1(z, e)e - ke \tag{25}$$

viewed as a system with input z and state e.

By assumption, system (24) possesses, when $e = 0$, an invariant set $\mathcal{A}$ which is asymptotically and locally exponentially stable, with a domain of attraction that contains the set Z of all admissible initial conditions. Thus, standard arguments (see, e. g [6].) can be invoked to claim that, if k is large enough, all trajectories of the interconnection (24)–(25) with initial conditions in $Z \times E$ remain bounded and the state (z, e) can be steered to an arbitrary small neighborhood of the set $\mathcal{A} \times \{0\}$. This does not solve the problem at issue, though, because the variable $e(t)$ is not guaranteed to converge to zero (but only to converge to a neighborhood of zero, whose size can be made arbitrarily small by increasing the gain coefficient k). The condition for having $e(t) \to 0$ as $t \to \infty$ is simply that the "coupling" term $q_0(z)$ vanishes on the set $\mathcal{A}$, but there is no reason for this to occur (see again, e. g.[6]). This is why a more elaborate, internal-model-based, controller is needed.

System (16) being affine in the control input u, it seems natural to look for a controller having a similar structure, namely a controller of the form

$$\begin{aligned}\dot{\xi} &= \varphi(\xi) + Gv \\ u &= \gamma(\xi) + v\end{aligned} \tag{26}$$

with state $\xi \in \mathbb{R}^\nu$, in which v is a residual control input, to be eventually chosen as a function of the measured output y. Here $\varphi(\cdot)$, G and $\gamma(\cdot)$ are functions to be determined. We will show in what follows that, if the triplet $\{\varphi(\xi), G, \gamma(\xi)\}$ possesses what we will define as *asymptotic internal model* property, the choice of the residual control v in (26) as

$$v = -ke$$

solves the problem of output regulation, provided that the gain coefficient k is sufficiently high.

The Internal Model

Controlling this system by means of (26) yields a closed-loop system

$$\begin{aligned}\dot{z} &= f_0(z) + f_1(z, e)e \\ \dot{e} &= q_0(z) + q_1(z, e)e + \gamma(\xi) + v \\ \dot{\xi} &= \varphi(\xi) + Gv\end{aligned} \tag{27}$$

which, regarded as a system with input v and output e, has relative degree 1 and zero dynamics given by

$$\begin{aligned}\dot{z} &= f_0(z) \\ \dot{\xi} &= \varphi(\xi) - G[\gamma(\xi) + q_0(z)]\,.\end{aligned} \tag{28}$$

System (27) can be put in normal form by means of the change of variables

$$\chi = \xi - Ge$$

which yields

$$\begin{aligned}\dot{z} &= f_0(z) + f_1(z, e)e\\ \dot{\chi} &= \varphi(\chi + Ge) - G\gamma(\chi + Ge) - Gq_0(z) - Gq_1(z, e)e\\ \dot{e} &= q_0(z) + q_1(z, e)e + \gamma(\chi + Ge) + v\,.\end{aligned} \tag{29}$$

Setting $x = (z, \chi)$, this system can be further rewritten in the form

$$\begin{aligned}\dot{x} &= f(x) + \ell(x, e)e\\ \dot{e} &= q(x) + r(x, e)e + v\end{aligned} \tag{30}$$

in which

$$f(x) = \begin{pmatrix} f_0(z) \\ \varphi(x) - G[\gamma(x) + q_0(z)] \end{pmatrix}$$

$$q(x) = q_0(z) + \gamma(x)$$

and $\ell(x, e)$, $r(x, e)$ are suitable continuous functions.

Suppose now that the residual control v is chosen as $v = -ke$. This yields a closed-loop system having a structure similar to the one considered in the previous subsection, namely a feedback interconnection of

$$\dot{x} = f(x) + \ell(x, e)e \tag{31}$$

viewed as a system with input e and state x, and

$$\dot{e} = q(x) + r(x, e)e - ke \tag{32}$$

viewed as a system with input x and state e. As claimed earlier, a high-gain control on e, namely a control $v = -ke$ with large k, would succeed in steering $e(t)$ to zero if two conditions are fulfilled:

(P1) the dynamics (28) possesses a compact invariant set which is asymptotically (and locally exponentially) stable, with a domain of attraction that contains the set $Z \times \Xi$ of all admissible initial conditions, and

(P2) the function $q_0(z) + \gamma(\xi)$ vanishes on this invariant set.

These are the properties that will be sought in what follows. Note that the fulfillment of these is determined only by properties of the autonomous system (23) and of the function

$$\rho = q_0(z) \tag{33}$$

which, in the composite system (28), can be viewed as the output of (23) driving a system of the form

$$\dot{\xi} = \varphi(\xi) - G[\gamma(\xi) + \rho]\,. \tag{34}$$

For convenience, we will say that triplet $\{\varphi(\xi), G, \gamma(\xi)\}$ *is an asymptotic internal model of the pair* (23) – (33) if properties (P1) and (P2) are satisfied. In this terminology, we can summarize as follows the conclusion obtained so far.

Proposition 1 *Pick compact sets Z, E and Ξ for the initial conditions of the closed-loop system (3), (21), (26). Assume that (i)-(ii)-(iii) hold and that the triplet $\{\varphi(\xi), G, \gamma(\xi)\}$ is an asymptotic internal model of (23) – (33). Then there exists $k^\star > 0$ such that for all $k \geq k^\star$ the controller (26) with $v = -ke$ solves the generalized tracking problem.*

The notion of steady state provides a useful interpretation of the properties in question. In fact, recall that, by assumption, all trajectories of system (23) with initial conditions in Z asymptotically converge to the compact invariant set $\mathcal{A}$, and the latter is also locally exponentially stable. If property (P1) holds, all trajectories of the composite system (28) with initial conditions in $Z \times \Xi$ asymptotically converge to the limit set $\omega(Z \times \Xi)$. Since (28) is a triangular system, it is readily seen that the set $\omega(Z \times \Xi)$ is the graph of a set-valued map defined on $\mathcal{A}$, i. e. that there exists a map

$$\tau : z \in \mathcal{A} \mapsto \tau(z) \subset \mathbb{R}^\nu\,,$$

such that

$$\omega(Z \times \Xi) = \{(z, \xi) \colon z \in \mathcal{A}, \xi \in \tau(z)\} \colon = \mathrm{gr}(\tau)\,.$$

The set $\mathrm{gr}(\tau)$ is the steady state locus of (28) and the restriction of the latter to this invariant set characterizes its steady state behavior. Property (P2), on the other hand, expresses the property that at each point of $(z, \xi) \in \mathrm{gr}(\tau)$

$$q_0(z) = -\gamma(\xi)\,. \tag{35}$$

Thus, looking again at system (28), it is realized that $\mathrm{gr}(\tau)$ is in fact invariant for

$$\begin{aligned}\dot{z} &= f_0(z)\\ \dot{\xi} &= \varphi(\xi)\,.\end{aligned} \tag{36}$$

Note that, if the map $\tau(z)$ is single-valued and C^1, its invariance for (36) is expressed by the property that

$$\frac{\partial \tau(z)}{\partial z} f_0(z) = \varphi(\tau(z)) \qquad \forall\, z \in \mathcal{A}\,, \tag{37}$$

while the fact that (35) holds at each point of $(z, \xi) \in \mathrm{gr}(\tau)$ is expressed by the property that

$$q_0(z) = -\gamma(\tau(z)) \qquad \forall\, z \in \mathcal{A}\,. \tag{38}$$

The Design of an Internal Model

As we have seen in the earlier sections, the proposed controller, if the asymptotic internal model property holds, is able to force – in the closed loop system – convergence to a steady state in which the regulated variable is identically zero. As a consequence, the controller solves the generalized tracking problem. It remains to be shown, therefore, how the asymptotic internal model property can be obtained. To this end, it is convenient to observe that the properties required in (P1) and (P2) are quite similar to properties that are usually sought in the design of *state observers*. As a matter of fact it is seen from (37) and (38) that, for each $z_0 \in \mathcal{A}$, the function of time

$$\hat{\xi}(t) = \tau(z(t, z_0))$$

which is defined (and bounded) for all $t \in \mathbb{R}$ satisfies

$$\frac{\mathrm{d}\hat{\xi}(t)}{\mathrm{d}t} = \varphi(\hat{\xi}(t)) \tag{39}$$

and, moreover

$$\gamma(\hat{\xi}(t)) = -q_0(z(t, z_0)) \,.$$

In view of the latter, system (34) can be rewritten in the form

$$\dot{\xi} = \varphi(\xi) + G[\gamma(\hat{\xi}) - \gamma(\xi)] \tag{40}$$

and interpreted as *a copy of the dynamics* (39) *of* $\hat{\xi}$ *corrected by an "innovation term"* $[\gamma(\hat{\xi}) - \gamma(\xi)]$ *weighted by an "output injection gain"* G. This is the classical structure on an *observer* and the requirement in (P1) expresses the property that the difference $\xi(t) - \hat{\xi}(t)$ (the "observation error", in our interpretation) should asymptotically decay to zero (with ultimate exponential decay).

This interpretation is at the basis of a number of major recent advances in the design of regulators. In fact, in a number of recent papers, this interpretation has been pursued and, taking into consideration various approaches to the design of nonlinear observers, has lead to effective design methods (see [5,9,22]). Two of such design methods are highlighted in the remaining part of this section.

The High-Gain Observer as an Internal Model (see [5])

The construction summarized in this section relies upon the following additional hypothesis.

Assumption (iv) *Suppose there exist an integer $d > 0$ and a locally Lipschitz function $f\colon \mathbb{R}^d \to \mathbb{R}$ such that, for any $z_0 \in \mathcal{A}$, the solution $z(t)$ of passing through z_0 at time $t = 0$ is such that the function $\rho(t) := q_0(z(t))$ satisfies*

$$\rho^{(d)}(t) = f(\rho(t), \rho^{(1)}(t), \ldots, \rho^{(d-1)}(t))$$

for all $t \in \mathbb{R}$.

Let $\tau\colon W \times \mathbb{R}^{n-1} \to \mathbb{R}^d$ be the map defined as

$$\tau(z) := \mathrm{col}(q_0(z), L_{f_0} q_0(z), \ldots, L_{f_0}^{d-1} q_0(z)) \tag{41}$$

and let $f_c\colon \mathbb{R}^d \to \mathbb{R}$ be a C^1 function with compact support which agrees with $f(\cdot)$ on $\tau(\mathcal{A})$. Then, it easy to check that the properties indicated in (37) and (38) are fulfilled by choosing

$$\varphi(\xi) = \begin{pmatrix} \xi_2 \\ \vdots \\ \xi_d \\ f_c(\xi_1, \xi_2, \ldots, \xi_d) \end{pmatrix}, \qquad \gamma(\xi) = \xi_1 \,. \tag{42}$$

Comparing this construction with the earlier remarks we observe, in particular, that system

$$\begin{aligned} \dot{z} &= f_0(z) \\ \rho &= q_0(z) \end{aligned} \tag{43}$$

is *immersed into a system which is uniformly observable*, in the sense of [12] (even though system (43) might not have had such a property). It is precisely this that makes it possible to choose G in such a way that the property indicated in (P1) can be achieved.

As a matter of fact, the property in question is achieved by choosing

$$G = D_g \begin{pmatrix} c_0 \\ \vdots \\ c_{d-1} \end{pmatrix}$$

where $D_g = diag(g, g^2, \cdots, g^d)$, g is a design parameter, and the c_i's are such that the polynomial $\lambda^d + c_0\lambda^{d-1} + \cdots + c_{d-1} = 0$ is Hurwitz, as formally proved in Lemmas 1 and 2 of [5] to which the interested reader is referred for details.

It is worth noting that the assumption in question clearly covers the interesting (and widely addressed in the recent past literature, see [15]) case in which the function $f(\cdot)$ is linear, namely the case in which (43) is immersed into a linear observable system. In this case, although the choice indicated above is clearly still valid, a more direct way of designing the regulator is to use $f(\cdot)$ instead of $f_c(\cdot)$ in the definition of $\varphi(\xi)$, and simply choose G in such a way that $\dot{\xi} = \varphi(\xi) - G\gamma(\xi)$ is a stable linear system.

The Andrieu-Praly's Observer as an Internal Model (see [22]) In this subsection we exploit certain results of the theory presented in [1] to weaken (and, to some extent, suppress) the Assumption (iv) presented at the beginning of the earlier subsection.

Let $(F, G) \in \mathbb{R}^{d \times d} \times \mathbb{R}^{d \times 1}$ be a controllable pair and set

$$\varphi(\xi) = F\xi + G\gamma(\xi), \tag{44}$$

with $\gamma\colon \mathbb{R}^d \to \mathbb{R}$ a continuous function to be determined later. If this is the case, the composite system (28) becomes

$$\begin{aligned} \dot{z} &= f_0(z) \\ \dot{\xi} &= F\xi - Gq_0(z)\,, \end{aligned} \tag{45}$$

which is precisely a system of the form (9), considered in the Example. If the matrix F is Hurwitz, and we restrict z to belong to the set $\mathcal{A}$, this system has a well defined steady state behavior, which is the graph of the map

$$\tau(z) = \int_{-\infty}^{0} \mathrm{e}^{-Fs} G q_0(z(s,z))\mathrm{d}s\,. \tag{46}$$

As shown in Example, the graph in question is invariant for system (45), is asymptotically (and locally exponentially) stable and with a domain of attraction that coincides with $W \times \mathbb{R}^d$. Moreover, it can also be shown that there exists a number $\ell > 0$ such that, if the eigenvalues of F have real part which is less ℓ, the map (46) is C^1 (see, e. g. [22]). If this is the case, to say that the graph of (46) is invariant for (45) is equivalent to say that

$$\frac{\partial \tau}{\partial z} f_0(z) = F\tau(z) - Gq_0(z) \qquad \forall\, z \in \mathcal{A}\,. \tag{47}$$

This being the case, it is immediate to check that properties (P1) and (P2) will be fulfilled if a function $\gamma(\xi)$ can be found that renders (38) satisfied. As a matter of fact, bearing in mind (44), condition (37) becomes

$$\frac{\partial \tau}{\partial z} f_0(z) = F\tau(z) - G\gamma(\tau(z)) \qquad \forall\, z \in \mathcal{A}$$

which, if condition (38) holds, reduces to (47). This, shows that a triplet having the asymptotic internal model property can be found if a function $\gamma(\cdot)$ exists which satisfies (38). It is here that the dimension d of the pair (F, G) plays a role, as formalized in the next proposition whose proof can be found in [22].

Proposition 2 *Suppose*

$$d \geq 2(s + n - r) + 2\,.$$

Then for almost all choices (see [22] for details) of a controllable pair (F, G), with F a Hurwitz matrix whose eigenvalues have real part which is less than ℓ, the map (46) satisfies

$$\tau(z_1) = \tau(z_2) \quad \Rightarrow \quad q_0(z_1) = q_0(z_2)\,.$$

As a consequence there exist a continuous map $\gamma\colon \tau(\mathcal{A}) \to \mathbb{R}$ such that

$$q_0(z) = -\gamma(\tau(z)) \qquad \forall\, z \in \mathcal{A}\,. \tag{48}$$

The map $\tau(\cdot)$ in (46) is defined only on $\mathcal{A}$, but is not difficult to extend it to a C^1 map defined on the whole set $W \times \mathbb{R}^{n-r}$, as shown in [22]. Also the map $\gamma(\cdot)$ that makes (48) true can be extended to the whole $\mathbb{R}^d$, but this extension is only known to be continuous.

We have shown in this way that the existence of triplet $\psi(\xi), G, \gamma(\xi)$ which has the internal model property can always be achieved, so long as the integer d is large enough. This result shows that the general design procedure outlined earlier in the article is always applicable (so long as the standing hypotheses (i)–(ii)–(iii) are applicable). From the constructive viewpoint, though, it must be observed that the result indicated in Proposition PR1 is only an existence result and that the function $\gamma(\xi)$, whose existence is guaranteed, is only known to be continuous. Obtaining continuous differentiability of such $\gamma(\xi)$ and a constructive procedure are likely to require further hypotheses, which should be in any case weaker than Assumption (iv) considered earlier, whose study is subject of current investigation.

