The two terms in Eq. (1) represent competing effects on the manifold: Elasticity favors a flat manifold with a constant $\mathbf{u}$, while the attractive force from impurities gives rise to a spatially varying $\mathbf{u}(\mathbf{r})$. The configuration $\mathbf{u}(\mathbf{r})$ which minimizes Eq. (1) satisfies the following force-equilibrium condition:

$$\gamma \nabla^2 \mathbf{u} - \nabla_{\mathbf{u}} V_R(\mathbf{r}, \mathbf{u}) = 0 . \qquad (2)$$

Complications arise when Eq. (2) has many solutions. Each solution corresponds to a local minimum of the energy function (1), separated by energy barriers from other local energy minima. The resulting energy surface (or landscape) is known as *rugged*.

Proper characterization of the energy landscape defined by Eq. (1) has been a long-standing problem in the statistical mechanics of disordered systems. For $D < 4$ and weak disorder, the ruggedness appears when the system size is greater than a characteristic length L_c along the manifold, known as the *pinning length*. This important observation was due to Larkin [44] for flux lines, Fukuyama, Lee and Rice [29,50] for CDWs, and Imry and Ma [37] for magnetic domain walls. On scales $L < L_c$, elasticity limits the transverse displacement $\mathbf{u}$ (known as roughness) to be within the respective correlation length $a_\perp$ of the impurity potential $V_R(\mathbf{r}, \mathbf{u})$, so that the manifold lies within a single minimum of the energy surface. On the scale L_c, the typical strength of the random force $\nabla_{\mathbf{u}} V_R$, averaged over a volume L_c^D, is estimated to be $\left|\overline{\nabla_{\mathbf{u}} V_R}\right| \simeq \frac{R^{1/2}(0)}{a_\perp} L_c^{-D/2}$. Balancing it with the elastic force $\gamma a_\perp / L_c^2$, one obtains,

$$L_c = \left(\frac{\gamma^2 a_\perp^4}{R(0)}\right)^{1/(4-D)} . \tag{3}$$

For $L > L_c$, Eq. (2) has an exponentially increasing number of solutions.

For $D > 4$, the elastic term in (2) dominates over the random force term on large length scales. Consequently, the rugged energy landscape is a small scale phenomenon which occurs when L_c is larger than the correlation length $a_\parallel$ of the disorder potential $V_R(\mathbf{r}, \mathbf{u})$ parallel to the manifold. From Eq. (3) we see that this condition requires the disorder strength to be sufficiently strong. Weak disorder is not able to produce pinning for manifolds with internal dimension greater than 4.

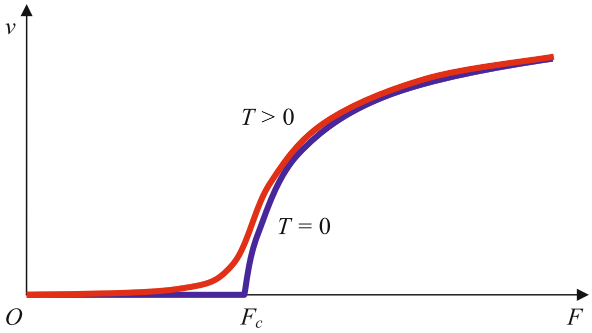
The qualitative analysis above shows that the energetics of the manifold problem are qualitatively different below and above four dimensions. The existence of a *critical dimension* $D_c = 4$ suggests systematic renormalization group approach to the problem. However, earlier attempts based on a perturbative treatment of the disorder potential failed to produce a renormalizable theory [1,22,32]. This was first achieved successfully by Daniel Fisher [28] in 1986 in the equilibrium case. Extension of the scheme to the driven depinning transition is discussed in Sect. "Analytical Treatments of the Depinning Transition and Universality".

Driven Depinning, Critical Properties, and Scaling

The Driven Depinning Transition

An applied force **F** coupled linearly to the displacement field $\mathbf{u}(\mathbf{r})$ tilts the equilibrium energy landscape as defined by Eq. (1) towards a particular direction. For small **F**, the manifold makes small adjustments locally to reach a new stationary state where force equilibrium is re-established, and this happens for the majority of solutions to Eq. (2). The number of such solutions, however, continues to decrease as **F** increases. When the magnitude of **F** exceeds a certain critical value, all stationary states disappear, and the manifold enters a running state. The transition from stationary to running states with increasing **F** is known as the *driven depinning transition*.

Figure 1 illustrates the dependence of the steady-state velocity v of the manifold against $F = |\mathbf{F}|$. In the absence of thermal fluctuations, there is a well-defined threshold F_c that separates the pinned from moving regimes. At finite temperatures, the transition from a pinned to a moving manifold is smeared out by thermally activated creep motion. At low temperatures, the rounding effect is weak except in a very small region around F_c.



Collective Transport and Depinning, Figure 1
Schematic plot showing the manifold velocity *v* against the driving force *F* at zero (*blue*) and finite (*red*) temperatures. Below the threshold F_c, the manifold is pinned by impurities in the medium, but thermal activation may generate a small but finite velocity

The discussion in Subsect. "Rugged Energy Landscape, Critical Dimension, and the Pinning Length" on the pinning length can be used to estimate the critical force needed to depin the manifold. For $D < 4$, the maximum pinning effect is seen on the scale L_c, where the typical strength of the first two terms in (5) is given by [10,26,50]

$$F_c \simeq \gamma a_\perp / L_c^2 = \frac{R^{2/(4-D)}(0)}{\gamma^{D/(4-D)} a_\perp^{(4+D)/(4-D)}} . \tag{4}$$

This is also the force needed to depin the manifold. For $D > 4$, pinning is possible only if $L_c > a_\parallel$ or $R^{1/2}(0) a_\perp^{-1} a_\parallel^{-D/4} > \gamma a_\perp / a_\parallel^2$, i. e., the strength of the pinning force is stronger than that of the elastic force on the minimal scale $a_\parallel$.

Continuum Model of the Manifold Dynamics

A dynamical model for the manifold can be constructed by assuming the motion to be completely overdamped. This is quite reasonable for the applications mentioned in Sect. "Introduction", where the displacement $\mathbf{u}(\mathbf{r}, t)$ represents a course-grained variable which changes on a time scale much longer than the relaxation time of underlying microscopic processes. With this assumption, the equation of motion for the manifold takes the form,

$$\mu^{-1} \frac{\partial \mathbf{u}}{\partial t} = \gamma \nabla^2 \mathbf{u} + \boldsymbol{\eta}(\mathbf{r}, \mathbf{u}) + \mathbf{F} .$$

Here μ is known as the mobility of the manifold, and $\boldsymbol{\eta}(\mathbf{r}, \mathbf{u}) = -\nabla_{\mathbf{u}} V_R(\mathbf{r}, \mathbf{u})$ is the random pinning force.

An interface is described by a height function $u(\mathbf{r},t)$, so that the dynamical equation, which defines the so-called *linear interface model* (LIM), takes a scalar form [10,26],

$$\mu^{-1}\frac{\partial u}{\partial t} = \gamma\nabla^2 u + \eta(\mathbf{r},u) + F\,. \tag{5}$$

The same equation applies to a CDW, but with $\eta(\mathbf{r},u+2\pi) = \eta(\mathbf{r},u)$ periodic in the phase variable [27]. Using the example of a single vortex line in three dimensions, Ertas and Kardar [23] have shown that the extra transverse dimensions do not change the main features of the depinning process. Hence Eq. (5) can be considered as the generic description of the driven manifold problem, where $u(\mathbf{r},t)$ stands for the component of the transverse displacement in the driven direction.

In Layman's terms, Eq. (5) may be viewed as describing the advance of a military front where the attacking side has more ammunition and manpower F but the defending side is able to exploit the hilly ground positions $\eta(\mathbf{r},u)$ to pose an effective resistance. In addition, stretching the front line into a convoluted form results in a decrease in attacking power and is hence discouraged!

For the analysis of Eq. (5), it is convenient to describe pinning effects in terms of the random force $\eta(\mathbf{r},u)$ instead of the random potential $V_R(\mathbf{r},u)$. Without loss of generality, one may assume the mean value of $\eta(\mathbf{r},u)$ to be zero. For Gaussian distributed random forces, it is suffice to specify the statistics of $\eta(\mathbf{r},u)$ with the correlator,

$$\langle\eta(\mathbf{r}_1,u_1)\,\eta(\mathbf{r}_2,u_2)\rangle = \Delta(u_1-u_2)\,\delta(\mathbf{r}_1-\mathbf{r}_2)\ . \tag{6}$$

On the "bare" scale, $\Delta(u) = -\partial^2 R/\partial u^2$ but as shown in [66] and [48], this relation breaks down in the driven case upon coarse-graining of the original degrees of freedom.

Critical Properties and Scaling Laws

Let us first consider the interface depinning problem as described by Eq. (5). This model has been studied extensively both analytically [14,66,69] and numerically [53,76] in recent years, and the main characteristics of the solution have been well-understood. These findings are summarized below.

The form of Eq. (5) suggests a "non-crossing condition" as first noted by Middleton [58]. Consider two interface configurations $u_1(\mathbf{r},t_0)$ and $u_2(\mathbf{r},t_0)$ at some initial time t_0. If $u_1(\mathbf{r},t_0) < u_2(\mathbf{r},t_0)$ for all $\mathbf{r}$ on the interface, one can easily show that $u_1(\mathbf{r},t) < u_2(\mathbf{r},t)$ at any later time $t > t_0$, i.e., the two solutions never touch if initially one is completely behind the other. This property in particular implies that the interface velocity $v = \overline{\mathrm{d}u/\mathrm{d}t}$ (averaged over all sites $\mathbf{r}$) in the steady state is a unique and continuous function of F, ruling out first order phase transition in this class of models.

On the moving side but close to the depinning threshold, advancement of the interface can be described with the help of Fig. 2. The thick line illustrates the interface position at a given time t_0. Pinning yields a roughness which grows as a power-law of the distance between two points on the interface, i.e.,

$$\left\langle\left[u(\mathbf{r},t_0)-u(\mathbf{r}',t_0)\right]^2\right\rangle \sim |\mathbf{r}-\mathbf{r}'|^{2\zeta}\ , \tag{7}$$

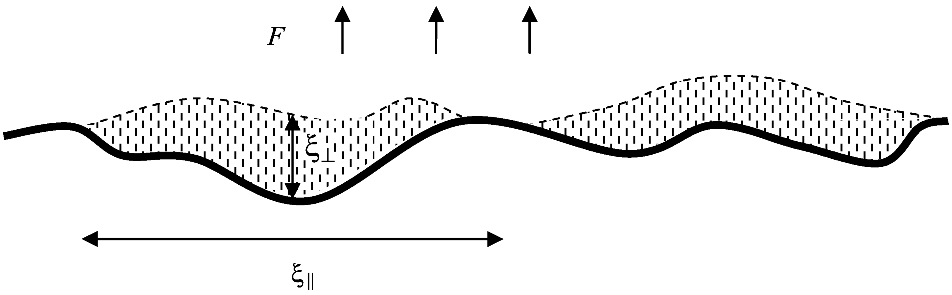
where ζ is known as the *roughness exponent*. This behavior holds on a range of length scales from the pinning length L_c to a correlation length $\xi_\parallel$ along the interface. The transverse displacement of the interface on scale $\xi_\parallel$ is given by $\xi_\perp \sim \xi_\parallel^\zeta$.

Motion of the interface within a correlation time τ also obeys scaling. On time scales shorter than τ, the interface advances through a sequence of rapid, localized movements (known as avalanches) of varying size up to the scale $\xi_\parallel$. The average time for a given site to move by a distance Δu grows as a power law: $\Delta t \sim \Delta u^{1/\beta}$. During this time, activities within a distance $l \sim \Delta t^{1/z}$ along the interface are correlated. The exponent $z = \zeta/\beta$ is known as the *dynamical exponent*. This scaling terminates when l reaches the correlation length $\xi_\parallel$, or $\Delta t = \tau \sim \xi_\parallel^z$, where the interface as a whole advances to a new disorder environment with a different distribution of pinning sites and pinning forces.

As F decreases towards F_c, the size of each correlated domain grows to infinity in a power-law fashion as well, e.g., $\xi_\parallel \sim |F-F_c|^{-\nu}$, where ν is known as the *correlation length exponent*. The three exponents ζ, z and ν together characterize the critical properties of the interface at the depinning transition. Through dimensional arguments, one may determine the critical behavior of quantities other than those discussed above. For example, the interface velocity near the transition can be estimated from $v \simeq \xi_\perp/\tau \sim \xi_\parallel^\zeta/\xi_\parallel^z \sim |F-F_c|^{\nu(z-\zeta)}$, hence the corresponding *velocity exponent* is given by,

$$\theta = \nu(z-\zeta) \tag{8}$$

The region between two interface configurations separated by time τ, as shown in Fig. 2, can be described as a set of "bubbles", each representing a correlated volume of base area $\xi_\parallel^D$ and height $\xi_\perp$. The average strength of the pinning forces within each bubble has a variation of the order $\xi_\parallel^{-D/2}\xi_\perp^{-1/2}$ from the system-wide average. Variation of this quantity among bubbles should be smaller than the excess driving force $F-F_c$ so that depinning can take place



Collective Transport and Depinning, Figure 2
An interface above but close to the depinning threshold. Depinning events within a correlation length $\xi_\parallel$ and correlation time τ are highly correlated and obey scaling at the transition. Shaded area represents the volume swept by the interface over the time interval τ

Collective Transport and Depinning, Table 1

uniformly across the system. This condition is fulfilled if the correlation length exponent satisfies the following inequality [35,66,69],

$$\nu \geq \frac{2}{D + \zeta} \tag{9}$$

The above description of interface depinning applies also to the CDW with one important caveat. Due to the noncrossing condition, steady-state motion of the CDW at $F > F_c$ is periodic in time, i. e., $\varphi(\mathbf{r}, t + \tau) = \varphi(\mathbf{r}, t) + 2\pi$ for all $\mathbf{r}$, with τ being the period of the attractor [58]. The dynamic phase advance at different sites has thus bounded variations described by $\zeta = 0$. Above but close to F_c, the activity at a given site, as measured by the phase velocity $\dot{\varphi}(\mathbf{r}, t)$, is typically concentrated in time windows much shorter than T, but acquires long-ranged spatial correlations up to a correlation length $\xi_\parallel \sim (F - F_c)^{-\nu}$. Both analytical [65] and numerical calculations [63] indicate that $\nu = 1/2$ in all dimensions, therefore violating Eq. (9). Although the origin of this behavior has not been settled completely [67], a plausible explanation is that fluctuations of the pinning force in a given region of the system are compensated by a static phase distortion $\varphi_0(\mathbf{r}) = \varphi(\mathbf{r}, t = 0)$, so that the system behaves much more homogeneous than the naïve estimate used to obtain Eq. (9). The sample-to-sample fluctuations of F_c, on the other hand, have been shown recently [7,25] to obey a Gaussian distribution with a width proportional to $L^{-D/2}$as predicted, where L stands for the linear system size.

Numerical Results for the Critical Exponents

The depinning transition of the elastic manifolds and the CDW has been studied extensively using various lattice models. Middleton and Fisher [60,61], Myers and Sethna [63], and Narayan and Middleton [67] simulated a discretized version of Eq. (5) for CDW depinning in one to three dimensions. The random force is given by $\eta(\mathbf{r}, \varphi) = V \sin(\varphi - \beta(\mathbf{r}))$, where V is the strength of the pinning force, and $\beta(\mathbf{r})$ is the preferred phase at site $\mathbf{r}$, chosen randomly from site to site. Values of critical exponents as determined in their numerical work are given in Table 1, which show good agreement with the analytic results in Sect. "Analytical Treatments of the Depinning Transition and Universality". The exponent ν_f (second row) is determined from quantities related to the avalanche propagation below the depinning threshold.

Leschorn [53] carried out large-scale simulations of a discretized version of the LIM. Exponents he obtained are also given in Table 1. These values are in good agreement with more recent studies [76]. Note that the roughness exponent ζ for a one-dimensional interface at the depinning threshold is greater than one. This gives rise to a subtlety in using Eq. (7) to measure ζ as discussed in [56].

Analytical Treatments of the Depinning Transition and Universality

The depinning transition differs from the usual critical phenomena in thermal equilibrium systems in terms of the vast separation of fast and slow time scales. Therefore the successful development of a renormalization group theory in the early 1990s to effectively capture this unique feature was an important milestone in the analytical studies of nonequilibrium phase transitions. The work acquired broader significance due to the later discovered correspondence between depinning and sand pile models of self-organized criticality (SOC), which we discuss in Sect. "Self-Organized Criticality".

Mean-Field Theory

Fisher [27] and others [43,52,55,65] considered a mean-field approximation to Eq. (5) which can be treated analytically. It is instructive to examine the calculation in some detail here as the solution reveals several important features of the depinning transition which extend to lower dimensions, while the mathematical manipulations can be kept at an elementary level.

In sufficiently high dimensions, one may approximate the Laplacian in Eq. (5) by a spring force, whose equilibrium point is set by the mean interface position $\bar{u}(t)$. The resulting dynamical equation for a given site on the interface takes the form,

$$\mathrm{d}u/\mathrm{d}t = \gamma(\bar{u} - u) + \eta(u) + F\,. \tag{10}$$

For simplicity we have dropped μ in (5) through a redefinition of t. In the steady-state, $\bar{u} = vt$, where v is the interface velocity to be determined self-consistently from the solution of Eq. (10). Since the disorder $\eta(u)$ is uncorrelated along the interface, the system-wide average $\bar{u}$ can be replaced by an average over the distribution of $\eta(u)$.

Following the discussion in [55], we adopt a moving frame and define $x = u - vt - (F - v)/\gamma$ to be the displacement away from the equilibrium position when the random force $\eta(u)$ is absent. In terms of x, Eq. (10) reads (after a rigid translation of $\eta(u)$),

$$\mathrm{d}x/\mathrm{d}t = -\gamma x + \eta(vt + x)\,. \tag{11}$$

The self-consistency condition becomes,

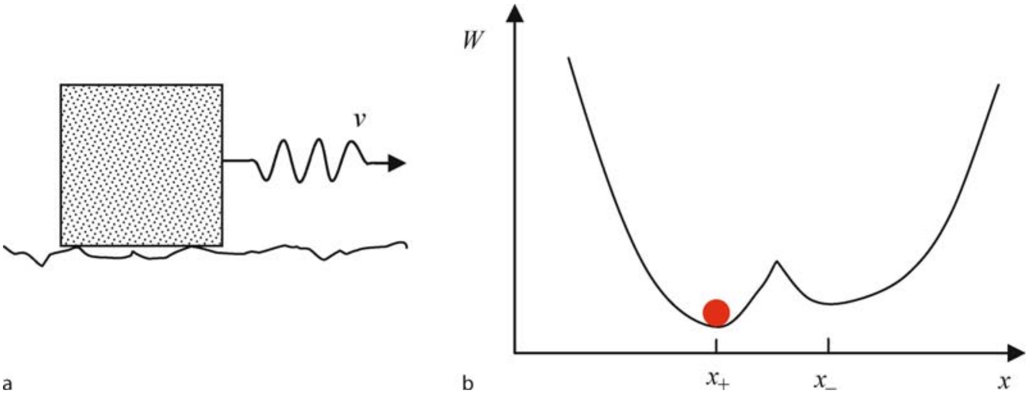
$$\gamma\,\langle x\rangle = -F + v\,. \tag{12}$$

The driving force F now disappears from the equation of motion (11) and can be computed from (12) as a function of v, once a solution to (11) is found.

As illustrated in Fig. 3, Eq. (11) describes the dynamics of an overdamped particle in a moving potential,

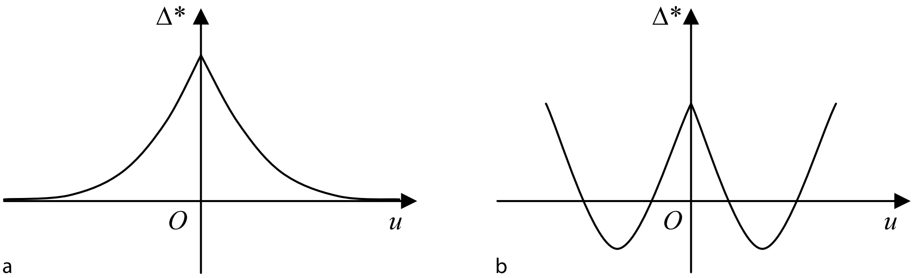
$$W(x,t) = \frac{\gamma}{2}x^2 + U(vt + x)\,. \tag{13}$$

The random part $U(vt + x) = -\int_{x_0}^{vt+x} \eta(u)\mathrm{d}u$ travels at a constant velocity v to the left or to the right depending



Collective Transport and Depinning, Figure 3

The mean-field model of depinning. a Block (representing the interface) dragged by a spring whose right end moves at a slow but constant velocity *v*. The block is sitting on a rough surface and immersed in a very viscous fluid, so that inertia effects can be neglected. b The effective potential *W* on the block at a particular instant when viewed in a co-moving frame. *W* is a sum of two parts: A quadratic spring potential plus a random potential *U* which travels slowly to the left. In the absence of thermal motion, the block (represented by the red ball in the figure) traces the left most minima x_+ of *W* until it disappears, followed by an "avalanche" into the next available minimum



Collective Transport and Depinning, Figure 4
Fixed point solutions to Eq. (14) for a the linear interface models and b the charge-density wave depinning

on the sign of v. In the quasi-static limit $v \to 0$, the particle stays in a local minimum of the potential W for the whole time, and is interrupted occasionally by jumps when the minimum it follows disappears. When the potential travels to the left ($v > 0$), the particle traces the leftmost minimum x_+ of W. The opposite occurs when the potential travels to the right.

With the above picture in mind, we may use Eq. (12) to calculate the thresholds $F_c^+ = -\gamma \lim_{v\to 0+}\langle x\rangle$ and $F_c^- = -\lim_{v\to 0-}\langle x\rangle$ for forward and backward depinning, respectively. For a continuous, slow-varying function $\eta(u)$ with a sufficiently small amplitude, the potential W has a unique minimum all the time, and hence $F_c^+ = F_c^- = 0$, i. e., the system is never pinned. However, for a discontinuous function $\eta(u)$ (or for sufficiently strong disorder), the potential W has, from time to time, more than one minimum, and hence $F_c^+ = -F_c^- > 0$. Note that only upward jumps in η (i. e. a sudden weakening of the pinning force) give rise to upward cusps in the potential which generate double minima in W.

When the potential $W(x,t)$ travels at a small but finite velocity v, the ball shown in Fig. 3b is displaced to the leftmost minimum of W by an amount proportional to v due to viscosity. From Eq. (12) and the value of F_c determined above, one finds $v = a(F - F_c)$, where a is a numerical constant. This behavior is confirmed by exact solution of a "two-state" model for the pinning force [52]. The mean-field velocity exponent is thus given by $\theta_{\text{MF}} = 1$.

Functional Renormalization Group

Equation (5) has been studied analytically since the 1970s. Earlier attempts by Efetov and Larkin [22] and others [26,43] based on a perturbative expansion of the noise term around a flat reference state ran into divergences for $D < D_c = 4$, which can not be cured with the usual renormalization group (RG) procedure. Breakthroughs were achieved in 1992 by Narayan and Fisher [65] for the CDW depinning and by Nattermann et al. [69] for the driven interface. In the field theory jargon, the model has an infinite number of relevant operators that correspond to the coefficients in a power-law expansion of the random force correlator $\Delta(u)$. Upon momentum shell integration on a running scale L, the one-loop corrections to these coefficients can be summarized in terms of a functional RG flow for $\Delta(u)$,

$$\frac{\mathrm{d}\Delta(u)}{\mathrm{d}\ln L} = -cL^{\varepsilon}\frac{\mathrm{d}^2}{\mathrm{d}u^2}\left[\frac{1}{2}\Delta^2(u) - \Delta(u)\Delta(0)\right] . \qquad (14)$$

Here $\varepsilon = 4 - D$ and c is a constant. Dependence on L can be absorbed with the scaling transformation $u \to L^{\zeta}u, \Delta \to L^{2\zeta-\varepsilon}\Delta$. The resulting flow equation has an infinite number of fixed points, which are distinguished by the number of nodes of the function Δ. Figure 4 shows two such solutions, the first with no node at $\zeta = \varepsilon/3$, and the second with infinitely many nodes (periodic) at $\zeta = 0$. The periodic fixed point is associated with the CDW depinning transition. The one with no node describes the interface depinning transition. The most prominent feature of the fixed point function Δ^* is the cusp singularity at $u = 0$, which is responsible for the failure of previous RG treatments.

Equation (14) is supplemented with a RG equation for the mobility μ that determines the dynamical response on scale L,

$$\frac{\mathrm{d}\ln\mu}{\mathrm{d}\ln L} = -c\Delta''(0+)L^{\varepsilon} . \qquad (15)$$

The elastic constant γ, on the other hand, is not renormalized. The latter property yields the scaling relation

$$\nu(2-\zeta) = 1 . \qquad (16)$$

The functional RG analysis has been carried out to two-loop order by Le Doussal and collaborators [14,48]. This study is particularly useful as it helps to clear up several subtleties which can not be easily resolved in the one-loop calculation. For interface depinning, exponents up to the second order in ε are given by,

$$\begin{aligned}\zeta &= \frac{1}{3}\varepsilon + 0.047771\varepsilon^2\\ z &= 2 - \frac{2}{9}\varepsilon - 0.0432087\varepsilon^2\\ \nu &= \frac{1}{2-\zeta} = \frac{1}{2} + \frac{1}{12}\varepsilon + 0.0258316\varepsilon^2\\ \theta &= \nu(z-\zeta) = 1 - \frac{1}{9}\varepsilon + 0.040123\varepsilon^2\,.\end{aligned} \tag{17}$$

Good agreement is seen with the numerical values given in Table 1.

For CDW depinning, the two-loop analysis yields the following exponents,

$$\begin{aligned}\zeta &= 0\\ z &= 2 - \frac{1}{3}\varepsilon - \frac{1}{9}\varepsilon^2\\ \nu &= \frac{1}{2-\zeta} = \frac{1}{2}\\ \theta &= \nu(z-\zeta) = 1 - \frac{1}{6}\varepsilon - \frac{1}{18}\varepsilon^2\,.\end{aligned} \tag{18}$$

Interestingly, here the expression for the dynamical exponent z truncated at first order in ε appears to be in better agreement with the simulation results given in Table 1.

Very recently, Rosso, Le Doussal and Wiese [77] proposed and implemented a scheme to measure numerically the effective pinning force and the renormalized correlator Δ on large distances. The idea is similar to the mean-field model discussed above, with the particle replaced by the center of mass of the manifold in a weak confining potential that introduces a running cut-off to spatial correlations. Their numerical results provide direct confirmation of the cusp singularity in Δ, which has become the hallmark of the RG theories for the manifold problem.

Contact Line Depinning

The above analysis has been extended by Ertas and Kardar [24] to the contact line depinning problem. The increase in surface free energy (or surface area) due to a deformation of the contact line from an ideal straight configuration has been worked out previously by Joanny and de Gennes [39]. Result of this analysis, generalized to a "contact manifold" with D internal dimensions, is that the Laplace term in Eq. (5) is replaced by a nonlocal term, $\gamma\nabla^2 u \to \int \mathrm{d}^D\mathbf{r}' K_D(\mathbf{r}-\mathbf{r}')[u(\mathbf{r}',t)-\bar{u}(t)]$. Here $\bar{u}(t)$ denotes the mean displacement. The function $K_D(\mathbf{r}) \sim |\mathbf{r}|^{-D-1}$ describes the decay of the long-ranged elastic coupling along the contact manifold, assuming the modes in the "bulk" have relaxed. This form of elastic coupling changes the critical dimension to $D_c = 2$. In terms of $\varepsilon = 2 - D$, the critical exponents of the depinning transition from a two-loop renormalization group calculation by Le Doussal et al. [48] are given by,

$$\begin{aligned}\zeta &= \frac{1}{3}\varepsilon + 0.13245\varepsilon^2\\ z &= 1 - \frac{2}{9}\varepsilon - 0.1132997\varepsilon^2\\ \nu &= \frac{1}{2-\zeta} = 1 + \frac{1}{3}\varepsilon + 0.24356\varepsilon^2\\ \theta &= \nu(z-\zeta) = 1 - \frac{2}{9}\varepsilon - 0.1873737\varepsilon^2\,.\end{aligned} \tag{19}$$

Interestingly, the same long-range coupling is found to describe tensile crack propagation [75]. Numerical simulations [21] of a discretized long-range model in $D = 1$ ($\varepsilon = 1$) yield $\zeta = 0.385(5)$, $z = 0.770(5)$, $\nu = 1.625(10)$, $\theta = 0.625(5)$, in good agreement with the theory.

Self-Organized Criticality

Close to the depinning threshold, motion of the system is intermittent. The growth activities are highly localized and exhibit strong correlations over time. The natural separation of slow and fast events at the onset of depinning invites comparison to models of self-organized criticality (SOC) and of earthquakes, which were made popular through the seminal work of Bak, Tang and Wissenfeld (BTW) [5,6] on the "sandpile" model. This observation prompted a number of detailed investigations of the microscopic processes leading to the build-up of spatiotemporal correlations as the depinning threshold is approached from below, as summarized in [72]. Subsequent work by several groups [67,71] established a direct link between these two classes of models. This development has also contributed to a better understanding of SOC in automaton models. It opens the door to a systematic exploration of their scaling properties which were hitherto hindered by the lack of a suitable continuum representation.