Future Directions

One of the basic hypotheses of the theory described in the previous sections is that the zero dynamics of the augmented system consisting of the controlled plant and of the exosystem possess a compact attractor which is also locally asymptotically stable. This assumption, with an acceptable abuse of terminology, is usually referred to as the "minimum-phase" property. Another standing hypothesis is that the regulated variable coincides with the measured variable. The future directions of the research in this area are aimed at the removal of these assumptions. There are several directions in which the problem can be tackled. One way is the use of control structures by means of which the controlled system (plus a part of the controller) can be interpreted with systems having a different zero dynamics (in particular a zero dynamics possessing a compact attractor). This is the nonlinear equivalent of certain design procedures for linear systems based on the assignment of zeros. This technique has proven to be powerful in the stabilization of certain classes of nonlinear systems (see [18]) and is expected to be successful, with appropriate enhancements, in the design of regulators. The analysis of the necessary conditions for output regulation has also shown that, if the generalized tracking problem is solvable, the inverse dynamics of the augmented system consisting of the controlled plant and of the exosystem possesses a compact invariant set to which all initial conditions are asymptotically controllable (by means of the regulated variable viewed as a control). This set is not necessarily asymptotically stable (as it would be under the "minimum-phase" hypothesis) but could be asymptotically stabilizable (by either full-state or measurement-based feedback). Thus, another direction in which the research will evolve, in the development of control schemes for possibly non "minimum-phase" nonlinear systems, is based on the exploitation of the (weaker) assumption that in the zero dynamics of the augmented system there is a compact set that can be made invariant and asymptotically stable by means of feedback. This will yield a design procedure in which a virtual control (either full-state or measurements-based) is designed to stabilize that compact invariant set. The (possibly dynamic) controller obtained in this way will then be embedded into a regulator designed according to the principles developed in this article.

Article Outline

Glossary

Complex disease A disease that has an etiology inconsistent with the simple models of genetic inheritance proposed by Gregor Mendel. A synonym for "complex disease" is "non-Mendelian disease." Type 2 diabetes is an example of a complex disease, as are most common diseases. The term "complex phenotype" is employed analogously to describe non-disease properties of individuals, such as height. Typically, complex diseases are influenced by multiple genetic and environmental factors. For most diseases, little is known about either of these sets of factors.

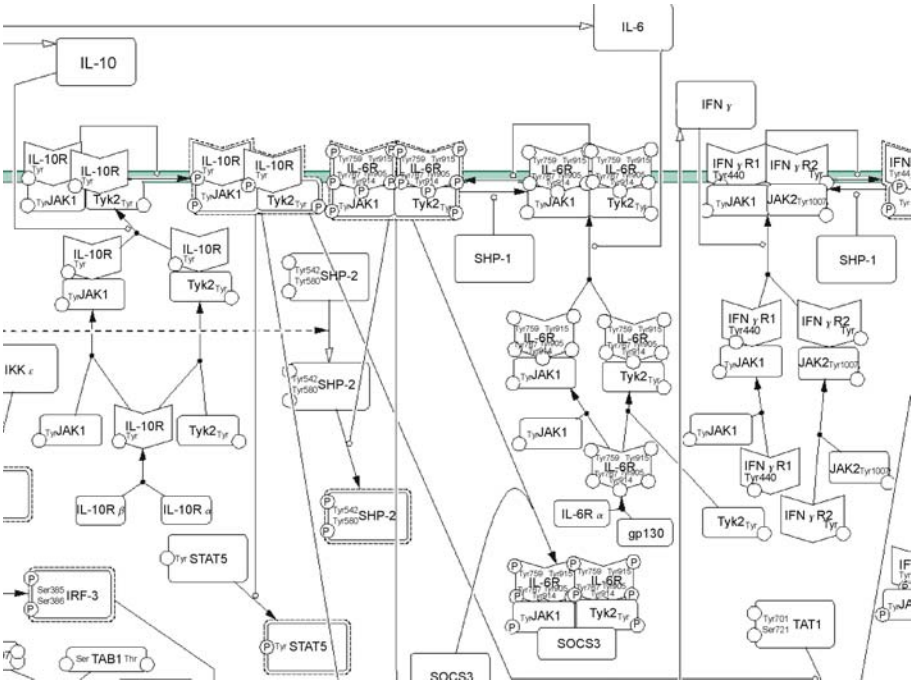
Nuclear regulation Many signals are integrated and processed on segments of DNA that are near or adjacent to genes. These segments of DNA are called cis-regulatory elements. Proteins that bind cis-regulatory elements are called transcription factors. The informational output of cis-regulatory signal integration is the rate of production of messenger RNA (mRNA) encoded by that gene. A major goal for many human systems biology projects is to understand key nuclear regulatory networks.

Regulatory network A paradigm for modeling information flow within a biological system, such as a cell. Elements of the system that can have multiple states are encoded as nodes; modes of communication between these elements are encoded as edges. A typical node would be a protein that might have multiple states related to its level of phosphorylation or cellular location. A typical edge would represent the catalytic effect of one protein upon another's state of phosphorylation.

Signaling pathway Signals typically reach cells through the binding of molecules to receptors on the cell surface. Over the course of seconds to minutes, the receptor interacts with other proteins or small molecules, changing their structure, concentration, or intracellular location. These changes can in turn cause other changes. One common ultimate effect is an alteration in transcription factor binding to target genes, in turn causing a change in mRNA levels. The term "signaling pathway" pre-dates modern systems biology, and represents a paradigm for information flow that is largely unidirectional and linear. Systems biology replaces this paradigm with that of a "regulatory network."

Definition of the Subject

Systems biology is the derivation of emergent properties of a multicomponent biological system through the construction of quantitative predictive models. These predictive models are typically formulated as networks. A portion of such a model is shown in Fig. 1. Human systems biology is the practice of systems biology to elucidate emergent properties of humans or any subcomponent of the human body, such as a cell. Human systems present challenges and opportunities not found in other organisms.



Systems Biology of Human Immunity and Disease, Figure 1

Example of a portion of a network model of a macrophage signaling network. This network was drafted with aid of CellDesigner software [34], and is reproduced with permission of The Systems Biology Institute (period)

Most problems in human systems biology are motivated by a desire to understand, predict, prevent, ameliorate, or cure a human disease. The human immune system is a mediator for most human diseases, and is the key system mediating autoimmune and infectious diseases. Many problems in human systems biology focus on the immune system.

As defined, human systems biology is a subset of systems biology. The subject merits special consideration largely because of medical importance. The human subset of systems biology is not an exceptionally distinct subset compared to other reasonable subsets, such as mammalian systems biology. However, it is fairly distinct from systems biology as applied to unicellular and invertebrate organisms.

Introduction

The difference between human systems biology and the practice of systems biology in other organisms is one of philosophy and emphasis [1]. The need to improve human health drives human systems biology. The emphasis of general systems biology is the development of technological, methodological, and algorithmic approaches to science. Human systems biology exploits these developments, but tends to be more focused on clinical endpoints. It is acceptable to approach these endpoints with incomplete, partial, hybrid, or modified versions of systems biology. Because these approaches include elements of systems biology, such as the analysis of high-throughput data, they are labeled as systems biology, even though they may not include all elements standard to general systems biology, such as the use of multiple orthologous data sets [5].

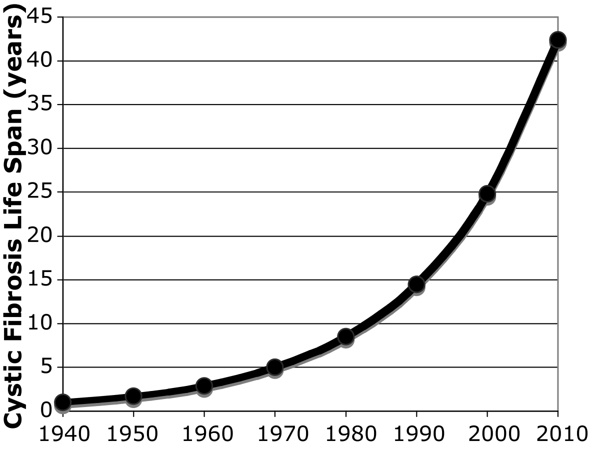
The needs of modern medicine set the context for human systems biology. From a data-driven point of view, there have been three major epochs of medicine: (1) observational medicine, (2) evidence-based medicine, and (3) predictive and personalized medicine [51]. These categories overlap to some extent, but they correspond fairly well to distinct periods of time. Observational medicine was prevalent from the dawn of civilization until early in the twentieth century. It is characterized by personal experience and oral tradition. An example and highlight of observational medicine was the discovery of digitalis as a treatment for dropsy, now known as edema. The discovery is credited in 1776 to William Withering, an English doctor who lived outside of London. Dr. Withering noticed that a patient with dropsy had been cured by a folk practitioner using a preparation from the foxglove plant. It is likely that this discovery had been made many times prior to the mid-eighteenth century, but lack of organized methods for communication and data handling kept the knowledge fragmented and incomplete. Dr. Withering was rich and connected. He was a member of the Lunar Society, a group of scientists founded by Matthew Boulton and Erasmus Darwin, the grandfather of Charles. These connections, foreshadowing those available to modern scientists through the internet, enabled the knowledge of foxglove to be preserved, distributed, and improved.

By the early twentieth century, incremental improvements to medical knowledge became increasingly common, and evidence-based medicine flourished. Advancements were enabled primarily by: (1) advances in communication, such as inexpensive publishing by printing presses, (2) chemistry, permitting the purification of active ingredients from botanical medicines, and (3) the nascent field of statistics. Statistics enabled legitimacy and falsifiability of medical facts. The first major application of statistics to medicine was the work of John Snow in 1843 to correlate water sources with cholera outbreaks. This correlation, and many others since, enabled preventive medicine. Chemistry, and later other fields of science and engineering, enabled reductionism. For example, reductionism enabled the identification of digitalis as the component of foxglove responsible for its effects on the cardiovascular system. The culmination of evidence-based medicine was the Framingham Heart Study circa 1948. Thousands of people from the town of Framingham and their descendants were observed longitudinally. Many health parameters were recorded. The Framingham study provided much of our modern knowledge concerning heart disease risk, including effects of diet, exercise, and aspirin. The Framingham Heart Study gave birth to the term "risk factor" and bolstered the recognition of prevention as the most cost-effective form of medicine. Prior to preventive medicine as a philosophy, a heart attack would be viewed as the beginning of a relationship between patient and doctor. With preventive medicine, the relationship would begin at birth or even before, and focus on modifying risk factors to prevent an attack from ever occurring. Data processing and analysis for such studies became increasingly sophisticated and required computers. Progress in evidence-based medicine was linked to the simultaneous revolution in computational power. In particular, the Framingham Heart Study benefited from scientific and sociological momentum generated in Word War II. Operations Research was largely born in the Battle of the Atlantic. The US population was willing to participate in large studies with society as the primary beneficiary. Command-and-control bureaucracies existed to coordinate large projects. Projects requiring the collaboration of hundreds of medical professionals were favorably viewed by researchers and their funding agencies.

By the end of the Human Genome Project at the beginning of the twenty-first century, limitations of the previous century's approach to evidence-based medicine were beginning to be recognized and solutions to these limitations were envisioned. Statistics, exemplified by linear regression models and chi-squared tests, required increasingly large cohorts to identify weaker risk factors. Knowledge gained from large cohorts was applicable only to populations (such as "all white males") and not individuals (such as the person reading this article). Studies became very expensive and could take decades or even centuries to elucidate correlations between causes and effects. The stage was set for the era of predictive and personalized medicine. A major approach to developing knowledge for this era of data-driven medicine has been and will be human systems biology.

In 1892, William Osler observed, "If it were not for the great variability among individuals medicine might be a science, not an art." Historically, the art of medicine was to personalize by trial and error. In the absence of personalization, a patient was prescribed a treatment based on population-based statistics. This is still the norm. If the treatment fails, the next best treatment from a population-inferred list will be prescribed. This process will repeat until the patient or doctor tires of it or dies, money becomes limiting, or effective treatment is achieved. Personalized medicine aims to match the best treatment for an individual without such perilous trial-and-error—and to turn Dr. Osler's art into a science. Previously, data for personalized models was based on orally conveyed family history, together gender and a crude estimate of genetic heritage, or race. Such personalization was tailored to subpopulations of people. 21st-century personalized medicine will develop predictions from an individual's genes and personal developmental and exposure history. Interventions will be tailored to that individual, not to a subpopulation to which the individual belongs. Systems-biology research creates the data and knowledge required by this approach. In particular, models are created based on the understanding of molecular mechanisms. Emergent properties arise from holistic analysis of the interactions in the modeled system. Each individual can be modeled based on their genetic risks, environmental exposures and their responses, biomarkers, and health assessments. Recommendations for particular medications, doses, interventions, and lifestyle changes will be personalized [12].

Expectations for modern research may be portrayed very highly in the popular press, with hopes for miracle cures. These may arise, but the most profound changes in medicine will most likely come from steady incremental advances. Research in all epochs of medicine has produced incremental advances. Cumulatively, these advances have enabled vast gains in human health (Fig. 2). Future incremental advances are expected throughout the epoch of personalized and preventive medicine begins.



Systems Biology of Human Immunity and Disease, Figure 2
Exponential rise in expected life span for cystic fibrosis. A fairly low exponent, 5.5% in this case, can lead to dramatic advances in human health over time. The goals of human systems biology are to drive such exponential advances

The phrase "systems biology" was first used early in the twentieth century to describe analyses of ecosystems, but the phrase never became popular until the turn of 21st century with the establishment of several institutes and research groups focused on systems-biology research and using the term "systems biology" to describe that research. The timing of this surge in interest was almost entirely due to the completion of the Human Genome Project and the need to develop research methodologies appropriate for the post-genomic era. The complete genome sequence provided a near-comprehensive "parts list" of genes. Coinciding approximately with the Human Genome Project, high-throughput technologies for measuring other important parts of human systems were developed, including technologies for measuring proteins and transcripts [18]. Neologisms with the suffix "omics" describing these new fields of analysis have become popular, including "proteomics" and "transcriptomics." Other factors driving modern systems biology have been (1) the tremendous boost to human collaboration and information sharing provided by the internet and (2) the conceptualization of biology as an information science. The digital nature of the genome has led to a belief that all of the individual components and interactions of biological systems are ultimately knowable, can be represented in data structures, and are amenable to computational analysis. The elucidation of the digital genome is a triumph of reductionism that has energized the pursuit of emergent properties. In the near future, complete sequences of the genomes of many humans will be known, further facilitating correlations between genotype and phenotype.

Modern systems biology focuses on systems at the cellular or subcellular level because systems of these complexities are considered to be neither too trivial to study nor too complex to comprehend. Some systems biology projects involve systems that are either more or less complex. In particular, human systems biology tends to focus on larger, more complex systems. For most problems of medical interest, it is generally anticipated that clinically useful predictions will require modeling at the multi-cellular level or at the level of the entire organism. The need to focus on very complex systems and to make clinically useful predictions underlies fundamental differences between the conduct of systems biology in humans and in other organisms.

There are tens of thousands of genes, small molecules, and proteins in a typical cellular system. Properties of these components and of the entire system need to be studied under many different conditions and dynamically over time periods ranging from seconds to years. There are several important generalizations that can be made about the techniques required to study such systems. Systems biology requires: (1) the analysis of high-throughput data sets, (2) the analysis of multiple qualitatively distinct different types of data ("orthologous data"), (3) a multidisciplinary collaborative team capable of both data generation ("bench work") and data analysis ("computational biology"). Also, because systems biology makes predictions, its practice is necessarily iterative: a model is built, predictions are tested, discrepancies between predictions and measurements are used to refine the model, predictions of the new model are tested, and so on until the incremental utility of the model refinements becomes small [47].

The application of the above approach to science is not new; it is merely new to biology. Other disciplines have used collaborative research employing multiple high-throughput data sources to produce models and emergent predictions. For example, in meteorology, a daily weather report is a simple prediction derived from such a process. One of the utilities of the phrase "systems biology" is that it brings attention to the methodological differences between this approach and the more prevalent reductionist approaches in biology during the twentieth century. The coining of the phrase thus helps catalyze a sociological change in biology.