The mapping between depinning and SOC automaton models is most easily understood by considering $u(\mathbf{r},t)$ in Eq. (5) as the accumulated activity of a given lattice site $\mathbf{r}$ after time t [71]. Take for example the original sandpile model introduced by BTW on a square lattice. The system is specified by an integer height $z(x,y)$ on each lattice site (x,y). Starting from a random set of values $z_0(x,y)$, "sand" is gradually added through a sequence of events $z(x, y) \to z(x, y) + 1$, each time only a single site is chosen randomly from all available sites in the system for updating. If the operation leads to an overflow, i. e., $z(x, y) > K$, then toppling takes place according to the rule,

$$\begin{aligned} z(x, y) &\to z(x, y) - 4 \\ z(x \pm 1, y) &\to z(x \pm 1, y) + 1 \\ z(x, y \pm 1) &\to z(x, y \pm 1) + 1 \,. \end{aligned} \tag{20}$$

This process is continued until no site has a height exceeding K. Let $u(x, y; t)$ be the total number of toppling events at site (x, y) from the beginning of the process. Counting the number of sand grains received and given away by the site yields immediately

$$\begin{aligned} z(x, y; t) = z_0(x, y) &- 4u(x, y; t) + u(x + 1, y; t) \\ &+ u(x - 1, y; t) + u(x, y + 1; t) \\ &+ u(x, y - 1; t) \\ = z_0(x, y) &+ \nabla^2 u \,, \end{aligned} \tag{21}$$

where ∇^2 is the Laplace operator on the lattice. The condition $z(x, y; t) > K$ for toppling $u \to u + 1$ is thus equivalent to

$$\nabla^2 u + z_0(x, y) - K > 0 \,. \tag{22}$$

The above growth rule is almost identical to a lattice automaton model introduced by Narayan and Middleton [67] for CDW depinning. Comparing (22) to Eq. (5), we see that here (i) u is restricted to take only integer values plus a random, site dependent shift $\beta(\mathbf{r})$, which can be considered as the preferred phase set by the local disorder; (ii) The dynamical rules obey a global symmetry $u \to u + 1$, as in CDW depinning. The usual wisdom in critical phenomena suggests that the two models are in the same universality class due to property (ii), while property (i) is a microscopic detail which does not affect the scaling properties at the depinning transition. Indeed, various scaling exponents determined through analytical and numerical studies of the two models are shown to be consistent with each other [67,82]. Subtle differences exist, however, in the way the system is driven to criticality [67,72]. The effect of boundary conditions also need to be treated with care [67].

To eliminate inertia effects in real sand pile avalanches [64] which prevented direct comparison with the BTW model, the Oslo group [15] designed a two-dimensional rice pile experiment that displays power-law scaling and self-organized criticality. The group also proposed an automaton model, known as the Oslo model, which yields critical exponents in good agreement with the experiment. The Oslo model differs from the BTW model only in the choice of the threshold value K for toppling: Instead of taking a constant value, K is site-dependent. Its value is updated after each toppling event at the site. Consequently, condition (22) changes to,

$$\nabla^2 u + z_0(\mathbf{r}) - K(\mathbf{r}, u) > 0 \,. \tag{23}$$

The symmetry $u \to u + 1$ is no longer present. A similar discussion as above links the Oslo rice-pile model to the LIM of depinning [8,71]. Other SOC models, such as the Manna model [57] and the Zaitsev model [87], have similar updating rules as the Oslo model and hence belong to the LIM universality class as well. The mechanism of self-organization and the development of spatiotemporal correlations in the SOC and depinning models have been discussed in detail by Paczuski, Maslov and Bak [72], who have also identified a large number of scaling relations that give all other exponents in terms of two basic ones.

As an example, let us consider the power-law distribution of the avalanche size which can be measured, e. g., by the total number of toppling events s when a new grain is added. For a system of linear size L, the distribution satisfies the finite-size scaling,

$$P(s, L) = s^{-\tau} F(s/L^{\delta}) \,. \tag{24}$$

The mapping discussed above identifies $\delta = D + \zeta$, i. e., the dimension of the total volume swept by the interface in a system-wide avalanche. On the other hand, a sum rule yields the following expression,

$$\tau = 2 - \frac{\zeta + \nu^{-1}}{\zeta + D} \tag{25}$$

For example, the exponents $\zeta = 0$ and $\nu = 1/2$ for the CDW depinning predicts $\tau = 2\,(D - 1)/D$, in excellent agreement with simulation results on the sandpile model in two and three dimensions [82]. Care must be taken, however, in applying Eq. (25) to the $D = 1$ rice pile model in the boundary driven case, as noted by Paczuski and Boettcher [71].

Interface Depinning in Anisotropic Medium

Easy and Hard Directions of Depinning

The linear interface model defined by Eq. (5) together with Eq. (6) for the random force is statistically invariant under the *tilt transformation* $u \to u + \mathbf{s} \cdot \mathbf{r}$, where $\mathbf{s}$ is the slope of the interface. Hence the depinning threshold F_c, as well as other critical properties, are independent of the orientation of the interface. This property holds for an interface moving in an isotropic medium.

When the medium is anisotropic, one or more of the model parameters that enter the estimate Eq. (4) for F_c may change with **s**. Consequently, the depinning threshold $F_c(\mathbf{s})$ becomes orientation-dependent [83]. An interface oriented in the "easy" direction enters the moving phase at the weakest driving. However, a moving interface in this direction is generically unstable against faceting towards directions of slower growth, particularly near the depinning threshold. To illustrate this point, we may consider a part of the interface that is slowed down by an exceptionally strong pin. As the rest of the interface moves forward at a higher velocity, a local tilt develops that moves the interface away from the easy direction. This further strengthens the pinning effect, producing a cone-like structure. Indeed, the depinning transition in the easy direction has been shown to be of first order with a velocity jump [38].

The story is different for an interface oriented in the "hard" direction. Both numerical [2,3,11,84] and experimental [2,11,12] studies have shown that the depinning transition here is continuous, but the critical exponents take different values from those of the LIM. Yet another set of critical exponents are encountered when the interface is forced to tilt away from the hard direction by, say boundary conditions [83]. The resulting depinning problem is related to *directed percolation*, which we consider in some detail below.

A Lattice Automaton

Tang and Leschhorn [84] introduced a lattice automaton for imbibition in a two-dimensional porous medium. A very similar model was studied by Buldyrev et al. [11] around the same time and reported together with experimental results. The automaton model is defined as follows. On a square lattice, each site (i, j) is assigned a random pinning force $\eta(i, j)$, uniformly distributed in the interval [0,1). At $t = 0$, the interface h_i is completely flat. In each time step, growth $h_i \to h_i + 1$ is performed in parallel when either of the following two conditions is satisfied: (i) the random force $\eta(i, h_i)$ on the interface at column i is less than a pre-specified driving force f; or (ii) $h_i < h_{i-1} - 1$ or $h_i < h_{i+1} - 1$. Thus to obtain a completely pinned interface, we must have $|h_i - h_{i-1}| \leq 1$ and $\eta(i, h_i) > f$ (called a blocking site) for all i. This condition requires the existence of a *directed percolating path* through blocking sites. Such paths exist if the density p of blocking sites exceeds a critical value $p_c \simeq 0.539$. Consequently, the depinning threshold is given by $f_c = 1 - p_c \simeq 0.461$. It is possible to show that, for $f < f_c$, the interface stops at the first directed percolating path that lies fully above its initial position.

The roughness of the incipient directed percolating path at $p = p_c$ is $\zeta = \nu_\perp / \nu_\parallel \simeq 0.63$, where $\nu_\parallel = 1.733$ and $\nu_\perp = 1.097$ are exponents that characterize the divergence of parallel and perpendicular correlation lengths, $\xi_\parallel \sim |p - p_c|^{-\nu_\parallel}$, $\xi_\perp \sim |p - p_c|^{-\nu_\perp}$, respectively [41]. This is also the roughness exponent assumed by the interface at the depinning threshold $f = f_c$. Simulations [84] have shown that the dynamic exponent $z = 1$ at the depinning transition of the above model, while the crossover length exponent $\nu = \nu_\parallel$. From Eq. (8) one obtains $\theta = \nu_\parallel - \nu_\perp \simeq 0.63$.

The orientational dependence of the depinning threshold in the automaton model has been studied by applying the helical boundary condition $h_{i+L} = h_i + sL$ which forces a global tilt [83]. The threshold force is indeed found to be lower. This behavior matches well with the well-known property of directed percolation: For $p > p_c$, percolating paths fall within a cone of opening angle $\varphi(p)$ around the symmetry direction [41]. If the average tilt s of the interface exceeds this angle, no spanning percolating path exists and the interface is free to move. The roughness exponent of the cone boundary is $\zeta = 1/2$, which belongs to yet another universality class of interface depinning away from a symmetry direction [83].

The above automaton model has been generalized by Buldyrev et al. [12] to higher dimensions. The directed percolating strings are replaced by directed percolating surfaces which have been considered in the context of resistor-diode percolation [20]. The roughness exponent of such a surface at the percolation threshold in $D + 1$ dimensions is given in Table 2. Havlin et al. [36] investigated in detail the temporal sequence of growth activities at the depinning transition, which exhibits an interesting super-diffusive behavior. They argued that the dynamic exponent z that describes the growth in size of the affected region after an initial depinning event is related to the scaling of minimal path length with Euclidean distance on the critical (isotropic) percolation cluster in D dimensions. The values of z from their work are also given in Table 2.

As in the $1 + 1$ dimensional case, a tilted interface has a lower depinning threshold. Just above the depinning threshold, the interface decomposes into stripes of inactive regions perpendicular to the tilt, separated by active fronts that propagate towards the "easy" direction at a finite velocity. Based on this phenomenology, Tang, Kardar and Dhar [83] determined exponents characterizing the depinning transition of a tilted interface. In particular, the velocity exponent $\theta = 1$ in all dimensions.

Collective Transport and Depinning, Table 2

Summary of the exponents for directed percolation depinning along the hard direction. After [2]

	$D = 1$	$D = 2$	$D = 3$	$D = 4$	$D = 5$	$D = 6$	MF
ζ (roughness)	0.63(1)	0.48(3)	0.35(1)	0.27(5)	0.25(5)	0.2(2)	0
z (dynamic)	1	1.15(5)	1.36 (5)	1.58(5)	1.7(1)	1.8(2)	2
ν (correlation length)	1.73(2)	1.16(5)	0.95(10)	0.66(10)	0.6(1)	0.5(1)	$1/2$
θ (velocity)	0.58(7)	0.8(2)	1.0(2)	1.0(2)			1

Quenched KPZ Equation

The slope-dependent depinning threshold can be modeled explicitly by adding the Kardar–Parisi–Zhang (KPZ) term to Eq. (5). The resulting equation of motion takes the form,

$$\mu^{-1}\frac{\partial u}{\partial t} = \gamma\nabla^2 u + \frac{1}{2}\lambda(\nabla u)^2 + \eta(\mathbf{r}, u) + F\,. \qquad (26)$$

In the original proposal [40], the λ-term is due to a kinematic effect known as lateral growth, and hence its strength is proportional to the interface velocity v. At the depinning threshold, however, this term is present only when the medium is anisotropic. A positive λ describes depinning along a hard direction, while a negative λ corresponds to growth along an easy direction. Directed numerical integrations [17,54] of Eq. (26) in $(1+1)$ dimensions yielded exponents consistent with the directed percolation models. The relevance of the KPZ nonlinearity in modifying the critical behavior of the LIM has also been confirmed by renormalization group calculations [47,81].

Future Directions

Through the intensive work by many groups in the past fifteen years, the depinning transition of elastic manifolds in a disordered medium has emerged as one of the best understood nonequilibrium critical phenomena with nontrivial scaling properties. The discovery of a renormalizable continuum theory provided the much needed theoretical foundation for the identification of universality classes and symmetry principles. Owing to this remarkable development, models and experimental systems that differ in microscopic details can be compared and classified with regard to their threshold behavior. More recent refinements of the theory by the Paris group (e. g., [46]) have yielded deeper insights on the role of the cusp singularity of the random force correlator in capturing the multiple-minima energy landscape of the disordered manifold problem.

Within the class of models describe by Eq. (5), there are still a few unresolved issues. For example, the roughness exponent ζ of the $(1+1)$-dimensional LIM has been found numerically to be indistinguishable to $5/4$, suggesting the possibility of an exact derivation. The effect of a thermal noise term added to the deterministic model has not been well-understood [13,59,86]. There now exist very good numerical estimates of the exponent ψ that describes the vanishing of the interface velocity $v \sim T^{\psi}$ with temperature T at the depinning threshold, but its value does not agree with any of the existing theoretical proposals [13]. Another puzzle is the closeness between the numerical estimates for the dynamical exponent z given in Table 1 and the one-loop RG prediction for the CDW depinning.

The mapping between the CDW depinning and the sandpile models offers a very powerful tool for the development of RG theories for systems that exhibit SOC. To our knowledge, this connection has not been fully explored so far. It would be interesting to see if SOC models other than the sandpile and the rice-pile, such as the Olami–Feder–Christensen model [70] for earthquakes, can also be mapped to some type of depinning model. Conversely, it would be nice to find out whether the lessons learned from the detailed characterization of avalanche dynamics [19] can contribute to a better understanding of critical correlations in the LIM at the depinning threshold from small to large scales.

On the experimental side, perhaps the best studied system is the CDW depinning, yet the CDW velocity generally grows faster than linear above the depinning threshold [85], while the elastic depinning theory predicts $\theta < 1$. It has been suggested that the apparent discrepancy could be due to a combination of factors: Nonuniform driving, thermal activation across energy barriers, and plasticity when dislocations in the phase field is present. Simultaneous presence of strong pinning sites and weak collective pinning in a finite system may also give rise to a complex I–V curve in experimental systems. While some of these effects have been investigated theoretically [79] (see also the review by Brazovskii and Nattermann), a clear picture is yet to emerge.

Moulinet et al. [62] designed an experimental system to study the roughness and dynamics of the contact line of a viscous fluid. The roughness exponent ζ obtained from experimental measurements is 0.5, much bigger than the value 0.385 obtained from numerical simulations [21] of the model considered by Ertas and Kardar [24]. Similar discrepancies have been reported in the experimental studies [9,74] of the roughness of crack fronts. Modifications of the LIM to include nonlinear couplings and wave-like dynamics [9] for avalanche propagation have been suggested. However, many unresolved issues remain.

It is perhaps not surprising to see that real physical systems almost always contain complications that invalidate direct comparison with the linear elasticity theory of depinning. The pinned state just below the transition is highly metastable and hence is susceptible to various relaxational processes that could possibly invalidate our simple assumptions (see, however [42] for a discussion of correlation lengths below the elastic depinning threshold). Inhomogeneities inside the sample, e. g., macroscopic variations in the concentration of impurity atoms, may also have a dramatic effect on the critical properties associated with the depinning transition. Incorporating the relevant microscopic processes into the generic description discussed here is expected to yield a more complete theory of depinning. It is hoped that future work in this direction will unleash the full impact of the theoretical progress that have been made in the past two decades, which in itself has been intellectually extremely stimulating.

Article Outline

Glossary

Graph A graph is a set of elements, called *vertices* or *nodes*, where pairs of vertices are connected by relational links, or *edges*. A graph can be considered as the simplest representation of a complex system, where the vertices are the elementary units of the system and the edges represent their mutual interactions.

Community A community is a group of graph vertices that “belong together” according to some precisely defined criteria which can be measured. Many definitions have been proposed. A common approach is to define a community as a group of vertices such that the density of edges between vertices of the group is higher than the average edge density in the graph. In the text also the terms *module* or *cluster* are used when referring to a community.

Partition A partition is a split of a graph in subsets with each vertex assigned to only one of them. This last condition may be relaxed to include the case of overlapping communities, imposing that each vertex is assigned to at least one subset.

Dendrogram A dendrogram, or hierarchical tree, is a branching diagram representing successive divisions of a graph into communities. Dendrograms are frequently used in social network analysis and computational biology, especially in biological taxonomy.

Scalability Scalability expresses the computational complexity of an algorithm. If the running time of a community detection algorithm, working on a graph with n vertices and m edges, is proportional to the product $n^{\alpha} m^{\beta}$, one says that the algorithm scales as $O(n^{\alpha} m^{\beta})$. Knowing the scalability allows to estimate the range of applicability of an algorithm.

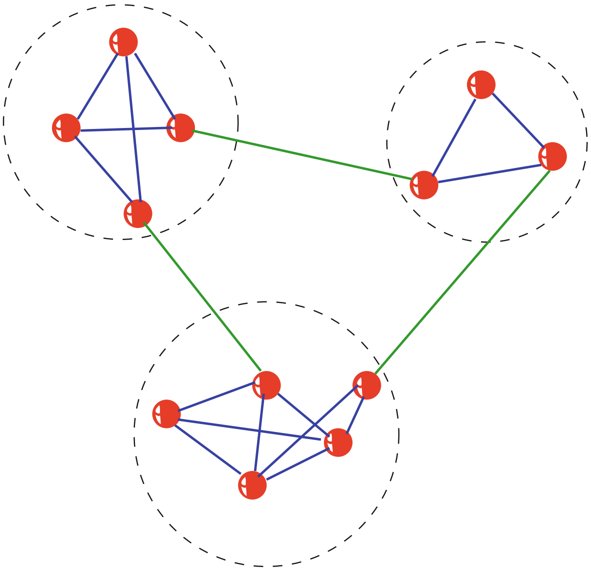
Definition of the Subject

Graph vertices are often organized into groups that seem to live fairly independently of the rest of the graph, with which they share but a few edges, whereas the relationships between group members are stronger, as shown by the large number of mutual connections. Such groups of vertices, or communities, can be considered as independent compartments of a graph. Detecting communities is of great importance in sociology, biology and computer science, disciplines where systems are often represented as graphs. The task is very hard, though, both conceptually, due to the ambiguity in the definition of community and in the discrimination of different partitions and practically, because algorithms must find "good" partitions among an exponentially large number of them. Other complications are represented by the possible occurrence of hierarchies, i. e. communities which are nested inside larger communities, and by the existence of overlaps between communities, due to the presence of nodes belonging to more groups. All these aspects are dealt with in some detail and many methods are described, from traditional approaches used in computer science and sociology to recent techniques developed mostly within statistical physics.

Introduction

The origin of graph theory dates back to Euler's solution [1] of the puzzle of Königsberg's bridges in 1736. Since then a lot has been learned about graphs and their mathematical properties [2]. In the 20th century they have also become extremely useful as representation of a wide variety of systems in different areas. Biological, social, technological, and information networks can be studied as graphs, and graph analysis has become crucial to understand the features of these systems. For instance, social network analysis started in the 1930s and has become one of the most important topics in sociology [3,4]. In recent times, the computer revolution has provided scholars with a huge amount of data and computational resources to process and analyze these data. The size of real networks one can potentially handle has also grown considerably, reaching millions or even billions of vertices. The need to deal with such a large number of units has produced a deep change in the way graphs are approached [5,6,7,8,9].

Real networks are not random graphs. The random graph, introduced by P. Erdös and A. Rényi [10], is the paradigm of a disordered graph: in it, the probability of having an edge between a pair of vertices is equal for all possible pairs. In a random graph, the distribution of edges among the vertices is highly homogeneous. For instance, the distribution of the number of neighbors of a vertex, or *degree*, is binomial, so most vertices have equal or similar degree. In many real networks, instead, there are big inhomogeneities, revealing a high level of order and organization. The degree distribution is broad, with a tail that often follows a power law: therefore, many vertices with low degree coexist with some vertices with large degree. Furthermore, the distribution of edges is not only globally, but also locally inhomogeneous, with high concentrations of edges within special groups of nodes, and low concentrations between these groups. This feature of real networks is called *community structure* and is the topic of this chapter. In Fig. 1 a schematic example of a graph with community structure is shown.



Community Structure in Graphs, Figure 1
A simple graph with three communities, highlighted by the *dashed circles*

Communities are groups of vertices which probably share common properties and/or play similar roles within the graph. So, communities may correspond to groups of pages of the World Wide Web dealing with related topics [11], to functional modules such as cycles and pathways in metabolic networks [12,13], to groups of related individuals in social networks [14,15], to compartments in food webs [16,17], and so on.

Community detection is important for other reasons, too. Identifying modules and their boundaries allows for a classification of vertices, according to their topological position in the modules. So, vertices with a central position in their clusters, i. e. sharing a large number of edges with the other group partners, may have an important function of control and stability within the group; vertices lying at the boundaries between modules play an important role of mediation and lead the relationships and exchanges between different communities. Such classification seems to be meaningful in social [18,19,20] and metabolic networks [12]. Finally, one can study the graph where vertices are the communities and edges are set between modules if there are connections between some of their vertices in the original graph and/or if the modules overlap. In this way one attains a coarse-grained description of the original graph, which unveils the relationships between modules. Recent studies indicate that networks of communities have a different degree distribution with respect to the full graphs [13]; however, the origin of their structures can be explained by the same mechanism [21].

The aim of community detection in graphs is to identify the modules only based on the topology. The problem has a long tradition and it has appeared in various forms in several disciplines. For instance, in parallel computing it is crucial to know what is the best way to allocate tasks to processors so as to minimize the communications between them and enable a rapid performance of the calculation. This can be accomplished by splitting the computer cluster into groups with roughly the same number of processors, such that the number of physical connections between processors of different groups is minimal. The mathematical formalization of this problem is called *graph partitioning*. The first algorithms for graph partitioning were proposed in the early 1970s. Clustering analysis is also an important aspect in the study of social networks. The most popular techniques are hierarchical clustering and k-means clustering, where vertices are joined into groups according to their mutual similarity.

In a seminal paper, Girvan and Newman proposed a new algorithm, aiming at the identification of edges lying between communities and their successive removal, a procedure that after a few iterations leads to the isolation of modules [14]. The intercommunity edges are detected according to the values of a centrality measure, the edge betweenness, that expresses the importance of the role of the edges in processes where signals are transmitted across the graph following paths of minimal length. The paper triggered a big activity in the field, and many new methods have been proposed in the last years. In particular, physicists entered the game, bringing in their tools and techniques: spin models, optimization, percolation, random walks, synchronization, etc., became ingredients of new original algorithms. Earlier reviews of the topic can be found in [22,23].

Section "Elements of Community Detection" is about the basic elements of community detection, starting from the definition of community. The classical problem of graph partitioning and the methods for clustering analysis in sociology are presented in Sect. "Computer Science: Graph Partitioning" and "Social Science: Hierarchical and k-Means Clustering", respectively. Section "New Methods" is devoted to a description of the new methods. In Sect. "Testing Methods" the problem of testing algorithms is discussed. Section "The Mesoscopic Description of a Graph" introduces the description of graphs at the level of communities. Finally, Sect. "Future Directions" highlights the perspectives of the field and sorts out promising research directions for the future.

This chapter makes use of some basic concepts of graph theory, that can be found in any introductory textbook, like [2]. Some of them are briefly explained in the text.

Elements of Community Detection

The problem of community detection is, at first sight, intuitively clear. However, when one needs to formalize it in detail things are not so well defined. In the intuitive concept some ambiguities are hidden and there are often many equally legitimate ways of resolving them. Hence the term "Community Detection" actually indicates several rather different problems.

First of all, there is no unique way of translating into a precise prescription the intuitive idea of community. Many possibilities exist, as discussed below. Some of these possible definitions allow for vertices to belong to more than one community. It is then possible to look for overlapping or nonoverlapping communities. Another ambiguity has to do with the concept of community structure. It may be intended as a single partition of the graph or as a hierarchy of partitions, at different levels of coarse-graining. There is then a problem of comparison. Which one is the best partition (or the best hierarchy)? If one could, in principle, analyze all possible partitions of a graph, one would need a sensible way of measuring their "quality" to single out the partitions with the strongest community structure. It may even occur that one graph has no community structure and one should be able to realize it. Finding a good method for comparing partitions is not a trivial task and different choices are possible. Last but not least, the number of possible partitions grows faster than exponentially with the graph size, so that, in practice, it is not possible to analyze them all. Therefore one has to devise smart methods to find 'good' partitions in a reasonable time. Again, a very hard problem.

Before introducing the basic concepts and discussing the relevant questions it is important to stress that the identification of topological clusters is possible only if the graphs are *sparse*, i. e. if the number of edges m is of the order of the number of nodes n of the graph. If $m \gg n$, the distribution of edges among the nodes is too homogeneous for communities to make sense.

Definition of Community

The first and foremost problem is how to define precisely what a community is. The intuitive notion presented in the Introduction is related to the comparison of the number of edges joining vertices within a module ("intracommunity edges") with the number of edges joining vertices of different modules ("intercommunity edges"). A module is characterized by a larger density of links "inside" than "outside". This notion can be however formalized in many ways. Social network analysts have devised many definitions of subgroups with various degrees of internal cohesion among vertices [3,4]. Many other definitions have been introduced by computer scientists and physicists. In general, the definitions can be classified in three main categories.

- *Local definitions*. Here the attention is focused on the vertices of the subgraph under investigation and on its immediate neighborhood, disregarding the rest of the graph. These prescriptions come mostly from social network analysis and can be further subdivided in *self-referring*, when one considers the subgraph alone, and *comparative*, when the mutual cohesion of the vertices of the subgraph is compared with their cohesion with the external neighbors. Self-referring definitions identify classes of subgraphs like *cliques*, *n-cliques*, *k-plexes*, etc. They are *maximal subgraphs*, which cannot be enlarged with the addition of new vertices and edges without losing the property which defines them. The concept of clique is very important and often recurring when one studies graphs. A clique is a maximal subgraph where each vertex is adjacent to all the others. In the literature it is common to call cliques also non-maximal subgraphs. Triangles are the simplest cliques, and are frequent in real networks. Larger cliques are rare, so they are not good models of communities. Besides, finding cliques is computationally very demanding: the Bron–Kerbosch method [24] runs in a time growing exponentially with the size of the graph. The definition of clique is very strict. A softer constraint is represented by the concept of n-clique, which is a maximal subgraph such that the distance of each pair of its vertices is not larger than n. A k-plex is a maximal subgraph such that each vertex is adjacent to all the others except at most k of them. In contrast, a *k-core* is a maximal subgraph where each vertex is adjacent to at least k vertices within the subgraph. Comparative definitions include that of *LS set*, or *strong community*, and that of *weak community*. An LS set is a subgraph where each node has more neighbors inside than outside the subgraph. Instead, in a weak community, the total degree of the nodes inside the community exceeds the external total degree, i. e. the number of links lying between the community and the rest of the graph. LS sets are also weak communities, but the inverse is not true, in general. The notion of weak community was introduced by Radicchi et al. [25].
- *Global definitions*. Communities are structural units of the graph, so it is reasonable to think that their distinctive features can be recognized if one analyzes a subgraph with respect to the graph as a whole. Global definitions usually start from a *null model*, i. e. a graph which matches the original in some of its topological features, but which does not display community structure. After that, the linking properties of subgraphs of the initial graph are compared with those of the corresponding subgraphs in the null model. The simplest way to design a null model is to introduce randomness in the distribution of edges among the vertices. A random graph à la Erdös–Rényi, for instance, has no community structure, as any two vertices have the same probability to be adjacent, so there is no preferential linking involving special groups of vertices. The most popular null model is that proposed by Newman and Girvan and consists of a randomized version of the original graph, where edges are rewired at random, under the constraint that each vertex keeps its degree [26]. This null model is the basic concept behind the definition of *modularity*, a function which evaluates the goodness of partitions of a graph into modules (see Sect. "Evaluating Partitions: Quality Functions"). Here a subset of vertices is a community if the number of edges inside the subset exceeds the expected number of internal edges that the subset would have in the null model. A more general definition, where one counts small connected subgraphs (*motifs*), and not necessarily edges, can be found in [27]. A general class of null models, including that of modularity, has been designed by Reichardt and Bornholdt [28].
- *Definitions based on vertex similarity*. In this last category, communities are groups of vertices which are similar to each other. A quantitative criterion is chosen to evaluate the similarity between each pair of vertices, connected or not. The criterion may be local or global: for instance one can estimate the distance between a pair of vertices. Similarities can be also extracted from eigenvector components of special matrices, which are usually close in value for vertices belonging to the same community. Similarity measures are at the basis of the method of hierarchical clustering, to be discussed in Sect. "Social Science: Hierarchical and k-Means Clustering". The main problem in this case is the need to introduce an additional criterion to select meaningful partitions.

It is worth remarking that, in spite of the wide variety of definitions, in many detection algorithms communities are not defined at all, but are a byproduct of the procedure. This is the case of the divisive algorithms described in Sect. "Divisive Algorithms" and of the dynamic algorithms of Sect. "Dynamic Algorithms".

Evaluating Partitions: Quality Functions

Strictly speaking, a partition of a graph in communities is a split of the graph in clusters, with each vertex assigned to only one cluster. The latter condition may be relaxed, as shown in Sect. "Overlapping Communities". Whatever the definition of community is, there is usually a large number of possible partitions. It is then necessary to establish which partitions exhibit a real community structure. For that, one needs a *quality function*, i. e. a quantitative criterion to evaluate how good a partition is. The most popular quality function is the modularity of Newman and Girvan [26]. It can be written in several ways, as

$$Q = \frac{1}{2m} \sum_{ij} \left(A_{ij} - \frac{k_i k_j}{2m} \right) \delta(C_i, C_j) , \tag{1}$$

where the sum runs over all pairs of vertices, A is the adjacency matrix, k_i the degree of vertex i and m the total number of edges of the graph. The element A_{ij} of the adjacency matrix is 1 if vertices i and j are connected, otherwise it is 0. The δ-function yields one if vertices i and j are in the same community, zero otherwise. Because of that, the only contributions to the sum come from vertex pairs belonging to the same cluster: by grouping them together the sum over the vertex pairs can be rewritten as a sum over the modules

$$Q = \sum_{s=1}^{n_m} \left[\frac{l_s}{m} - \left(\frac{d_s}{2m} \right)^2 \right] . \tag{2}$$

Here, n_m is the number of modules, l_s the total number of edges joining vertices of module s and d_s the sum of the degrees of the vertices of s. In Eq. (2), the first term of each summand is the fraction of edges of the graph inside the module, whereas the second term represents the expected fraction of edges that would be there if the graph were a random graph with the same degree for each vertex. In such a case, a vertex could be attached to any other vertex of the graph, and the probability of a connection between two vertices is proportional to the product of their degrees. So, for a vertex pair, the comparison between real and expected edges is expressed by the corresponding summand of Eq. (1).