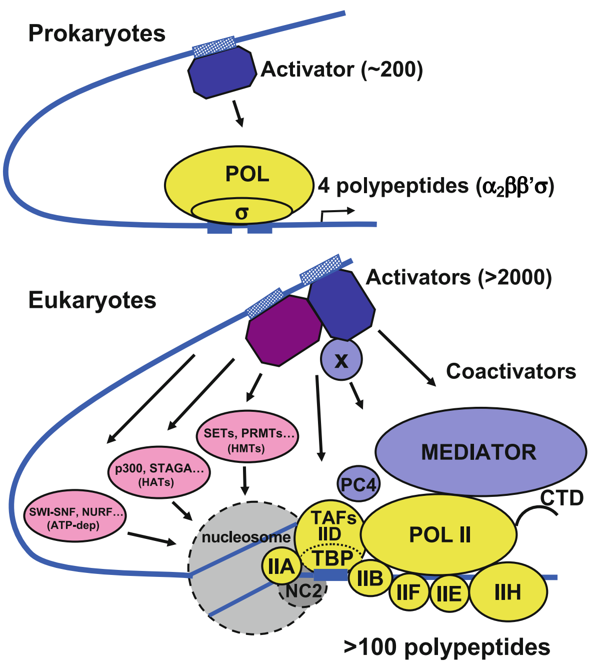
A number of disciplines that might semantically be considered to fit the definition of systems biology are not usually implied by users of the phrase because these disciplines were well established prior to the completion of the Human Genome Project. These include ecology, physiology, and biochemistry. In these fields, research may involve formulation of hypotheses as networks, and prediction of emergent properties of multicomponent systems [26].

Challenges and Solutions for Human Systems Biology

Human systems biology requires asking questions that are distinct from typical questions asked of prokaryotic systems. These distinct questions require distinct methodologies to answer [30].

There are many challenges for human systems biology. Underlying network models are far more complex than those of prokaryotes [43]. There are more components, or network nodes, of nearly every type. For example, there are more genes, as discussed in the accompanying chapter on genome complexity. Each gene has more cis-regulatory elements. On average, any given gene has more functions and products. These products are primarily mRNAs. On average, any given mRNA has more functions and products. These products are primarily proteins. Eukaryotic cells have more cellular compartments, including mitochondria, lysomomes, phagosomes, a nucleus, endoplasmic reticulum, and secretory granules. Humans have many more cells, and more cell types, and they are organized into different tissues [6]. Furthermore, there is no guarantee that insights gained from one human tissue will be easily extrapolatable to other human tissues; the same protein may play a very different role. In addition to many more nodes in human networks, there are many more interactions. In particular, the number and complexity of interactions operating on cis-regulatory elements of eukaryotic genes is greater (Fig. 3) [42,48].

Not only are human systems much more complex than other systems, but it is much harder to acquire data from these systems. Many experiments possible in other organisms are impossible in humans due to ethical concerns. Such concerns prevent the intentional creation of humans with identical genomes. Humans have very long life spans that essentially rule out acquiring data over the life span of particular individuals, particularly for systems biology, which requires iteration. Projects that might take weeks in a prokaryotic context would take many centuries if the experimental strategies were directly applied to human problems. The cost of performing experiments on human



Systems Biology of Human Immunity and Disease, Figure 3
Eukaryotic versus prokaryotic cis-regulation. The number of factors involved in regulating expression of a eukaryotic gene is at least an order of magnitude greater than for a prokaryotic gene. The complexity of the interactions is also greater. Reprinted from [42]

systems also tends to be much higher than in other systems.

As a consequence of the difficulty of research in mammals, whether that research is reductionist or holistic, on average for any given node or edge of a human network there is less prior information available than there would be for a simple model organism. In many cases, a literature or database search for information pertaining to a human gene will yield either no information or information restricted to a few cell types under only a few conditions [11]. For example, the target genes and sequences of most human transcription factors are completely unknown, leading to substantial uncertainties in models of human nuclear regulatory networks.

There are many solutions to these challenges. Some solutions remain visionary or require technologies that are in development, such as the ability to sequence an individuals genome for less than $1,000. If the sole goal of human research was knowledge for the sake of knowledge, then the most economically efficient approach to most human systems biology problems would be to wait for these technologies to be fully developed before applying them directly to disease research. However, medicine carries a personal urgency not found in most other areas of research. Delays in research can be measured in human life and well being. So in addition to investing in technology and methodology, human systems biology must work with the tools at hand.

Because so much less is known about the basic elements of human systems, a continued focus on the individual nodes and edges is important. Human systems biology projects do not displace traditional reductionist biology projects, but rather rely on them. A key fundamental question to be asked of all possible nodes in a network is that of membership: "Does this node belong in the network?" The same question can be asked of each possible edge. The various qualities of the network components also need to be determined. These include directionality of directed edges and rate constants for parts of the network modeled dynamically. If the most important nodes and edges in a network can be determined, future reductionist research can be appropriately directed to expand information on these network components. The complexity of human systems, the difficulty of automatically parsing the literature, and the high false positive rate in many human high-throughput data sets demands increased expert curation at all steps in the process. The sheer volume of the data makes such a call for human curation seemingly futile, but currently without such curation, most models will not make useful medical predictions. Appropriately directed projects will employ automated tools to reduce the burden of curation. For this purpose some of the most useful tools will be interfaces that present curators with information in forms that are easy to comprehend and integrate manually and that also permit decisions and rationales to be quickly recorded. The visual computer interfaces imagined for the 2002 science fiction movie "Minority Report" serve to stimulate ideas of what such interfaces might become.

Human systems biologists must also model simpler, or smaller, networks than would be appropriate for a simple model organism. Although somewhat paradoxical, this need arises from the intense need for data curation and the difficulty of acquiring high-quality data. The more complex the systems, the greater the number of free parameters. For larger networks, the lack of experimental data prevents these parameters from being constrained, and so no statistical confidence can be placed in predictions. Therefore, a reasonable approach for building a predictive network in a human system is to start very small. In some cases, networks with as few as two nodes and a single connecting edge can form a reasonable nucleus for the iterative process of building a systems biology network. Although such a network would be too trivial to discuss in a prokaryotic setting, it might be capable of making a clinically useful prediction and so would merit consideration in a human disease setting.

One possible approach to reducing the network complexity is to focus on only a few key nodes. Another is to model systems at grosser levels [9]. Thus rather than representing each protein as a node, one might group a set of proteins as a conceptual "module," and only represent the module as a node in the network. However, this approach requires exceptional care and curation, as it becomes hard to define and even harder to measure quantitative properties of modules [30]. One approach to developing hypotheses related to the functionality of modules is to perform comparative network analysis between different vertebrates [8]. Such analysis requires at least a moderate understanding of a network in at least two systems, which is currently rare, but may become more available over the next few decades.

It is easy for researchers to be distracted by the vast quantity of high-throughput data available, and to yield to reporting analyzes that are the result of automated in silico predictions of algorithms that often cannot be tested against gold standards. Human curation is often viewed as subjective, as it is hard to provide numerical statistics associated with such curation. Numerical statistics, on the other hand, are fairly easy to provide with output from automated algorithms, and these outputs are considered objective. From a medical point of view, however, the criterion of utility must trump evaluation of research based on simple ratio of subjectivity to objectivity. Medical objectivity must be evaluated at a deeper level of objectivity: quantitative measures of improved health care. Frequently, the output of automated algorithms is indeed objective, but is also nonsense. Examples of such nonsense are often manifested as very large networks consisting of hundreds or thousands of nodes and edges. Such networks are said to resemble hairballs and have been termed "ridiculomes." These networks have little if any predictive capability [32]. A weather report, as published in a daily newspaper, offers an example of a prediction in a useful form. Systems biology predictions should aim to be more like weather reports and less like hairballs.

Despite the large number of obstacles facing human research, there are a few paths to knowledge that work very well in humans. These derive largely from the ability of human research subjects to intellectually contribute to a research project. This is especially true for phenotypes of higher cognitive function. The most successful examples of human-specific research projects are family and genome-wide association studies. Volunteers with specific phenotypes bring themselves to the attention of researchers, permitting the genetic difference between affected and unaffected individuals to be determined. This is the most powerful and productive method that human systems biologists currently have for identifying the genes that are key nodes in human disease systems.

Given the fairly large number of differences in the state of knowledge and in the constraints on how research might be performed, the genre of questions asked by human systems biologists differs markedly from questions asked in other systems. Whereas design of a synthetic microorganism from the ground up might be a reasonable experimental agenda for a microbial biofuel project, other questions are more natural in human medicine.

Human-Specific Problems

It became fairly clear by the height of the era of evidence-based medicine that prevention has the highest ratio of benefit versus cost to society. Prevention is most effective when coupled to prediction. Interventions have risks and costs, so should be targeted to those predicted to have sufficient risk to benefit from a preventive intervention. Therefore a major goal of systems biology is to develop personalized predictive risk assessments. These risk assessments can be absolute (e. g., an individual's risk at the time of birth or at the time of a clinic visit) or conditional (e. g., risk if the individual stopped smoking). The types of outcomes that are useful to predict for an individual include whether or not a vaccination is protective, and whether a disease might occur and when it is likely to do so. A particular world health challenge today is the unpredictability of the effectiveness of the BCG vaccine for tuberculosis. Individuals who receive the vaccine have little way of knowing whether or not they will develop protective immunity [3]. The identification of biomarkers enabling such a prediction would be useful for counseling individuals as well as developing society-wide measures for preventing tuberculosis. Predictions at the level of a cell or tissue include what developmental programs these cells might follow or specific outcomes such as apoptosis, endocytosis, or mobility.

Other types of questions that can be asked in human systems include:

1. The identification of key information-transducing nodes in a system, as well as the inference of nodes that must be part of the system but are currently unsuspected or unknown. Such inference would be based on experimental results that differed from predicted results.
2. The identification of therapeutic drug targets [19].

3. Prediction of the effects of a gene knockout or knockdown, or overexpression of that gene.
4. Most generally, prediction of the effects of any perturbation to a system, including chemical and environmental perturbations.
5. Prediction of a particular property of a node or edge, such as Gene Ontology category, the presence of negative regulation, or the presence of positive or negative feedback.
6. Prediction of the concentration or flux or production of a specific gene, mRNA, or protein under a specific set of conditions at a specific time in a system.

The most successful projects will define exactly what questions will be addressed by the project before the project begins, and will define measurable quantitative variables that will be predicted by models [23]. The ability of a research group to precisely and accurately make quantitative predictions is one useful measure of whether a particular research methodology and approach is working effectively. Some questions lend themselves more naturally to quantitative predictions, such as those related to flux or concentration of small molecules. Others, such as the identification of drug targets, are very difficult to evaluate on any timescale less than a few decades.

Systems biology must be applied to all human diseases, as the urgency of clinical discovery is paramount. However, from the point of view of leveraging human systems biology research to gain fundamental understanding of a system, some human diseases may lend themselves more readily to knowledge discovery. These will be the diseases for which the etiology lies contained in a fairly small network and can be understood by understanding the interactions of a relatively few nodes. Thus, one might predict that research with Noonan Syndrome, which appears to be related to defects within the Ras signaling network may lead more immediately to fundamental understanding than research in type 1 diabetes, which appears to have etiologic effects spread throughout many cell types that arise from both genetic and environmental influences, and that act at disparate timepoints throughout the life of the individual.

Examples

Research in Noonan Syndrome represents an elegant example of systems biology as applied to human disease. Phenotypes of Noonan Syndrome include congenital heart malformation, short stature, and learning problems. Approximately 1 in 2,000 children are born with Noonan Syndrome. The range and severity of features can vary greatly between individuals, suggesting that there are multiple causes of the syndrome that affect common etiologic pathways, but in subtly different manners. Frequent transmission from parent to child suggested a genetic defect with autosomal dominant inheritance. Traditional genetic approaches mapped Noonan Syndrome to chromosome 12q24. By 2001, it was shown that about half of all individuals with Noonan syndrome were caused by a mutation of the PTPN11 gene at position 12q24. The PTPN11 gene encodes a tyrosine phosphatase. This discovery provided the first insight into the formation of a predictive model for Noonan Syndrome. With an underlying hypothesis that Noonan Syndrome was the emergent result of the output of an unknown dysfunctional network, the discovery that PTPN11 was part of that network allowed orthologous data sets and analysis to be leveraged [28,29]. PTPN11 is a node in an intracellular signaling network, including the traditional Ras/MAP kinase signaling pathway. This network governs cell division and differentiation. This network was fairly well characterized prior to the discovery of the association of PTP11 with Noonan Syndrome, so the network knowledge could be immediately applied to predict other nodes that, when perturbed, might also result in a Noonan Syndrome phenotype [13]. When tested, using an iterative network-refinement approach, several of these genes were also found to be fundamental to Noonan Syndrome etiology. These genes include RAF1, SOS1, HRAS, KRAS, and RAF1 [36,39,44,46,52].

Genetic association studies show great promise for breaking into etiologic network models for other human diseases. The technology for association studies for autoimmune diseases has been progressing steadily since the 1970s. However, until 2006, the only major genetic association with these diseases had been the MHC locus, which encodes the molecular complexes that train the immune system to recognize particular peptides as activators. The accumulated progress in technology moved research across a discovery threshold early in the twenty-first century and a large number of additional gene associations in a variety of autoimmune diseases have been discovered, as well in other complex human diseases. These include the discovery of IFIH1 for type 2 diabetes [45], ITPR3 for type 1 diabetes [40], and IL7R for multiple sclerosis [15,22]. Further progress in these diseases will be somewhat slower than for Noonan Syndrome, but there is every reason to believe that these larger and more complex networks can be modeled in clinically useful ways by applying the techniques discussed in the previous section.

In addition to genetic association studies, data analysis from high-throughput sources can also help enumerate key nodes in human networks. Carefully curated analyzes of orthologous high-throughput data sets can yield lists of nodes that are likely to be fundamental to predictive network models. One of the more promising human systems for this systems biology approach is modeling macrophage activation through innate immune receptors [2]. Non-predictive network diagrams based on extensive literature analysis are available for the macrophage [34]. Such diagrams facilitate the development of predictive network hypotheses [35].

Rather than breaking into an unknown network, Bergholdt et al. [7] have approached the type 1 diabetes network by assuming that it is a subnetwork of current iterations of the global human protein-protein interaction network. They take key-node analysis a step further by developing a statistic for key subnetworks. Significance is computed from genetic association data for all genes in the subnetwork, as well as the interactions between these genes. This approach is amenable to further refinement by the incorporation of additional orthologous data sets, such as function and expression, into the significance metric. Bergholdt et al. succeed in identifying a number of candidate subnetworks that may transduce signals that cause diabetes.

Human macrophages are tractable experimental systems even when taken out of the context of the human body, and much of the macrophage regulatory network operates in a near native fashion even when isolated from other human cells. Because systems biology of the human immune system can in cases be reduced to the analysis of single cells, it shares some simplicities with prokaryotic systems biology. Systems biology of the human immune system is therefore a natural initial focus for human systems biology.

A large number of high-throughput data sets have been acquired from macrophages, particularly time-series following stimulation through toll-like receptors. Several preliminary comparative network analyzes are available [21,37]. Reasonable near-term expectations from such studies, which may involve dozens of researchers and years of research, are the addition of one or several nodes and key interactions to a basic network such as the identification of the role of ATF3 as a important negative regulator of macrophage activation [14] or the bulk identification of many key nodes without their interactions such as the identification of all transcriptionally active transcription factors [33,41]. Studies of signaling networks in T-cells have also resulted in predictive models, but are impeded by the resistance of T-cells to some forms of genetic perturbations, such as RNAi interference [25].

A lot of clinical value is currently being generated through analyzes of high-throughput data sets that result in predictive models for disease [27]. In some cases these analyzes are done on only one type of data, such as microarray data, and are not orthologous data sets in the truest sense. Furthermore, the results are frequently statements of correlation, rather than causation, and thus are a fairly preliminary step towards a true understanding of the system, or a true predictive etiologic model. Nevertheless these predictions are amenable to iterative refinement with a good prospect that such refinements will eventually elevate these models to the level of understanding. Examples of such efforts include diagnosis and stratification.

Statistical methodologies such as discriminant or principle components analysis can extract variables that are highly informative for classifying systems. Quantitative values can be obtained from many thousand nodes in systems with known properties. For example, one can measure the expression of thousands of genes in a set of malignant tumors and controls. Simplified classifiers can be extracted from these many thousand variables. Clinically useful stratification of breast cancers into subtypes that respond preferentially to different therapeutic interventions has been one example of this approach [16,49,50]. These multivariate approaches also show promise for diagnosing disease, including acute infections [38], arthritis [4], and diabetes [24]. These diagnostic techniques show promise for detecting presymptomatic disease, in which cases the semantic line between prediction and diagnosis blurs considerably. These methodologies can also stratify disease, allowing for the tailoring of specific therapies to the disease. Additionally, responses to diseases, medications, therapies, or the environment can themselves be stratified, permitting the early identification of adverse reactions and changes towards a more positive therapeutic direction.