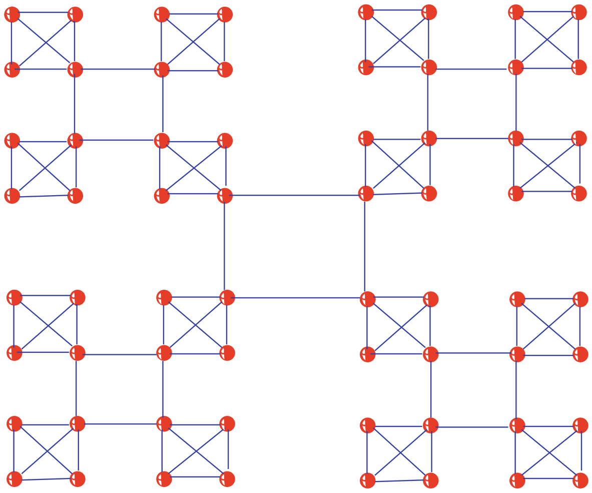
Equation (2) embeds an implicit definition of community: a subgraph is a module if the number of edges inside it is larger than the expected number in modularity's null model. If this is the case, the vertices of the subgraph are more tightly connected than expected. Basically, if each summand in Eq. (2) is non-negative, the corresponding subgraph is a module. Besides, the larger the difference between real and expected edges, the more "modular" the subgraph. So, large positive values of Q are expected to indicate good partitions. The modularity of the whole graph, taken as a single community, is zero, as the two terms of the only summand in this case are equal and opposite. Modularity is always smaller than one, and can be negative as well. For instance, the partition in which each vertex is a community is always negative. This is a nice feature of the measure, implying that, if there are no partitions with positive modularity, the graph has no community structure. On the contrary, the existence of partitions with large negative modularity values may hint to the existence of subgroups with very few internal edges and many edges lying between them (*multipartite structure*).

Modularity has been employed as a quality function in many algorithms, like some of the divisive algorithms of Sect. "Divisive Algorithms". In addition, modularity optimization is itself a popular method for community detection (see Sect. "Modularity Optimization"). Modularity also allows to assess the stability of partitions [29] and to transform a graph into a smaller one by preserving its community structure [30].

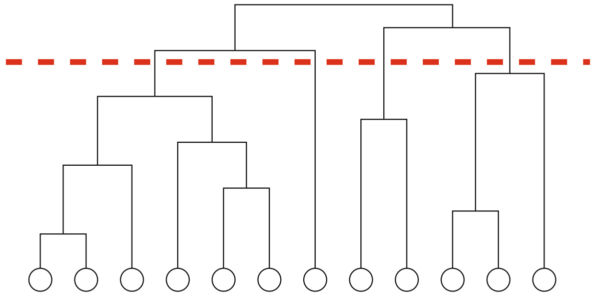
However, there are some caveats on the use of the measure. The most important concerns the value of modularity for a partition. For which values one can say that there is a clear community structure in a graph? The question is tricky: if two graphs have the same type of modular structure, but different sizes, modularity will be larger for the larger graph. So, modularity values cannot be compared for different graphs. Moreover, one would expect that partitions of random graphs will have modularity values close to zero, as no community structure is expected there. Instead, it has been shown that partitions of random graphs may attain fairly large modularity values, as the probability that the distribution of edges on the vertices is locally inhomogeneous in specific realizations is not negligible [31]. Finally, a recent analysis has proved that modularity increases if subgraphs smaller than a characteristic size are merged [32]. This fact represents a serious bias when one looks for communities via modularity optimization and is discussed in more detail in Sect. "Modularity Optimization".

Hierarchies

Graph vertices can have various levels of organization. Modules can display an internal community structure, i. e.



Community Structure in Graphs, Figure 2
Schematic example of a hierarchical graph. Sixteen modules with four vertices each are clearly organized in groups of four



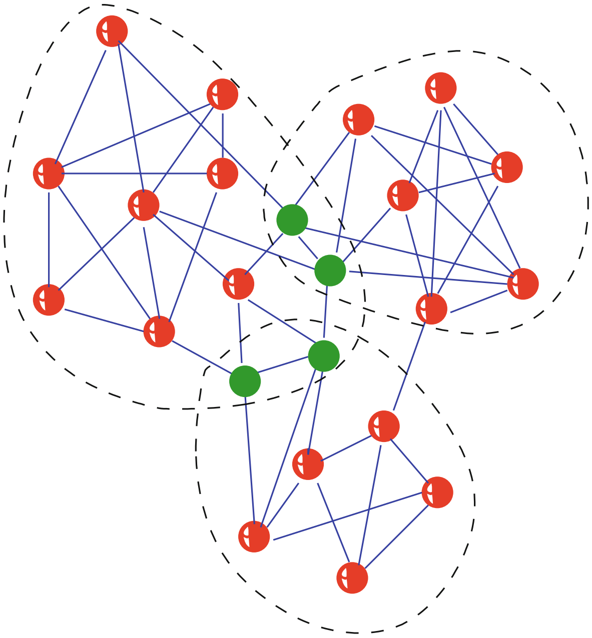
Community Structure in Graphs, Figure 3
A dendrogram, or hierarchical tree. *Horizontal cuts* correspond to partitions of the graph in communities. Reprinted figure with permission from [26]

they can contain smaller modules, which can in turn include other modules, and so on. In this case one says that the graph is hierarchical (see Fig. 2). For a clear classification of the vertices and their roles inside a graph, it is important to find all modules of the graph as well as their hierarchy.

A natural way to represent the hierarchical structure of a graph is to draw a *dendrogram*, like the one illustrated in Fig. 3. Here, partitions of a graph with twelve vertices are shown. At the bottom, each vertex is its own module. By moving upwards, groups of vertices are successively aggregated. Merges of communities are represented by horizontal lines. The uppermost level represents the whole graph as a single community. Cutting the diagram horizontally at some height, as shown in the figure (dashed line), displays one level of organization of the graph vertices. The diagram is hierarchical by construction: each community belonging to a level is fully included in a community at a higher level. Dendrograms are regularly used in sociology and biology. The technique of hierarchical clustering, described in Sect. "Social Science: Hierarchical and *k*-Means Clustering", lends itself naturally to this kind of representation.

Overlapping Communities

As stated in Sect. "Evaluating Partitions: Quality Functions", in a partition each vertex is generally attributed only to one module. However, vertices lying at the boundary between modules may be difficult to assign to one module or another, based on their connections with the other vertices. In this case, it makes sense to consider such intermediate vertices as belonging to more groups, which are then called *overlapping communities* (Fig. 4). Many real networks are characterized by a modular structure with sizeable overlaps between different clusters. In social networks, people usually belong to more communities, according to their personal life and interests: for instance a person may have tight relationships both with the people of its working environment and with other individuals involved in common free time activities.



Community Structure in Graphs, Figure 4
Overlapping communities. In the partition highlighted by the *dashed* contours, some vertices are shared between more groups

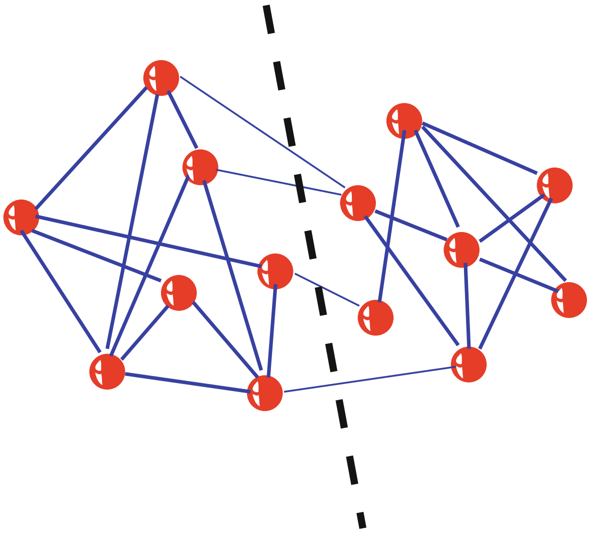
Accounting for overlaps is also a way to better exploit the information that one can derive from topology. Ideally, one could estimate the degree of participation of a vertex in different communities, which corresponds to the likelihood that the vertex belongs to the various groups. Community detection algorithms, instead, often disagree in the classification of peripheral vertices of modules, because they are forced to put them in a single cluster, which may be the wrong one.

The problem of community detection is so hard that very few algorithms consider the possibility of having overlapping communities. An interesting method has been recently proposed by G. Palla et al. [13] and is described in Sect. "Clique Percolation". For standard algorithms, the problem of identifying overlapping vertices could be addressed by checking for the stability of partitions against slight variations in the structure of the graph, as described in [33].

Computer Science: Graph Partitioning

The problem of graph partitioning consists in dividing the vertices in g groups of predefined size, such that the number of edges lying between the groups is minimal. The number of edges running between modules is called *cut size*. Figure 5 presents the solution of the problem for a graph with fourteen vertices, for $g = 2$ and clusters of equal size.

The specification of the number of modules of the partition is necessary. If one simply imposed a partition with the minimal cut size, and left the number of modules free, the solution would be trivial, corresponding to all vertices ending up in the same module, as this would yield a vanishing cut size.



Community Structure in Graphs, Figure 5
Graph partitioning. The *cut* shows the partition in two groups of equal size

Graph partitioning is a fundamental issue in parallel computing, circuit partitioning and layout, and in the design of many serial algorithms, including techniques to solve partial differential equations and sparse linear systems of equations. Most variants of the graph partitioning problem are NP-hard, i. e. it is unlikely that the solution can be computed in a time growing as a power of the graph size. There are however several algorithms that can do a good job, even if their solutions are not necessarily optimal [34]. Most algorithms perform a bisection of the graph, which is already a complex task. Partitions into more than two modules are usually attained by iterative bisectioning.

The *Kernighan–Lin algorithm* [35] is one of the earliest methods proposed and is still frequently used, often in combination with other techniques. The authors were motivated by the problem of partitioning electronic circuits onto boards: the nodes contained in different boards need to be linked to each other with the least number of connections. The procedure is an optimization of a benefit function Q, which represents the difference between the number of edges inside the modules and the number of edges lying between them. The starting point is an initial partition of the graph in two clusters of the predefined size: such initial partition can be random or suggested by some information on the graph structure. Then, subsets consisting of equal numbers of vertices are swapped between the two groups, so that Q has the maximal increase. To reduce the risk to be trapped in local maxima of Q, the procedure includes some swaps that decrease the function Q. After a series of swaps with positive and negative gains, the partition with the largest value of Q is selected and used as starting point of a new series of iterations. The Kernighan–Lin algorithm is quite fast, scaling as $O(n^2)$ in worst-case time, n being the number of vertices. The partitions found by the procedure are strongly dependent on the initial configuration and other algorithms can do better. However, the method is used to improve on the partitions found through other techniques, by using them as starting configurations for the algorithm.

Another popular technique is the *spectral bisection method*, which is based on the properties of the Laplacian matrix. The Laplacian matrix (or simply Laplacian) of a graph is obtained from the adjacency matrix A by placing on the diagonal the degrees of the vertices and by changing the signs of the other elements. The Laplacian has all non-negative eigenvalues and at least one zero eigenvalue, as the sum of the elements of each row and column of the matrix is zero. If a graph is divided into g connected components, the Laplacian would have g degenerate eigenvectors with eigenvalue zero and can be written in block-diagonal form, i. e. the vertices can be ordered in such a way that the Laplacian displays g square blocks along the diagonal, with entries different from zero, whereas all other elements vanish. Each block is the Laplacian of the corresponding subgraph, so it has the trivial eigenvector with components $(1, 1, 1, \ldots, 1, 1)$. Therefore, there are g degenerate eigenvectors with equal non-vanishing components in correspondence of the vertices of a block, whereas all other components are zero. In this way, from the components of the eigenvectors one can identify the connected components of the graph.

If the graph is connected, but consists of g subgraphs which are weakly linked to each other, the spectrum will have one zero eigenvalue and $g - 1$ eigenvalues which are close to zero. If the groups are two, the second lowest eigenvalue will be close to zero and the corresponding eigenvector, also called *Fiedler vector*, can be used to identify the two clusters as shown below.

Every partition of a graph with n vertices in two groups can be represented by an index vector $\mathbf{s}$, whose component $\mathbf{s}_i$ is $+1$ if vertex i is in one group and -1 if it is in the other group. The cut size R of the partition of the graph in the two groups can be written as

$$R = \frac{1}{4}\mathbf{s}^{\mathrm{T}}\mathbf{L}\mathbf{s} \, , \tag{3}$$

where $\mathbf{L}$ is the Laplacian matrix and $\mathbf{s}^{\mathrm{T}}$ the transpose of vector $\mathbf{s}$. Vector $\mathbf{s}$ can be written as $\mathbf{s} = \sum_i a_i \mathbf{v}_i$, where $\mathbf{v}_i$, $i = 1, \ldots, n$ are the eigenvectors of the Laplacian. If $\mathbf{s}$ is properly normalized, then

$$R = \sum_i a_i^2 \lambda_i \, , \tag{4}$$

where λ_i is the Laplacian eigenvalue corresponding to eigenvector $\mathbf{v}_i$. It is worth remarking that the sum contains at most $n - 1$ terms, as the Laplacian has at least one zero eigenvalue. Minimizing R equals to the minimization of the sum on the right-hand side of Eq. (4). This task is still very hard. However, if the second lowest eigenvector λ_2 is close enough to zero, a good approximation of the minimum can be attained by choosing $\mathbf{s}$ parallel to the Fiedler vector $\mathbf{v}_2$: this would reduce the sum to λ_2, which is a small number. But the index vector cannot be perfectly parallel to $\mathbf{v}_2$ by construction, because all its components are equal in modulus, whereas the components of $\mathbf{v}_2$ are not. The best one can do is to match the signs of the components. So, one can set $\mathbf{s}_i = +1(-1)$ if $\mathbf{v}_2^i > 0 \; (< 0)$. It may happen that the sizes of the two corresponding groups do not match the predefined sizes one wishes to have. In this case, if one aims at a split in n_1 and $n_2 = n - n_1$ vertices, the best strategy is to order the components of the Fiedler vector from the lowest to the largest values and to put in one group the vertices corresponding to the first n_1 components from the top or the bottom, and the remaining vertices in the second group. If there is a discrepancy between n_1 and the number of positive or negative components of $\mathbf{v}_2$, this procedure yields two partitions: the better solution is the one that gives the smallest cut size.

The spectral bisection method is quite fast. The first eigenvectors of the Laplacian can be computed by using the Lanczos method [36], that scales as $m/(\lambda_3 - \lambda_2)$, where m is the number of edges of the graph. If the eigenvalues λ_2 and λ_3 are well separated, the running time of the algorithm is much shorter than the time required to calculate the complete set of eigenvectors, which scales as $O(n^3)$. The method gives in general good partitions, that can be further improved by applying the Kernighan–Lin algorithm.

Other methods for graph partitioning include level-structure partitioning, the geometric algorithm, multilevel algorithms, etc. A good description of these algorithms can be found in [34].

Graph partitioning algorithms are not good for community detection, because it is necessary to provide as input both the number of groups and their size, about which in principle one knows nothing. Instead, one would like an algorithm capable to produce this information in its output. Besides, using iterative bisectioning to split the graph in more pieces is not a reliable procedure.

Social Science: Hierarchical and *k*-Means Clustering

In social network analysis, one partitions actors/vertices in clusters such that actors in the same cluster are more similar between themselves than actors of different clusters. The two most used techniques to perform clustering analysis in sociology are *hierarchical clustering* and *k-means clustering*.

The starting point of hierarchical clustering is the definition of a similarity measure between vertices. After a measure is chosen, one computes the similarity for each pair of vertices, no matter if they are connected or not. At the end of this process, one is left with a new $n \times n$ matrix X, the similarity matrix. Initially, there are n groups, each containing one of the vertices. At each step, the two most similar groups are merged; the procedure continues until all vertices are in the same group.

There are different ways to define the similarity between groups out of the matrix X. In *single linkage clustering*, the similarity between two groups is the minimum element x_{ij}, with i in one group and j in the other. On the contrary, the maximum element x_{ij} for vertices of different groups is used in the procedure of *complete linkage clustering*. In *average linkage clustering* one has to compute the average of the x_{ij}.

The procedure can be better illustrated by means of dendrograms, like the one in Fig. 3. One should note that hierarchical clustering does not deliver a single partition, but a set of partitions.

There are many possible ways to define a similarity measure for the vertices based on the topology of the network. A possibility is to define a distance between vertices, like

$$x_{ij} = \sqrt{\sum_{k \neq i,j} (A_{ik} - A_{jk})^2} \,. \tag{5}$$

This is a dissimilarity measure, based on the concept of structural equivalence. Two vertices are structurally equivalent if they have the same neighbors, even if they are not adjacent themselves. If i and j are structurally equivalent, $x_{ij} = 0$. Vertices with large degree and different neighbors are considered very "far" from each other. Another measure related to structural equivalence is the Pearson correlation between columns or rows of the adjacency matrix,

$$x_{ij} = \frac{\sum_k (A_{ik} - \mu_i)(A_{jk} - \mu_j)}{n\sigma_i\sigma_j} \,, \tag{6}$$

where the averages $\mu_i = (\sum_j A_{ij})/n$ and the variances $\sigma_i = \sum_j (A_{ij} - \mu_i)^2/n$.

An alternative measure is the number of edge- (or vertex-) independent paths between two vertices. Independent paths do not share any edge (vertex), and their number is related to the maximum flow that can be conveyed between the two vertices under the constraint that each edge can carry only one unit of flow (max-flow/min-cut theorem). Similarly, one could consider all paths running between two vertices. In this case, there is the problem that the total number of paths is infinite, but this can be avoided if one performs a weighted sum of the number of paths, where paths of length l are weighted by the factor α^l, with $\alpha < 1$. So, the weights of long paths are exponentially suppressed and the sum converges.

Hierarchical clustering has the advantage that it does not require a preliminary knowledge on the number and size of the clusters. However, it does not provide a way to discriminate between the many partitions obtained by the procedure, and to choose that or those that better represent the community structure of the graph. Moreover, the results of the method depend on the specific similarity measure adopted. Finally, it does not correctly classify all vertices of a community, and in many cases some vertices are missed even if they have a central role in their clusters [22].

Another popular clustering technique in sociology is k-means clustering [37]. Here, the number of clusters is preassigned, say k. The vertices of the graph are embedded in a metric space, so that each vertex is a point and a distance measure is defined between pairs of points in the space. The distance is a measure of dissimilarity between vertices. The aim of the algorithm is to identify k points in this space, or *centroids*, so that each vertex is associated to one centroid and the sum of the distances of all vertices from their respective centroids is minimal. To achieve this, one starts from an initial distribution of centroids such that they are as far as possible from each other. In the first iteration, each vertex is assigned to the nearest centroid. Next, the centers of mass of the k clusters are estimated and become a new set of centroids, which allows for a new classification of the vertices, and so on. After a sufficient number of iterations, the positions of the centroids are stable, and the clusters do not change any more. The solution found is not necessarily optimal, as it strongly depends on the initial choice of the centroids. The result can be improved by performing more runs starting from different initial conditions.

The limitation of k-means clustering is the same as that of the graph partitioning algorithms: the number of clusters must be specified at the beginning, the method is not able to derive it. In addition, the embedding in a metric space can be natural for some graphs, but rather artificial for others.

New Methods

From the previous two sections it is clear that traditional approaches to derive graph partitions have serious limits. The most important problem is the need to provide the algorithms with information that one would like to derive from the algorithms themselves, like the number of clusters and their size. Even when these inputs are not necessary, like in hierarchical clustering, there is the question of estimating the goodness of the partitions, so that one can pick the best one. For these reasons, there has been a major effort in the last years to devise algorithms capable of extracting a complete information about the community structure of graphs. These methods can be grouped into different categories.

Divisive Algorithms

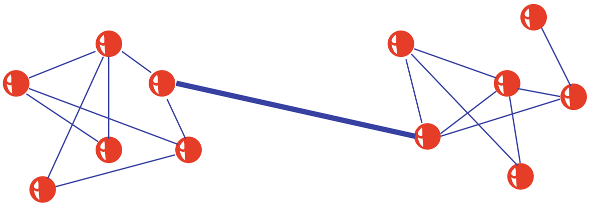
A simple way to identify communities in a graph is to detect the edges that connect vertices of different communities and remove them, so that the clusters get disconnected from each other. This is the philosophy of divisive algorithms. The crucial point is to find a property of intercommunity edges that could allow for their identification. Any divisive method delivers many partitions, which are by construction hierarchical, so that they can be represented with dendrograms.

Algorithm of Girvan and Newman. The most popular algorithm is that proposed by Girvan and Newman [14]. The method is also historically important, because it marked the beginning of a new era in the field of community detection. Here edges are selected according to the values of measures of *edge centrality*, estimating the importance of edges according to some property or process running on the graph. The steps of the algorithm are:

1. Computation of the centrality for all edges;
2. Removal of edge with largest centrality;
3. Recalculation of centralities on the running graph;
4. Iteration of the cycle from step 2.

Girvan and Newman focused on the concept of *betweenness*, which is a variable expressing the frequency of the participation of edges to a process. They considered three alternative definitions: edge betweenness, current-flow betweenness and random walk betweenness.

Edge betweenness is the number of shortest paths between all vertex pairs that run along the edge. It is an extension to edges of the concept of site betweenness, introduced by Freeman in 1977 [20]. It is intuitive that intercommunity edges have a large value of the edge betweenness, because many shortest paths connecting vertices of different communities will pass through them (Fig. 6). The betweenness of all edges of the graph can be calculated in a time that scales as $O(mn)$, with techniques based on breadth-first-search [26,38].



Community Structure in Graphs, Figure 6
Edge betweenness is highest for edges connecting communities. In the figure, the *thick* edge in the middle has a much higher betweenness than all other edges, because all shortest paths connecting vertices of the two communities run through it

Current-flow betweenness is defined by considering the graph a resistor network, with edges having unit resistance. If a voltage difference is applied between any two vertices, each edge carries some amount of current, that can be calculated by solving Kirchoff's equations. The procedure is repeated for all possible vertex pairs: the current-flow betweenness of an edge is the average value of the current carried by the edge. Calculation of current-flow betweenness requires the inversion of an $n \times n$ matrix (once), followed by obtaining and averaging the current for all pairs of nodes. Each of these two tasks takes a time $O(n^3)$ for a sparse matrix.

The random-walk betweenness of an edge says how frequently a random walker running on the graph goes across the edge. We remind that a random walker moving from a vertex follows each edge with equal probability. A pair of vertices is chosen at random, s and t. The walker starts at s and keeps moving until it hits t, where it stops. One computes the probability that each edge was crossed by the walker, and averages over all possible choices for the vertices s and t. The complete calculation requires a time $O(n^3)$ on a sparse graph. It is possible to show that this measure is equivalent to current-flow betweenness [39].

Calculating edge betweenness is much faster than current-flow or random walk betweenness ($O(n^2)$ versus $O(n^3)$ on sparse graphs). In addition, in practical applications the Girvan–Newman algorithm with edge betweenness gives better results than adopting the other centrality measures. Numerical studies show that the recalculation step 3 of Girvan–Newman algorithm is essential to detect meaningful communities. This introduces an additional factor m in the running time of the algorithm: consequently, the edge betweenness version scales as $O(m^2 n)$, or $O(n^3)$ on a sparse graph. Because of that, the algorithm is quite slow, and applicable to graphs with up to $n \sim 10\,000$ vertices, with current computational resources. In the original version of Girvan–Newman's algorithm [14], the authors had to deal with the whole hierarchy of partitions, as they had no procedure to say which partition is the best. In a successive refinement [26], they selected the partition with the largest value of modularity (see Sect. "Evaluating Partitions: Quality Functions"), a criterion that has been frequently used ever since. There have been countless applications of the Girvan–Newman method: the algorithm is now integrated in well known libraries of network analysis programs.

Algorithm of Tyler et al. Tyler, Wilkinson and Huberman proposed a modification of the Girvan–Newman algorithm, to improve the speed of the calculation [40].

The modification consists in calculating the contribution to edge betweenness only from a limited number of vertex pairs, chosen at random, deriving a sort of Monte Carlo estimate. The procedure induces statistical errors in the values of the edge betweenness. As a consequence, the partitions are in general different for different choices of the sampling pairs of vertices. However, the authors showed that, by repeating the calculation many times, the method gives good results, with a substantial gain of computer time. In practical examples, only vertices lying at the boundary between communities may not be clearly classified, and be assigned sometimes to a group, sometimes to another. The method has been applied to a network of people corresponding through email [40] and to networks of gene co-occurrences [41].

Algorithm of Fortunato et al. An alternative measure of centrality for edges is information centrality. It is based on the concept of efficiency [42], which estimates how easily information travels on a graph according to the length of shortest paths between vertices. The information centrality of an edge is the variation of the efficiency of the graph if the edge is removed. In the algorithm by Fortunato, Latora and Marchiori [43], edges are removed according to decreasing values of information centrality. The method is analogous to that of Girvan and Newman, but slower, as it scales as $O(n^4)$ on a sparse graph. On the other hand, it gives a better classification of vertices when communities are fuzzy, i. e. with a high degree of interconnectedness.

Algorithm of Radicchi et al. Because of the high density of edges within communities, it is easy to find loops in them, i. e. closed non-intersecting paths. On the contrary, edges lying between communities will hardly be part of short loops. Based on this intuitive idea, Radicchi et al. proposed a new measure, the edge clustering coefficient, such that low values of the measure are likely to correspond to intercommunity edges [25]. The edge clustering coefficient generalizes to edges the notion of clustering coefficient introduced by Watts and Strogatz for vertices [44]. The latter is the number of triangles including a vertex divided by the number of possible triangles that can be formed. The edge clustering coefficient is the number of loops of length g including the edge divided by the number of possible cycles. Usually, loops of length $g = 3$ or 4 are considered. At each iteration, the edge with smallest clustering coefficient is removed, the measure is recalculated again, and so on. The procedure stops when all clusters obtained are LS-sets or "weak" communities (see Sect. "Definition of Community"). Since the edge clustering coefficient is a local measure, involving at most an extended neighborhood of the edge, it can be calculated very quickly. The running time of the algorithm to completion is $O(m^4/n^2)$, or $O(n^2)$ on a sparse graph, so it is much shorter than the running time of the Girvan–Newman method. On the other hand, the method may give poor results when the graph has few loops, as it happens in several non-social networks. In this case, in fact, the edge clustering coefficient is small and fairly similar for all edges, and the algorithm may fail to identify the bridges between communities.

Modularity Optimization

If Newman–Girvan modularity Q (Sect. "Evaluating Partitions: Quality Functions") is a good indicator of the quality of partitions, the partition corresponding to its maximum value on a given graph should be the best, or at least a very good one. This is the main motivation for modularity maximization, perhaps the most popular class of methods to detect communities in graphs. An exhaustive optimization of Q is impossible, due to the huge number of ways in which it is possible to partition a graph, even when the latter is small. Besides, the true maximum is out of reach, as it has been recently proved that modularity optimization is an NP-hard problem [45], so it is probably impossible to find the solution in a time growing polynomially with the size of the graph. However, there are currently several algorithms able to find fairly good approximations of the modularity maximum in a reasonable time.

Greedy techniques. The first algorithm devised to maximize modularity was a greedy method of Newman [46]. It is an agglomerative method, where groups of vertices are successively joined to form larger communities such that modularity increases after the merging. One starts from n clusters, each containing a single vertex. Edges are not initially present, they are added one by one during the procedure. However, modularity is always calculated from the full topology of the graph, since one wants to find its partitions. Adding a first edge to the set of disconnected vertices reduces the number of groups from n to $n-1$, so it delivers a new partition of the graph. The edge is chosen such that this partition gives the maximum increase of modularity with respect to the previous configuration. All other edges are added based on the same principle. If the insertion of an edge does not change the partition, i. e. the clusters are the same, modularity stays the same. The number of partitions found during the procedure is n, each with a different number of clusters, from n to 1. The largest value of modularity in this subset of partitions is the approximation of the modularity maximum given by the algorithm. The update of the modularity value at each iteration step can be performed in a time $O(n+m)$, so the algorithm runs to completion in a time $O((m+n)n)$, or $O(n^2)$ on a sparse graph, which is fast. In a later paper by Clauset et al. [47], it was shown that the calculation of modularity during the procedure can be performed much more quickly by use of max-heaps, special data structures created using a binary tree. By doing that, the algorithm scales as $O(md \log n)$, where d is the depth of the dendrogram describing the successive partitions found during the execution of the algorithm, which grows as $\log n$ for graphs with a strong hierarchical structure. For those graphs, the running time of the method is then $O(n \log^2 n)$, which allows to analyze the community structure of very large graphs, up to 10^7 vertices. The greedy algorithm is currently the only algorithm that can be used to estimate the modularity maximum on such large graphs. On the other hand, the approximation it finds is not that good, as compared with other techniques. The accuracy of the algorithm can be considerably improved if one accounts for the size of the groups to be merged [48], or if the hierarchical agglomeration is started from some good intermediate configuration, rather than from the individual vertices [49].