Future Directions

The most productive element of the systems biology paradigm is collaboration. Collaboration between scientists with similar skills allows projects of greater size and complexity to be tackled. Collaboration between scientists with different knowledge and skill sets permits knowledge to be combined in manners previously unimaginable and opens previously inaccessible vistas of knowledge. For decades, both types of collaboration have been widely used in other branches of science, such as meteorology, astronomy, and particle physics. Therefore the most promising future directions for system biology are those that maximize collaborations.

These collaborations will be enabled by new methods of data sharing, most likely leveraging the worldwide web. Interactive and updateable sources of information such as wikis and blogs will be key. Many online scientific journals have recently begun to encourage online commenting of papers. New methods of collaboration may evolve. These may involve virtual collaboration and might leverage peer-to-peer networks such as Facebook. The Nature publishing group has initiated such a tool, Nature Network.

New societal methods of career recognition and funding will likely stimulate systems biology. Traditional methods have recognized single-author or first author papers and tend to focus on journal publishing as a measure of productivity and utility. New methods will recognize collaboration and non-traditional measures of productivity, such as the creation of online resources. Recently, the NIH has altered its tenure track rules in recognition of these needs. Many of these changes will require a new generation of researchers willing to embrace them. Progress in systems biology will be increasingly driven by distributed worldwide collaborations that may involve researchers unaware of each other, with the collaborative element being contributions to virtual online projects. Projects will involve both specialists and generalists. In many cases data will be generated by a specialist in an experimental technique, and analyzed by distinct specialists in analytical techniques. Generalists will need to have skills in multiple disciplines and will be needed to direct projects and integrate data. Among the traditional twentieth-century fields of biology, immunology required extensive multidisciplinary knowledge from its practitioners; it is not surprising that many of the pioneers of systems biology were immunologists. Investigators trained in the clinical practice of medicine will be needed to set clinical priorities and recognize opportunities for the transfer of information from bench to bedside. Walls between disciplines will need to erode.

New and improved technologies will increasingly yield lower-costs, higher-throughputs, better sensitivity, better reproducibility and precision, better accuracy, and more comprehensivity [17,20]. Sequencing technologies continue to show promise for all of these characteristics, and dropping costs may permit them to underlie many measurements. Transcriptomics is currently performed mostly with arrays which may have fundamental upper limits on accuracy. Future transcriptomics may breach the accuracy barrier by employing transcript enumeration technologies that aim to sequence, for example, every mRNA in a single cell. Improvement in computational prediction and direct measurement of transcription factor binding to targets will permit these interactions to be confidently added to networks, and will vastly improve the predictive power of models of nuclear regulation. New methods of creating, storing, and sharing medical information electronically must be adopted that allow efficient use of aggregate information for research while preserving patient confidentiality and their rights to control their own information.

Effective improvements to human health cannot be made solely by a small group of individuals. Society must participate. Individuals must be informed, must support research, and must be willing to participate in and receive therapeutic interventions. Systems biology must therefore be alert to the broad needs of society [10]. These needs can help focus priorities. A society willing to modify its diet but reluctant to take pharmaceuticals would inform systems biology to prioritize models that predict the effects of altered diets over models of drug metabolism, and vice versa. Because human systems biology relies on human participation in research, such as in the Framingham Study and in gene association studies, efforts must be made to continue to educate all people in a deep inquiry-based scientific knowledge and to encourage them to share their personal medical histories and experience with the common knowledge pool. Current cultural shifts in the US towards increased guarding of personal information and mistrust of scientific information will create substantial challenges for the next generation of systems biologists.

Systems Biology, Introduction to

ROBERT A. MEYERS
Ramtech Limited, Larkspur, USA

Systems biology is a relatively new branch of life sciences that is highly interdisciplinary and aims to provide a quantitative analysis and understanding of life systems within a mathematical framework. Systems biology is the study of the interconnected aspect of molecular, cellular, tissue, whole animal and ecological processes, and comprises mathematical and mechanistic studies of dynamical, mesoscopic, open, spatiotemporally defined, nonlinear, complex systems that are far from thermodynamic equilibrium. The animating principle of systems biology is that the most important behaviors and networks of interacting elements (e. g.,molecules, cells, etc.), rather than by individual elements and interactions. This really necessitates the integrated application of high-throughput measurement technologies and advanced computational methods to model and predict biological responses. The 11 articles comprising this section describe the basic aspects and processes of systems biology and the relationship of systems biology to complexity and systems science. The basis and content of each of the 11 articles in this section are described below. There are six additional articles that were nominated and accepted into other sections which are connected to complexity in Systems Biology, and supplement the 11 articles in this section. These six are listed at the end of this Introduction.

With rare exceptions, all known living organisms encode their genetic material in the form of double-stranded DNA, in one or more chromosomes, collectively referred to as the "genome" (▶ Genome Organization). The genome includes most of the information needed by the cells to stay alive, to differentiate into new cell types, and to perform their functions in the context of the organism. As such, it is the ultimate resource for identifying the full set of components in the living system. Eukaryotic genomes are much larger than strictly needed to encode the relatively modest set of genes in them, but several mechanisms give rise to a very complex transcriptome. It is necessary to understand how the genome is organized and how it evolved and be able to build suitable null hypotheses for testing whether predictions are likely to be real, and thereby understand whether specific observations are likely to be biologically meaningful.

Sequence data alone is currently of limited use for identifying the functional elements of a genome and for elucidating how these elements interact to control physiological processes.

The field of functional genomics aims to meet these challenges using the sequence data as a blueprint (▶ Functional Genomics for Characterization of Genome Sequences). In a broad sense, functional genomics is defined as the large-scale experimental study of gene function and interactions. In the above article, the techniques and challenges in functional genomics are illustrated in the context of an ever more common case scenario: given a complete genome sequence, how does one figure out what the sequence means? The current state of the art is interpreted to arrive at the function or functions of a given genome sequence.

Among the most fundamental problems in biology is deciphering the relationship between genotype and phenotype in the complex system of life forms. Understanding a complex system broadly requires that one (1) identify the elements, (2) determine the function of each element, (3) identify and characterize the interactions between elements, and (4) assemble all of this information into a mathematical model that accurately simulates the system and predicts its responses to novel perturbations (▶ Systems Genetics and Complex Traits). In the context of systems biology, this process begins with sequencing an organism's genome and identifying the functional elements, e. g. the genes. There are numerous methods for determining the function(s) of a given gene product, where "function" can describe both the specific biochemical activity carried out by the gene product and the role that activity plays in the organism's response to an environmental or developmental stimulus. Understanding complex genetics is of increasing relevance to the study of human health and is essential to the development of predictive, preventive, and personalized medicine.

Systems biology is the derivation of emergent properties of a multicomponent biological system through the construction of quantitative predictive models. These predictive models are typically formulated as networks. Human systems biology is the practice of systems biology to elucidate emergent properties of humans or any subcomponent of the human body, such as a cell (▶ Systems Biology of Human Immunity and Disease). Human systems present challenges and opportunities not found in other organisms. Most problems in human systems biology are motivated by a desire to understand, predict, prevent, ameliorate, or cure a human disease. The human immune system is a mediator for most human diseases, and is the key system mediating autoimmune and infectious diseases.

Understanding the operation of cellular networks is probably one of the most challenging and intellectually exciting scientific fields today (▶ Biological Models of Molecular Network Dynamics). Cellular networks are some of the most complex natural systems we know. Even in a "simple" organism such as E. coli, there are at least four thousand genes with many thousands of interactions between molecules of many different sizes. With the availability of new experimental and theoretical techniques, our understanding of the operation of cellular networks has made great strides in the last few decades. An important outcome of this work is the development of predictive quantitative models. Such models of cellular function will have a profound impact on our ability to manipulate living systems which will lead to new opportunities for generating energy, mitigating our impact on the biosphere and last but not least, opening up new approaches and understanding of important disease states such as cancer and aging.

Biological research over the past century or so has been dominated by reductionism – identifying and characterizing individual biomolecules – and has enjoyed enormous success. Throughout this history, however, it has become increasingly clear that an individual biomolecule can rarely account for a discrete biological function on its own. A biological process is almost always the result of a complex interplay of relationships amongst biomolecules, and the treatment of these relationships as a graph is a natural and useful abstraction (▶ Biomolecular Network Structure and Function).

Broadly speaking, a biomolecular network is a graph representation of relationships (of which there are many types) amongst a group of biomolecules. Vertices or nodes represent biomolecules, including macromolecules such as genes, proteins, and RNAs, or small biomolecules like amino acids, sugars, and nucleic acids. An edge or link between two vertices indicates a relationship between the corresponding biomolecules, which could include physical interaction, genetic interaction, or a regulatory relationship (e. g., the protein product of gene A regulates the expression of gene B). This abstraction, although simplifying, converts a complex web of biological relationships into a mathematical graph, from which we can study its structural features as well as their implications on biological functions.

Data integration and model building have become essential activities in biological research as technological advancements continue to empower the measurement of biological data of increasing diversity and scale (▶ Biological Data Integration and Model Building). High-throughput technologies provide a wealth of global data sets (e. g. genomics, transcriptomics, proteomics, metabolomics), and the challenge becomes how to integrate this data to maximize the amount of useful biological information that can be extracted. Integrating biological data is important and challenging because of the nature of biology. Biological systems have evolved over the course of billions of years, and in that time biological mechanisms have become very diverse, with molecular machines of intricate detail. Thus, while there are certainly great general scientific principles to be distilled – such as the foundational evolutionary theory – much of biology is found in the details of these evolved systems. This emphasis on the details of systems and the history by which they came into being (i. e. evolution) are distinct features of biology as a science, and influence the need for large-scale data integration. Also, biological systems are responsive to varying environments, with potential system states influenced by the combinatorics of all possible molecular and environmental perturbations. Thus, data space in this realm is extraordinarily large. There is no shortage of possibilities to explore, and vast amounts of data will be needed to reengineer biological systems and understand their workings at a (near) complete level of detail or at a level where accurate prediction can be achieved.

Another reason data integration is essential, is that biology arises through the complex interworking of many components. Thus, to understand biology we must integrate biological data in a way that will allow us, not only to access all our acquired data efficiently, but even more importantly allow us to study, predict, modify, and even engineer the emergent properties of biological systems, where the whole is more than the sum of the parts.

Boolean Networks are a class of discrete dynamical systems that can be characterized by the interaction of a set of Boolean variables. Random Boolean Networks, which are ensembles of random network structures, are a simple model class for studying dynamical properties of gene regulatory networks (▶ Boolean Modeling of Biological Networks). Boolean Networks have been used as generic models for dynamics of complex systems of interacting entities, such as social and economic networks, neural networks, as well as gene and protein interaction networks. Despite their conceptual simplicity, Boolean Networks exhibit complex nonlinear behaviors that are, to this day, a challenging object of investigation for theoretical physicists and mathematicians. Further, a discretization of gene expression is often regarded as an experimentally justifiable simplification making Boolean network models attractive tools for the biologist.

Many processes in cell biology, such as those that carry out metabolism, the cell cycle, and various types of signaling, are comprised of biochemical reaction networks. It has proven useful to study these networks using computer simulations because they allow us to quantitatively investigate hypotheses about the networks. Deterministic simulations are sufficient to predict average behaviors at the population level, but they cannot address questions about noise, random switching between stable states of the system, or the behaviors of systems with very few molecules of key species. These topics are investigated with stochastic simulations (▶ Stochastic Models of Biological Processes). The dominant types of stochastic simulation methods that are used to investigate biochemical reaction networks are covered, as well as some of the results that have been found with them. As new biological experiments continue to reveal more detail about biological systems, and as computers continue to become more powerful, researchers will increasingly turn to simulation methods that can address stochastic and spatial details.

Systems biology has various definitions. Common features among accepted definitions generally involve the description and analysis of interacting biomolecular components. Systems analysis of a biological network is quickly demonstrating its utility as it helps to characterize biomolecular behavior that could not otherwise be produced by the individual components alone. Three areas in which systems analysis has been implemented in biology include: (1) the generation and statistical analysis of high-throughput data in an effort to catalog and characterize cellular components; (2) the construction and analysis of computational models for various biological systems (e. g., metabolism, signaling, and transcriptional regulation); and (3) the integration of the knowledge of parts and computational models to predict and engineer biological systems (synthetic biology). Metabolism, as a system, has played an important role in the development of systems biology, especially in the modeling sense (▶ Metabolic Systems Biology). This is because the network components (e. g., enzymes and metabolites) have been studied in detail for decades, and many links between components have been experimentally characterized. Metabolic systems biology, compared to systems biology in general, entails the computational analysis of these enzymes and metabolites and the metabolic pathways in which they participate. Metabolic systems biology, using genome-scale metabolic network reconstructions and their models, has helped (1) to elucidate biomolecular function; (2) to predict phenotypic behavior; (3) to discover new biological knowledge; and (4) to design experiments for engineering applications. Constraint-based methods have played a pivotal role in the analysis of large and genome-scale metabolic networks. The structure, mathematical formulation, and analytical techniques of constraints-based methods have also paved the way for the successful modeling of other complex biological networks, such as transcriptional regulation and signaling networks.

Finally, ecological systems are paradigmatic examples of complex systems. For example, consider the thousands of species interacting in complex ways within rich communities such as tropical rainforests or coral reefs. The most pressing questions ecologists face deal with concepts such as stability, resilience, thresholds and non-linearities which are at the core of the sciences of complexity. How robust are these cathedrals of biodiversity? At which rate will they disassemble as a consequence of global change. For example, one of the long-standing questions in ecology is the relationship between complexity and stability. A review of some of the applications of the complexity sciences in the realm of ecological systems is presented (▶ Ecological Systems). Predicting the consequences of global change on biodiversity requires an interdisciplinary approach in which complexity approaches may be very useful. Information theory and diversity, networks, complex dynamics and spatiotemporal dynamics are all discussed relative to ecology as a complex system.

Systems and Control, Introduction to

MATTHIAS KAWSKI
Department of Mathematics and Statistics,
Arizona State University, Tempe, USA

Control of dynamical systems has a long history: Watt's automatic centrifugal governor designed to regulate steam engines in the 1780s is considered a precursor of modern feedback control. Similarly, Bernoulli's work in the 1690s on the brachystochrone problem is a progenitor of optimal control. A distinguishing external feature of *controlled* dynamical systems is the presence of inputs that interact with the system in the form of deliberate controls, or unavoidable perturbations. Commonly control systems also have outputs (observations) that typically provide only incomplete information about the state of the system. Systems and control theory utilizes a broad array of mathematical disciplines – but a uniting, characteristic feature is the kind of questions being asked. In the 1950s the field became more formalized, it began to develop its own distinctive identity, and it has rapidly evolved ever since. Naturally, the linear theory developed first and quickly became a mature subject, with controllers now pervading everyday life, from thermostats, dozens of controllers in every automobile, to cell phones, attitude control of satellites, electric power networks, highway traffic control, to name just a few.

The articles in this section focus on the more recent developments, articulating how the fundamental problems and questions of systems and control theory are addressed in ever new settings, on new tools, and new applications.

Whereas in classical dynamical systems one tries to predict the uniquely determined future, a basic distinguishing question in control theory asks whether it is possible to steer the system to any desired target. This question about *controllability* has a simple and elegant answer in the case of linear systems. While much also is known for nonlinear systems, many challenges remain in both the finite dimensional setting [see ▶ Finite Dimensional Controllability] and in the setting of *distributed systems* modeled by partial differential equations [see ▶ Control of Non-linear Partial Differential Equations].

Assuming controllability using controls that are functions of time, the next question asks whether one can *automate* the control using feedback, that is, by making it a function of the state or of a measured output. Whereas for linear systems the theory is straightforward, unavoidable topological obstacles make nonlinear feedback stabilization problems much more challenging [see ▶ Stability and Feedback Stabilization]. A notion dual to controllability is that of observability: Rather than asking about the map from inputs to the state, a system is observable if the history of the outputs (measurements) determines the state of the system [see ▶ Observability (Deterministic Systems) and Realization Theory]. The typical engineering problem involves much more complex multi-tasking, dealing with multiple objectives in the presence of diverse constraints. Much of this well developed theory of output regulation, disturbance rejection, while attending to performance criteria, has recently been generalized to nonlinear systems [see ▶ System Regulation and Design, Geometric and Algebraic Methods in]. Generally, if there is one, then there are many control strategies that achieve a certain task – naturally one likes to single out a strategy that is the best. This leads to optimal control theory, which supersedes much of the classical calculus of variations, and which has rich interfaces with Lagrangian and Hamiltonian mechanics [see ▶ Maximum Principle in Optimal Control].

In many applications all one has to work with are sampled data for inputs and measured outputs. Moreover, commonly these are also corrupted by measurement errors and noises. A fundamental problem is to devise algorithms to *identify* the best model system that could generate these input-output pairs. Characteristically such algorithm should work in real time and improve the model upon newly available measurements. This well developed broad field includes geometric approaches to stochastic systems [see ▶ Stochastic Noises, Observation, Identification and Realization with] as well as more formal learning theories [see ▶ Learning, System Identification, and Complexity].

Systems and control theory is unified by a common core of questions, but employs a diverse array of models. Consequently it interfaces a wide range of mathematical disciplines, utilizes many different mathematical tools, but also fosters new development in diverse subdisciplines. An area that has evolved closely together with control is nonsmooth analysis with its rich theory of tangent objects to nonsmooth sets. Not only are controlled dynamical systems naturally modeled by differential inclusions, but control intrinsically is full of objects that are not differentiable in a classical sense. Most important is the value function in optimal control which encodes the minimal cost (time) to the target. Closely related to classical dynamic programming, this function ought to satisfy the Hamilton–Jacobi–Bellmann equation, a first order partial differential equation, but the value function generally is not differentiable in a traditional sense [see ▶ Nonsmooth Analysis in Systems and Control Theory]. Complementary to the nonsmooth approach are differential geometric approaches which include Lie theory and symplectic geometry. Closely related is a functional analytic operator calculus introduced into control by Agrachëv and Gamkrelidze which linearizes problems by imbedding them into infinite dimensional settings. This dramatically facilitates formal manipulations of nonlinear objects, and also gives new ways of looking at the underlying geometry [see ▶ Chronological Calculus in Systems and Control Theory].

Many of the early successful engineering implementations of systems and control theory used models with both continuous time and states (differential equations). But with the advent of ubiquitous digital controllers as well as ever broadening fields of applications the theories for increasingly diverse models are becoming well developed, too. These include, systems with or mix of continuous and discrete states (suitable, for example, to model systems with hysteresis) [see ▶ Hybrid Control Systems] and discrete time Hamiltonian and Lagrangian systems [see ▶ Discrete Control Systems] There are many new applications with quickly developing theories such as control of biological and biomedical applications, social dynamics, manufacturing systems, financial markets, and many more. Some of the most intense research in recent years has focused on systems with distributed intelligent agents (controllers) each of which has access to only local information [see ▶ Robotic Networks, Distributed Algorithms for]. Compared to these emerging areas the geometric theory of mechanical systems is one of the most mature and thriving research areas with scores of exciting new problems. It serves as a role model for the depth of geometric insight and for its well-understood close interconnections with many other disciplines [see ▶ Mechanical Systems: Symmetries and Reduction].

Systems Genetics and Complex Traits

Gregory W. Carter, Aimée M. Dudley
Institute for Systems Biology, Seattle, USA

Article Outline

Glossary

Allele A copy or alternate version of a gene.

Complex phenotype A trait (or phenotype) caused by polymorphisms in multiple genes.

Diploid An organism with two copies of each chromosome.

Epistasis A genetic interaction in which the double-mutant phenotype is identical to one of the single-mutants (masking epistasis); sometimes used as a general term for genetic interaction.

Genetic interaction A relationship that characterizes how two (or more) genetic perturbations or alleles combine to affect a phenotype.

Genetic network A representation of functional relationships between genes, gene products, or gene perturbations, often displayed as a graph.

Genetic perturbation The modification of a gene's presence, structure, or activity by a change in the DNA sequence in or near a gene.

Genetic transformation Genetic modification of a cell by the introduction of exogenous genetic material.

Haploid An organism with one copy of each chromosome.

Haplotype A set of polymorphisms that are linked and thus inherited as a unit.

Homolog One of two or more genes with similar DNA sequence due to shared ancestry.

Hybrid A diploid offspring from the mating of individuals from two distinct populations.

Intercross The mating of individuals from two distinct populations.

Isogenic A term describing strains of model organisms that are derived from the same individual or inbred line, e. g. the yeast deletion collection, in which each strain differs only by the presence of a specifically engineered mutation (e. g. a gene knock-out).

Masking epistasis A genetic interaction in which the double-mutant phenotype is identical to one of the single-mutants.

Mendelian genetics The study of traits caused by variations of a single gene.

Microarray hybridization Sequence-specific binding of nucleic acid (DNA or RNA) to short nucleic acid sequences tethered to a microarray chip.

Molecular barcode A short, unique sequence inserted into DNA that can be used to identify or quantify a gene, gene product, or strain.

Network motif A small subnetwork repeated in a larger network, suggesting repeated organization for a specific function.

Phenotype An observable property of an organism; sometimes implies an aberrant property, e. g. the mutant has a phenotype.

Pleiotropy The phenomenon in which a mutation in a single gene causes multiple phenotypes.

Quantitative trait locus (QTL) A chromosomal region linked to a measurable phenotype.

RNA interference (RNAi) A method of silencing a gene's expression by introducing a small RNA molecule with sequences complementary to a portion of the gene's mRNA transcript.

Reciprocal-hemizygote A hybrid in which one copy of a gene or chromosomal region has been removed.

Sporulation The formation of spores in fungi, produced by meiosis.

Synthetic sickness or lethality (SSL) A genetic interaction in which two genetic perturbations without individual fitness effects combine to cause a fitness defect or inviability.

3′ Untranslated region (UTR) The RNA sequence that follows the protein-coding region of a messenger RNA.

Definition of the Subject

Among the most fundamental problems in biology is deciphering the relationship between genotype and phenotype. Genetics, the study of how the DNA sequence of an individual (genotype) affects an observable characteristic (phenotype), has many properties of a systems science. Organisms contain large number of protein-coding genes, with ∼500 predicted in the simple bacterium *Mycoplasma genitalium*, ∼25,000 in the human genome, and over 50,000 in some plants. The relationship between genotype and phenotype can be complex, with multiple traits per gene (pleiotropy) and multiple genes per trait (complex phenotypes). Genes are the blueprints for both RNA transcripts and proteins that interact physically and functionally to produce the emergent behaviors that characterize life. Furthermore, biological systems can be systematically studied by perturbing elements of the system, such as genes or environmental factors, and quantitatively measuring the effects. This research strategy is generally considered a central component of systems biology [39,40], and here we refer to its application to the genotype-phenotype problem as *systems genetics*.

Understanding a complex system broadly requires one to (1) identify the elements, (2) determine the function of each element, (3) identify and characterize the interactions between elements, and (4) assemble all of this information into a mathematical model that accurately simulates the system and predicts its responses to novel perturbations. In the context of biology, this process usually begins with sequencing an organism's genome and identifying the functional elements, e. g. the genes. There are numerous methods for determining the function(s) of a given gene product, where "function" can describe both the specific activity carried out by the gene product and the role that activity plays in the organism's response to an environmental or developmental stimulus. For example, molecular or biochemical methods may reveal a protein to be enzyme that converts a substrate to a product, while genetic analysis may reveal that this activity is required for growth in the presence if a specific drug. Similarly, there are both molecular and genetic means of determining which gene products interact with each other, by detecting physical interactions (e. g. protein binding) and genetic interactions (e. g. a mutation in one gene modifies the effect of a mutation in a second gene). These interactions vary with respect to the nature, strength, and directionality of the interaction. Integrating these data into a coherent computational model of the system is a major challenge of systems biology, with early examples including a comprehensive analysis of the galactose utilization pathway in yeast [40] and bacterial chemotaxis [70].

Systems genetics approached to this problem use large-scale, high-throughput methods to decipher the network of gene functions and genetic interactions in an organism. Apart from their genome-wide scale, the data and methods used often mimic those of conventional genetic analysis. In classical Mendelian genetics, genes are defined as the entities by which traits are inherited. A specific trait exhibited by an organism thus depends on the version(s) of the corresponding gene, known as an allele, carried by that individual. Modern molecular biology has narrowed the concept of a gene to a distinct DNA sequence that is transcribed to encode an RNA or protein product. However, few phenotypes are entirely determined by a single gene. In most cases, multiple genes interact to confer a phenotype. These interactions can vary from simple modifier relationships, in which an allele of one gene alters the phenotype of another gene, to multiple genes with complicated interdependencies. The study of how multiple genes interact to influence a trait is generally known as complex genetics.

Understanding complex genetics is of increasing relevance to the study of human health and is essential to the development of predictive, preventive, and personalized medicine. Many diseases, such as asthma, diabetes, heart disease, and cancer, show a degree of heritability that cannot be traced to a single gene [3]. Moreover, risks inherited from identified disease genes are often modified by background gene variation [11,22,33,34]. Genetic risk in these cases is determined by an individual's allelic profile across many genes, combined with multiple environmental factors. Many of these allelic variations consistently appear together, as haplotypes, which are being mapped in the human HapMap project [1]. Multiple genes involved in cancer are being cataloged in The Cancer Genome Atlas [17]. This data must be combined with new modeling techniques to develop models for understanding the multigenic, molecular basis of human diseases. Developing new treatments for diseases with genetic susceptibilities will require not only the ability to genotype and classify patients on the basis of molecular fingerprints in tissues, but also an understanding of how genetic variants interact to affect clinical outcomes.

Introduction

Genetic interaction refers to the phenotypic effect of combining two or more genes with allelic variations. Genetic interactions are ideally observed under constant environmental conditions and in isogenic strains of model organisms, so that the lone variables are the genetic perturbations (i. e. the allele forms) carried by the strains being compared. Since genetic variants often combine in complex ways to affect phenotypes, it is necessary to infer and model the functional interactions between trait genes rather than viewing each gene as an independent factor. These functional interactions include all modes of activation or repression of one gene's activity by another. Take as an example, a measurable phenotype and a wild-type strain that defines the genetic background. Next consider two genes, A and B, which can be varied from that of the wild-type strain by mutations such that the (isogenic) genetic background is otherwise unchanged. Taking cell growth in the presence of the drug caffeine as an example phenotype, imagine that a mutation in A inhibits growth in the presence of caffeine. The presence of an additional mutation (B) in the strain (i. e. an AB double mutant) could have one of many different effects. B could of suppress the phenotype of A (restoring wild-type growth on caffeine), enhance the phenotype (decreasing growth on caffeine further than that observed in the A single mutant), or show no effect at all (growth equal to that of the A mutant). Interactions such as these have historically been used to map functional pathways [36].

In addition to the direction of the effect, the magnitude of phenotypic suppression or enhancement also provides important information about the nature of the genetic interaction. Additive effects, where the magnitude of an AB double mutant is equal to the combined effect of each individual's phenotype, are consistent with independent (non-interacting) genes in the same genetic pathway (e. g. where A and B both confer a phenotype) or in different genetic pathways (e. g. where A displays the phenotype, but B does not). Synergistic effects describe an AB double mutant trait that is quantitatively more extreme than would be expected from the linear combination of both. Perhaps the best studied class of synergistic interaction is synthetic lethality [21], in which the combination of two non-lethal mutations, A and B, combine to confer lethality in the AB double mutant. The concept has been appreciated for many years in both fruit fly [75] and yeast [30], and synthetic lethal interactions have identified redundant functions in a common (essential) biological pathways and parallel functions in separate pathways that are able to buffer each other [32]. Such buffering against genetic defects has long been believed to confer a fitness advantage [84]. The buffering of disease-related genes is of particular interest in identifying alleles that either alleviate or aggravate effects within individuals across a genetically diverse population.

In addition to assigning genes to functional pathways and uncovering functional relationships between pathways, the direction and magnitude of genetic interactions can also be used to determine the fine-structure of a genetic network and information flow through the system. Analysis of synthetic and epistatic interactions (Fig. 1) can be used to determine functional topology and the direction of information flow, commonly referred to by geneticists as "ordering genes in a pathway" [4]. Taking again the example of a mutation in gene A that inhibits growth in the presence of caffeine, now consider a mutation in another gene, C, that enhances growth under that condition. If the phenotype of an AC double mutant is a caffeine growth defect equal to that of the A single mutant, A is said to be epistatic to C. Such an interaction is often interpreted as evidence that A acts downstream of C, in that its mutation masks any modifications that occur further upstream of the phenotypic output [4]. This hypothesis is an example of serial information flow through the system, with the perturbed genes influencing each other and the growth phenotype in a linear sequence.

While genetic interaction analysis cannot, when taken alone, decipher the biochemical activity of the gene products, it can establish functional relationships between gene pairs. One can thus view a genetic interaction as providing a comprehensive view of the coordinated activity of two genes, encompassing every step in cellular processing between genotype and phenotype. A broad picture of complex genetic control emerges when these interactions are assembled into a network.

Measuring Genetic Interactions Genome-Wide

Since assaying a genetic interaction requires measuring the phenotype of interest in multiple strains, inferring genetic interactions on a genome-wide scale has historically been intractable. The application of high-throughput assays in model organisms with sequenced genomes has made the systematic study of complex genetics possible. To date, these studies have primarily involved the yeast *Saccharomyces cerevisiae*, which is easy to genetically modify and has a large community of researchers committed to the public dissemination of genome-wide reagent sets, and the nematode worm *Caenorhabditis elegans*, which has proven amenable to perturbations by RNAi. The large-scale study of how a genotype contributes to the control of a phenotype has been greatly aided by advances in methods to both systematically perturb genes and measure phenotypes on a genomic scale. These high-throughput methods produce large, quantitative data sets, requiring parallel development of computational and numerical modeling methods to interpret the output in terms of biological function. The primary objective of these methods is to identify functionally relevant genes and describe how they influence one another to generate cellular activity. Using a systems biology approach to integrate this knowledge with other data types has the potential to generate models capable of validating biological insights and identifying high-priority candidate molecules for targeted therapeutic intervention.

Synthetic Sickness and Lethality

Functional profiling of individual genes is most directly carried out by deleting the gene and observing phenotypic consequences. Through advances in genomics [87], a library of yeast mutants [27] now exists with deletions for every gene in the background of the laboratory strain derived from S288c [86], which was sequenced in the yeast genome project [29]. The yeast genome contains ~ 6000 protein coding genes (also know as open reading frames or ORFs). Approximately 5000 of these genes are nonessential and were deleted by replacing the gene of interest with a "marker gene" that confers drug resistance and two molecular barcodes, short DNA sequences that uniquely identify each deletion mutant. ing ∼ 1000 genes are essential for cell viability under standard laboratory conditions and thus must be maintained in strains that contain another functional copy of the gene. The lists of essential and non-essential genes are continually updated [44] as ORF annotation and verification improves [46] and closely-related strains of *S. cerevisiae* that have slight variations in essential genes are discovered [63]. Nonetheless, the observation that only 15–20% of yeast genes are essential, at least under optimal growth conditions, suggests that the genetic network governing yeast growth buffers the cell against genetic variation [32] and implies that multiple genetic mutations may compromise cell growth to a much greater degree than that observed for any single mutation.