Simulated annealing. Simulated annealing [50] is a probabilistic procedure for global optimization used in different fields and problems. It consists in performing an exploration of the space of possible states, looking for the global optimum of a function F, say its maximum. Transitions from one state to another occur with probability 1 if F increases after the change, otherwise with a probability $\exp(\beta \Delta F)$, where ΔF is the decrease of the function and β is an index of stochastic noise, a sort of inverse temperature, which increases after each iteration. The noise reduces the risk that the system gets trapped in local optima. At some stage, the system converges to a stable state, which can be an arbitrarily good approximation of the maximum of F, depending on how many states were explored and how slowly β is varied. Simulated annealing was first employed for modularity optimization by R. Guimerá et al. [31]. Its standard implementation combines two types of "moves": local moves, where a single vertex is shifted from one cluster to another, taken at random; global moves, consisting of merges and splits of communities. In practical applications, one typically combines n^2 local moves with n global ones in one iteration. The method can potentially come very close to the true modularity maximum, but it is slow. Therefore, it can be used for small graphs, with up to about 10^4 vertices. Applications include studies of potential energy landscapes [51] and of metabolic networks [12].

Extremal optimization. Extremal optimization is a heuristic search procedure proposed by Boettcher and Percus [52], in order to achieve an accuracy comparable with simulated annealing, but with a substantial gain in computer time. It is based on the optimization of local variables, expressing the contribution of each unit of the system to the global function at study. This technique was used for modularity optimization by Duch and Arenas [53]. Modularity can be indeed written as a sum over the vertices: the local modularity of a vertex is the value of the corresponding term in this sum. A fitness measure for each vertex is obtained by dividing the local modularity of the vertex by its degree. One starts from a random partition of the graph in two groups. At each iteration, the vertex with the lowest fitness is shifted to the other cluster. The move changes the partition, so the local fitnesses need to be recalculated. The process continues until the global modularity Q cannot be improved any more by the procedure. At this stage, each cluster is considered as a graph on its own and the procedure is repeated, as long as Q increases for the partitions found. The algorithm finds an excellent approximation of the modularity maximum in a time $O(n^2 \log n)$, so it represents a good tradeoff between accuracy and speed.

Spectral optimization. Modularity can be optimized using the eigenvalues and eigenvectors of a special matrix, the modularity matrix B, whose elements are

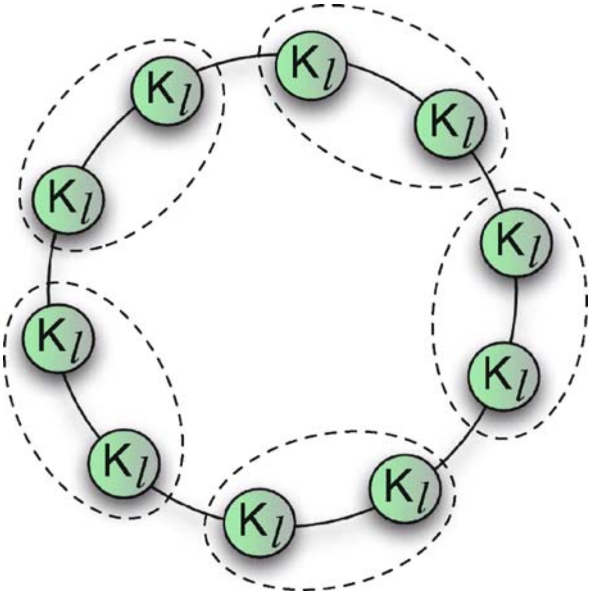
$$B_{ij} = A_{ij} - \frac{k_i k_j}{2m} \,, \tag{7}$$

where the notation is the same used in Eq. (1). The method [54,55] is analogous to spectral bisection, described in Sect. "Computer Science: Graph Partitioning". The difference is that here the Laplacian matrix is replaced by the modularity matrix. Between Q and B there is the same relation as between R and L in Eq. (3), so modularity can be written as a weighted sum of the eigenvalues of B, just like Eq. (4). Here one has to look for the eigenvector of B with largest eigenvalue, $\mathbf{u}_1$, and group the vertices according to the signs of the components of $\mathbf{u}_1$, just like in Sect. "Computer Science: Graph Partitioning". The Kernighan–Lin algorithm can then be used to improve the result. The procedure is repeated for each of the clusters separately, and the number of communities increases as long as modularity does. The advantage over spectral bisection is that it is not necessary to specify the size of the two groups, because it is determined by taking the partition with largest modularity. The drawback is similar as for spectral bisection, i. e. the algorithm gives the best results for bisections, whereas it is less accurate when the number of communities is larger than two. The situation could be improved by using the other eigenvectors with positive eigenvalues of the modularity matrix. In addition, the eigenvectors with the most negative eigenvalues are important to detect a possible multipartite structure of the graph, as they give the most relevant contribution to the modularity minimum. The algorithm typically runs in a time $O(n^2 \log n)$ for a sparse graph, when one computes only the first eigenvector, so it is faster than extremal optimization, and slightly more accurate, especially for large graphs.

Finally, some general remarks on modularity optimization and its reliability. A large value for the modularity maximum does not necessarily mean that a graph has a community structure. Random graphs can also have partitions with large modularity values, even though clusters are not explicitly built in [31,56]. Therefore, the modularity maximum of a graph reveals its community structure only if it is appreciably larger than the modularity maximum of random graphs of the same size [57].

In addition, one assumes that the modularity maximum delivers the "best" partition of the network in communities. However, this is not always true [32]. In the definition of modularity (Eq. (2)) the graph is compared with a random version of it, that keeps the degrees of its vertices. If groups of vertices in the graphs are more tightly connected than they would be in the randomized graph, modularity optimization would consider them as parts of the same module. But if the groups have less than $\sqrt{m}$ internal edges, the expected number of edges running between them in modularity's null model is less than one, and a single interconnecting edge would cause the merging of the two groups in the optimal partition. This holds for every density of edges inside the groups, even in the limit case in which all vertices of each group are connected to each other, i. e. if the groups are cliques. In Fig. 7 a graph is made out of n_c identical cliques, with l vertices each, connected by single edges. It is intuitive to think that the modules of the best partition are the single cliques: instead, if n_c is larger than about l^2, modularity would be higher for the partition in which pairs of consecutive cliques are parts of the same module (indicated by the dashed lines in the figure). The problem holds for a wide class of possible null models [58]. Attempts have been made to solve it within the modularity framework [59,60,61].

Modifications of the measure have also been suggested. Massen and Doye proposed a slight variation of modularity's null model [51]: it is still a graph with the same degree sequence as the original, and with edges rewired at random among the vertices, but one imposes the additional constraint that there can be neither multiple edges between a pair of vertices nor edges joining a vertex with itself (self-edges). Muff, Rao and Caflisch remarked that modularity's null model implicitly assumes that each vertex could be attached to any other, whether in real cases a cluster is usually connected to few other clusters [62]. Therefore, they proposed a local version of modularity, in which the expected number of edges within a module is not calculated with respect to the full graph, but considering just a portion of it, namely the subgraph including the module and its neighboring modules.

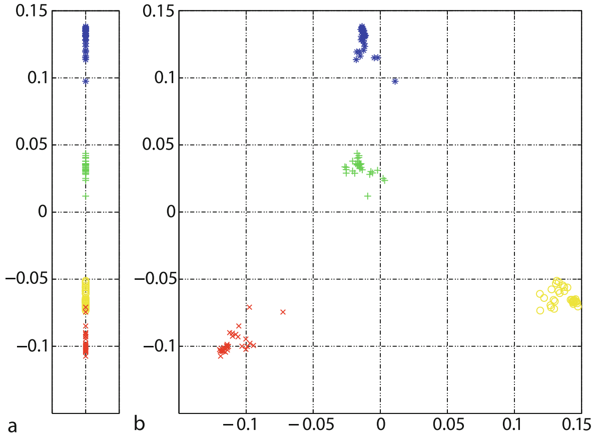


Community Structure in Graphs, Figure 7
Resolution limit of modularity optimization. The natural community structure of the graph, represented by the individual cliques (*circles*), is not recognized by optimizing modularity, if the cliques are smaller than a scale depending on the size of the graph. Reprinted figure with permission from [32]

Spectral Algorithms

As discussed above, spectral properties of graph matrices are frequently used to find partitions. Traditional methods are in general unable to predict the number and size of the clusters, which instead must be fed into the procedure. Recent algorithms, reviewed below, are more powerful.

Algorithm of Donetti and Muñoz. An elegant method based on the eigenvectors of the Laplacian matrix has been devised by Donetti and Muñoz [63]. The idea is simple: the values of the eigenvector components are close for vertices in the same community, so one can use them as coordinates to represent vertices as points in a metric space. So, if one uses M eigenvectors, one can embed the vertices in an M-dimensional space. Communities appear as groups of points well separated from each other, as illustrated in Fig. 8. The separation is the more visible, the larger the number of dimensions/eigenvectors M. The space points



Community Structure in Graphs, Figure 8
Spectral algorithm by Donetti and Muñoz. Vertex *i* is represented by the values of the *i*th components of Laplacian eigenvectors. In this example, the graph has an adhoc division in four communities, indicated by different symbols. The communities are better separated in two dimensions (b) than in one (a). Reprinted figure with permission from [63]

are grouped in communities by hierarchical clustering (see Sect. "Social Science: Hierarchical and *k*-Means Clustering"). The final partition is the one with largest modularity. For the similarity measure between vertices, Donetti and Muñoz used both the Euclidean distance and the angle distance. The angle distance between two points is the angle between the vectors going from the origin of the M-dimensional space to either point. Applications show that the best results are obtained with complete-linkage clustering. The algorithm runs to completion in a time $O(n^3)$, which is not fast. Moreover, the number M of eigenvectors that are needed to have a clean separation of the clusters is not known a priori.

Algorithm of Capocci et al. Similarly to Donetti and Muñoz, Capocci et al. used eigenvector components to identify communities [64]. In this case the eigenvectors are those of the *normal matrix*, that is derived from the adjacency matrix by dividing each row by the sum of its elements. The eigenvectors can be quickly calculated by performing a constrained optimization of a suitable cost function. A similarity matrix is built by calculating the correlation between eigenvector components: the similarity between vertices i and j is the Pearson correlation coefficient between their corresponding eigenvector components, where the averages are taken over the set of eigenvectors used. The method can be extended to directed graphs. It is useful to estimate vertex similarities, however it does not provide a well-defined partition of the graph.

Algorithm of Wu and Huberman. A fast algorithm by Wu and Huberman identifies communities based on the properties of resistor networks [65]. It is essentially a method for bisectioning graph, similar to spectral bisection, although partitions in an arbitrary number of communities can be obtained by iterative applications. The graph is transformed into a resistor network where each edge has unit resistance. A unit potential difference is set between two randomly chosen vertices. The idea is that, if there is a clear division in two communities of the graph, there will be a visible gap between voltage values for vertices at the borders between the clusters. The voltages are calculated by solving Kirchoff's equations: an exact resolution would be too time consuming, but it is possible to find a reasonably good approximation in a linear time for a sparse graph with a clear community structure, so the more time consuming part of the algorithm is the sorting of the voltage values, which takes time $O(n \log n)$. Any possible vertex pair can be chosen to set the initial potential difference, so the procedure should be repeated for all possible vertex pairs. The authors showed that this is not necessary, and that a limited number of sampling pairs is sufficient to get good results, so the algorithm scales as $O(n \log n)$ and is very fast. An interesting feature of the method is that it can quickly find the natural community of any vertex, without determining the complete partition of the graph. For that, one uses the vertex as source voltage and places the sink at an arbitrary vertex. The same feature is present in an older algorithm by Flake et al. [11], where one uses max-flow instead of current flow.

Previous works have shown that also the eigenvectors of the *transfer matrix* $\mathbf{T}$ can be used to extract useful information on community structure [66,67]. The element T_{ij} of the transfer matrix is $1/k_j$ if i and j are neighbors, where k_j is the degree of j, otherwise it is zero. The transfer matrix rules the process of diffusion on graphs.

Dynamic Algorithms

This section describes methods employing processes running on the graph, focusing on spin-spin interactions, random walk and synchronization.

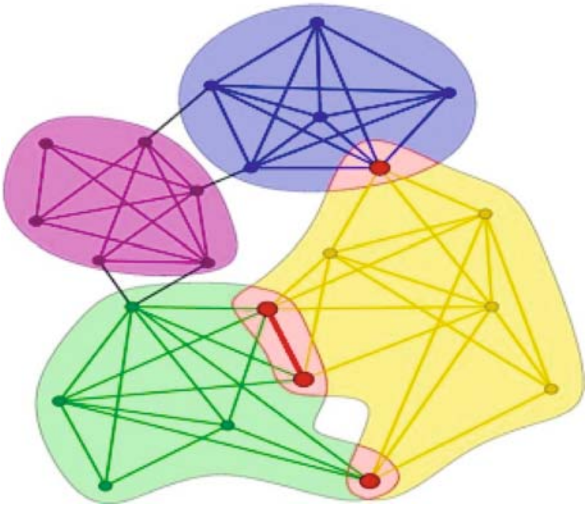
Q-state Potts model. The Potts model is among the most popular models in statistical mechanics [68]. It describes a system of spins that can be in q different states. The interaction is ferromagnetic, i. e. it favors spin alignment, so at zero temperature all spins are in the same state. If antiferromagnetic interactions are also present, the ground state of the system may not be the one where all spins are aligned, but a state where different spin values coexist, in homogeneous clusters. If Potts spin variables are assigned to the vertices of a graph with community structure, and the interactions are between neighboring spins, it is likely that the topological clusters could be recovered from like-valued spin clusters of the system, as there are many more interactions inside communities than outside. Based on this idea, inspired by an earlier paper by Blatt, Wiseman and Domany [69], Reichardt and Bornholdt proposed a method to detect communities that maps the graph onto a q-Potts model with nearest-neighbors interactions [70]. The Hamiltonian of the model, i. e. its energy, is the sum of two competing terms, one favoring spin alignment, one antialignment. The relative weight of these two terms is expressed by a parameter γ, which is usually set to the value of the density of edges of the graph. The goal is to find the ground state of the system, i. e. to minimize the energy. This can be done with simulated annealing [50], starting from a configuration where spins are randomly assigned to the vertices and the number of states q is very high. The procedure is quite fast and the results do not depend on q. The method also allows to identify vertices shared between communities, from the comparison of partitions corresponding to global and local energy minima. More recently, Reichardt and Bornholdt derived a general framework [28], in which detecting community structure is equivalent to finding the ground state of a q-Potts model spin glass [71]. Their previous method and modularity optimization are recovered as special cases. Overlapping communities can be discovered by comparing partitions with the same (minimal) energy, and hierarchical structure can be investigated by tuning a parameter acting on the density of edges of a reference graph without community structure.

Random walk. Using random walks to find communities comes from the idea that a random walker spends a long time inside a community due to the high density of edges and consequent number of paths that could be followed. Zhou used random walks to define a distance between pairs of vertices [72]: the distance d_{ij} between i and j is the average number of edges that a random walker has to cross to reach j starting from i. Close vertices are likely to belong to the same community. Zhou defines the "global attractor" of a vertex i to be the closest vertex to i (smallest d_{ij}), whereas the "local attractor" of i is its closest neighbor. Two types of communities are defined, according to local or global attractors: a vertex i has to be put in the same community of its attractor and of all other vertices for which i is an attractor. Communities must be minimal subgraphs, i. e. they cannot include smaller subgraphs which are communities according to the chosen criterion. Applications to real and artificial networks show that the method can find meaningful partitions. In a successive paper [73], Zhou introduced a measure of dissimilarity between vertices based on the distance defined above. The measure resembles the definition of distance based on structural equivalence of Eq. (5), where the elements of the adjacency matrix are replaced by the corresponding distances. Graph partitions are obtained with a divisive procedure that, starting from the graph as a single community, performs successive splits based on the criterion that vertices in the same cluster must be less dissimilar than a running threshold, which is decreased during the process. The hierarchy of partitions derived by the method is representative of actual community structures for several real and artificial graphs. In another work [74], Zhou and Lipowsky defined distances with biased random walkers, where the bias is due to the fact that walkers move preferentially towards vertices sharing a large number of neighbors with the starting vertex. A different distance measure between vertices based on random walks was introduced by Latapy and Pons [75]. The distance is calculated from the probabilities that the random walker moves from a vertex to another in a fixed number of steps. Vertices are then grouped into communities through hierarchical clustering. The method is quite fast, running to completion in a time $O(n^2 \log n)$ on a sparse graph.

Synchronization. Synchronization is another promising dynamic process to reveal communities in graphs. If oscillators are placed at the vertices, with initial random phases, and have nearest-neighbor interactions, oscillators in the same community synchronize first, whereas a full synchronization requires a longer time. So, if one follows the time evolution of the process, states with synchronized clusters of vertices can be quite stable and long-lived, so they can be easily recognized. This was first shown by Arenas, Díaz–Guilera and Pérez–Vicente [76]. They used Kuramoto oscillators [77], which are coupled two-dimensional vectors endowed with a proper frequency of oscillations. If the interaction coupling exceeds a threshold, the dynamics leads to synchronization. Arenas et al. showed that the time evolution of the system reveals some intermediate time scales, corresponding to topological scales of the graph, i. e. to different levels of organization of the vertices. Hierarchical community structure can be revealed in this way. Based on the same principle, Boccaletti et al. designed a community detection method based on synchronization [79]. The synchronization dynamics is a variation of Kuramoto's model, the opinion changing rate (OCR) model [80]. The evolution equations of the model are solved for decreasing values of a parameter that tunes the strength of the interaction coupling between neighboring vertices. In this way, different partitions are recovered: the partition with the largest value of modularity is chosen. The algorithm scales in a time $O(mn)$, or $O(n^2)$ on sparse graphs, and gives good results on practical examples. However, synchronization-based algorithms may not be reliable when communities are very different in size.

Clique Percolation

In most of the approaches examined so far, communities have been characterized and discovered, directly or indirectly, by some global property of the graph, like betweenness, modularity, etc., or by some process that involves the graph as a whole, like random walks, synchronization, etc. But communities can be also interpreted as a form of local organization of the graph, so they could be defined from some property of the groups of vertices themselves, regardless of the rest of the graph. Moreover, very few of the algorithms presented so far are able to deal with the problem of overlapping communities (Sect. "Overlapping Communities"). A method that accounts both for the locality of the community definition and for the possibility of having overlapping communities is the Clique Percolation Method (CPM) by Palla et al. [13]. It is based on the concept that the internal edges of community are likely to form cliques due to their high density. On the other hand, it is unlikely that intercommunity edges form cliques: this idea was already used in the divisive method of Radicchi et al. (see Sect. "Divisive Algorithms"). Palla et al. define a k-clique as a complete graph with k vertices. Notice that this definition is different from the definition of n-clique (see Sect. "Definition of Community") used in social science. If it were possible for a clique to move on a graph, in some way, it would probably get trapped inside its original community, as it could not cross the bottleneck formed by the intercommunity edges. Palla et al. introduced a number of concepts to implement this idea. Two k-cliques are *adjacent* if they share $k-1$ vertices. The union of adjacent k-cliques is called *k-clique chain*. Two k-cliques are connected if they are part of a k-clique chain. Finally, a *k-clique community* is the largest connected subgraph obtained by the union of a k-clique and of all k-cliques which are connected to it. Examples of k-clique communities are shown in Fig. 9. One could say that a k-clique community is identified by making a k-clique "roll" over adjacent k-cliques, where rolling means rotating a k-clique about the $k-1$ vertices it shares with any adjacent k-clique. By construction, k-clique communities can share vertices, so they can be overlapping. There may be vertices belonging to non-adjacent k-cliques, which could be reached by different paths and end up in different clusters. In order to find k-clique communities, one searches first for maximal cliques, a task that is known to require a running time that grows exponentially with the size of the graph. However, the authors found that, for the real networks they analyzed, the procedure is quite fast, allowing to analyze graphs with up to 10^5 vertices in a reasonably short time. The actual scalability of the algorithm depends on many factors, and cannot be expressed in closed form. The algorithm has been extended to the analysis of weighted [81] and directed [82] graphs. It was recently used to study the evolution of community structure in social networks [83]. A special software, called *CFinder*, based on the CPM, has been designed by Palla and coworkers and is freely available. The CPM has the same limit as the algorithm of Radicchi et al.: It assumes that the graph has a large number of cliques, so it may fail to give meaningful partitions for graphs with just a few cliques, like technological networks.



Community Structure in Graphs, Figure 9
Clique Percolation Method. The example shows communities spanned by adjacent 3-cliques (*triangles*). Overlapping vertices are shown by the *bigger* dots. Reprinted figure with permission from [13]

Other Techniques

This section describes some algorithms that do not fit in the previous categories, although some overlap is possible.

Markov Cluster Algorithm (MCL). This method, invented by van Dongen [84], simulates a peculiar process of flow diffusion in a graph. One starts from the *stochastic matrix* of the graph, which is obtained from the adjacency matrix by dividing each element A_{ij} by the degree of i. The element S_{ij} of the stochastic matrix gives the probability that a random walker, sitting at vertex i, moves to j. The sum of the elements of each column of S is one. Each iteration of the algorithm consists of two steps. In the first step, called expansion, the stochastic matrix of the graph is raised to an integer power p (usually $p = 2$). The entry M_{ij} of the resulting matrix gives the probability that a random walker, starting from vertex i, reaches j in p steps (diffusion flow). The second step, which has no physical counterpart, consists in raising each single entry of the matrix M to some power α, where α is now real-valued. This operation, called inflation, enhances the weights between pairs of vertices with large values of the diffusion flow, which are likely to be in the same community. Next, the elements of each row must be divided by their sum, such that the sum of the elements of the row equals one and a new stochastic matrix is recovered. After some iterations, the process delivers a stable matrix, with some remarkable properties. Its elements are either zero or one, so it is a sort of adjacency matrix. Most importantly, the graph described by the matrix is disconnected, and its connected components are the communities of the original graph. The method is really simple to implement, which is the main reason of its success: as of now, the MCL is one of the most used clustering algorithms in bioinformatics. Due to the matrix multiplication of the expansion step, the algorithm should scale as $O(n^3)$, even if the graph is sparse, as the running matrix becomes quickly dense after a few steps of the algorithm. However, while computing the matrix multiplication, MCL keeps only a maximum number k of non-zero elements per column, where k is usually much smaller than n. So, the actual worst-case running time of the algorithm is $O(nk^2)$ on a sparse graph. A problem of the method is the fact that the final partition is sensitive to the parameter α used in the inflation step. Therefore several partitions can be obtained, and it is not clear which are the most meaningful or representative.

Maximum likelihood. Newman and Leicht have recently proposed an algorithm based on traditional tools and techniques of statistical inference [85]. The method consists in deducing the group structure of the graph by checking which possible partition better "fits" the graph topology. The goodness of the fit is measured by the likelihood that the observed graph structure was generated by the particular set of relationships between vertices that define a partition. The latter is described by two sets of model parameters, expressing the size of the clusters and the connection preferences among the vertices, i. e. the probabilities that vertices of one cluster are linked to any vertex. The partition corresponding to the maximum likelihood is obtained by iterating a set of coupled equations for the variables, starting from a suitable set of initial conditions. Convergence is fast, so the algorithm could be applied to fairly large graphs, with up to about 10^6 vertices. A nice feature of the method is that it discovers more general types of vertex classes than communities. For instance, multipartite structure could be uncovered, or mixed patterns where multipartite subgraphs coexist with communities, etc. In this respect, it is more powerful than most methods of community detection, which are bound to focus only on proper communities, i. e. subgraphs with more internal than external edges. In addition, since partitions are defined by assigning probability values to the vertices, expressing the extent of their membership in a group, it is possible that some vertices are not clearly assigned to a group, but to more groups, so the method is able to deal with overlapping communities. The main drawback of the algorithm is the fact that one needs to specify the number of groups at the beginning of the calculation, a number that is often unknown for real networks. It is possible to derive this information self-consistently by maximizing the probability that the data are reproduced by partitions with a given number of clusters. But this procedure involves some degree of approximation, and the results are often not good.

L-shell method. This is an agglomerative method designed by Bagrow and Bollt [86]. The algorithm finds the community of any vertex, although the authors also presented a more general procedure to identify the full community structure of the graph. Communities are defined locally, based on a simple criterion involving the number of edges inside and outside a group of vertices. One starts from a vertex-origin and keeps adding vertices lying on successive shells, where a shell is defined as a set of vertices at a fixed geodesic distance from the origin. The first shell includes the nearest neighbors of the origin, the second the next-to-nearest neighbors, and so on. At each iteration, one calculates the number of edges connecting vertices of the new layer to vertices inside and outside the running cluster. If the ratio of these two numbers ("emerging degree") exceeds some predefined threshold, the vertices of the new shell are added to the cluster, otherwise the process stops. Because of the local nature of the process, the algorithm is very fast and can identify communities very quickly. By repeating the process starting from every vertex, one could derive a *membership matrix M*: the element M_{ij} is one if vertex j belongs to the community of vertex i, otherwise it is zero. The membership matrix can be rewritten by suitably permutating rows and columns based on their mutual distances. The distance between two rows (or columns) is defined as the number of entries whose elements differ. If the graph has a clear community structure, the membership matrix takes a block-diagonal form, where the blocks identify the communities. Unfortunately, the rearrangement of the matrix requires a time $O(n^3)$, so it is quite slow. In a different algorithm, local communities are discovered through greedy maximization of a local modularity measure [87].

Algorithm of Eckmann and Moses. This is another method where communities are defined based on a local criterion [88]. The idea is to use the clustering coefficient [44] of a vertex as a quantity to distinguish tightly connected groups of vertices. Many edges mean many loops inside a community, so the vertices of a community are likely to have a large clustering coefficient. The latter can be related to the average distance between pairs of neighbors of the vertex. The possible values of the distance are 1 (if neighbors are connected) or 2 (if they are not), so the average distance lies between 1 and 2. The more triangles there are in the subgraph, the shorter the average distance. Since each vertex has always distance 1 from its neighbors, the fact that the average distance between its neighbors is different from 1 reminds what happens when one measures segments on a curved surface. Endowed with a metric, represented by the geodesic distance between vertices/points, and a curvature, the graph can be embedded in a geometric space. Communities appear as portions of the graph with a large curvature. The algorithm was applied to the graph representation of the World Wide Web, where vertices are Web pages and edges are the hyperlinks that take users from a page to the other. The authors found that communities correspond to Web pages dealing with the same topic.

Algorithm of Sales–Pardo et al. This is an algorithm designed to detect hierarchical community structure (see Sect. "Hierarchies"), a realistic feature of many natural, social and technological networks, that most algorithms usually neglect. The authors [89] introduce first a similarity measure between pairs of vertices based on Newman–Girvan modularity: basically the similarity between two vertices is the frequency with which they coexist in the same community in partitions corresponding to local optima of modularity. The latter are configurations for which modularity is stable, i. e. it cannot increase if one shifts one vertex from one cluster to another or by merging or splitting clusters. Next, the similarity matrix is put in block-diagonal form, by minimizing a cost function expressing the average distance of connected vertices from the diagonal. The blocks correspond to the communities and the recovered partition represents the largest scale organization level. To determine levels at lower scales, one iterates the procedure for each subgraph identified at the previous level, which is considered as an independent graph. The method yields then a hierarchy by construction, as communities at each level are nested within communities at higher levels. The algorithm is not fast, as both the search of local optima for modularity and the rearrangement of the similarity matrix are performed with simulated annealing, but delivers good results for computer generated networks, and meaningful partitions for some social, technological and biological networks.

Algorithm by Rosvall and Bergstrom. The modular structure can be considered as a reduced description of a graph to approximate the whole information contained in its adjacency matrix. Based on this idea, Rosvall and Bergstrom [90] envisioned a communication process in which a partition of a network in communities represents a synthesis Y of the full structure that a signaler sends to a receiver, who tries to infer the original graph topology X from it. The best partition corresponds to the signal Y that contains the most information about X. This can be quantitatively assessed by the maximization of the mutual information $I(X;Y)$ [91]. The method is better than modularity optimization, especially when communities are of different size. The optimization of the mutual information is performed by simulated annealing, so the method is rather slow and can be applied to graphs with up to about 10^4 vertices.

Testing Methods

When a community detection algorithm is designed, it is necessary to test its performance, and compare it with other methods. Ideally, one would like to have graphs with known community structure and check whether the algorithm is able to find it, or how closely can come to it. In any case, one needs to compare partitions found by the method with "real" partitions. How can different partitions of the same graph be compared? Danon et al. [92] used a measure borrowed from information theory, the *normalized mutual information*. One builds a *confusion matrix* N, whose element N_{ij} is the number of vertices of the real community i that are also in the detected community j. Since the partitions to be compared may have different numbers of clusters, N is usually not a square matrix. The similarity of two partitions A and B is given by the following expression

$$I(A,B) = \frac{-2\sum_{i=1}^{c_A}\sum_{j=1}^{c_B} N_{ij}\log(N_{ij}N/N_{i.}N_{.j})}{\sum_{i=1}^{c_A} N_{i.}\log(N_{i.}/N) + \sum_{j=1}^{c_B} N_{.j}\log(N_{.j}/N)}, \tag{8}$$

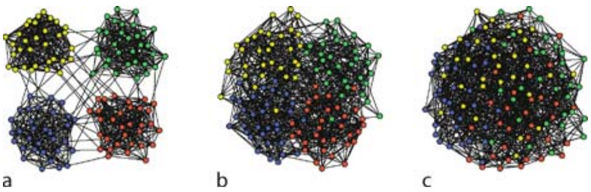
where $c_B(c_A)$ is the number of communities in partition $A(B)$, $N_{i.}$ is the sum of the elements of N on row i and $N_{.j}$ is the sum of the elements of N on column j. Another useful measure of similarity between partitions is the *Jaccard index*, which is regularly used in scientometric research.

Given two partitions A and B, the Jaccard index is defined as

$$I_J(A, B) = \frac{n_{11}}{n_{11} + n_{01} + n_{10}} , \tag{9}$$

where n_{11} is the number of pairs of vertices which are in the same community in both partitions and $n_{01}(n_{10})$ denotes the number of pairs of elements which are put in the same community in $A(B)$ and in different communities in $B(A)$. A nice presentation of criteria to compare partitions can be found in [93].

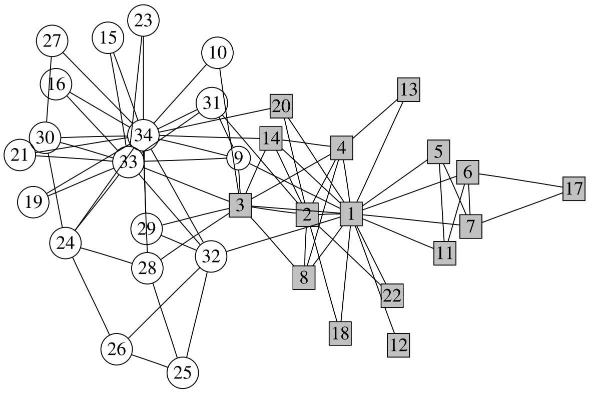
In the literature on community detection, algorithms have been generally tested on two types of graphs: computer generated graphs and real networks. The most famous computer generated benchmark is a class of graphs designed by Girvan and Newman [14]. Each graph consists of 128 vertices, arranged in four groups with 32 vertices each: 1–32, 33–64, 65–96 and 97–128. The average degree of each vertex is set to 16. The density of edges inside the groups is tuned by a parameter z_{in}, expressing the average number of edges shared by each vertex of a group with the other members (internal degree). Naturally, when z_{in} is close to 16, there is a clear community structure (see Fig. 10a), as most edges will join vertices of the same community, whereas when $z_{\text{in}} \leq 8$ there are more edges connecting vertices of different communities and the graph looks fuzzy (see Fig. 10c). In this way, one can realize different degrees of mixing between the groups. In this case the test consists in calculating the similarity between the partitions determined by the method at study and the natural partition of the graph in the four equal-sized groups. The similarity can be calculated by using the measure of Eq. (8), but in the literature one used a different quantity, i. e. the fraction of correctly classified vertices. A vertex is correctly classified if it is in the same cluster with at least 16 of its "natural" partners. If the model partition has clusters given by the merging of two or more natural groups, all vertices of the cluster are considered incorrectly classified. The number of correctly classified vertices is then divided by the total size of the graph, to yield a number between 0 and 1. One usually builds many realizations of the graph for a particular value of z_{in} and computes the average fraction of correctly classified vertices, which is a measure of the sensitivity of the method. The procedure is then iterated for different values of z_{in}. Many different algorithms have been compared with each other according to the diagram where the fraction of correctly classified vertices is plotted against z_{in}. Most algorithms usually do a good job for large z_{in} and start to fail when z_{in} approaches 8. The recipe to label vertices as correctly or incorrectly classified is somewhat arbitrary, though, and measures like those of Eq. (8) and (9) are probably more objective. There is also a subtle problem concerning the reliability of the test. Because of the randomness involved in the process of distributing edges among the vertices, it may well be that, in specific realizations of the graph, some vertices share more edges with members of another group than of their own. In this case, it is inappropriate to consider the initial partition in four groups as the real partition of the graph.



Community Structure in Graphs, Figure 10
Benchmark of Girvan and Newman. The three pictures correspond to $z_{\text{in}} = 15$ (a), $z_{\text{in}} = 11$ (b) and $z_{\text{in}} = 8$ (c). In c the four groups are basically invisible. Reprinted figure with permission from [12]

Tests on real networks usually focus on a limited number of examples, for which one has precise information about the vertices and their properties.

The most popular real network with a known community structure is the social network of Zachary's karate club (see Fig. 11). This is a social network representing the personal relationships between members of a karate club at an American university. During two years, the sociologist Wayne Zachary observed the ties between members, both inside and outside the club [94]. At some point, a conflict arose between the club's administrator (vertex 1) and one of the teachers (vertex 33), which led to the split of the club



Community Structure in Graphs, Figure 11
Zachary's karate club network, an example of graph with known community structure. Reprinted figure with permission from [26]

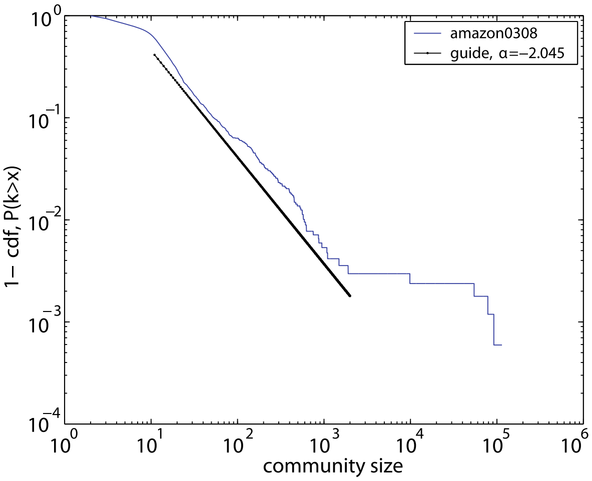
in two smaller clubs, with some members staying with the administrator and the others following the instructor. Vertices of the two groups are highlighted by squares and circles in Fig. 11. The question is whether the actual social split could be predicted from the network topology. Several algorithms are actually able to identify the two classes, apart from a few intermediate vertices, which may be misclassified (e. g. vertices 3, 10). Other methods are less successful: for instance, the maximum of Newman–Girvan modularity corresponds to a split of the network in four groups [53,63]. It is fundamental however to stress that the comparison of community structures detected by the various methods with the split of Zachary's karate club is based on a very strong assumption: that the split actually reproduced the separation of the social network in two communities. There is no real argument, beyond common wisdom, supporting this assumption.

Two other networks have frequently been used to test community detection algorithms: the network of American college football teams derived by Girvan and Newman [14] and the social network of bottlenose dolphins constructed by Lusseau [95]. Also for these networks the caveat applies: Nothing guarantees that "reasonable" communities, defined on the basis of non-topological information, must coincide with those detected by methods based only on topology.

The Mesoscopic Description of a Graph

Community detection algorithms have been applied to a huge variety of real systems, including social, biological and technological networks. The partitions found for each system are usually similar, as the algorithms, in spite of their specific implementations, are all inspired by close intuitive notions of community. What are the general properties of these partitions? The analysis of partitions and their properties delivers a *mesoscopic description* of the graph, where the communities, and not the vertices, are the elementary units of the topology. The term mesoscopic is used because the relevant scale here lies between the scale of the vertices and that of the full graph. A simple question is whether the communities of a graph are usually about of the same size or whether the community sizes have some special distribution. It turns out that the distribution of community sizes is skewed, with a tail that obeys a power law with exponents in the range between 1 and 3 [13,22,23,47]. So, there seems to be no characteristic size for a community: small communities usually coexist with large ones.

As an example, Fig. 12 shows the cumulative distribution of community sizes for a recommendation network of the online vendor Amazon.com. Vertices are products and there is a connection between item A and B if B was frequently purchased by buyers of A. We remind that the cumulative distribution is the integral of the probability distribution: if the cumulative distribution is a power law with exponent α, the probability distribution is also a power law with exponent $\alpha + 1$.



Community Structure in Graphs, Figure 12
Cumulative distribution of community sizes for the Amazon purchasing network. The partition is derived by greedy modularity optimization. Reprinted figure with permission from [47]

If communities are overlapping, one could derive a network, where the communities are the vertices and pairs of vertices are connected if their corresponding communities overlap [13]. Such networks seem to have some special properties. For instance, the degree distribution is a particular function, with an initial exponential decay followed by a slower power law decay. A recent analysis has shown that such distribution can be reproduced by assuming that the graph grows according to a simple preferential attachment mechanism, where communities with large degree have an enhanced chance to interact/overlap with new communities [21].

Finally, by knowing the community structure of a graph, it is possible to classify vertices according to their roles within their community, which may allow to infer individual properties of the vertices. A nice classification has been proposed by Guimerá and Amaral [12,96]. The role of a vertex depends on the values of two indices, the z-score and the participation ratio, that determine the position of the vertex within its own module and with respect to the other modules. The z-score compares the internal degree of the vertex in its module with the average internal degree of the vertices in the module. The participation ratio says how the edges of the vertex are distributed among the modules. Based on these two indices, Guimerá and Amaral distinguish seven roles for a vertex. These roles seem to be correlated to functions of vertices: in metabolic networks, for instance, vertices sharing many edges with vertices of other modules ("connectors") are often metabolites which are more conserved across species than other metabolites, i. e. they have an evolutionary advantage [12].

Future Directions

The problem of community detection is truly interdisciplinary. It involves scientists of different disciplines both in the design of algorithms and in their applications. The past years have witnessed huge progresses and novelties in this topic. Many methods have been developed, based on various principles. Their scalability has improved by at least one power in the graph size in just a couple of years. Currently partitions in graphs with up to millions of vertices can be found. From this point of view, the limit is close, and future improvements in this sense are unlikely. Algorithms running in linear time are very quick, but their results are often not very good.

The major breakthrough introduced by the new methods is the possibility of extracting graph partitions with no preliminary knowledge or inputs about the community structure of the graph. Most new algorithms do not need to know how many communities there are, a major drawback of computer science approaches: they derive this information from the graph topology itself. Similarly, algorithms of new generation are able to select one or a few meaningful partitions, whereas social science approaches usually produce a whole hierarchy of partitions, which they are unable to discriminate. Especially in the last two years, the quality of the output produced by some algorithms has considerably improved. Realistic aspects of community structure, like overlapping and hierarchical communities, are now often taken into account.

The main question is: is there at present a good method to detect communities in graphs? The answer depends on what is meant by "good". Several algorithms give satisfactory results when they are tested as described in Sect. "Testing Methods": in this respect, they can be considered good. However, if examined in more detail, some methods disclose serious limits and biases. For instance, the most popular method used nowadays, modularity optimization, is likely to give problems in the analysis of large graphs. Most algorithms are likely to fail in some limit, still one can derive useful indications from them: from the comparison of partitions derived by different methods one could extract the cores of real communities. The ideal method is one that delivers meaningful partitions and handles overlapping communities and hierarchy, possibly in a short time. No such method exists yet.

Finding a good method for community detection is a crucial endeavor in biology, sociology and computer science. In particular, biologists often rely on the application of clustering techniques to classify their data. Due to the bioinformatics revolution, gene regulatory networks, protein–protein interaction networks, metabolic networks, etc., are now much better known that they used to be in the past and finally susceptible to solid quantitative investigations. Uncovering their modular structure is an open challenge and a necessary step to discover properties of elementary biological constituents and to understand how biological systems work.

Article Outline

This *glossary* consists of a list of terms used inside the paper in mathematics, in probability, in engineering, and, on occasion, in physics. To clarify the seemingly confusing use of up to four different names for the same idea or concept, we have further added informal explanations spelling out the reasons behind the differences in current terminology from neighboring fields.

DISCLAIMER: This glossary has the structure of four areas. A number of terms are listed line by line, and each line is followed by explanation. Some "terms" have up to four separate (yet commonly accepted) names.

Glossary

MATHEMATICS: function (measurable), PROBABILITY: random variable, ENGINEERING: signal, PHYSICS: state Mathematically, functions may map between any two sets, say, from X to Y; but if X is a probability space (typically called Ω), it comes with a σ-algebra $\mathcal{B}$ of measurable sets, and probability measure P. Elements E in $\mathcal{B}$ are called events, and $\mathrm{P}(E)$ the probability of E. Corresponding measurable functions with values in a vector space are called random variables, a terminology which suggests a stochastic viewpoint. The function values of a random variable may represent the outcomes of an experiment, for example "throwing of a die".

Yet, function theory is widely used in engineering where functions are typically thought of as signal. In this case, X may be the real line for time, or $\mathbb{R}^d$. Engineers visualize functions as signals. A particular signal may have a stochastic component, and this feature simply introduces an extra stochastic variable into the "signal", for example noise.

Turning to physics, in our present application, the physical functions will be typically be in some L^2-space, and L^2-functions with unit norm represent quantum mechanical "states".

MATHEMATICS: sequence (incl. vector-valued), PROBABILITY: random walk, ENGINEERING: time-series, PHYSICS: measurement Mathematically, a sequence is a function defined on the integers $\mathbb{Z}$ or on subsets of $\mathbb{Z}$, for example the natural numbers $\mathbb{N}$. Hence, if time is discrete, this to the engineer represents a time series, such as a speech signal, or any measurement which depends on time. But we will also allow functions on lattices such as $\mathbb{Z}^d$.

In the case $d = 2$, we may be considering the grayscale numbers which represent exposure in a digital camera. In this case, the function (grayscale) is defined on a subset of $\mathbb{Z}^2$, and is then simply a matrix.

A random walk on $\mathbb{Z}^d$ is an assignment of a sequential and random motion as a function of time. The randomness presupposes assigned probabilities. But we will use the term "random walk" also in connection with random walks on combinatorial trees.

MATHEMATICS: nested subspaces, PROBABILITY: refinement, ENGINEERING: multiresolution, PHYSICS: scales of visual resolutions While finite or infinite families of nested subspaces are ubiquitous in mathematics, and have been popular in Hilbert space theory for generations (at least since the 1930s), this idea was revived in a different guise in 1986 by Stéphane Mallat, then an engineering graduate student. In its adaptation to wavelets, the idea is now referred to as the multiresolution method.

What made the idea especially popular in the wavelet community was that it offered a skeleton on which various discrete algorithms in applied mathematics could be attached and turned into wavelet constructions in harmonic analysis. In fact what we now call multiresolutions have come to signify a crucial link between the world of discrete wavelet algorithms, which are popular in computational mathematics and in engineering (signal/image processing, data mining, etc.) on the one side, and on the other side continuous wavelet bases in function spaces, especially in $L^2(\mathbb{R}^d)$. Further, the multiresolution idea closely mimics how fractals are analyzed with the use of finite function systems.

But in mathematics, or more precisely in operator theory, the underlying idea dates back to work of John von Neumann, Norbert Wiener, and Herman Wold, where nested and closed subspaces in Hilbert space were used extensively in an axiomatic approach to stationary processes, especially for time series. Wold proved that any (stationary) time series can be decomposed into two different parts: The first (deterministic) part can be exactly described by a linear combination of its own past, while the second part is the opposite extreme; it is *unitary*, in the language of von Neumann.

Von Neumann's version of the same theorem is a pillar in operator theory. It states that every isometry in a Hilbert space $\mathcal{H}$ is the unique sum of a shift isometry and a unitary operator, i. e., the initial Hilbert space $\mathcal{H}$ splits canonically as an orthogonal sum of two subspaces $\mathcal{H}_s$ and $\mathcal{H}_u$ in $\mathcal{H}$, one which carries the shift operator, and the other $\mathcal{H}_u$ the unitary part. The shift isometry is defined from a nested scale of closed spaces V_n, such that the intersection of these spaces is $\mathcal{H}_u$. Specifically,

$$\cdots \subset V_{-1} \subset V_0 \subset V_1 \subset V_2 \subset \cdots \subset V_n \subset V_{n+1} \subset \cdots$$

$$\bigwedge_n V_n = \mathcal{H}_u \,, \quad \text{and} \quad \bigvee_n V_n = \mathcal{H} \,.$$

However, Stéphane Mallat was motivated instead by the notion of scales of resolutions in the sense of optics. This, in turn, is based on a certain "artificial-intelligence" approach to vision and optics, developed earlier by David Marr at MIT, an approach which imitates the mechanism of vision in the human eye.

The connection from these developments in the 1980s back to von Neumann is this: Each of the closed subspaces V_n corresponds to a level of resolution in such a way that a larger subspace represents a finer resolution. Resolutions are relative, not absolute! In this view, the relative complement of the smaller (or coarser) subspace in larger space then represents the visual detail which is added in passing from a blurred image to a finer one, i. e., to a finer visual resolution.

This view became an instant hit in the wavelet community, as it offered a repository for the fundamental father and the mother functions, also called the scaling function φ, and the wavelet function ψ. Via a system of translation and scaling operators, these functions then generate nested subspaces, and we recover the scaling identities which initialize the appropriate algorithms. What results is now called the family of pyramid algorithms in wavelet analysis. The approach itself is called the multiresolution approach (MRA) to wavelets. And in the meantime various generalizations (GMRAs) have emerged.

In all of this, there was a second "accident" at play: As it turned out, pyramid algorithms in wavelet analysis now lend themselves via multiresolutions, or nested scales of closed subspaces, to an analysis based on frequency bands. Here we refer to bands of frequencies as they have already been used for a long time in signal processing.

One reason for the success in varied disciplines of the same geometric idea is perhaps that it is closely modeled on how we historically have represented numbers in the positional number system. Analogies to the Euclidean algorithm seem especially compelling.

MATHEMATICS: **operator,** PROBABILITY: **process,** ENGINEERING: **black box,** PHYSICS: **observable (if selfadjoint)** In linear algebra students are familiar with the distinctions between (linear) transformations T (here called "operators") and matrices. For a fixed operator $T\colon V \to W$, there is a variety of matrices, one for each choice of basis in V and in W. In many engineering applications, the transformations are not restricted to be linear, but instead represent some experiment ("black box", in Norbert Wiener's terminology), one with an input and an output, usually functions of time. The input could be an external voltage function, the black box an electric circuit, and the output the resulting voltage in the circuit. (The output is a solution to a differential equation.)

This context is somewhat different from that of quantum mechanical (QM) operators $T\colon V \to V$ where V is a Hilbert space. In QM, selfadjoint operators represent observables such as position Q and momentum P, or time and energy.

MATHEMATICS: **Fourier dual pair,** PROBABILITY: **generating function,** ENGINEERING: **time/frequency,** PHYSICS: ***P*/*Q*** The following dual pairs position Q/momentum P, and time/energy may be computed with the use of Fourier series or Fourier transforms; and in this sense they are examples of Fourier dual pairs. If for example time is discrete, then frequency may be represented by numbers in the interval $[\,0, 2\pi)$; or in $[\,0, 1)$ if we enter the number 2π into the Fourier exponential. Functions of the frequency are then periodic, so the two endpoints are identified. In the case of the interval $[\,0, 1)$, 0 on the left is identified with 1 on the right. So a low frequency band is an interval centered at 0, while a high frequency band is an interval centered at 1/2. Let a function W on $[\,0, 1)$ represent a probability assignment. Such functions W are thought of as "filters" in signal processing. We say that W is low-pass if it is 1 at 0, or if it is near 1 for frequencies near 0.

Low-pass filters pass signals with low frequencies, and block the others.

If instead some filter W is 1 at 1/2, or takes values near 1 for frequencies near 1/2, then we say that W is high-pass; it passes signals with high frequency.

MATHEMATICS: **convolution,** PROBABILITY: **—,** ENGINEERING: **filter,** PHYSICS: **smearing** Pointwise multiplication of functions of frequencies corresponds in the Fourier dual time-domain to the operation of convolution (or of Cauchy product if the time-scale is discrete.) The process of modifying a signal with a fixed convolution is called a linear filter in signal processing. The corresponding Fourier dual frequency function is then referred to as "frequency response" or the "frequency response function".

More generally, in the continuous case, since convolution tends to improve smoothness of functions, physicists call it "smearing."

MATHEMATICS: **decomposition (e. g., Fourier coefficients in a Fourier expansion),** PROBABILITY: **–,** ENGINEERING: **analysis,** PHYSICS: **frequency components** Calculating the Fourier coefficients is "analysis," and adding up the pure frequencies (i. e., summing the Fourier series) is called synthesis. But this view carries over more generally to engineering where there are more operations involved on the two sides, e. g., breaking up a signal into its frequency bands, transforming further, and then adding up the "banded" functions in the end. If the signal out is the same as the signal in, we say that the analysis/synthesis yields perfect reconstruction.

MATHEMATICS: **integrate (e. g., inverse Fourier transform),** PROBABILITY: **reconstruct,** ENGINEERING: **synthesis,** PHYSICS: **superposition** Here the terms related to "synthesis" refer to the second half of the kind of signal-processing design outlined in the previous paragraph.

MATHEMATICS: **subspace,** PROBABILITY: **—,** ENGINEERING: **resolution,** PHYSICS: **(signals in a) frequency band** For a space of functions (signals), the selection of certain frequencies serves as a way of selecting special signals. When the process of scaling is introduced into optics of a digital camera, we note that a nested family of subspaces corresponds to a grading of visual resolutions.

MATHEMATICS: **Cuntz relations,** PROBABILITY: **—,** ENGINEERING: **perfect reconstruction from subbands,** PHYSICS: **subband decomposition**

$$\sum_{i=0}^{N-1} S_i S_i^* = \mathbf{1} \,, \quad \text{and} \quad S_i^* S_j = \delta_{i,j}\mathbf{1} \,.$$

MATHEMATICS: **inner product,** PROBABILITY: **correlation,** ENGINEERING: **transition probability,** PHYSICS: **probability of transition from one state to another** In many applications, a vector space with inner product captures perfectly the geometric and probabilistic features of the situation. This can be axiomatized in the language of Hilbert space; and the inner product is the most crucial ingredient in the familiar axiom system for Hilbert space.

MATHEMATICS: $\boldsymbol{f_{\text{out}} = T f_{\text{in}}}$, PROBABILITY: **—,** ENGINEERING: **input/output,** PHYSICS: **transformation of states** Systems theory language for operators $T\colon V \to W$. Then vectors in V are input, and in the range of T output.

MATHEMATICS: **fractal,** PROBABILITY: **—,** ENGINEERING: **—,** PHYSICS: **—** Intuitively, think of a fractal as reflecting similarity of scales such as is seen in fern-like images that look "roughly" the same at small and at large scales. Fractals are produced from an infinite iteration of a finite set of maps, and this algorithm is perfectly suited to the kind of subdivision which is a cornerstone of the discrete wavelet algorithm. Self-similarity could refer alternately to space, and to time. And further versatility is added, in that flexibility is allowed into the definition of "similar".

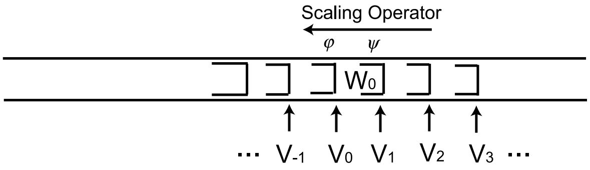
MATHEMATICS: **—,** PROBABILITY: **—,** ENGINEERING: **data mining,** PHYSICS: **—** The problem of how to handle and make use of large volumes of data is a corollary of the digital revolution. As a result, the subject of data mining itself changes rapidly. Digitized information (data) is now easy to capture automatically and to store electronically. In science, commerce, and industry, data represent collected observations and information: In business, there are data on markets, competitors, and customers. In manufacturing, there are data for optimizing production opportunities, and for improving processes. A tremendous potential for data mining exists in medicine, genetics, and energy. But raw data are not always directly usable, as is evident by inspection. A key to advances is our ability to *extract information and knowledge* from the data (hence "data mining"), and to understand the phenomena governing data sources. Data mining is now taught in a variety of forms in engineering departments, as well as in statistics and computer science departments.

One of the structures often hidden in data sets is some degree of *scale*. The goal is to detect and identify one or more natural global and local scales in the data. Once this is done, it is often possible to detect associated similarities of scale, much like the familiar scale-similarity from multidimensional wavelets, and from fractals. Indeed, various adaptations of wavelet-like algorithms have been shown to be useful. These algorithms themselves are useful in *detecting* scale-similarities, and are applicable to other types of pattern recognition. Hence, in this context, generalized multiresolutions offer another tool for discovering structures in large data sets, such as those stored in the resources of the Internet. Because of the sheer volume of data involved, a strictly manual analysis is out of the question. Instead, sophisticated query processors based on statistical and mathematical techniques are used in generating insights and extracting conclusions from data sets.

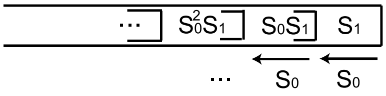
Multiresolutions Haar's work in 1909–1910 had implicitly the key idea which got wavelet mathematics started on a roll 75 years later with Yves Meyer, Ingrid Daubechies, Stéphane Mallat, and others—namely the idea of a multiresolution. In that respect Haar was ahead of his time. See Figs. 1 and 2 for details.

$$\cdots \subset V_{-1} \subset V_0 \subset V_1 \subset \cdots \,, \quad V_0 + W_0 = V_1$$

The word "multiresolution" suggests a connection to optics from physics. So that should have been a hint to



Comparison of Discrete and Continuous Wavelet Transforms, Figure 1
Multiresolution. $L^2(\mathbb{R}^d)$-version (continuous); $\varphi \in V_0$, $\psi \in W_0$



Comparison of Discrete and Continuous Wavelet Transforms, Figure 2
Multiresolution. $l^2(\mathbb{Z})$-version (discrete); $\varphi \in V_0$, $\psi \in W_0$

mathematicians to take a closer look at trends in signal and image processing! Moreover, even staying within mathematics, it turns out that as a general notion this same idea of a "multiresolution" has long roots in mathematics, even in such modern and pure areas as operator theory and Hilbert-space geometry. Looking even closer at these interconnections, we can now recognize scales of subspaces (so-called multiresolutions) in classical algorithmic construction of orthogonal bases in inner-product spaces, now taught in lots of mathematics courses under the name of the Gram–Schmidt algorithm. Indeed, a closer look at good old Gram–Schmidt reveals that it is a matrix algorithm, Hence new mathematical tools involving non-commutativity!

If the signal to be analyzed is an image, then why not select a fixed but suitable *resolution* (or a subspace of signals corresponding to a selected resolution), and then do the computations there? The selection of a fixed "resolution" is dictated by practical concerns. That idea was key in turning computation of wavelet coefficients into iterated matrix algorithms. As the matrix operations get large, the computation is carried out in a variety of paths arising from big matrix products. The dichotomy, continuous vs. discrete, is quite familiar to engineers. The industrial engineers typically work with huge volumes of numbers.

Numbers! – So why wavelets? Well, what matters to the industrial engineer is not really the wavelets, but the fact that special wavelet functions serve as an efficient way to encode large data sets – I mean encode for computations. And the wavelet algorithms are computational. They work on numbers. Encoding numbers into pictures, images, or graphs of functions comes later, perhaps at the very end of the computation. But without the graphics, I doubt that we would understand any of this half as well as we do now. The same can be said for the many issues that relate to the crucial mathematical concept of self-similarity, as we know it from fractals, and more generally from recursive algorithms.

Definition of the Subject

In this paper we outline several points of view on the interplay between discrete and continuous wavelet transforms; stressing both pure and applied aspects of both. We outline some new links between the two transform technologies based on the theory of representations of generators and relations. By this we mean a finite system of generators which are represented by operators in Hilbert space. We further outline how these representations yield sub-band filter banks for signal and image processing algorithms.

The word "wavelet transform" (WT) means different things to different people: Pure and applied mathematicians typically give different answers the questions "What is the WT?" And engineers in turn have their own preferred quite different approach to WTs. Still there are two main trends in how WTs are used, the *continuous* WT on one side, and the *discrete* WT on the other. Here we offer a user friendly outline of both, but with a slant toward geometric methods from the theory of operators in Hilbert space.

Our paper is organized as follows: For the benefit of diverse reader groups, we begin with Glossary (Sect. "Glossary"). This is a substantial part of our account, and it reflects the multiplicity of how the subject is used.

The concept of multiresolutions or multiresolution analysis (MRA) serves as a link between the discrete and continuous theory.

In Sect. "List of Names and Discoveries", we summarize how different mathematicians and scientists have contributed to and shaped the subject over the years.

The next two sections then offer a technical overview of both discrete and the continuous WTs. This includes basic tools from Fourier analysis and from operators in Hilbert space. In Sect. "Tools from Mathematics" and Sect. "A Transfer Operator", we outline the connections between the separate parts of mathematics and their applications to WTs.

Introduction

While applied problems such as time series, signals and processing of digital images come from engineering and from the sciences, they have in the past two decades taken a life of their own as an exciting new area of applied mathematics. While searches in Google on these keywords typically yield sites numbered in the millions, the diversity of applications is wide, and it seems reasonable here to narrow our focus to some of the approaches that are both more mathematical and more recent. For references, see for example [1,6,23,31]. In addition, our own interests (e. g., [20,21,27,28]) have colored the presentation below. Each of the two areas, the discrete side, and the continuous theory is huge as measured by recent journal publications. A leading theme in our article is the independent interest in a multitude of interconnections between the discrete algorithm and their uses in the more mathematical analysis of function spaces (continuous wavelet transforms). The mathematics involved in the study and the applications of this interaction we feel is of benefit to both mathematicians and to engineers. See also [20]. An early paper [9] by Daubechies and Lagarias was especially influential in connecting the two worlds, discrete and continuous.