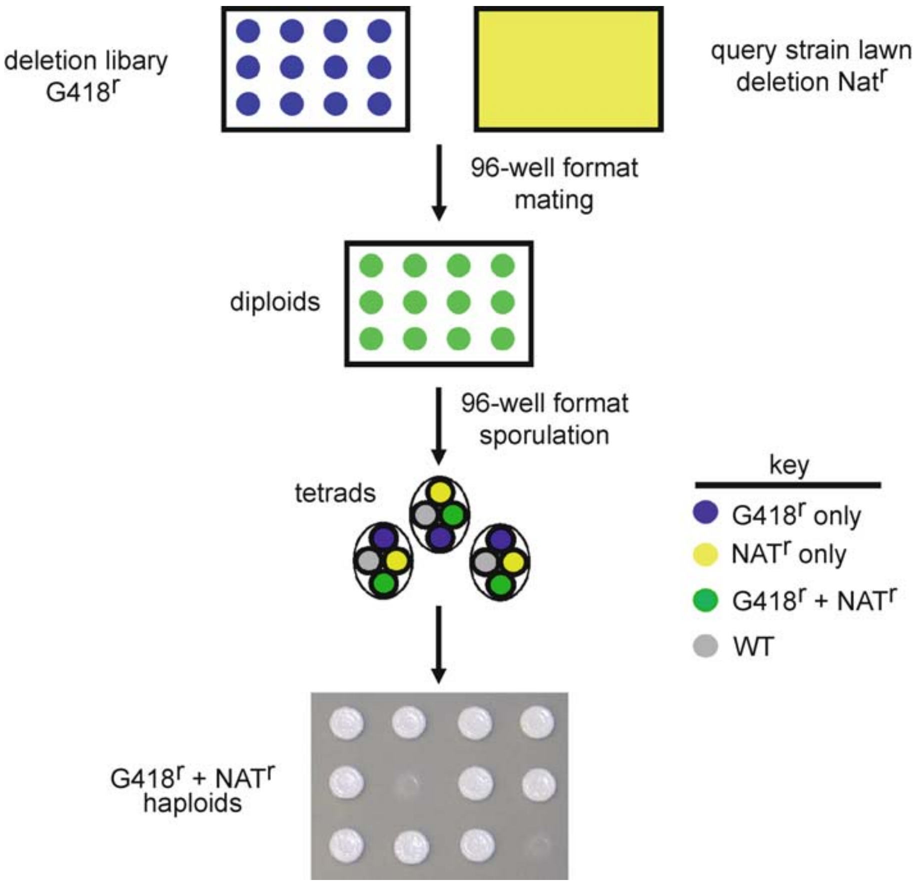
Using the yeast deletion library as a starting point, three methods – synthetic genetic array (SGA), diploid-based synthetic lethality analysis with microarrays (dSLAM), and epistatic miniarray profiles (E-MAP) – have been developed as comprehensive, high-throughput assays for detecting pair-wise genetic interactions that



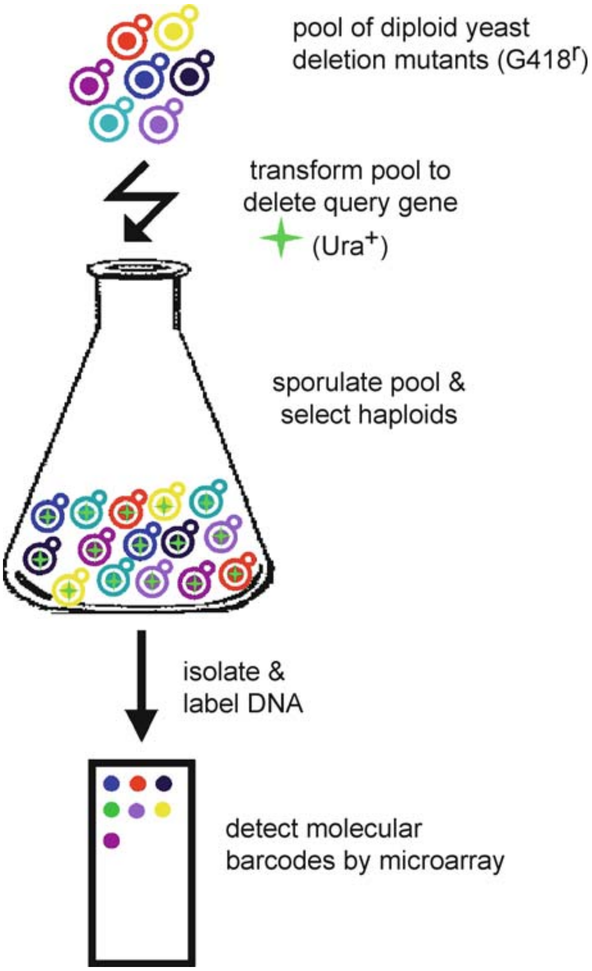
Systems Genetics and Complex Traits, Figure 2
Overview of the synthetic genetic array (SGA) and diploid-based synthetic lethality with microarrays (dSLAM) methods. Many of the experimental details have been simplified, more detailed descriptions are presented in [6]. In the SGA method a haploid strain (*yellow*) is constructed that contains a deletion of the "query gene" marked by a selectable drug marker (Nat^r) and a specialized reporter gene that facilitates high-throughput selection of haploid progeny that have mated and undergone sporulation 79. The query strain is mated to an ordered grid, haploid yeast deletion library (*blue*) marked by the selectable drug marker G418^r, forming diploids (*green*) that contain both deletion mutants, but which also contain a functional copy of each gene. Those diploids are then sporulated, allowing random shuffling of the genes and produces haploid progeny, which will only contain one copy of each gene of interest, i. e. the deleted or functional copy of the query gene. In the final step (photograph of actual yeast grids), haploid progeny that contain both the query gene (Nat^r) and the deletion strain present in that position of the grid (G418^r) are selected. The ability of the haploid progeny to grow in the presence of both drugs indicates that both deletions are present in the same strain, i. e. no interaction. Lack of growth indicates the inability to recover the double mutant combination, i. e. synthetic lethality

confer synthetic growth defects. Experimental details of these methods have been extensively reviewed [6,48,56]. We briefly summarize them here, as data generated by these methods dominates the genetic interaction data currently available. We then discuss other methods now being applied to comprehensively measure genetic interactions in yeast, worm, and mouse.

The synthetic genetic array (SGA) method (Fig. 2) was developed by Boone and colleagues [79,80] and extended to incorporate essential genes by transcriptional control via an artificial promoter [20]. The availability of a variety of drug-resistance markers enables a simple strategy for efficient construction of double gene deletion strains in yeast. Each strain in the haploid yeast deletion library harbors a gene (Kan) that confers resistance to the drug G418. In the SGA method a second haploid strain is constructed. This strain is a different mating type, and contains a deletion of the gene of interest marked by a gene (Nat) encoding resistance to a second drug (nourseothricin) and a reporter gene that enables selection for haploid progeny strains. This strain is mated to the deletion library, the resulting diploid strains are sporulated, and haploid progeny resistant to both drugs are selected. Synthetic lethality is indicated by the inability to recover haploid strains with both drug markers, suggesting that this combination of mutant alleles is inviable. Double mutants which show significant growth defects (so called "synthetic sickness") can also be identified by this method. The throughput of the method is increased by robotic manipulation of strains and phenotype scoring by image analysis software. To date, over 400,000 interactions have been tested and tens of thousands have been discovered [61], providing sufficient data for sophisticated network analysis and a valuable source of functional relationships between hundreds of yeast genes [80].

The issue of precise growth quantification of double-mutants has been addressed by a modification of the SGA method. In this approach, called epistatic miniarray profiles (E-MAP), growth rates are quantified and genetic interactions are identified as cases in which a double mutant strain exhibits a growth rate significantly above or below the expectation based on the two single mutants [19,64]. Essential genes were tested in this study by decreasing mRNA abundance via destabilization of the 3' UTR. Precise quantification of growth rates was performed by photo-assays of colony size and, based on the assumption that genetic interactions are rare, identifying the most significant deviations from the expectation that a double-mutant growth rate will be the product of the two single-mutant growth rates. Interactions with expected growth rates were classified as neutral, those with growth rates above expectation were labeled alleviating, and those with growth rates below expectation were labeled aggravating. To date, pair-wise interactions between 424 genes that localized to the endoplasmic reticulum [64] and 743 *Saccharomyces cerevisiae* genes involved in various aspects of chromosome biology (e. g. DNA replication/repair, chromosome segregation and transcriptional regulation) [18] have been tested.

Diploid-based synthetic lethality analysis with microarrays (dSLAM) (Fig. 3) is an alternate, transformation-based approach to assaying synthetic lethal interactions [57,58]. The method relies on molecular barcodes that uniquely mark each deletion strain to identify double-mutant fitness defects by DNA microarray hybridization. Heterozygous diploid knockouts [27] are initially transformed with a reporter gene that enables their conversion to haploid mutants following sporulation. Then, the gene of interest is deleted via high-efficiency integrative transformation, and the pool of yeast strains is sporulated and separated into single and double mutants using the drug resistance markers. Genomic DNA containing identifying bar codes from each pool is isolated. Bar codes are am-



pool of diploid yeast deletion mutants (G418^r)
transform pool to delete query gene
(Ura$^+$)
sporulate pool & select haploids
isolate & label DNA
detect molecular barcodes by microarray

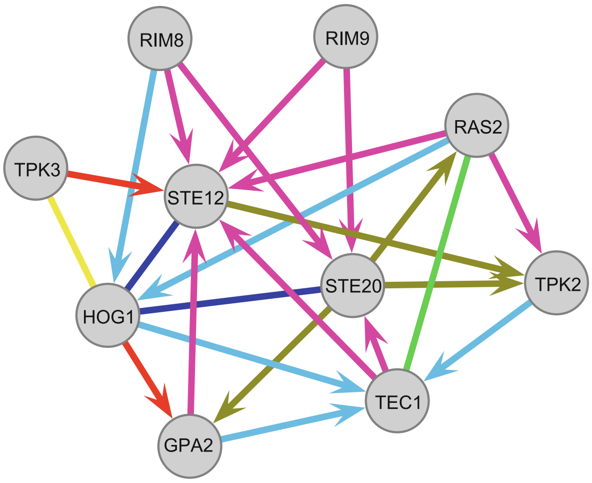
Systems Genetics and Complex Traits, Figure 3
The dSLAM method takes advantage of the molecular barcodes present in each deletion strain to facilitate the manipulation of strains in a pooled format. This method uses a diploid version of the yeast deletion set (heterozygous diploids) in which each strain contains both the gene deletion (G418^r) and a functional copy of the same gene. Prior to the analysis, the same reporter gene that facilitates high-throughput selection of haploid progeny used in SGA is introduced into all of the strains (not shown). The first step is the deletion of the query gene in (ideally) all the strains in the pool by transforming in a construct that will delete the gene of interest and contains a marker that will allow successfully transformed cells to grow in the absence of the nutrient uracil (Ura$^+$). The pool is then sporulated and haploid progeny containing both the G418^r deletion from the collection and Ura$^+$ query deletion are selected. DNA is then isolated from the pool of strains and the sequences containing the molecular barcodes are fluorescently labeled and hybridized to a DNA microarray that can detect the barcode sequences. Thus, microarray intensity provides a quantitative readout of the amount of each mutant recovered in the selection, with extremely low microarray intensity indicating synthetic lethality

plified, labeled, and hybridized to microarrays to quantify the ratio of single to double mutant growth rates. SSL interactions, also referred to as synthetic fitness or lethality (SFL) defects, are identified by high ratios that correspond to reduced double-mutant growth. Initial comparisons provide evidence that the dSLAM method achieves higher data consistency and lower false-negative rates than the SGA approach. dSLAM can also be modified to study dosage dependent SSL, genetic suppression, and haplo-insufficiency. Although the microarray based method potentially allows a more quantitative measure of synthetic sickness, the low signal intensity observed for many barcodes has hindered precise quantification. Because it relies on growth in mutant pools, the dSLAM method may be the most efficient method for genome-wide SSL screens.

The relatively recent introduction of RNA interference (RNAi) technology for gene knock-down allows multiple loss-of-function genetic perturbations to be carried out at high throughput [43,50] in model organisms such as the worm *C. elegans* and the fruit fly *D. melanogaster*. Large-scale RNAi based synthetic lethal screens have been performed in *C. elegans* [49]. Approximately 350 synthetic interactions between 160 genes in the worm EGF/Ras, Notch, and Wnt signaling pathways were discovered among 65,000 tested gene pairs. The highly-connected "hub" genes encode chromatin regulation proteins that are conserved across multiple species, which were hypothesized to be general buffers of genetic variation. Another study used the same experimental techniques to test functional redundancy between duplicated genes in *C. elegans* [78]. Synthetic interactions were detected in eleven percent of the duplicated pairs tested (16/143), suggesting that in some cases duplicated genes have a degree of functional redundancy. Interestingly, the majority of the interacting gene pairs were found to be duplicated over 80 million years ago, strongly suggesting that this functional redundancy can be conserved by positive selection.

Genetic Interactions for Quantitative Phenotypes

The vast majority of genetic interactions detected by the large-scale methods described above have been limited to the phenotype space of growth in rich yeast medium. However, phenotypes can be derived from any observable trait, including growth under a variety of environmental conditions, cell morphology, metabolite production, or gene expression pattern. To date, the most comprehensive analysis of genetic interactions detected using a phenotype other than growth in rich media include an analysis of interactions in nitrogen-poor media [23], or in the presence of a DNA damaging agent [71].



Systems Genetics and Complex Traits, Figure 4
Subsection of the yeast invasion network showing genes from various pathways and the variety of genetic interactions observed. Edge colors correspond to different interaction modes, e. g. *violet* is epistasis, *yellow* is synthesis, and *dark blue* is additivity. Subset of data from [23]

A mixture of gene deletions and high-copy, gain-of-function gene mutations were combined to map interactions in the yeast invasion network for nitrogen-poor media (Fig. 4) [23]. When starved for nitrogen, many strains of *S. cerevisiae* undergo cell differentiation into a pathogen-like, filamentous growth form and colonies subsequently invade solid media [28]. Drees and co-workers measured invasive growth by photographing colonies before and after vigorously washing cells from the agar surface (Fig. 1a). Multiple replicates of each genotype were assessed using image analysis software to quantitatively determine a mean invasion score and its variance (Fig. 1b). Since the phenotypes of the original single mutants ranged from non-invasive to strongly hyper-invasive, a wide variety of genetic interactions were possible. These interactions were first translated into mathematical inequalities that defined the relationship between the wild-type strain, the two single mutants, and the double mutant in terms of "less than", "greater than", and "equal to" relationships. For example, a synthetic interaction in which a double mutant (AB) exhibits a phenotype not shown by either single mutant (A or B) would be either "$AB < A = B = WT$" or "$A = B = WT < AB$". After systematically enumerating all 45 possible inequalities, the equations were grouped into nine "modes" of genetic interaction. Many of these interaction modes, such as synthesis, epistasis, or suppression, are well known to geneticists, but less familiar modes also appear. For example, the mode labeled "asynthesis" was defined as a double mutant phenotype which matched that of both single mutants but was distinct from the wild type. This general analysis was applied to over 130 genes and over 1800 pair-wise interactions were tested, revealing a rich spectrum of functional interactions that included examples of all nine modes.

A similarly multi-modal genetic interaction network was more recently constructed for genes that impart resistance to the DNA-damaging agent methyl methanesulfonate (MMS) [71]. Twenty-six such gene deletions (out of over 4700 tested) were identified by reduced growth rate in the presence of MMS, and double-mutant strains were constructed and assayed for all 325 pair-wise combinations. Although the selection method precluded the detection of synthetic interactions, this study is a quantitative analysis of genetic interactions among a set of genes implicated in a specific biological process.

Analysis of Complex Phenotypes that Result from Natural Variation

Although the majority of systems biology approaches to complex genetics have involved engineered genetic perturbations, genetic interaction studies are being extended to models of natural populations. A series of papers by Kruglyak and colleagues have attempted to infer genetic interactions in recombinant progeny strains [7,8,74]. In this work, two parent yeast strains, the sequenced "laboratory strain" (BY) and a "wild strain" isolated from a vineyard (RM) were mated and 112 haploid progeny strains were isolated. Each strain was genotyped at approximately 3000 markers and RNA expression levels were measured using DNA microarrays [9]. Statistical linkages were found between expression variations and quantitative trait loci (QTLs), and these loci were then assessed for interactions [74]. Although the data suggest that most transcripts were influenced by multiple loci [7], statistically significant pair-wise interactions have only been found for 225 transcripts [8]. Another series of yeast studies, taking high-temperature growth (HTG) as a quantitative phenotype, used reciprocal-hemizygosity as a tool to dissect QTLs in yeast [72]. The contribution of each allele to HTG was inferred by constructing hybrids of two yeast strains and then systematically deleting one copy of each gene within a candidate QTL. The QTL architecture was found to be more complex than expected, featuring both *in cis* and *in trans* linkages and suggesting that QTL regions cannot always be narrowed to a single local gene. The method was also used to explore how the influences of three trait genes were affected by variation in genetic backgrounds [69]. Reciprocal-hemizygosity analysis with ten other yeast strains demonstrated that the trait genes identified in one background did not necessarily contribute in the same way in other genetic backgrounds. These results demonstrate that, in addition to complexity within a QTL region, there is additional complexity due to genetic interactions. Together these studies illustrate some of the substantial complications that will arise in the analysis of complex genetics in the context of natural populations, such as the identification of trait loci in a background of genetic random variance, the separation of phenotypic effects from *cis*-acting and *trans*-acting polymorphisms, and the limitations of the pair-wise interaction analysis to complex genetics.

Furthermore, the logic of genetic interactions could be applied to functional interactions between different types of biomolecules. For example, recent work has studied the genetic basis of drug response in yeast [59]. Multiple polymorphisms were found that linked genetic loci to certain small molecule drugs, constituting a set of 124 gene-drug interactions. This approach provides a model for understanding variation in drug response within a genetically diverse population. Another study directly applied genetic interaction techniques to pair-wise interactions between drugs by mapping a set of compounds into classes that correspond to the cellular functions they affect [93]. These works begin to address how the understanding of complex genetics can be extended to involve additional system elements and, ultimately, generate a view of the organism as a complex system.