The Discrete vs. Continuous Wavelet Algorithms

The Discrete Wavelet Transform

If one stays with function spaces, it is then popular to pick the d-dimensional Lebesgue measure on $\mathbb{R}^d$, $d = 1, 2, \ldots$, and pass to the Hilbert space $L^2(\mathbb{R}^d)$ of all square integrable functions on $\mathbb{R}^d$, referring to d-dimensional Lebesgue measure. A wavelet basis refers to a family of basis functions for $L^2(\mathbb{R}^d)$ generated from a finite set of normalized functions ψ_i, the index i chosen from a fixed and finite index set I, and from two operations, one called scaling, and the other translation. The scaling is typically specified by a d by d matrix over the integers $\mathbb{Z}$ such that all the eigenvalues in modulus are bigger than one, lie outside the closed unit disk in the complex plane. The d-lattice is denoted $\mathbb{Z}^d$, and the translations will be by vectors selected from $\mathbb{Z}^d$. We say that we have a wavelet basis if the triple indexed family $\psi_{i,j,k}(x) := |\det A|^{j/2}\psi(A^j x + k)$ forms an orthonormal basis (ONB) for $L^2(\mathbb{R}^d)$ as i varies in I, $j \in \mathbb{Z}$, and $k \in \mathbb{R}^d$. The word "orthonormal" for a family F of vectors in a Hilbert space $\mathcal{H}$ refers to the norm and the inner product in $\mathcal{H}$: The vectors in an orthonormal family F are assumed to have norm one, and to be mutually orthogonal. If the family is also total (i. e., the vectors in F span a subspace which is dense in $\mathcal{H}$), we say that F is an orthonormal basis (ONB.)

While there are other popular wavelet bases, for example frame bases, and dual bases (see e. g., [2,18] and the papers cited there), the ONBs are the most agreeable at least from the mathematical point of view.

That there are bases of this kind is not at all clear, and the subject of wavelets in this continuous context has gained much from its connections to the discrete world of signal- and image-processing.

Here we shall outline some of these connections with an emphasis on the mathematical context. So we will be stressing the theory of Hilbert space, and bounded linear operators acting in Hilbert space $\mathcal{H}$, both individual operators, and families of operators which form algebras.

As was noticed recently the operators which specify particular subband algorithms from the discrete world of signal-processing turn out to satisfy relations that were found (or rediscovered independently) in the theory of operator algebras, and which go under the name of Cuntz algebras, denoted $\mathcal{O}_N$ if n is the number of bands. For additional details, see e. g., [21].

In symbols the C^*-algebra has generators $(S_i)_{i=0}^{N-1}$, and the relations are

$$\sum_{i=0}^{N-1} S_i S_i^* = \mathbf{1} \tag{1}$$

(where $\mathbf{1}$ is the identity element in $\mathcal{O}_N$) and

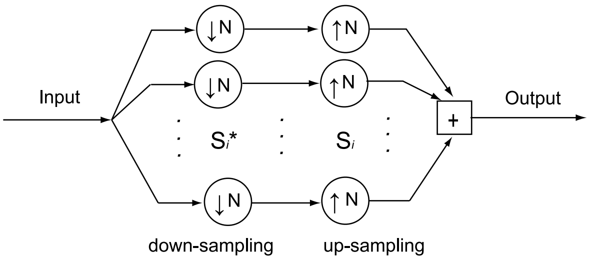
$$\sum_{i=0}^{N-1} S_i S_i^* = \mathbf{1}\,, \quad \text{and} \quad S_i^* S_j = \delta_{i,j}\mathbf{1}\,. \tag{2}$$

In a representation on a Hilbert space, say $\mathcal{H}$, the symbols S_i turn into bounded operators, also denoted S_i, and the identity element $\mathbf{1}$ turns into the identity operator I in $\mathcal{H}$, i. e., the operator $I\colon h \to h$, for $h \in \mathcal{H}$. In operator language, the two formulas (1) and (2) state that each S_i is an isometry in $\mathcal{H}$, and that the respective ranges $S_i\mathcal{H}$ are mutually orthogonal, i. e., $S_i\mathcal{H} \perp S_j\mathcal{H}$ for $i \neq j$. Introducing the projections $P_i = S_i S_i^*$, we get $P_i P_j = \delta_{i,j} P_i$, and

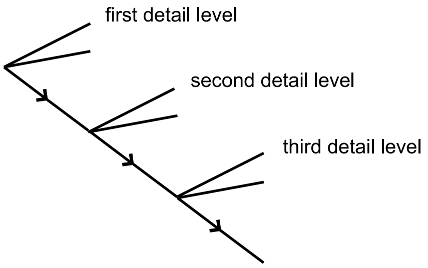
$$\sum_{i=0}^{N-1} P_i = I\,.$$

In the engineering literature this takes the form of programming diagrams: Fig. 3. If the process of Fig. 3 is repeated, we arrive at the discrete wavelet transform (Fig. 4) or stated in the form of images ($n = 5$) (Fig. 5).

Selecting a resolution subspace V_0 = closure span $\{\varphi(\cdot - k) | k \in \mathbb{Z}\}$, we arrive at a wavelet subdivision $\{\psi_{j,k} | j \geq 0, k \in \mathbb{Z}\}$, where $\psi_{j,k}(x) = 2^{j/2}\psi(2^j x - k)$, and the continuous expansion $f = \sum_{j,k} \langle \psi_{j,k} | f \rangle \psi_{j,k}$ or the discrete analogue derived from the isometries, $i = 1, 2, \ldots, N-1$, $S_0^k S_i$ for $k = 0, 1, 2, \ldots$; called the discrete wavelet transform.



Comparison of Discrete and Continuous Wavelet Transforms, Figure 3
Perfect reconstruction in a subband filtering as used in signal- and image-processing

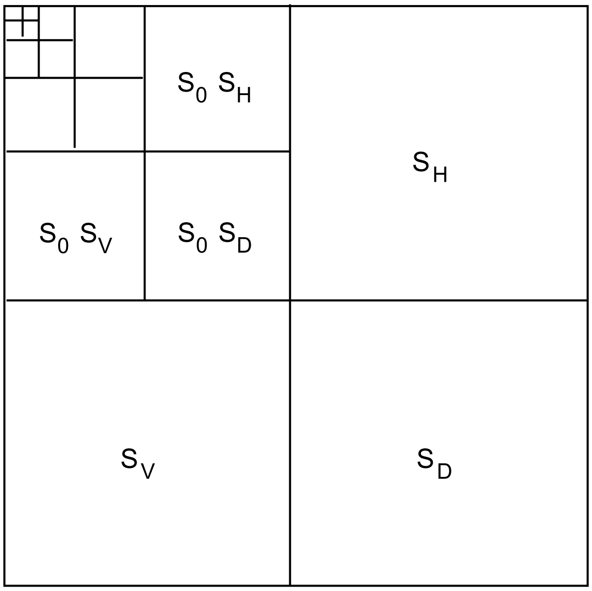


Comparison of Discrete and Continuous Wavelet Transforms, Figure 4
Binary decision tree for a sequential selection of filters.

Notational Convention In algorithms, the letter N is popular, and often used for counting more than one thing.

In the present contest of the discrete wavelet algorithm (DWA) or DWT, we count two things, "the number of times a picture is decomposed via subdivision". We have used n for this. The other related but different number N is the number of subbands, $N = 2$ for the dyadic DWT, and $N = 4$ for the image DWT. The image-processing WT in our present context is the tensor product of the 1-D dyadic WT, so $2 \times 2 = 4$. Caution: Not all DWAs arise as tensor products of $N = 2$ models. The wavelets coming from tensor products are called separable. When a particular image-processing scheme is used for generating continuous wavelets it is not transparent if we are looking at a separable or inseparable wavelet!

To clarify the distinction, it is helpful to look at the representations of the Cuntz relations by operators in Hilbert space. We are dealing with representations of the two distinct algebras $\mathcal{O}_2$, and $\mathcal{O}_4$; two frequency subbands vs. four subbands. Note that the Cuntz $\mathcal{O}_2$, and $\mathcal{O}_4$ are given axiomatic, or purely symbolically. It is only when subband filters are chosen that we get representations. This also means that the choice of N is made initially; and the same N is used in different runs of the programs. In contrast, the number of times a picture is decomposed varies from one experiment to the next!



Comparison of Discrete and Continuous Wavelet Transforms, Figure 5
The subdivided squares represent the use of the pyramid subdivision algorithm to image processing, as it is used on pixel squares. At each subdivision step the *top left-hand square* represents averages of nearby pixel numbers, averages taken with respect to the chosen low-pass filter; while the three directions, horizontal, vertical, and diagonal represent detail differences, with the three represented by separate bands and filters. So in this model, there are four bands, and they may be realized by a tensor product construction applied to dyadic filters in the separate x- and the y-directions in the plane. For the discrete WT used in image-processing, we use iteration of four isometries S_0, S_H, S_V, and S_D with mutually orthogonal ranges, and satisfying the following sum-rule $S_0S_0^* + S_HS_H^* + S_VS_V^* + S_DS_D^* = I$, with I denoting the identity operator in an appropriate l^2-space

Summary: $N = 2$ for the dyadic DWT: The operators in the representation are S_0, S_1. One average operator, and one detail operator. The detail operator S_1 "counts" local detail variations.

Image-processing. Then $N = 4$ is fixed as we run different images in the DWT: The operators are now: S_0, S_H, S_V, S_D. One average operator, and three detail operator for local detail variations in the three directions in the plane.

The Continuous Wavelet Transform

Consider functions f on the real line $\mathbb{R}$. We select the Hilbert space of functions to be $L^2(\mathbb{R})$ To start a continuous WT, we must select a function $\psi \in L^2(\mathbb{R})$ and $r, s \in \mathbb{R}$

Comparison of Discrete and Continuous Wavelet Transforms, Figure 6
$n = 2$ Jorgensen. The selection of filters (Fig 4) is represented by the use of one of the operators S_i in Fig 3. A planar version of this principle is illustrated in Fig 6. For a more detailed discussion, see e. g., [3]

such that the following family of functions

$$\psi_{r,s}(x) = r^{-1/2}\psi\left(\frac{x-s}{r}\right)$$

creates an over-complete basis for $L^2(\mathbb{R})$. An over-complete family of vectors in a Hilbert space is often called a coherent decomposition. This terminology comes from quantum optics. What is needed for a continuous WT in the simplest case is the following representation valid for all $f \in L^2(\mathbb{R})$:

$$f(x) = C_\psi^{-1} \iint_{\mathbb{R}^2} \langle\psi_{r,s}|f\rangle\psi_{r,s}(x)\frac{\mathrm{d}r\mathrm{d}s}{r^2}$$

where $C_\psi := \int_\mathbb{R} |\hat{\psi}(\omega)|^2 \frac{\mathrm{d}\omega}{\omega}$ and where $\langle\psi_{r,s}|f\rangle = \int_\mathbb{R} \overline{\psi_{r,s}(y)} f(y)\mathrm{d}y$. The refinements and implications of this are spelled out in tables in Sect. "Connections to Group Theory".

Some Background on Hilbert Space

Wavelet theory is the art of finding a special kind of basis in Hilbert space. Let $\mathcal{H}$ be a Hilbert space over $\mathbb{C}$ and denote the inner product $\langle\cdot\mid\cdot\rangle$. For us, it is assumed linear in the second variable. If $\mathcal{H} = L^2(\mathbb{R})$, then

$$\langle f \mid g\rangle := \int_\mathbb{R} \overline{f(x)}\, g(x)\,\mathrm{d}x\,.$$

If $\mathcal{H} = \ell^2(\mathbb{Z})$, then

$$\langle \xi \mid \eta\rangle := \sum_{n\in\mathbb{Z}} \bar{\xi}_n \eta_n\,.$$

Let $\mathbb{T} = \mathbb{R}/2\pi\mathbb{Z}$. If $\mathcal{H} = L^2(\mathbb{T})$, then

$$\langle f \mid g\rangle := \frac{1}{2\pi}\int_{-\pi}^{\pi} \overline{f(\theta)}\, g(\theta)\,\mathrm{d}\theta\,.$$

Functions $f \in L^2(\mathbb{T})$ have Fourier series: Setting $e_n(\theta) = \mathrm{e}^{in\theta}$,

$$\hat{f}(n) := \langle e_n \mid f\rangle = \frac{1}{2\pi}\int_{-\pi}^{\pi} \mathrm{e}^{-in\theta} f(\theta)\,\mathrm{d}\theta\,,$$

and

$$\|f\|^2_{L^2(\mathbb{T})} = \sum_{n\in\mathbb{Z}} \left|\hat{f}(n)\right|^2\,.$$

Similarly if $f \in L^2(\mathbb{R})$, then

$$\hat{f}(t) := \int_\mathbb{R} \mathrm{e}^{-ixt} f(x)\,\mathrm{d}x\,,$$

and

$$\|f\|^2_{L^2(\mathbb{R})} = \frac{1}{2\pi}\int_\mathbb{R} \left|\hat{f}(t)\right|^2 \mathrm{d}t\,.$$

Let J be an index set. We shall only need to consider the case when J is countable. Let $\{\psi_\alpha\}_{\alpha\in J}$ be a family of nonzero vectors in a Hilbert space $\mathcal{H}$. We say it is an *orthonormal basis* (ONB) if

$$\langle \psi_\alpha \mid \psi_\beta\rangle = \delta_{\alpha,\beta} \qquad \text{(Kronecker delta)} \tag{3}$$

and if

$$\sum_{\alpha\in J} |\langle \psi_\alpha \mid f\rangle|^2 = \|f\|^2 \quad \text{holds for all} f \in \mathcal{H}\,. \tag{4}$$

If only Eq. (4) is assumed, but not Eq. (3), we say that $\{\psi_\alpha\}_{\alpha\in J}$ is a (normalized) *tight frame*. We say that it is a *frame* with *frame constants* $0 < A \leq B < \infty$ if

$$A\,\|f\|^2 \leq \sum_{\alpha\in J} |\langle \psi_\alpha \mid f\rangle|^2 \leq B\,\|f\|^2$$

holds for all $f \in \mathcal{H}$.

Introducing the rank-one operators $Q_\alpha := |\psi_\alpha\rangle\langle\psi_\alpha|$ of Dirac's terminology, see [3], we see that $\{\psi_\alpha\}_{\alpha\in J}$ is an ONB if and only if the Q_α's are projections, and

$$\sum_{\alpha\in J} Q_\alpha = I \qquad (= \text{the identity operator in } \mathcal{H})\,. \tag{5}$$

It is a (normalized) tight frame if and only if Eq. (5) holds but with no further restriction on the rank-one operators Q_α. It is a frame with frame constants A and B if the operator

$$S := \sum_{\alpha\in J} Q_\alpha$$

satisfies

$$AI \leq S \leq BI$$

in the order of Hermitian operators. (We say that operators $H_i = H_i^*$, $i = 1, 2$, satisfy $H_1 \leq H_2$ if $\langle f \mid H_1 f\rangle \leq \langle f \mid H_2 f\rangle$ holds for all $f \in \mathcal{H}$). If h, k are vectors in a Hilbert space $\mathcal{H}$, then the operator $A = |h\rangle\langle k|$ is defined by the identity $\langle u \mid Av\rangle = \langle u \mid h\rangle\langle k \mid v\rangle$ for all $u, v \in \mathcal{H}$.

Wavelets in $L^2(\mathbb{R})$ are generated by simple operations on one or more functions ψ in $L^2(\mathbb{R})$, the operations come in pairs, say scaling and translation, or phase-modulation and translations. If $N \in \{2, 3, \ldots\}$ we set

$$\psi_{j,k}(x) := N^{j/2}\psi\left(N^j x - k\right) \quad \text{for } j, k \in \mathbb{Z}\,.$$

Increasing the Dimension In wavelet theory, [7] there is a tradition for reserving φ for the father function and ψ for the mother function. A 1-level wavelet transform of an $N \times M$ image can be represented as

$$\mathbf{f} \mapsto \begin{pmatrix} \mathbf{a}^1 & | & \mathbf{h}^1 \\ - & & - \\ \mathbf{v}^1 & | & \mathbf{d}^1 \end{pmatrix} \tag{6}$$

where the subimages $\mathbf{h}^1, \mathbf{d}^1, \mathbf{a}^1$ and $\mathbf{v}^1$ each have the dimension of $N/2$ by $M/2$.

$$\begin{aligned}
\mathbf{a}^1 &= V_m^1 \otimes V_n^1 : \varphi^A(x, y) = \varphi(x)\varphi(y) \\
&= \sum_i \sum_j h_i h_j \varphi(2x - i)\varphi(2y - j) \\
\mathbf{h}^1 &= V_m^1 \otimes W_n^1 : \psi^H(x, y) = \psi(x)\varphi(y) \\
&= \sum_i \sum_j g_i h_j \varphi(2x - i)\varphi(2y - j) \\
\mathbf{v}^1 &= W_m^1 \otimes V_n^1 : \psi^V(x, y) = \varphi(x)\psi(y) \\
&= \sum_i \sum_j h_i g_j \varphi(2x - i)\varphi(2y - j) \\
\mathbf{d}^1 &= W_m^1 \otimes W_n^1 : \psi^D(x, y) = \psi(x)\psi(y) \\
&= \sum_i \sum_j g_i g_j \varphi(2x - i)\varphi(2y - j)
\end{aligned} \tag{7}$$

where φ is the father function and ψ is the mother function in sense of wavelet, V space denotes the average space and the W spaces are the difference space from multiresolution analysis (MRA) [7].

In the formulas, we have the following two indexed number systems $\mathbf{a} := (h_i)$ and $\mathbf{d} := (g_i)$, $\mathbf{a}$ is for averages, and $\mathbf{d}$ is for local differences. They are really the input for the DWT. But they also are the key link between the two transforms, the discrete and continuous. The link is made up of the following scaling identities:

$$\begin{aligned}
\varphi(x) &= 2\sum_{i\in\mathbb{Z}} h_i \varphi(2x - i)\,; \\
\psi(x) &= 2\sum_{i\in\mathbb{Z}} g_i \varphi(2x - i)\,;
\end{aligned}$$

and (low-pass normalization) $\sum_{i\in\mathbb{Z}} h_i = 1$. The scalars (h_i) may be real or complex; they may be finite or infinite in number. If there are four of them, it is called the "four tap", etc. The finite case is best for computations since it corresponds to compactly supported functions. This means that the two functions φ and ψ will vanish outside some finite interval on a real line.

The two number systems are further subjected to orthogonality relations, of which

$$\sum_{i\in\mathbb{Z}} \bar{h}_i h_{i+2k} = \frac{1}{2}\delta_{0,k} \tag{8}$$

is the best known.

The systems h and g are both low-pass and high-pass filter coefficients. In Eq. (7), $\mathbf{a}^1$ denotes the first averaged image, which consists of average intensity values of the original image. Note that only φ function, V space and h coefficients are used here. Similarly, $\mathbf{h}^1$ denotes the first detail image of horizontal components, which consists of intensity difference along the vertical axis of the original image. Note that φ function is used on y and ψ function on x, W space for x values and V space for y values; and both h and g coefficients are used accordingly. The data $\mathbf{v}^1$ denote the first detail image of vertical components, which consists of intensity difference along the horizontal axis of the original image. Note that φ function is used on x and ψ function on y, W space for y values and V space for x values; and both h and g coefficients are used accordingly. Finally, $\mathbf{d}^1$ denotes the first detail image of diagonal components, which consists of intensity difference along the diagonal axis of the original image. The original image is reconstructed from the decomposed image by taking the sum of the averaged image and the detail images and scaling by a scaling factor. It could be noted that only ψ function, W space and g coefficients are used here. See [28,33].

This decomposition not only limits to one step but it can be done again and again on the averaged detail depending on the size of the image. Once it stops at certain level, quantization (see [26,32]) is done on the image. This quantization step may be lossy or lossless. Then the lossless entropy encoding is done on the decomposed and quantized image.

The relevance of the system of identities Eq. (8) may be summarized as follows. Set

$$m_0(z) := \frac{1}{2}\sum_{k\in\mathbb{Z}} h_k z^k \quad \text{for all } \; z \in \mathbb{T}\;;$$

$$g_k := (-1)^k \bar{h}_{1-k} \quad \text{for all } \; k \in \mathbb{Z}\;;$$

$$m_1(z) := \frac{1}{2}\sum_{k\in\mathbb{Z}} g_k z^k; \quad \text{and}$$

$$(S_j f)(z) = \sqrt{2} m_j(z) f(z^2)\,,$$
$$\text{for } \; j = 0, 1\,, \quad f \in L^2(\mathbb{T})\,, \quad z \in \mathbb{T}\,.$$

Then the following conditions are equivalent:

(a) The system of Eq. (8) is satisfied.
(b) The operators S_0 and S_1 satisfy the Cuntz relations.
(c) We have perfect reconstruction in the subband system of Fig. 4.

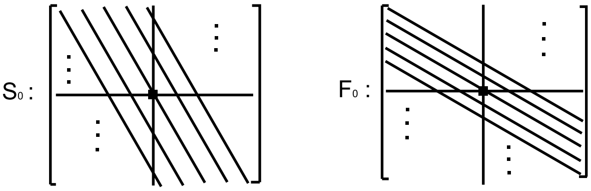
Note that the two operators S_0 and S_1 have equivalent matrix representations. Recalling that by Parseval's formula, we have $L^2(\mathbb{T}) \simeq l^2(\mathbb{Z})$. So representing S_0 instead as an $\infty \times \infty$ matrix acting on column vectors $x = (x_j)_{j\in\mathbb{Z}}$ we get

$$(S_0 x)_i = \sqrt{2}\sum_{j\in\mathbb{Z}} h_{i-2j} x_j$$

and for the adjoint operator $F_0 := S_0^*$, we get the matrix representation

$$(F_0 x)_i = \frac{1}{\sqrt{2}}\sum_{j\in\mathbb{Z}} \bar{h}_{j-2i} x_j$$

with the overbar signifying complex conjugation. This is computational significance to the two matrix representations, both the matrix for S_0, and for $F_0 := S_0^*$, is slanted.



Comparison of Discrete and Continuous Wavelet Transforms, Figure 7
Matrix representation of filters operations.

However, the slanting of one is the mirror-image of the other, i. e., Fig. 7.

Significance of Slanting The slanted matrix representations refers to the corresponding operators in L^2. In general operators in Hilbert function spaces have many matrix representations, one for each orthonormal basis (ONB), but here we are concerned with the ONB consisting of the Fourier frequencies z^j, $j \in \mathbb{Z}$. So in our matrix representations for the S operators and their adjoints we will be acting on column vectors, each infinite column representing a vector in the sequence space l^2. A vector in l^2 is said to be of finite size if it has only a finite set of non-zero entries.

It is the matrix F_0 that is effective for iterated matrix computation. Reason: When a column vector x of a fixed size, say 2s is multiplied, or acted on by F_0, the result is a vector y of half the size, i. e., of size s. So $y = F_0 x$. If we use F_0 and F_1 together on x, then we get two vectors, each of size s, the other one $z = F_1 x$, and we can form the combined column vector of y and z; stacking y on top of z. In our application, y represents averages, while z represents local differences: Hence the wavelet algorithm.

$$\begin{bmatrix} \vdots \\ y_{-1} \\ y_0 \\ y_1 \\ \vdots \\ - \\ \vdots \\ z_{-1} \\ z_0 \\ z_1 \\ \vdots \end{bmatrix} = \begin{bmatrix} F_0 \\ - \\ F_1 \end{bmatrix} \begin{bmatrix} \vdots \\ x_{-2} \\ x_{-1} \\ x_0 \\ x_1 \\ x_2 \\ \vdots \end{bmatrix}$$

$$y = F_0 x$$
$$z = F_1 x$$

$\sum_{i=0}^{N-1} \lVert S_i^* c\rVert^2 = \lVert c\rVert^2 \quad \forall c \in \ell^2$	$\sum_{i=0}^{N-1} \langle S_i^* c \mid \tilde S_i^* d \rangle = \langle c \mid d \rangle \quad \forall c, d \in \ell^2$

Connections to Group Theory

The first line in the two tables below is the continuous wavelet transform. It comes from what in physics is called *coherent vector decompositions*. Both transforms applies to vectors in Hilbert space $\mathcal{H}$, and $\mathcal{H}$ may vary from case to case. Common to all transforms is vector input and output. If the input agrees with output we say that the combined process yields the identity operator image. $\mathbf{1}\colon \mathcal{H} \to \mathcal{H}$ or written $\mathbf{1}_{\mathcal{H}}$. So for example if $(S_i)_{i=0}^{N-1}$ is a finite operator system, and input/output operator example may take the form

$$\sum_{i=0}^{N-1} S_i S_i^* = \mathbf{1}_{\mathcal{H}} \,.$$

The Summary of and variations on the resolution of the identity operator $\mathbf{1}$ in L^2 or in ℓ^2, for ψ and $\tilde\psi$ where $\psi_{r,s}(x) = r^{-\frac{1}{2}} \psi\left(\frac{x-s}{r}\right)$,

$$C_\psi = \int_{\mathbb{R}} \frac{d\omega}{|\omega|} |\hat\psi(\omega)|^2 < \infty \,,$$

similarly for $\tilde\psi$ and $C_{\psi,\tilde\psi} = \int_{\mathbb{R}} \frac{d\omega}{|\omega|} \overline{\hat\psi(\omega)}\, \hat{\tilde\psi}(\omega)$ is given in Table 1.

Then the assertions in Table 1 amount to the equations in Table 2.

A function ψ satisfying the resolution identity is called a *coherent vector* in mathematical physics. The representation theory for the $(ax + b)$-group, i. e., the matrix group $G = \left\{ \left(\begin{smallmatrix} a & b \\ 0 & 1 \end{smallmatrix}\right) \mid a \in \mathbb{R}_+,\ b \in \mathbb{R} \right\}$, serves as its underpinning. Then the tables above illustrate how the $\{\psi_{j,k}\}$ wavelet system arises from a discretization of the following unitary representation of G:

$$\left(U_{\left(\begin{smallmatrix} a & b \\ 0 & 1 \end{smallmatrix}\right)} f \right)(x) = a^{-\frac{1}{2}} f\left(\frac{x-b}{a}\right)$$

acting on $L^2(\mathbb{R})$. This unitary representation also explains the discretization step in passing from the first line to the second in the tables above. The functions $\{\, \psi_{j,k} \mid j, k \in \mathbb{Z} \,\}$ which make up a wavelet system result from the choice of a suitable coherent vector $\psi \in L^2(\mathbb{R})$, and then setting

$$\psi_{j,k}(x) = \left(U_{\left(\begin{smallmatrix} 2^{-j} & k\cdot 2^{-j} \\ 0 & 1 \end{smallmatrix}\right)} \psi \right)(x) = 2^{\frac{j}{2}} \psi\left(2^j x - k\right) \,.$$

Even though this representation lies at the historical origin of the subject of wavelets, the $(ax + b)$-group seems to be now largely forgotten in the next generation of the wavelet community. But Chaps. 1–3 of [7] still serve as a beautiful presentation of this (now much ignored) side of the subject. It also serves as a link to mathematical physics and to classical analysis.

List of Names and Discoveries

Many of the main discoveries summarized below are now lore.

1807 *Jean Baptiste Joseph Fourier mathematics, physics (heat conduction)*
Expressing functions as sums of sine and cosine waves of frequencies in arithmetic progression (now called Fourier series).

1909 *Alfred Haar mathematics*
Discovered, while a student of David Hilbert, an orthonormal basis consisting of step functions, applicable both to functions on an interval, and functions on the whole real line. While it was not realized at the time, Haar's construction was a precursor of what is now known as the Mallat subdivision, and multiresolution method, as well as the subdivision wavelet algorithms.

1946 *Denes Gabor (Nobel Prize): physics (optics, holography)*
Discovered basis expansions for what might now be called time-frequency wavelets, as opposed to time-scale wavelets.

1948 *Claude Elwood Shannon mathematics, engineering (information theory)*
A rigorous formula used by the phone company for sampling speech signals. Quantizing information, entropy, founder of what is now called the mathematical theory of communication.

1976 *Claude Garland, Daniel Esteban (both) signal processing*
Discovered subband coding of digital transmission of speech signals over the telephone.

1981 *Jean Morlet petroleum engineer*
Suggested the term "ondelettes." J.M. decomposed reflected seismic signals into sums of "wavelets (Fr.: ondelettes) of constant shape," i. e., a decomposition of signals into wavelet shapes, selected from a library of such shapes (now called wavelet series). Received somewhat late recognition for his work. Due to contributions by A. Grossman and Y. Meyer, Morlet's discoveries have now come to play a central role in the theory.

1985 *Yves Meyer mathematics, applications*
Mentor for A. Cohen, S. Mallat, and other of the wavelet pioneers, Y.M. discovered infinitely often differentiable wavelets.

1989 *Albert Cohen mathematics (orthogonality relations), numerical analysis*
Discovered the use of wavelet filters in the analysis of wavelets — the so-called Cohen condition for orthogonality.

1986 *Stéphane Mallat mathematics, signal and image processing*
Discovered what is now known as the subdivision, and multiresolution method, as well as the subdivision wavelet algorithms. This allowed the effective use of operators in the Hilbert space $L^2(\mathbb{R})$, and of the parallel computational use of recursive matrix algorithms.

1987 *Ingrid Daubechies mathematics, physics, and communications*
Discovered differentiable wavelets, with the number of derivatives roughly half the length of the support interval. Further found polynomial algorithmic for their construction (with coauthor Jeff Lagarias; joint spectral radius formulas).

1991 *Wayne Lawton mathematics (the wavelet transfer operator)*
Discovered the use of a transfer operator in the analysis of wavelets: orthogonality and smoothness.

1992 *The FBI using wavelet algorithms in digitizing and compressing fingerprints*
C. Brislawn and his group at Los Alamos created the theory and the codes which allowed the compression of the enormous FBI fingerprint file, creating A/D, a new database of fingerprints.

2000 *The International Standards Organization*
A wavelet-based picture compression standard, called JPEG 2000, for digital encoding of images.

1994 *David Donoho statistics, mathematics*
Pioneered the use of wavelet bases and tools from statistics to "denoise" images and signals.

History

While wavelets as they have appeared in the mathematics literature (e. g., [7]) for a long time, starting with Haar in 1909, involve function spaces, the connections to a host of discrete problems from engineering is more subtle. Moreover the deeper connections between the discrete algorithms and the function spaces of mathematical analysis are of a more recent vintage, see e. g., [31] and [21].