Overall, the study of genetic interactions is a field that has seen substantial development in the past decade. High-throughput methods will continue to open new avenues of research and expand established approaches to genome-wide scales. Data generated by these experiments will require formal and systematic approaches for analysis. Currently, network methods are the dominant framework.

Constructing Genetic Interaction Networks

Prior to high-throughput experimentation, genetic studies mapped interactions between a few genes in isolated functional pathways. These pathways represent information flow through a small number of elements that regulate a specific cell behavior, such as response to osmotic stress. Today, high-throughput techniques enable the assembly of large-scale genetic interaction data into networks and hold the potential for constructing semi-global maps of multiple, inter-connected pathways.

This wealth of data requires a formalism to efficiently analyze relationships between system elements. Complex systems are often best visualized as networks in which individual points, called *nodes*, are connected by lines or arrows, called *edges*. In genetic interaction networks, the nodes commonly represent genes, alleles, or gene perturbations (e. g. a gene deletion). Edges that connect nodes can take on different meanings, ranging from classic regulatory influences of one gene's activation or repression of another's activity to edges that signify a direct observation, such as synthetic lethality. The central challenge is to represent the richness of complex genetics in an informative way. Because the construction of each study is informed by a different biological problem, diverse network approaches have been pursued in the literature.

Since they are binary, synthetic lethal interactions are easily represented as a network of gene deletions connected by SSL edges. Although the formal information content of the edges is low, SSL networks have the advantage of relatively high coverage. Pair-wise combination of about 1000 yeast genes have been tested, and although this represents only 3% of all possible yeast pairs it encompasses 500,000 experiments. Four thousand of these pairs were SSL positive, producing a sparse but topologically interesting network. Non-essential genes averaged 34 synthetic lethal partners, and essential genes were found to have more interaction partners on average [80]. Extrapolating these results genome-wide, the authors estimate 200,000 essential pair-wise combinations in yeast, a number of lethal outcomes that is much larger than the 1000 genes that are essential individually [6]. The current network of 4000 genetic interactions demonstrates that SSL interactions are more likely to occur between non-essential genes of the same or related function, unlike SSL partners of essential genes that tend to show a broad spectrum of functions. This suggests that network location can be a predictor of gene function for non-essential genes, enabling novel functional hypotheses for genes based on a common function of interaction partners.

The known SSL network exhibits two interesting topological properties. First, it appears to be a *small world* network, defined as a network in which the length of the shortest path between two nodes is smaller than random expectation. Nodes are densely grouped into local clusters in which the interaction partners of any gene also tend to interact. Thus, the most likely candidates for SSL interactions for a given gene are the interaction partners of its known SSL partners, greatly increasing the likelihood of finding additional interaction partners in a targeted screen [80]. The second network property observed is that the number of SSL partners for each gene follows a power-law or *scale-free* distribution in both the yeast [80] and worm [49] data. As a result, most genes have relatively few interactions, and a small number of genes have relatively large number of interactions. This latter set, referred to as hubs, can be viewed as more important for fitness since the organism is most sensitive to pair-wise perturbations involving them. If this property is also a feature of human networks, the hub concept may inform the treatment of disease. Taking cancer as an example, hubs of cancer cell networks might be targeted for perturbation to increase the chance of a SSL interaction with a gene already genetically perturbed in the cancerous cell.

Nearly 5000 additional, and mostly novel, synthetic fitness or SSL interactions were discovered by studying genes involved in processes related to DNA integrity in yeast using dSLAM [57]. A total of 16 gene modules were identified in the network by clustering genes with a high congruence in SSL interactions, and each module was assigned a function based on its member genes. The resulting network mapped compensatory pathways among multiple biological processes, including DNA replication, DNA repair, checkpoint signaling, chromatin structure maintenance, and the response to oxidative stress. The modular architecture was consistent with prior models, and involved many genes with human homologs linked to cancer and aging.

The study of SSL interaction networks has the practical advantages of a simple, rapid assay and the direct mapping of each positive result to an edge in the interaction network. This narrow definition of genetic interaction, however, cannot explore other types of genetic interaction that have proved informative, such as suppression and masking epistasis. Encompassing all types of genetic interaction requires a systematic formalism such as the inequality relationships developed by Drees et al. [23]. As described above, these inequalities can be grouped into rules of genetic interaction corresponding to familiar and newly defined interaction modes. While many of these modes, such as synthesis, were symmetric with respect to the interacting genes, four of the modes produce directional edges. For example, instances of suppression were rendered with a colored arrow from the suppressor gene to its target gene. The resulting 1800 genetic interactions between 133 genes compose a genetic interaction network, derived with the *PhenotypeGenetics* plug-in for the *Cytoscape* software platform [67]. The nodes of this network included both gene deletions and plasmid-borne over-expressers, and the edges were mapped using nine colors corresponding to the nine modes of genetic interaction based on classical genetic interaction rules. This produced a richly multichromatic network suitable for informatic analysis (Fig. 4).

The multiplicity of genetic interaction modes facilitates the inference of relationships between individual genes and specific biological functions. In the Drees study, individual alleles were often found to interact in a particular mode, or *monochromatically*, with partner genes of coherent biological function, leading to hypotheses for regulatory and pathway organization [23]. Large-scale patterns of mutual information were also extracted from the data set, and groups of genes with significant mutual information between them formed network cliques corresponding to physical pathways. The genetic interaction patterns define a map of information flow from specific genetic perturbations to quantifiable phenotype effects.

This network was further analyzed by Taylor and Galitski [76], who searched for repeated subnetworks or *motifs* of three or four nodes, in which repetition suggested functional organization. Statistically enriched motifs were then assessed for functional coherence and many instances of functional monochromaticity were observed involving multiple genes. For example, deletions of multiple protein kinase genes were found to suppress gain-of-function perturbations of both signaling and transcription factor genes. This suggests that the kinases mediate information flow from the signaling proteins to transcriptional factors, and these pathways are broken by kinase deletions.

Multi-modal genetic interaction analysis was also performed on the MMS-sensitivity network of St. Onge et al. [71]. Genetic interactions were initially classified as aggravating, alleviating, or neutral interactions based on the double-mutant growth rates relative to that of the two single mutants. Alleviating interactions were of particular interest since there are many ways genes can mask or mimic another's effect. Thus, these interactions were sub-classified into five rules of interaction based on models of pathway ordering and protein co-function, four of which were assigned directionality. The resulting network model uncovered functional relationships and pathway order. The principle of genetic congruence, that genes with similar functional roles will share interaction patterns with functionally related genes in the system, was used to implicate a new regulator in DNA repair.

Both the yeast invasion and MMS networks classified genetic interactions into multiple modes based on interaction inequalities as described above. However, the authors used slightly different classification schemes. For example, in the invasion network "epistasis" included any interaction in which one single-mutant phenotype masks the phenotype of another. In the MMS network a further distinction was drawn between "masking epistasis", in which the single-mutant with a stronger effect masks the other, and "suppression", in which a weakly defective single-mutant masks the strongly defective one. While both networks proved informative, it is unclear which choice of mode classifications are the most meaningful for a given data set. This issue can be analyzed from the perspective of information theory. A measure of network complexity that places information in the context of the system under study could be used for the unsupervised classification of interaction modes for these two data sets. Network classification schemes that produce greater complexity might also generate more biologically meaningful information, i. e. more "biological statements" linking genes to functions were obtained in the more complex networks. Such complexity-based methods represent a powerful and general approach to genetic interaction analysis, with potential for the study of mammalian systems in which interactions are complex and gene annotation data is sparse.

Fully quantitative studies of genetic interactions have been hindered by the limited amount of numeric phenotype data required for more sophisticated mathematical techniques that might decipher the principles underlying genetic interaction. To overcome this limitation many researchers have adopted gene expression microarrays as a quantitative phenotype [9,41,42,47,62,85]. For each strain and environmental condition, genome-wide transcript levels constitute thousands of quantitative phenotype measurements that provide much greater molecular detail than a whole-cell phenotype, such as growth rate. This approach was combined with classical epistasis analysis by Van Driessche et al. [82]. By clustering mutants based on genome-wide expression profiles and applying the principle of masking epistasis, the authors accurately reconstructed the protein kinase A signaling pathway. In a more recent study, gene expression data was combined with whole-cell phenotype data and mathematical modeling to infer and predict genetic interactions relevant for yeast cell differentiation [12]. This analysis used combinatorial perturbations to infer how a set of regulatory genes quantitatively affect each other's activity as well as the expression of thousands of downstream genes. This quantitative model of genetic interaction in terms of genetic influences allowed the prediction of the effects of novel pair-wise genetic perturbations. The decreasing costs of microarrays and advances in genome-wide data analysis make gene expression data an increasingly attractive option for genetic interaction analysis.

Interpreting Genetic Interactions

The functional relationships described by genetic interaction networks reveal pathway organization and gene function. For predictive and therapeutic purposes, however, it is useful to translate these functional relationships into biomolecular hypotheses. Such hypotheses can suggest additional genetic perturbations to test and validate models, establishing the applicability of network analysis techniques and enabling an iterative process of model refinement. Moreover, the implication of specific alleles, molecules, and interactions in health-related processes can identify candidate genes and gene products for targeted therapeutic intervention with drug compounds or RNA interference. Thus, the interpretation of genetic interaction networks is necessary to improve the basic understanding of complex genetics as well as facilitate the development of personalized and predictive medicine.

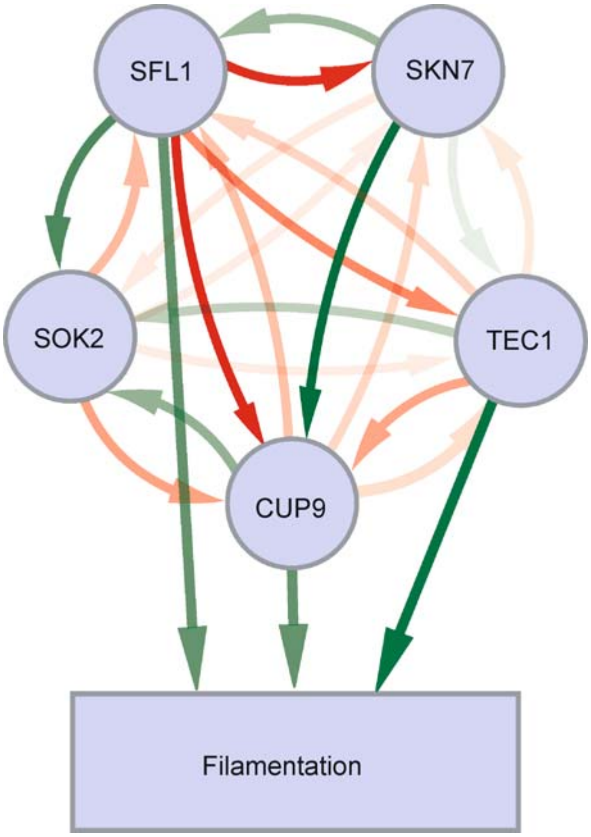
Formulating such hypotheses generally involves both molecular data integration and computational modeling. While genetic interactions define functional relationships and uncover pathways of information flow, molecular interaction databases provide a wiring diagram of possible mechanisms for the transmission of functional information. These complementary data types can be integrated to generate models of phenotype regulation [13,31,83,88]. Various computational methods enable this data integration. Kinetic modeling, for example, uses differential equations to predict the functional outcomes when a subset of physical interactions is active. Constraint based approaches use data analysis techniques to narrow the possible mechanisms that may have generated an observation, until the best hypothesis is identified [5,65,89,91]. Finally, whole-cell phenotypes can be dissected at the molecular level by integrating RNA expression levels and proteomic data [12,35,40]. These systems biology approaches have recently been applied to interpret complex genetic networks.

One particularly model-driven approach involves the use of computational models that simulate cellular processes to predict genetic interactions *in silico*. This requires a model, often highly detailed, that captures the relevant activity of every gene product involved in the process being simulated. Metabolic models based on Flux-Balance Analysis (FBA) have been successful in predicting growth rates for yeast [26] and bacteria [25] under a range of environmental conditions and genetic perturbations. Segré and collaborators used an FBA model to explore genetic interactions among metabolic genes in yeast by performing single and double gene knockouts *in silico* [66]. The model predicted that genetic interactions for growth rates fall into three distinct modes: cases in which the double deletion effect is significantly less than the product of the two single mutants (alleviating); cases in which the double deletion effect is significantly greater than the product of the two single mutants (aggravating); and cases in which the double deletion is not significantly different than the product of the two single mutants (neutral). The study also predicted similarity in interaction modes, or monochromaticity, between co-functional genes, a result that echoes the finding that genes with common functions preferentially interact in SSL networks. This work illustrates the power of using a system-wide computational simulation to predict complex genetic interactions using sensitive, quantitative whole-cell phenotypes. One of the major disadvantages of such an approach is the extensive amount of information necessary to formulate an FBA model. Furthermore, these predictions have not been empirically verified, and this would involve a major experimental undertaking.

As an alternative to model-based approaches, data-driven computational analysis has also been used to predict interacting gene pairs. Multiple types of relationships between gene products, such as common localization, function, and patterns of gene expression, were used to create a decision tree for predicting SSL interactions in yeast [88]. Genetic interactions were also predicted on a genome-wide scale in the nematode worm *Caenorhabditis elegans* by computationally integrating physical interactions, genetic interaction, gene expression, phenotype, and functional annotation data from yeast, worm, and fly [95]. The authors of this study used logistic regression to determine the predictive power of each type of data, or *feature*, based on a training set of 1816 known genetic interactions in *C. elegans*. Each feature was thereby weighted according to its predictive importance and the probability of interaction between every pair of *C. elegans* genes was calculated. In total, this procedure generated over 18,000 likely genetic interactions. As with previous studies, co-functional genes proved more likely to exhibit genetic interactions (although this is not an entirely independent result given that known genetic interactions between co-functional homologs were the predictors with greatest weight in the logistic regression). A handful of interaction candidates were experimentally tested using RNAi, and about half of the pair-wise perturbations exhibited some degree of genetic interaction in either a vulval development or pharyngeal pumping phenotypes. Interestingly, the vast majority of newly implicated genes did not have vulval development phenotypes when perturbed individually, supporting the hypothesis that the observed double-perturbation phenotypes were the result of genetic interaction. The trade-off inherent in this approach to predicting genetic interactions is that although the analysis can be performed on a genome-wide scale, the nature of each interaction (e. g. additivity, suppression) cannot be predicted. Nevertheless, the approach enables the computational prioritization of potential interaction pairs and greatly reduces the space of likely genetic interactions.

Targeted strategies of data integration have also been used to provide biological context to observed genetic interactions. Kelley and Ideker [45] demonstrated a use for protein-protein and protein-DNA binding networks in understanding the synthetic lethal interaction network in yeast. The study evaluated three standard pathway models for SSL interaction [30,81]: the *between-pathway model*, in which SSL interaction partners are situated in parallel pathways with redundant functions; the *within-pathway model*, in which SSL gene pairs occur for protein subunits of a single complex or pathway that does not lose function until multiple components are removed; and *indirect effects*, in which many pathways are affected and the SSL deletions cannot be associated with specific molecular mechanisms. Based on maximum likelihood, the authors estimated that 40% of yeast SSL interactions could be explained by either the within-pathway or between-pathway models. These models suggest specific patterns of genetic interaction. For the between-pathway model, near-bipartite SSL subnetworks suggest that the missing bipartite links represent undetected interactions. Alternatively, the within-pathway model suggests that genes with many common interaction partners should themselves interact. These predictions were cross-validated by removing one-fifth of the interactions from the data set and then tested to see how well the withheld interactions could be predicted. Both models showed enhanced prediction accuracy relative to randomly predicted interactions, although the between-pathway model was a significantly better predictor, a finding consistent with those suggested by a decision tree approach [88] and an analysis of dSLAM modularity [57,90]. In the worm, integration of protein data also reinforces the compensatory pathway interpretation for SSL interactions [49]. A concurrent study by Zhang et al. [94] integrated molecular and genetic interaction data using the concept of network motifs [53] to guide biological interpretation [92]. In this work, a global network containing protein-protein binding, protein-DNA binding, gene co-expression, sequence homology, and SSL relationships was systematically searched for all possible three-node motifs. A motif in which two proteins linked by protein-protein interaction both have SSL interactions with a third protein was detected in the network ten times more often than random expectation. This was interpreted as a sign of higher-order organization: two proteins that bind in the same complex or pathway share genetic interactions with other proteins in a separate complex or pathway. This interpretation was supported by a search for a four-protein motif in which two parallel pairs of co-binding proteins are linked by all four possible SSL interactions. This motif was found over two hundred times more than random expectation, further supporting the interpretation that SSL interactions are often hallmarks of parallel or compensatory pathways. The goals of integrative analysis are the systematic interpretation of SSL interactions in terms of molecular interactions and the association of specific pathways with observed genetic interactions.