Here we begin with the function spaces. This part of wavelet theory refers to continuous wavelet transforms (details below). It dominated the wavelet literature in the 1980s, and is beautifully treated in the first four chapters in [7] and in [8]. The word "continuous" refers to the continuum of the real line $\mathbb{R}$. Here we consider spaces of functions in one or more real dimensions, i. e., functions on the line $\mathbb{R}$ (signals), the plane $\mathbb{R}^2$ (images), or in higher dimensions $\mathbb{R}^d$, functions of d real variables.

Tools from Mathematics

In our presentation, we will rely on tools from at least three separate areas of mathematics, and we will outline how they interact to form a coherent theory, and how they come together to form a link between what is now called the discrete and the continuous wavelet transform. It is the discrete case that is popular with engineers ([1,23,29,30]), while the continuous case has come to play a central role in the part of mathematics referred to as harmonic analysis, [8]. The three areas are, operator algebras, dynamical systems, and basis constructions:

a. Operator algebras. The theory of operator algebras in turn breaks up in two parts: One the study of "the algebras themselves" as they emerge from the axioms of von Neumann (von Neumann algebras), and Gelfand, Kadison and Segal (C^*-algebras.) The other has a more applied slant: It involves "the representations" of the algebras. By this we refer to the following: The algebras will typically be specified by generators and by relations, and by a certain norm-completion, in any case by a system of axioms. This holds both for the norm-closed algebras, the so called C^*-algebras, and for the weakly closed algebras, the von Neumann algebras. In fact there is a close connection between the two parts of the theory: For example, representations of C^*-algebras generate von Neumann algebras.
   To talk about representations of a fixed algebra say A we must specify a Hilbert space, and a homomorphism ρ from A into the algebra $\mathcal{B}(H)$ of all bounded operators on $\mathcal{H}$. We require that ρ sends the identity element in A into the identity operator acting on $\mathcal{H}$, and that $\rho(a^*) = (\rho(a))^*$ where the last star now refers to the adjoint operator.
   It was realized in the last ten years (see for example [3,21,22] that a family of representations that wavelets which are basis constructions in harmonic analysis, in signal/image analysis, and in computational mathematics may be built up from representations of an especially important family of simple C^*-algebras, the Cuntz algebras. The Cuntz algebras are denoted $\mathcal{O}_2, \mathcal{O}_3, \ldots$, including $\mathcal{O}_\infty$.
b. Dynamical systems. The connection between the Cuntz algebras $\mathcal{O}_N$ for $N = 2, 3, \ldots$ are relevant to the kind of dynamical systems which are built on branching-laws, the case of $\mathcal{O}_N$ representing N-fold branching. The reason for this is that if N is fixed, $\mathcal{O}_N$ includes in its definition an iterated subdivision, but within the context of Hilbert space. For more details, see e. g., [12,13,14,15,16,17,22].
c. Analysis of bases in function spaces. The connection to basis constructions using wavelets is this: The context for wavelets is a Hilbert space $\mathcal{H}$, where $\mathcal{H}$ may be $L^2(\mathbb{R}^d)$ where d is a dimension, $d = 1$ for the line (signals), $d = 2$ for the plane (images), etc. The more successful bases in Hilbert space are the orthonormal bases ONBs, but until the mid 1980s, there were no ONBs in $L^2(\mathbb{R}^d)$ which were entirely algorithmic and effective for computations. One reason for this is that the tools that had been used for 200 years since Fourier involved basis functions (Fourier wave functions) which were not localized. Moreover these existing Fourier tools were not friendly to algorithmic computations.

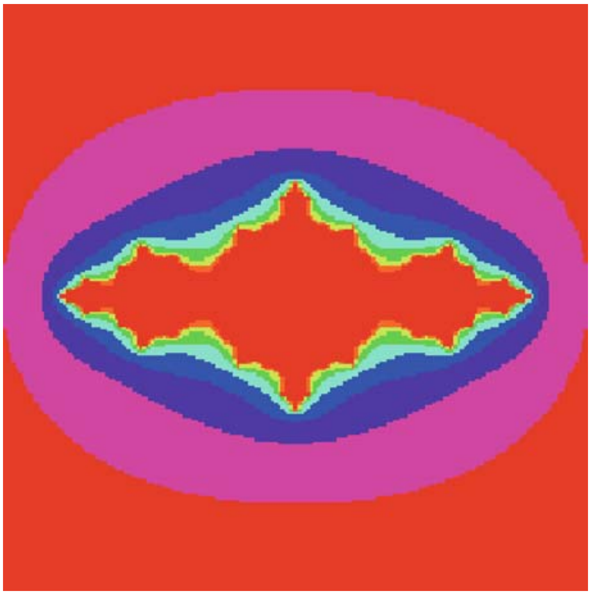
A Transfer Operator

A popular tool for deciding if a candidate for a wavelet basis is in fact an ONB uses a certain transfer operator. Variants of this operator is used in diverse areas of applied mathematics. It is an operator which involves a weighted average over a finite set of possibilities. Hence it is natural for understanding random walk algorithms. As remarked in for example [12,20,21,22], it was also studied in physics, for example by David Ruelle, who used to prove results on phase transition for infinite spin systems in quantum statistical mechanics. In fact the transfer operator has many incarnations (many of them known as Ruelle operators), and all of them based on N-fold branching laws.

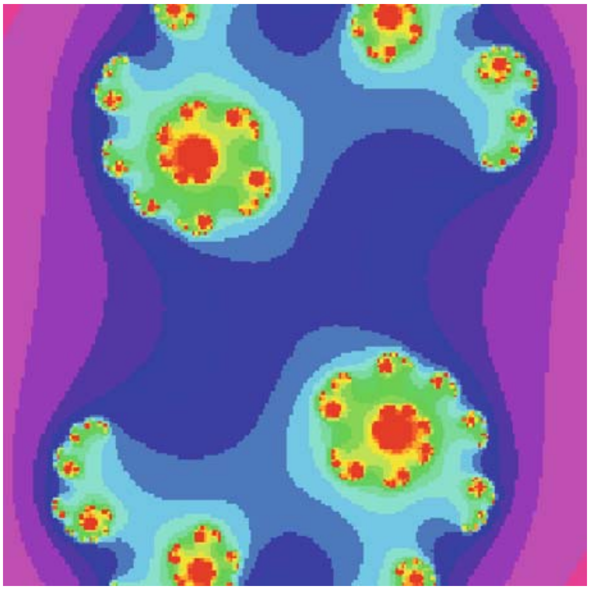
In our wavelet application, the Ruelle operator weights in input over the N branch possibilities, and the weighting is assigned by a chosen scalar function W. the and the W-Ruelle operator is denoted R_W. In the wavelet setting there is in addition a low-pass filter function m_0 which in its frequency response formulation is a function on the d-torus $\mathbf{T}^d = \mathbb{R}^d/\mathbb{Z}^d$.

Since the scaling matrix A has integer entries A passes to the quotient $\mathbb{R}^d/\mathbb{Z}^d$, and the induced transformation $r_A : \mathbb{T}^d \to \mathbb{T}^d$ is an N-fold cover, where $N = |\det A|$, i. e., for every x in $\mathbb{T}^d$ there are N distinct points y in $\mathbb{T}^d$ solving $r_A(y) = x$.

In the wavelet case, the weight function W is $W = |m_0|^2$. Then with this choice of W, the ONB problem for a candidate for a wavelet basis in the Hilbert space $L^2(\mathbb{R}^d)$



Comparison of Discrete and Continuous Wavelet Transforms, Figure 8
Julia set with $c = -1$ These images are generated by Mathematica by authors for different c values for $\varphi_c(z) = z^(2) + c$.



Comparison of Discrete and Continuous Wavelet Transforms, Figure 9

as it turns out may be decided by the dimension of a distinguished eigenspace for R_W, by the so called Perron–Frobenius problem.

This has worked well for years for the wavelets which have an especially simple algorithm, the wavelets that are initialized by a single function, called the scaling function. These are called the multiresolution analysis (MRA) wavelets, or for short the MRA-wavelets. But there are instances, for example if a problem must be localized in frequency domain, when the MRA-wavelets do not suffice, where it will by necessity include more than one scaling function. And we are then back to trying to decide if the output from the discrete algorithm, and the $\mathcal{O}_N$ representation is an ONB, or if it has some stability property which will serve the same purpose, in case where asking for an ONB is not feasible.

Future Directions

The idea of a scientific analysis by subdividing a fixed picture or object into its finer parts is not unique to wavelets. It works best for structures with an inherent self-similarity; this self-similarity can arise from numerical scaling of distances. But there are more subtle non-linear self-similarities. The Julia sets in the complex plane are a case in point [4,5,10,11,24,25]. The simplest Julia set come from a one parameter family of quadratic polynomials $\varphi_c(z) = z^2 + c$, where z is a complex variable and where c is a fixed parameter. The corresponding Julia sets J_c have a surprisingly rich structure. A simple way to understand them is the following: Consider the two branches of the inverse $\beta_\pm = z \mapsto \pm\sqrt{z-c}$. Then J_c is the unique minimal non-empty compact subset of $\mathbb{C}$, which is invariant under $\{\beta_\pm\}$. (There are alternative ways of presenting J_c but this one fits our purpose. The Julia set J of a holomorphic function, in this case $z \mapsto z^2 + c$, informally consists of those points whose long-time behavior under repeated iteration, or rather iteration of substitutions, can change drastically under arbitrarily small perturbations.) Here "long-time" refers to large n, where $\varphi^{(n+1)}(z) = \varphi(\varphi^{(n)}(z))$, $n = 0, 1, \ldots$, and $\varphi^{(0)}(z) = z$.

It would be interesting to adapt and modify the Haar wavelet, and the other wavelet algorithms to the Julia sets. The two papers [13,14] initiate such a development.

Literature

As evidenced by a simple Google check, the mathematical wavelet literature is gigantic in size, and the manifold applications spread over a vast number of engineering journals. While we cannot do justice to this volume st literature, we instead offer a collection of the classics [19] edited recently by C. Heil et al.

Complex Dynamics of Traffic Management, Introduction to

Boris S. Kerner
GR/ETI, HPC: G021, Daimler AG, Sindelfingen, Germany

Traffic management is an extremely complex dynamic process associated with the spatiotemporal behavior of many-particle non-linear systems. In this Encyclopedia of Complexity and Systems Science, there are several review articles devoted to various aspects of the complex dynamics of vehicular traffic management, air traffic management, and pedestrian traffic management.

The complexity of vehicular traffic management is associated with non-linear interactions between the following three main dynamic processes:

(i) travel *decision* behavior,
(ii) traffic *assignment* in a traffic network, and
(iii) traffic flow behavior, in particular, *traffic congestion* occurrence within the network.

Travel decision behavior determines travel demand. Traffic assignment in the network is associated with travel supply. However, traffic congestion occurring within the traffic network restricts free flow travel. This influences both travel decision behavior (e. g., because of traffic congestion, a person decides to stay at home or travel by train rather than by car) and traffic assignment in the network (e. g., because of traffic congestion on a route from an origin to a destination usually used, a person changes their route of travel). The articles presented in this Encyclopedia cover all these main scientific fields of traffic management.

The review article of Goulias (see ▶ Travel Behavior and Demand Analysis and Prediction) is devoted to a detailed consideration of the theoretical and modeling approaches to travel behavior analysis. As shown in Goulias's article, traveler values and attitudes are referred to motivational, cognitive, situational, and disposition factors determining human behavior. Goulias presents a sequential chronological order merging technological innovations and theoretical innovations to the modeling of travel behavior. There are a diverse variety of approaches to the modeling of travel behavior, which are based on mathematical methods like multi-agent microsimulation widely used in many other fields of systems science. Inputs to these models are the typical regional model data about social, economic, and demographic information of potential travelers and land use information to create schedules followed by people in their everyday life. The output are detailed lists of activities pursued, times spent in each activity, and travel information from activity to activity. The in-depth understanding of transportation-related human behavior is essential to all kinds of traffic management. This is because travel behavior refers primarily to the modeling and analysis of travel demand.

Traffic assignment and control as well as methods for traffic prediction in various traffic networks are reviewed in the articles of Rakha and Tawfik (see ▶ Traffic Networks: Dynamic Traffic Routing, Assignment, and Assessment), Gartner and Stamatiadis (see ▶ Traffic Networks, Optimization and Control of Urban), Hegyi, Bellemans and De Schutter (see ▶ Freeway Traffic Management and Control), Rehborn and Klenov (see ▶ Traffic Prediction of Congested Patterns). In particular, Rakha and Tawfik review methods for modeling of dynamic traffic assignment in traffic networks. Gartner and Stamatiadis consider methods for traffic modeling and light signal control in city and urban traffic networks. Traffic control methods developed for traffic on freeway networks are discussed in the article of Hegyi, Bellemans, and De Schutter. Rehborn and Klenov discuss methods for traffic prediction required for dynamic traffic assignment in urban and freeway traffic networks.

In an urban network with short enough network links, dynamic traffic phenomena are determined mostly by traffic signals and other traffic regulations at link intersections. The dynamic traffic phenomena in the urban network can be nevertheless very complex, because traffic regulations at one of the link intersections can have a great influence on the probability of traffic congestion occurring on other links of the network. In their article, Gartner and Stamatiadis (▶ Traffic Networks, Optimization and Control of Urban) present a historical model development beginning from a consideration of traffic control methods at an isolated link intersection to a discussion of very complex approaches to dynamic traffic signal control and optimization in a complex city network.

Driver interactions, which are always essential for traffic dynamics on highways, lead to very complex spatiotemporal phenomena in vehicular traffic.

Hegyi, Bellemans and De Schutter (▶ Freeway Traffic Management and Control) present an introduction to control and managements methods currently used in field trials on freeways as well as to some recent control and managements approaches. These methods include on-ramp feedback metering, congestion pricing, speed limitation, collective and individual route guidance systems. Future traffic management methods will include also diverse driver assistance systems, in particular, with the use of vehicle ad-hoc networks and vehicle-to-infrastructure communication.

A dynamic traffic management in a traffic network requires a dynamic traffic assignment model. Rakha and Tawfik (▶ Traffic Networks: Dynamic Traffic Routing, Assignment, and Assessment) provide a detailed discussion of the problem of dynamic traffic assignment. A dynamic traffic assignment model should find the link inflows for the network. The model usually includes a traffic flow model (traffic modeler), which makes a prognosis of traffic in the network, and a traffic routing model (traffic router) associated with the problem of traffic optimization. The traffic router computes the sequence of roadways that minimize some utility objective function, i. e., minimize travel "costs" of the traffic network. Examples of the travel costs are travel time, fuel consumption, or HC and CO_2 emissions. In a real traffic network, traffic routing can be organized through the use for example of individual and collective driver guidance systems as well as congestion pricing. The traffic modeler and router are connected by a feedback loop. As a result, traffic congestion in the network predicted by the traffic modeler changes results of dynamic traffic assignment considerably. For this reason, the traffic modeler should model traffic congestion as close as possible to real traffic congestion found in empirical observations.

In the dynamic traffic management models, a reliable prognosis of traffic is also required. As shown in the article of Rehborn and Klenov (▶ Traffic Prediction of Congested Patterns), there are two main approaches to traffic prognosis: (a) "physics-of-traffic", i. e., traffic prognosis models and methods based on the understanding of the nature of empirical spatiotemporal features of traffic patterns; (b) methods of mathematical statistics or artificial intelligence, which are also called "data mining" methods, in which the understanding of traffic patterns is not necessarily needed.

Data mining models for traffic prognosis do not usually require the understanding of traffic data, which these methods use for traffic prediction. Using a huge number of historical traffic data, such a method learns predictable features of traffic data without the pretension of their understanding. The data mining methods used for traffic prognosis include statistical methods based on regression, a wavelet approach, or filtering models as well as neural networks. It should be noted that there are many articles in this Encyclopedia, in which these and other methods of artificial intelligence are reviewed.

The physics-of-traffic approach to traffic prognosis is based on the understanding of measurements of traffic variables made in space and time as well as on simulations of the traffic variables associated with empirical data. The key element for a successful prediction concept lies in the correct and reliable understanding of the empirical features of the traffic process and their reproducible characteristics. Furthermore, this understanding of real traffic should be incorporated in a traffic flow model, which should explain and predict the empirical traffic features. Therefore, in the physics-of-traffic approach a traffic flow prediction model is based on empirical features of phase transitions or/and resulting congested patterns; current and historical measured traffic data are used in the model, which reconstructs traffic phases and makes the tracking and prediction of the propagation of traffic congestion in a traffic network.

Thus we see that the understanding of empirical traffic congestion is the key for effective traffic management, control, organization, and all other traffic applications.

Empirical congested patterns exhibit a complex spatiotemporal behavior that was studied during the last 75 years by several generations of scientists. It was found that traffic congestion in the traffic network results from traffic breakdown in an initially free flow: vehicle speeds decrease abruptly to lower speeds in congested traffic. Traffic breakdown is observed mostly at highway bottlenecks. A bottleneck can be a result of road works, on- and off-ramps, a decrease in the number of freeway lanes, road curves and road gradients, bad weather conditions, accidents, etc. In congested traffic a "stop-and-go" mode, i. e., a sequence of moving traffic jams is very often observed.

However, the puzzle of empirical spatiotemporal features of traffic congestion has been solved only recently. Consequently, an alternative traffic flow theory that is called three-phase traffic theory and the associated three-phase traffic flow models, which can predict and explain the empirical spatiotemporal features of traffic congestion, have had to be introduced. The development of various traffic flow theories and modeling approaches to traffic congestion is discussed in (▶ Traffic Congestion, Modeling Approaches to). These modeling approaches include microscopic, mesoscopic and macroscopic traffic flow models, in particular based on cellular automata and gas kinetic models widely used in many other fields of systems science. A probabilistic theory of traffic breakdown is considered in the review article of Kerner and Klenov (see ▶ Traffic Breakdown, Probabilistic Theory of). Spatiotemporal features of traffic congested patterns resulting from traffic breakdown are considered in the review article (▶ Traffic Congestion, Spatiotemporal Features of). Empirical observations of traffic congestion discussed in these articles show that phenomena of traffic breakdown and the subsequent evolution of resulting congested patterns are associated with diverse phase transitions and complex spatiotemporal self-organization effects in vehicular traffic.

On the one hand, the phase transitions and self-organization traffic phenomena, which can occur randomly over time and space within a traffic network, depend considerably on the spatiotemporal distribution of traffic demand in the network. On the other hand, the occurrence of traffic congestion changes travel decision behavior and traffic assignment considerably. In turn, travel decision behavior and traffic assignment determine the spatiotemporal distribution of traffic demand in this network. Thus the recent understanding of empirical features of the phase transitions and spatiotemporal effects in vehicular traffic (see ▶ Traffic Congestion, Modeling Approaches to and ▶ Traffic Congestion, Spatiotemporal Features of) should be taken into account in future models and theories of dynamic traffic assignment as well as in the subsequent development of traffic management and control strategies. This will be one of the most important and difficult challenges for transportation research in the next future.

Thus the complexity of traffic management is associated with diverse phase transitions in vehicular traffic resulting in various complex self-organizing spatiotemporal congested patterns propagating within a traffic network as well as with the necessity in the optimization of the traffic congested patterns. This optimization should ensure either the dissolution of traffic congestion or, if this is not possible to achieve, the minimization of the influence of traffic congestion on travel costs like travel time, fuel consumption, or HC and CO_2 emissions.

Modeling approaches to vehicular traffic management discussed in the mentioned above review articles of the Encyclopedia are also very important for studies of air traffic and pedestrian traffic.

Air traffic continues to grow at a steady pace in the world. For this reason, the discussion of air traffic dynamics as well as approaches to air traffic modeling made in the review article of Sridhar and Sheth (see ► Air Traffic Control, Complex Dynamics of) is an important contribution to the fields of traffic management.

Currently, we can observe a continuous growth of publications devoted to modeling approaches to pedestrian traffic and crowd dynamics. In particular, the interest to pedestrian traffic is associated with necessity in the development of effective evacuation strategies required for the relocation of people to safely escape hazardous disaster impacts. During the evacuation, destinations are chosen to escape the hazardous disaster impacts as quickly as possible. This is a peculiarity of the evacuation process in comparison with vehicle traffic in which every vehicle has usually a defined destination. This very interesting and important field of traffic management is considered in the review articles of Helbing and Johansson, Schadschneider et al., and Goudie.

Helbing and Johansson (see ► Pedestrian, Crowd and Evacuation Dynamics) and Schadschneider et al. (see ► Evacuation Dynamics: Empirical Results, Modeling and Applications) consider various aspects of the modeling of pedestrian interactions during evacuation as well as a comparison of the associated theoretical and empirical results. Based on an example of Australian fire zone research, Goudie (see ► Evacuation as a Communication and Social Phenomenon) considers evacuation as a communication and social phenomenon. Goudie's article describes the influence of communication and social aspects on possible evacuation scenarios.

Acknowledgments

I would like to thank Konstadinos Goulias, Sergey Klenov, Hesham Rakha, Hubert Rehborn, Andreas Schadschneider, and Bart De Schutter for useful suggestions.

Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination

SUI HUANG, STUART A. KAUFFMAN
Institute for Biocomplexity and Informatics,
Department of Biological Sciences, University of Calgary,
Calgary, Canada

Article Outline

Glossary

Transcription factor A protein that binds to the regulatory region of a target gene (its promoter or enhancer regions) and thereby, controls its expression (*transcription* of the target gene into a mRNA which is ultimately *translated* into the *protein* encoded by the target gene). Transcription factors account for temporal and contextual specificity of the expression of genes; for instance, a developmentally regulated gene is expressed only during a particular phase in development and in particular tissues.

Gene regulatory network (GRN) Transcription factors regulate the expression of other transcription factor genes as well as other 'non-regulatory' genes which encode proteins, such as metabolic enzymes or structural proteins. A regulatory relationship between two genes thus is formalized as: "transcription factor A is the regulator of target gene B" or: A → B. The entirety of such regulatory interactions forms a network = the gene regulatory network (GRN). Synonyms: genetic network or gene network, transcriptional network.

Gene network architecture and topology The GRN can be represented as a "*directed graph*". The latter consists of a set of nodes (= vertices) representing the genes connected by arrows (directed *links* or *edges*) representing the regulatory interactions pointing from the regulator to the regulated target gene. [In contrast, in an *undirected* graph, the links are simple lines without arrowheads. The protein-interaction network can be represented as undirected graph]. The topology of a network is the structure of this graph and is an abstract notation, without physicality, of all the potential regulatory interactions between the genes. Topology usually is used to denote the simple interactions captured by the directed graph. For defining the network dynamics, however, additional aspects of interactions need to be specified, including: modalities or "sign" of an arrow (inhibitory vs. activating regulation), the 'transfer functions' (relationship between magnitude of input to that of the output = target gene) and the logical function (notably, in Boolean network, defining how multiple inputs are related to each other and are integrated to shaping the output). In this article when all this additional information is implied to be included, the term gene network *architecture* is used. Thus, the graph topology is a subset of network architecture.

Gene network dynamics The collective change of the gene expression levels of the genes in a network, essentially, the change over time of the network state *S*.

State space Phase space = the abstract space that contains all possible states *S* of a dynamical system. For (autonomous) gene regulatory networks, each state *S* is specified by the configuration of the expression levels of each of the *N* genes of the network; thus a system state S is one point in the *N*-dimensional state space. As the system changes its state over time, S moves along trajectories in the state space.

Transcriptome Gene expression pattern across the entire (or large portion of) the genome, measured at the level of mRNA levels. Used as synonym to "gene expression profile". The transcriptome can in a first approximation be considered a snapshot of the network state *S* of the GRN in gene network dynamics.

Cell type A distinct, whole-cell phenotype characteristic of a mature cell specialized to exert an organ-specific function. Example of cell types are: liver cell, red blood cell, skin fibroblast, heart muscle cell, fat cell, etc. Cell types are characterized by their distinct cell morphology and their gene expression pattern.

Cell fate A potential developmental outcome of a (stem or progenitor) cell. A cell fate of a stem cell can be the development into a particular mature cell type.

Multipotency The ability of a cell to generate multiple cell types; a hallmark of stem cells. Stem cells are said to be multipotent (see also under Stem cells).

Stem cell A multi-potent cell capable of "self-renewal" (division in which both daughter cells have the same degree of multi-potency as the mother cell) and can give rise to multiple cell types. There is a hierarchy of multipotency: a *toti-potent embryonic stem cell* can generate all possible cell types in the body, including extra-embryonic tissues, such as placenta. A *pluripotent embryonic stem cell* can generate tissues of three germ layers, i. e., it can produce all cell types of the foetus and the adult. A *multipotent (sensu stritiore) stem cell* of a tissue (e. g., blood) can give rise to all cell types of that tissue (e. g., a hematopoietic stem cell can produce all the blood cells). A multipotent *progenitor* cell can give rise to more than one cell types within a tissue (e. g. the granulocyte-monocyte progenitor cell).

Cell lineage Developmental trajectory of a multipotent cell towards one of multiple cell types, e. g., the "myeloid lineage" among blood cells, comprising the white blood cells granulocytes, monocytes, etc. Thus, a cell fate decision is a decision between multiple lineages accessible to a stem or progenitor cell.

Differentiation The process of cell fate decision in a stem or progenitor cell and the subsequent maturation into a mature cell type.

Definition of the Subject

Current studies of complex gene regulatory networks (GRN) in which thousands of genes regulate each others' expression have revealed interesting features of the network structure using graph theory methods. But how does the particular network architecture translate into biology? Since individual genes alter their expression level as a consequence of the network interactions, the genome-wide gene expression pattern (*transcriptome*), which manifests the dynamics of the entire network, changes as a whole in a highly constrained manner. The transcriptome in turn determines the cell phenotype. Hence, the constraints in the global dynamics of the GRN directly map into the most elementary "biological observable": the existence of distinct cell types in the metazoan body and their development from pluripotent stem cells.

In this article a historical overview of the various levels at which GRNs are studied, starting from network architecture analysis to the dynamics are first presented. An introduction is given to continuous and discrete value models of GRN commonly used to understand the dynamics of small genetic circuits or of large genome wide networks, respectively. This will allow us to explain how the intuitive metaphor of the "epigenetic landscape", a key idea that was proposed by Waddington in the 1940s to explain the generation of discrete cell fates, formally arises from gene network dynamics. This central idea appears in its modern form in formal and molecular terms as the concept that cell types represent *attractor states* of GRNs, first proposed by Kauffman in 1969. This raises two fundamental questions currently addressed by experimental biologists in the era of "systems biology": (1) Are cell types in the metazoan body indeed high-dimensional attractors of GRNs and (2) is the dynamics of GRNs in the "critical regime" – poised between order and chaos? A summary of recent experimental findings on these questions is given, and the broader implications of network concepts for cell fate commitment of stem cells are also briefly discussed. The idea of the epigenetic landscape is key to our understanding of how genes and gene regulatory networks give rise to the observable cell behavior, and thus to a formal and integrated view of molecular causation in biology.

Introduction

With the rise of "systems biology" over the past decade, molecular biology is moving away from the paradigm of linear genetic pathways which has long served as linear chains of causation (e. g., Gene A → Gene B→ Gene C→ phenotype) in explaining cell behaviors. It has begun to embrace the idea of molecular networks as an integrated information processing system of the cell [93,138]. The departure from the gene-centered, mechanistic 'arrow-arrow' schemes that embody 'proximal causation' [189] towards an integrative view will also entail a change in our paradigm of what an "explanation" means in biology: How do we map the collective behavior of thousands of interacting genes, obtained from molecular dissection, to the "***biological observable***"? The latter term, borrowed from the statistical physics idea of the "macroscopic observable", is most prosaically epitomized in whole-cell behavior in metazoan organisms: its capacity to adopt a large variety of easily recognizable, discretely distinct phenotypes, such as a liver cell vs. a red blood cell, or different functional states, such as the proliferative, quiescent or the apoptotic state.

All these morphologically and functionally distinct phenotypes are produced by the very same set of genes of the genome as a result of the joint action of the genes. This is achieved by the differential expression ("turning ON or OFF") of individual genes. Thus, in a first approximation, each cell phenotype is determined by a specific configuration of the status of expression of all individual genes across the genome. This genome-wide ***gene expression pattern or profile***, or ***transcriptome***, is the direct output of the GRN and maps almost uniquely into a cell phenotype (see overview in Fig. 1).