For networks that include multiple modes of genetic interactions, such as suppression, additivity, and genetic synthesis, finding biologically meaningful, non-random network topologies in an integrated network is hindered by the enormous number of possible motifs and the large datasets required for adequate statistics. One strategy for interpreting these rich genetic interaction networks is a quantitative generalization of the classical genetic interaction approach of observing how genetic perturbations interact to affect phenotypes [4]. This method has historically been used to infer how genes influence one another and thereby affect a downstream phenotype, revealing functional relationships such as activation, repression, and pathway order. Using filamentous growth in yeast as a model system (a precursor to invasive growth due to nitrogen starvation), a data decomposition technique was developed to separate genetically "direct" (not necessarily molecularly direct) effects of regulator genes from the genetically "indirect" effects that involve genetic interactions between regulator genes (Fig. 5) [12]. Molecular interaction data were then integrated with the decomposition results to construct regulatory network models of information flow through paths of genes (and gene products) linked by physical interactions. These networks represented quantitative hypotheses of influence from the causal perturbation, through a series of molecular interactions, to the expression of affected genes. Since additional genes were implicated in specific influence-mediator roles in the network, quantitative predictions could be made for gene expression effects arising from their deletion and combinations of deletions. This was done by removing the quantitative influence corresponding to the molecular pathways involving the deleted gene(s). A second round of gene expression data was collected to test a set of predictions and the results demonstrated genome-wide success. Next, by using additional decomposition methods to link gene expression patterns with the filamentous growth phenotype, a network model of whole-cell phenotype regulation was constructed. Predictions for additional perturbations were formulated and experimentally tested. The model successfully implicated new regulators of the phenotype and was used to accurately predict phenotypes for novel combinatorial deletions. While this initial work used laboratory-engineered mutant strains, the techniques can be readily extended to dissect and map complex genetic systems in which a handful of trait genes have been identified. With the increasing availability of human interaction



Systems Genetics and Complex Traits, Figure 5

Edge intensity denotes influence strength. (Adapted from [12])

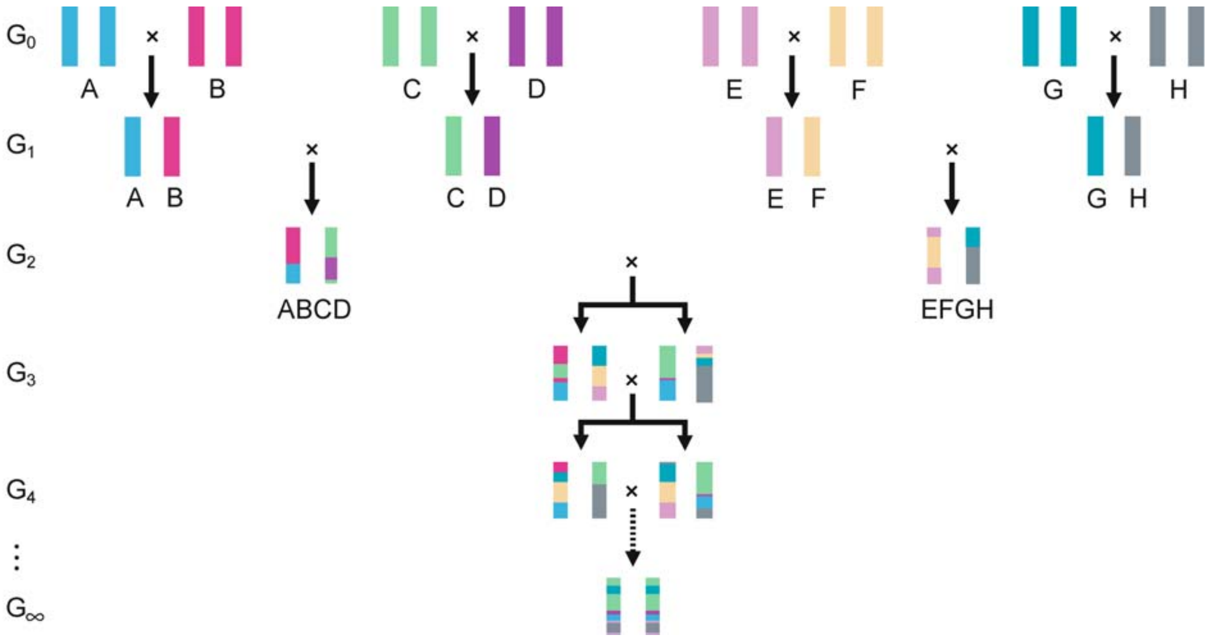
data [73] and further modeling developments to address allelic variation in outbred populations, similar quantitative and integrative techniques may ultimately be applied to disease-related models.

Future Directions

Although genetic complexity is central to all life, systems biology approaches to complex genetics have to this point focused on simpler model organisms. The genetic manipulability, rapid reproduction, and genome-wide interaction databases for yeast, worm, and model prokaryotes have enabled efficient development of experimental and analytical methods. However, the possibility of understanding human disease through the study of complex genetics has catalyzed substantial advances in genetic association studies in mammalian models and human populations [54,55]. The current status of systems approaches to human heath are discussed elsewhere in this encyclopedia (see ► Systems Biology, Introduction to and ► Systems Biology of Human Immunity and Disease), and here we will limit discussion to research opportunities in model systems that are candidates for the systems approaches discussed in this chapter. Future developments can be roughly split into developments in two categories: laboratory resources and computational methods.

Recent programs in rodent breeding have engineered controlled yet genetically diverse populations. These experiments conceptually resemble the analysis of recombinant meiotic progeny generated by crosses in yeast (Sect. "Measuring Genetic Interactions Genome-Wide"). In mouse, two inbred, homozygous parent strains are crossed and two of the resulting F_1 offspring are mated (Fig. 6). The resulting F_2 progeny are then segregated into breeding pairs, and each pair begins a line of repeated sibling inbreeding that continues until a homozygous inbred strain is obtained. Unlike yeast, in which homozygous diploids can be obtained in a matter of weeks, producing recombinant inbred (RI) lines in mice typically requires 20 generations, or 7–8 years, to produce the desired RI lines. Nevertheless, RI genetics have been integrated with gene expression and phenotype assays in mice [10,15,51] and rats [37]. While each of these studies was able to associate individual loci with gene expression patterns, implicating new genes in metabolic, nervous system, and stem cell function, the relatively small numbers of RI strains (approximately 30 in each study) was insufficient for systematically inferring polygenic effects. Inferring such effects would require additional model parameters to encompass the quantitative interaction between each gene pair, leading to overfitting for small data sets. Nevertheless, these works provide prototypes for further studies using RI strains.

While constructing RI strains is expensive and laborious, they have significant advantages over simpler intercross strains in the study of complex genetics. Multiple mice from each RI line will allow biological replication and the observation of isogenic strains under a variety of environmental conditions. Strains can be assayed over long time scales and multiple generations. A collection of shared RI strains would be especially valuable as a community asset both in terms of labor saved, since the strains need only be constructed and genotyped once, and data sharing, since the results from multiple researchers can be integrated in novel analysis. With this in mind, the Complex Trait Consortium is pursuing the Collaborative Cross project [16], which aims to create approximately 1000 RI strains derived from eight inbred founder strains. This set of RI strains will contain a degree of genetic diversity suf-



Systems Genetics and Complex Traits, Figure 6

The collaborative cross strategy for breeding recombinant inbred (RI) strains. The starting parents of the cross (Generation 0, G_0) consists of eight inbred laboratory mouse strains. The goal of the breeding strategy is to create 1000 new RI mouse lines that contain different combinations of alleles from the original parents. A theoretical example of the generation of a single chromosome for a single RI strain is shown. In the first generation of the cross (G_1) progeny receive an unaltered copy of a chromosome from each parent. In all subsequent generations chromosomal material is exchanged between chromosomes generating chromosomes that contain genomic regions from a variety of parents. The lines are ultimately converted to recombinant inbred (RI) strains, in which an individual contains identical copies of these hybrid chromosomes (G_{infinity}) by multiple generations of inbreeding, in this case mating brother-sister pairs. (Reprinted with permission from The Complex Trait Consortium [16])

ficient to uncover gene-gene, gene-drug, and gene-environment interactions. Furthermore, the resulting 1000 inbred mouse lines could be crossed to produce hundreds of thousands of intercross (RIX) strains. Inbred homozygosity ensures that these genotypes will be reproducible and the genetic differences between RI strains will produce low coefficients of inbreeding. Because the RIX strains are not themselves inbred, they will more closely resemble the human population in terms of heterozygosity, genetic mixing, and hybrid vigor. When combined with the proliferation of gene annotation and molecular interaction data, resources like the mice derived from the Collaborative Cross will allow systems approaches to mammalian genetics and provide a platform for adaption to human disease.

In addition to improvements in laboratory resources, a number of analytical advances are required to better understand large-scale genetic interaction networks. These include further developments in data integration, quantitative prediction, data analysis, ontologies, and frameworks for classifying complex genetics.

Strategies of data integration have taken diverse forms. These range from all-inclusive, nearly universal strategies of data pooling [88,95], to integrating only a handful of physical interactions implicated by phenotype modeling [13,45], to modeling constrained by incomplete data resources [52]. The accuracy and reliability of data varies greatly both across data types (e. g. protein-protein versus SSL interactions) and within data types (e. g. protein-protein data from yeast two-hybrid versus co-immunoprecipitation assays). Some methods have used machine learning techniques to weigh data types based on predictive utility [38,94]. Through the repeated application of such methods to multiple data sets and biological systems a consistent picture of data reliability might emerge, providing valuable information for modeling and interpretation of complex genetic systems. Finally, in many cases the integration of published data appears to be performed at a late stage in the work as researchers seek more complete explanations for their results. While this is to some extent an inevitable result of large-scale screens or discovery-driven science, it would be advantageous for investigators to consider from the outset the types of data that may be most complementary and form a coherent plan of data integration [24]. The use of successful mathematical models and biological simulations at such an early stage of research would aid in this integrative research design.

Genetic interaction analysis is often showcased for its predictive modeling potential. Since genetic interactions inherently reveal functional information, under-characterized genes can be assigned to biological pathways [23,71] or functions [80], and these implicit hypotheses about gene function can be experimentally tested. However, physical interaction networks organized into pathways of information flow can also explicitly predict the consequences of additional perturbation [12,66]. The predictions are often quantitative and represent a potentially powerful tool for predictive medicine when applied to the development of therapeutic interventions. Expanded use of computational modeling has the potential to generate more accurate and sophisticated predictions of how systems respond to genetic or environmental perturbations. Established modeling strategies include kinetic modeling, which has been used to understand complex cell circuitry [14,60] and to elucidate subtle stochastic effects [2], and Boolean network approaches, which have been used to model sophisticated systems such as host-parasite interactions [77] and uncover fundamental properties of biological dynamics [68]. Combined with time-series assays of responses to environmental stimuli in genetically diverse organisms, these quantitative modeling techniques can be a powerful tool in understanding the dynamics of polygenic traits.

In the analysis of genetic interaction data, the field of systems genetics now is primarily focused on synthetic lethal interactions, to the extent that many authors use the terms genetic interaction and synthetic lethality synonymously. However, synthetic lethal interactions may be less relevant in the complex genetics of natural populations than in laboratory-based screens. Their broad application may also be limited by reliance on technology specific to model organisms and networks composed of binary interactions. For instance, although synthetic screens can reveal compensatory modules and classify genes into functional pathways, the scale-free architecture of these networks often features many pathways connected to a common hub [49]. Since newly discovered synthetic interactions are most likely to include a hub and a non-hub gene, many pathways will be connected to the hub, and thus be equally likely candidates. It may therefore be difficult to place the latter gene in the correct pathway without additional information. Alternatively, considering a broader spectrum of genetic interactions can both resolve pathway membership, via mutually informative partners, and provide information about pathway structure, e. g. the placement of a factor in a signaling or transcriptional cascade. A network encoding a more general set of genetic interaction rules can thus enable the modeling of specific mechanisms in detail rather than congruence methods based on guilt-by-association. Examples of such rules are directional, targeted interactions like epistasis and suppression (Fig. 4) [23,71] or quantifiable influences describing one gene's influence on another (Fig. 5) [12].

To this point, the classification and interpretation of genetic interactions has been inconsistent due to the paucity of quantitative phenotypes that can be widely screened paired with a limited knowledge of the nature and prevalence of genetic interactions. As the field of complex genetics evolves, so too will the meaning of genetic interaction. To date, genetic interaction studies have primarily focused on pair-wise interactions that are interpreted on a network level. This is often a result of exploring complex genetics with engineered strains, in which single and double genetic perturbations are systematically performed. The combinatorial expansion makes systematic construction of higher-order perturbations (such as triple-mutants) intractable. Indeed, a comprehensive set of double perturbations is daunting, and would be made even more complicated when one considers the corresponding increase in the number and richness of possible phenotypes. In contrast, populations derived from genetically diverse strains, such as yeast and mouse crosses, will sample all genetic combinations of arbitrarily high order. It is possible that network analysis based on pair-wise interactions will be inadequate for experiments involving these strains. Modules or densely interacting "gene complexes" may better describe the space of polygenic effects. With these issues being compounded by the limited capacity to assay many of the phenotypes most relevant to disease, it is currently unknown which approaches will yield the most information about the underlying biology. It is likely that the optimal approach will vary by organism and experiment.

Mature network analyses developed in a broad and systematic framework could be readily expanded beyond genotype-phenotype modeling. To model effects of environment and drugs, additional factors that affect phenotype might be integrated. Potential factors include metabolites, exogenous molecules such as drugs or environmental compounds, and external conditions such as temperature or cell density. A model encompassing multiple factors could quantify how each factor interacts or influences each other factor, in order to produce a map of how effectors interact to generate a phenotype or outcome. Predictive network models focused on specific phenotypes would allow the development of highly specific drugs and aid in the prediction of side effects by observing how a particular perturbation affects connected systems *in silico*. These models could also aid in the identification of allelic combinations that cause genetic disease, the prediction of desired drug-allele interactions for personalized medicine, and the development of multi-drug treatments. Creating such models will require substantial advances in integration of mathematical modeling and genetics, with the focus modest-sized systems rather than genome-scale screens.

In addition to advancing biomedicine, predictive models could also inform evolutionary biology and bioengineering. Rare mutations that confer fitness advantages could be identified by systematically predicting the fitness consequences of perturbations. Perturbations predicted to have effects on multiple phenotypes may uncover evolutionary trade-offs, in which the fitness balance might vary as the environment changes. Fitness assays, such as the E-MAP method in yeast [64], could be used to experimentally test these predictions in model organisms. These effects could in turn be used as input for population modeling and predict evolutionary trends suitable for laboratory testing with fast-replicating yeast or bacteria. As a more practical application, the ability to predict the behavior of re-engineered and synthetic biological networks is a key ingredient in the design and development of novel bioengineered systems. Models that predict complex phenotypes quantitatively and precisely will be a necessary component of elaborate modeling schemes that link genotype, phenotype, and ecosystem.

High throughput data acquisition and the development of computational approaches have enabled the field of systems genetics to progress rapidly. Far-sighted experimental planning and continued technological advances can be expected to fuel continued progress. Current studies, primarily focused on yeast as a model system, are laying the groundwork for network analysis and modeling methods that may be adapted to higher organisms. A target for early adaption may lie in the field of metazoan development to study complex genetic networks involved in multicellular biology, possibly expanding the use of *C. elegans* as a model due to its ease of manipulation by RNAi technology [43,48]. Knowledge accrued from these studies coupled with advances in statistical genetics may form a solid basis for applications in more genetically diverse populations, including the RI mouse strains generated by the Collaborative Cross and their RIX intercross counterparts. The result will be new tools for complex human genetics. Meanwhile, the mapping of the human HapMap, The Cancer Genome Atlas, and human interaction networks will begin to provide data necessary to make use of these tools in personalized and predictive medicine.