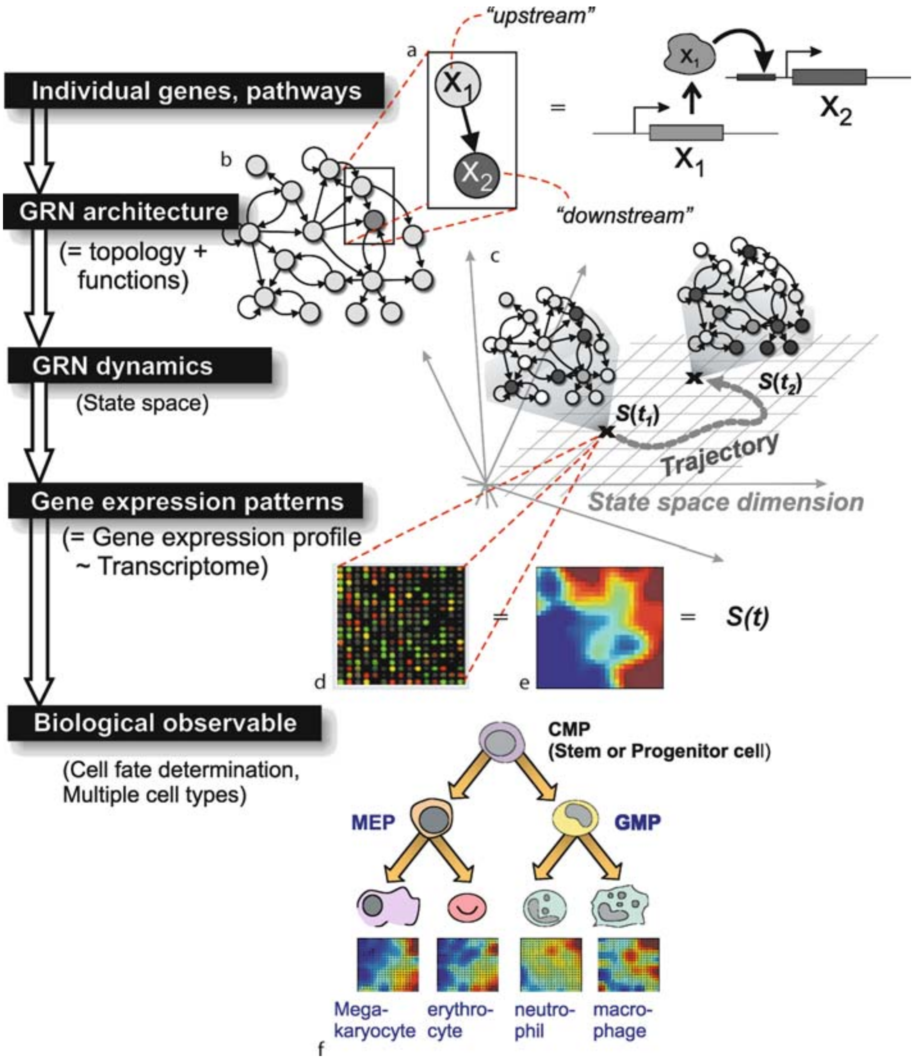
A ***network*** is the most elementary conceptualization of a complex system which is composed of interacting elements and whose behavior as an entity we wish to understand: it formalizes how a set of distinct elements (nodes) influence each other as predetermined by a fixed scheme of their interactions (links between the nodes) and the modality of interactions (rules associated with each node). In this article we focus on the ***gene regulatory network*** (GRN), the network formed by interactions through which genes regulate each other's expression (Fig. 1a), and we ask how they control the global ***behavior*** of the network, and thereby, govern development of cells into the thousands of cell types found in the metazoan body.

Because in a network a node exerts influence onto others, we can further formalize networks as ***directed graphs***, that is, the links are arrows pointing from one node to another (Fig. 1b). The information captured in an undirected or directed graph is the ***network topology*** (see Glossary). In addition, the arrows have a ***modality*** ("sign"), namely, activating or inhibiting their target gene. But since each node can receive several inputs ("upstream regulators"), it is more appropriate to combine modality of interaction together with the way the target gene integrates the various inputs to change its expression behavior (= output). Thus, each node can be assigned a ***function*** that maps all its inputs in a specific way to the output (Fig. 1, top). For instance, "promoter logics" [209] which may dictate that two stimulating inputs, the transcription factors, act synergistically, or that one inhibitory input may, when present, override all other activating inputs, is one way to represent such an input integrating function.

Here we use ***network architecture*** as a term that encompasses both network topology as well as the interaction modalities or the functions. The latter add the ingredients to the topology information that are necessary to describe the ***dynamics*** (***behavior***) of the network.

The Core Gene Regulatory Network (GRN) in Mammals

How complex is the effective GRN of higher, multicellular organisms, such as mammals? Virtually every cell type in mammals contains the ∼25,000 genes in the genome [44,158,178] which could potentially interact with each other. However, in a first approximation, we do not need to deal with all the 25,000 genes but only with those intrinsic regulators that have direct influence on other genes. A subset of roughly 5–10% of the genes in the genome encode ***transcription factors*** (TF) [194] a class of DNA binding pro-



Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination, Figure 1

Overview: Concepts at different levels for understanding emergence of biological behavior from genes and networks. a Elementary interaction: regulator gene X_1 interacts with target (regulated) gene X_2, simplified as one link of a graph and the corresponding standard 'cartoon' it represents. b Notation of gene regulatory network topology as *directed graph*. c Schematic of a higher dimensional gene expression state space, showing that a network state *S*(*t*) maps onto one point (denoted as *cross*) in the state space. *Dashed curve/arrow* represents state space trajectory. d Spotted DNA microarray for measuring gene expression (mRNA) profiles, representing a network state *S*(*t*) and e the associated "GEDI map" visualization of gene expression pattern. The map is obtained using the program GEDI [57,83]. This program places genes that behave similarly (with respect to their expression in a set of microarray measurements) onto the same pixel (= minicluster of genes) of the map. Similar miniclusters are arranged in nearby pixels in the two-dimensional picture of an *n* × *m* array of pixels. The assignment of genes to a pixel is achieved by a self-organizing map (SOM) algorithm. The *color of each pixel* represents the centroid gene expression level (mRNA abundance) of the genes in the minicluster. For a stack of GEDI maps, all genes are forced to be assigned to the same pixels in the different maps, hence the global coherent patterns of each GEDI map allows for a one-glance 'holistic' comparison of gene expression profiles of different conditions *S*(*t*) (tissue types, time points in a trajectory, etc). f Scheme of branching development of a subset of four different blood cells with their distinct GEDI maps, starting from the multipotent *CMP* = common myeloid progenitor cell [150]. *MEP* = Megakaryocte-Erythorid progenitor cell; *GMP* = Granulocyte-Monocyte progenitor

teins that regulate the expression of genes by binding to the promoter region of the 'target genes' (Fig. 1a). Another few hundred loci in the genome encode microRNAs (miRNA), which are transcribed to RNA but do not encode proteins. miRNAs regulate the expression of genes by interfering with the mRNA of their target genes based on sequence complementarity (for reviews see [41,89,141]). Thus, in this discussion we can assume a regulatory network of around 3000 regulator genes rather than the 25,000 genes of the genome. The genes that do not encode TFs are the "effector genes", encoding the work horses of the cell, including metabolic enzymes and structural genes. In our approximation, we also assume that the effector genes do not directly control other genes (although they may have global effects such as change of pH that may affect the expression of some genes). Further we do not count genes encoding proteins of the signal transduction machinery since they act to mediate external signals (such as hormones) that can be viewed as perturbations to the network and can in a first approximation be left out when discussing cell-intrinsic processes. Thus, the directed graph describing the genome-wide GRN network has a "medusa" structure [112], with a core set of regulators (medusa head) and a periphery of regulated genes (arms) which in a first approximation do not feedback to the core.

The Core GRN as a Graph That Governs Cell Phenotype

The next question is: do the 3000 core regulatory genes form a *connected* graph or rather independent (detached) "modules"? The idea of modularity would have justified the classical paradigm of independent causative pathways and has in fact actively been promoted in an attempt to mitigate the discouragement in view of the unfathomable complexity of the genome [85]. While a systematic survey that would provide a precise number is still not available, we can, based on patchy knowledge from the study of individual TFs, safely assume that a substantial fraction of TFs control the expression of more than one other TF. Many of them also control entire batteries [50] of effector genes, while perhaps a third subset may be specialized in regulating solely the effector genes. In any case, the core regulatory network of ~3000 nodes controls directly or indirectly the entire gene expression profile of 25,000 genes, and hence, the cell phenotype.

Then, assuming that on a average each TF controls at least two (typically more) other TFs [128,188], and considering statistical properties of random evolved networks (graphs) [36], we can safely assume that the core transcriptional network is a connected graph or at least its giant component (largest connected subgraph) covers the vast majority of its nodes. This appears to be the case in GRNs of simple organisms for which more data are available for parts of the network, as in yeast [128], *C. elegans* [54]; sea urchin [50] or, for even more limited subnetworks in mammalian systems [32,183] although studies focused on selected subnetworks may be subjected to investigation bias. However, recent analysis of DNA binding by 'master transcription factors' in mammalian cells using systemic (hence in principle unbiased) chromatin immunoprecipitation techniques [177] show that they typically bind to hundreds if not thousands of target genes [48, 70,105,155], strongly suggesting a global interconnectedness of the GRN. This however, does not exclude the possibility that the genome-wide network may exhibit some "modularity" in terms of weakly connected modules that are locally densely connected [166].

Structure of This Article

The goal of this article is to present both to biologists and physicists a set of basic concepts for understanding how the maps of thousands of interacting genes that systems biology researchers are currently assembling, ultimately control cell phenotypes. In Sect. "Overview: Studies of Networks in Systems Biology" we present an overview to experimental biologists on the history of the analysis of networks in systems biology. In Sect. "Network Architecture" we briefly discuss core issues in studies of network *topology*, before explaining basic ideas of network *dynamics* in Sect. "Network Dynamics" based on two-gene circuits. The central concepts of multi-stability will be explained to biologists, assuming a basic calculus background. Waddington's *epigenetic landscape* will also be addressed in this conjunction. In Sect. "Cell Fates, Cell Types: Terminology and Concepts" we discuss the actual "*biological observable*" that the gene regulatory network controls by introducing to non-biologists central concepts of cell fate regulation. Section "History of Explaning Cell Types" offers a historical overview of various explanations for metazoan cell type diversity, including dynamical, network-based concepts, as well as more 'reductionist' explanations that still prevail in current mainstream biology. Here the formal link between network concepts and Waddington's landscape metaphor will be presented. We then turn from small gene circuits to large, complex networks, and in Sect. "Boolean Networks as Model for Complex GRNs" we introduce the model of random Boolean networks which, despite their simplicity, have provided a useful conceptual framework and paved the way to learning what an integrative understanding of global network dynamics would look like, leading to the first central hypothesis: *Cell types may be high-dimensional attractors of the complex gene regulatory network*. In Sect. "Three Regimes of Behaviors for Boolean Networks" the more fundamental dynamical properties of ordered, critical and chaotic behavior are discussed, leading to the second hypothesis: *Networks that control living cells may be in the critical regime*. In Sect. "Experimental Evidence from Systems Biology" we summarize current experimental findings that lend initial support to these ideas, and in Sect. "Future Directions and Questions" we conclude with an outlook on how these general concepts may impact future biology.

Overview: Studies of Networks in Systems Biology

Cellular networks of biological molecules currently studied by "systems biologists" encompass three large classes: metabolic, protein–protein interaction and gene regulatory (transcriptional) networks (GRN). The formalization of these systems into networks is often taken for granted but is an important issue. It is noteworthy that metabolic network diagrams [193] represent physical networks in that there is a *flow* of information or energy in the links, and thus, the often used metaphors inspired by man-made transport or communication networks ('bottleneck', 'hubs' etc.) are more appropriate than in the other two classes. Moreover, metabolic networks are subjected to the constraint of mass preservation at each node – in compliance with Lavoisier's mass conservation in chemistry. In contrast to such flow networks, protein–protein interaction networks and GRN are abstract notations of "influence networks" in which the nodes influence the behavior of other nodes directly or indirectly – as represented by the links of the graph. There is no actual flow of matter in the links (although of course information is exchanged) and there is no obvious physical law that constrains the architecture, thus allowing for much richer variations of the network structure. The links are hence abstract entities, representing *potential* interactions assembled from independent observations that may not coexist in a particular situation. Thus, in this case the network is rather a convenient graphical representation of a collection of potential interactions.

Studies of such biomolecular influence networks can fundamentally be divided between two levels (Table 1): (A) network architecture and (B) network dynamics (system behavior).

The study of network architecture in molecular biology can further be divided into (A1) efforts to *determine* the actual graph structure that represent the specific interactions of the genes for particular instance (a species) and (A2) the more recent *analysis* of its structure, e. g., for interesting topological features [2]. The determination of the graph structure of the genome-wide GRNs in turn is either achieved (*i*) by direct *experimental demonstration* of the physical interactions, which has in the past decade greatly benefited from novel massively parallel technologies, such as chromatin IP, promoter one-hybrid or protein binding DNA microarrays [35,54,177], or (*ii*) via theoretical *inference* based on observed correlations in gene expression behavior from genome-wide gene expression profiling experiments. Such correlations are the consequence of mutual dependencies of expression in the influence network.

The next section provides a concise overview of the study of the network architecture, which due to limitations of available data is mostly an exercise in studying graph topology, and briefly discusses associated problems.

Network Architecture

Network Inference

An emerging challenge is the determination of entire networks, including the connection graph (topology), the direction of interactions ('arrows") and, ideally, the interaction modality and logical function, using systematic inference from genome-wide patterns of gene expression ("inverse problem"). Gene expression profiles (transcriptomes) represent a snap-shot of the mRNA levels in cell or tissue samples. The arrival of DNA microarrays for efficient measuring gene expression profiles for almost all the genes in the genome has stimulated the development of algorithms that address the daunting inverse problem, and the number of proposed algorithms has recently exploded. Most approaches concentrate on inference based on the more readily available static gene expression profiles, although time course microarray experiments, where time evolution of transcriptomes are monitored at close intervals would be advantageous, especially to infer the arrow direction of network links (directed graph) and the interaction functions.

However, because of uncertainties and the paucity of experimental data, systematic network inference faces formidable technical and formal challenges, and most theoretical work has been developed and tested based on simulated networks. A fundamental concern is that microarray based expression levels reflect the average expression of a population of millions of cells that – as recently demonstrated – exhibit vastly diverse behaviors even when they are clonal. Thus, the actual quantity used for inference is not a direct but a convoluted manifestation of network regulation (this issue is discussed in Sect. "Are Cell Types Attractors?"). Moreover, while mRNA levels reflect relatively well the activity status of the corresponding gene promoter, i. e., revealing the *regulated* activity, they are poor indicator of the *regulating* activity of a gene, because of the loose relationship between mRNA level and effective activity of the transcription factor that it encodes. Since the true network architecture ('gold standard') is not known, validation of the theoretical approaches remains unsatisfactory. Nevertheless, the recent availability of large numbers of gene expression profiles and the increasing (although not complete) coverage of gene regulation maps for single-cell organisms (notably E. coli and yeast) open the opportunity to directly study the mapping between gene expression profile and network structure [39,42,61,88,135,190].

Here we refer to [2,131,139] for a survey of inference methods and instead briefly discuss the study of network topology before we move on to network dynamics.

Analyzing Network Structures

Once the network topology is known, even if direction, modality and logics of links are not specified to offer the complete system architecture, it can be analyzed using graph theory tools for the presence of global or local structures (subgraphs) that are "interesting". A potentially interesting feature can be defined as a one which cannot be explained by chance occurrence in some randomized version of the graph (null model), i. e., which departs from what one would expect in a "random" network (see below). Most of the graph theoretical studies have been stimulated by the *protein–protein interaction networks* which have been available for some years, of which the best characterized is that of the yeast *S. cerevisiae* [29]. Such networks represent non-directed graphs, since the links between the nodes (proteins) have been determined by the identification of physical protein interactions (heterodimer or higher complex formation). Here we provide only a cursory overview of this exploding field, while focusing on conceptual issues.

A large array of structural network features, many of them inspired by the study of ecological and social networks [152,160,199] have been found in biomolecular networks. These features include global as well as local features, such as, to mention a few, the scale-free or broad-scale distribution of the connectivity k_i of the nodes i [3,10,20], betweenness of node i [107,208], hierarchical organization [164], modularity [102,121,133,166,206], assortativity [140], and enrichment for specific local topology motifs [147], etc. (for a review of this still expanding field see [2,21,29,152]).

The global property of a scale-free distribution of connectivity k_i, which has attracted most attention early on and quickly entered the vocabulary of the biologist, means that the probability $P(k_i)$ for an arbitrary node (gene) i in the network to have the connectivity k_i has the form $P(k_i) \sim k_i^{\gamma}$ where the characteristic constant γ is the power-law exponent – the slope of the line in a $P(k_i)$ vs. k_i double-logarithmic plot. This distribution implies that there is no characteristic scale, i. e., no stable average value of k: sampling of larger number of nodes N will lead to larger "average" k values. In other words, there is an "unexpectedly" high fraction of nodes which are highly connected ("hubs") while the majority exhibits low connectivity. This property has attracted as much interest as it has stirred controversy because of the connotation of "universality" of scale-freeness on the one hand, and several methodological concerns on the other hand [21,24,73,76,175,181,193]

The Problem of Choosing the Null Model In addition to well-articulated caveats due to incompleteness, bias and noise of the data [29,52], an important general methodological issue in the identification of structural features of interest, especially if conclusion on functionality and evolution is drawn, is the choice of the appropriate "null model" – or "negative control" in the lingo of experimentalists. A total random graph obviously is not an ideal null model, for on its background, any bias due to obvious constraints imposed by the physical reality of the molecular network will appear non-random and hence, be falsely labeled "interesting" even if one is not interested in the physical constraints but in evidence for functional organization [14,93]. For instance, the fact that gene duplication, a general mechanism of genome growth during evolution, will promote the generation of the network motif in which one regulator regulates two target genes, needs to be considered before a "purposeful" enrichment for such a motif due to increased fitness is assumed [93]. Similarly, the rewiring of artificial regulatory networks through reshuffling of *cis* and *trans* regions or the construction of networks based on promoter-sequence information content reveal constraints that lead to bias for particular structures in the absence of selection pressure [18,46]

The problem amounts to the practical question of which structural property of the network should be preserved when randomizing an observed graph to generate a null model. Arbitrarily constrained randomization based on preservation of some a priori graph properties [18,140] thus may not suffice. However, the question of which feature to keep cannot be satisfactorily answered given the lack of detailed knowledge of all physical processes underlying the genesis and evolution of the network. The more one knows of the latter, the more appropriate constraints can be applied to the randomization in order to expose novel biological feature that cannot be (trivially) explained by the neglected elementary construction constrains.

Evolution of Network Structure: Natural Selection or Natural Constraint?

This question goes beyond the technicality of choosing a null model for it reaches into the realm of a deeper questions of evolutionary biology: which features are inevitably linked to the very physical processes through which networks have grown in evolution and which arose due to natural selection because they confer a survival advantage [15,77,78,93,203]? Often this question is taken for granted and an all-mighty selection process is assumed that can produce any structure as long as it contributes sufficiently to fitness. This however, would require that during natural selection the random, mutation-driven reshuffling of nodes and connections has no constrains and that Darwinian evolution explores the entire space of possible architectures. Clearly this is not the case: physical constraints in the rearrangement of DNA (insertions, deletions, duplications, conversion, etc) [16,170,187] as well as graph theoretical considerations channel the possibilities for how one graph can transform into another [93,203]. For instance, growth of the network due to the increase of genome-size (gene number) by gene duplication can, without the invisible hand of selection, give rise to the widely-found scale-free structure [23,186] although it remains to be seen whether this mechanism (and not some more fundamental statistical process) accounts for the ubiquitous (near) scale-free topology. The fact that the scale-free (or at least, broad-scale [10]) architecture has dynamical consequences (see Sect. "Architectural Features of Large Networks and Their Dynamics") raises the question whether properties such as robustness may be inherent to some structure that is "self-organized", rather than sculpted by the invisible hand of natural selection. Thus, one certainly cannot simply argue that the scale-free structure has evolved "because of some functional advantage". Instead, it is reminded here that natural selection can benefit from spontaneous, self-organized structures [116]. This structuralist view [200], in which the physically most likely and not the biologically most functional is realized, need to be considered when analyzing the anatomy of networks [93].

In summary, the choice of the null model has to be made carefully and requires knowledge of the biochemical and physicochemical process that underlies genome evolution. This methodological caveat has its counterpart in the identification of "interesting" nucleotide sequence motifs when analyzing genome sequences [167].

Gene-Specific Information: More Functional Analysis Based on Topology

Beyond pure graph theoretical analysis, there have been attempts to link the topology with functional biological significance. For instance, one question is how the global graph structure changes (such as the size of the giant component) when nodes or links are randomly or selectively (e. g., hubs) removed. It should be noted that the term "robustness" used in such structural studies [5] refer to networks with the aforementioned connotation of transport or communication function with flow in the links and thus, differs fundamentally from robustness in a *dynamical* sense in the influence networks that we will discuss below.

Another approach towards connecting network topology with biological functionality is to employ bioinformatics and consider the *biological identity* of the genes or proteins represented by the nodes. Then one can ask whether some graph-related node properties (e. g., degree of connectivity, betweenness/centrality, contribution to network entropy, etc.) are correlated with known biological properties of the genes, of which the most prosaic is the "essentiality" of the protein, derived from genetic studies [84, 137,207,208]. To mention just a few of the earlier studies of this expanding field, it has been suggested that proteins with large connectivity ("hubs") appear to be enriched for "essential proteins" [104], that hubs evolve slower [68], and that they tend to be older in evolution [58] – in accordance with the model of preferential attachment that generates the scale-free distribution of the connectivity $\underline{k}_i$. However, many of these findings have been contested for statistical or other reasons [27,28,67,106,107]. The conclusion of such functional bioinformatics analysis need to be re-examined when more reliable and complete data become available.

Network Dynamics

While the graph theoretical studies, including the ramifications into core questions of evolution outlined above, are interesting eo ipso, life is breathed into these networks only with the 'dynamics'. Understanding the system-level dynamics of networks is an essential step in our desire to map the static network diagrams which are merely "*anatomical* observables", into the *functional* observable of cell behavior. Dynamics is introduced by considering that a given gene (node) has a time-dependent expression value $x_i(t)$ which in a first approximation represents the activity state of gene *i* (an active gene is expressed and post-translationally activated). Instead of seeing dynamics as a sequence of gene activation, epitomizing the chain of causation of the gene-centric view (as outlined in Sect. "Introduction") a goal in the study of complex systems is to understand the integrated, "emergent" behavior of systems as a holistic entity. We thus define a system (network) state $S(t)$ as $S(t) = [x_1(t), x_2(t), \ldots, x_N(t)]$ which is determined by the expression values x_i of all the N genes of a network which change over time. It is obvious that not all theoretically possible state configurations S can be realized since the individual variables x_i cannot change independently. This global constraint on S imposed by the gene regulatory interactions ultimately determines the "system behavior" which is equivalent to whole-cell phenotype changes, such as switching between cell phenotypes. Thus, one key question is: given a particular network architecture, what is the dynamics of S, and does it reproduce typical cell behaviors, or even predict the particular behavior of a specific cell? Before plunging into complex GRNs, let us introduce basic concepts of modeling dynamics using small circuits (Fig. 2, B1 in Table 1.).

Small Gene Circuits

Basic Formalism The dynamics of the network can be written as a system of ordinary differential equations (ODE) that describe the rate of change of x_i as a function of the state of the all the x_j:

$$\frac{\mathrm{d}\mathbf{x}}{\mathrm{d}t} = \mathbf{F}(\mathbf{x}) \,, \tag{1}$$

where $\mathbf{x}$ is the state vector $\mathbf{x}(t) = [x_1, x_2, \ldots, x_N]$ for a network of N genes, and $\mathbf{F}$ describes the interactions (including the interaction matrix), defining how the components influence each other. Concretely, for individual genes in small circuits, e. g. of two genes, $N = 2$:

$$\begin{aligned} \frac{\mathrm{d}x_1}{\mathrm{d}t} &= f_1(x_1, x_2) \\ \frac{\mathrm{d}x_2}{\mathrm{d}t} &= f_2(x_1, x_2) \,. \end{aligned} \tag{1a}$$

Here the functions f_i are part of the network "architecture" that determine how the inputs onto gene *i* jointly determine its dynamical behavior – as defined in Sect. "Introduction". An example of f is shown in Fig. 2b. Its form is further specified by *system parameters* that are constants for the time period of observation. The solution of these system equations is the movement of the state vector $\mathbf{x}$ in the N-dimensional ***gene expression state space*** spanned by x_i.

$$\mathbf{x}(t) = S(t) = [x_1, x_2, \ldots, x_N] \,. \tag{2}$$

The Network State For a larger number of genes, it is convenient to describe the dynamics of the network with the vector $\mathbf{x}$ which roughly represents the system state S, Eq. (2), that biologists measure using DNA microarrays and is known as the "*gene expression profile*" (see Sect. "Definition of the Subject", Fig. 1). We will thus refer to S instead of the vector x in discussing biological system states. Since Eq. (1) is a first order differential equation, S specifies a system state at time t which for $t = 0$ represents an ***initial condition***. In other words, unlike in macroscopic mechanical systems with inertia, in which the velocity $\mathrm{d}x_i/\mathrm{d}t$ of the "particles" is also important to specify an initial state, in cells a photographic snapshot of all the positions of x_i, that is $S(t)$ itself, specifies the system state. (This will become important for experimental monitoring of network dynamics).

Role of Dynamical Models in Biology Small networks, or more precisely, "*circuits*" of a handful of interacting proteins and genes, have long been the object of modeling efforts in cell biology that use ODEs of the type of (1a) to model the behavior of the circuit [109,192] (Table 1, B1). In contrast, the objects of interest in the study of complex system sciences are large, i. e., "complex" networks of thousands of nodes, such as the 3000-node core GRN, mentioned earlier, and has largely been driven by

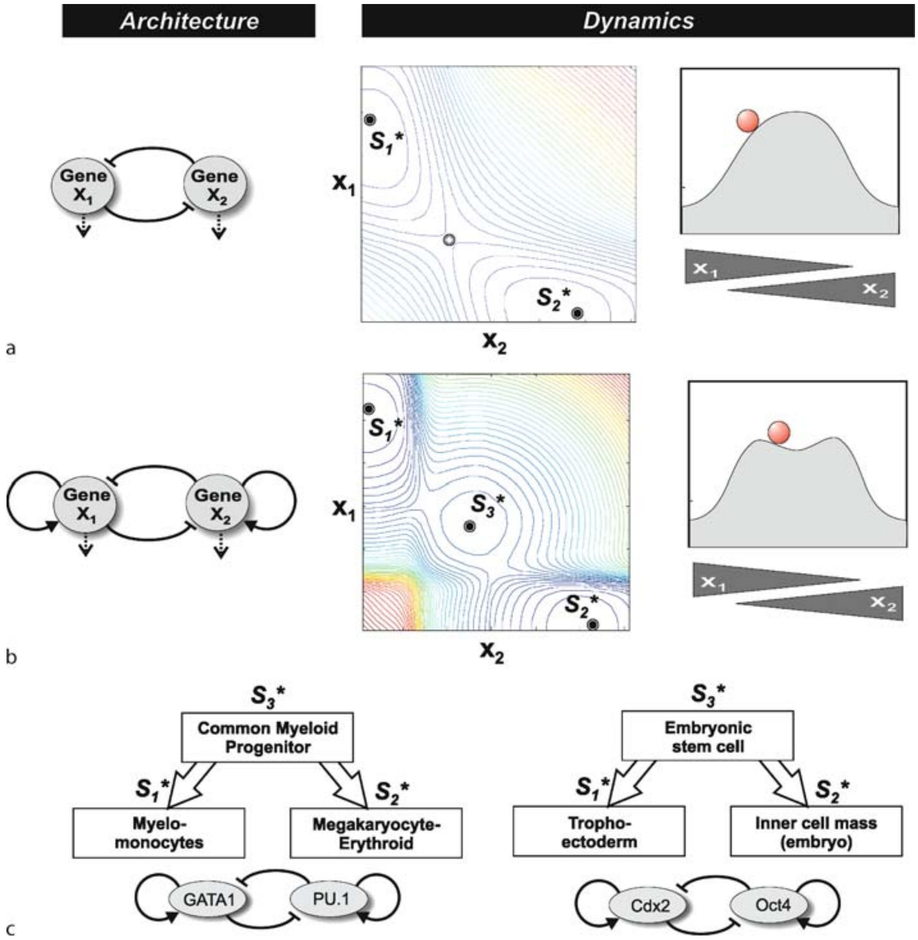
Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination, Figure 2

From gene circuit architecture to dynamics, exemplified on a bistable two-gene circuit. a Circuit architecture: two mutually inhibitory genes X_1 and X_2 which are expressed at constant rate and inactivated with first-order kinetics ("bistable toggle switch"). b Typical ODE system equations for the circuit in a (see [71,109]). c State space (x_1–x_2-phase-plane). *Each dot* is an example initial state $S_o = [x_1(t = 0), x_2(t = 0)]$ with the emanating tick revealing direction and extent that the state S_o would travel in the next time unit Δt. *Solid circles*, S_1^* and S_2^*, denote stable fixed-points ("attractors"). *Empty circle* denotes unstable fixed-point (saddle-node). d, e, f Various schematic representations of the probability $P(S)$ (for a noisy circuit) to find the system in state $S = [x_1, x_2]$. The "elevation" (z-axis over the x_1–x_2 plane) is calculated as – $\ln(P)$; thus, the most probable = stable states are the lowest in the emerging landscape. g Waddington's metaphoric epigenetic landscape, in the 1957 version [198]



Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination, Figure 3

Expansion of the bistable two-gene circuit by self-stimulation – creating a central metastable attractor. a The bistable circuit of Fig. 2 and associated epigenetic landscape, now as *contour graph*. b If the two genes exert self-activation, then, for a large range of parameters and additive effect of the two inputs that each gene receives, the epigenetic landscape is altered such that the central unstable fixed-point in a. becomes locally stable, S_3^*, giving rise to robust "tristable" dynamics [99]. c Two specific examples of observed gene circuits that represent the circuit of *C*. Such network motifs are typically found to regulate the branch points where multipotent progenitor cells make binary cell fate decisions [99,162]. The metastable central attractor S_3^* can be modeled as representing the metastable bi-potent progenitor cell which is poised in a state of locally stable indeterminacy between the two prospective fate attractors S_1^* and S_2^*

experimental monitoring of $S(t)$ using microarrays since the function $\boldsymbol{F}$ that represents the architecture of the network is not known (Table 1, B3).

What is the actual aim of modeling a biological network? In mathematical modeling of small gene circuits or of signal transduction pathways, one typically predicts the temporal evolution (time course) of the concentration of the modeled variables $x_1(t)$, or $x_2(t)$, and characterizes critical points, such as stable steady states or oscillations in the low-dimensional state space, e. g. in the $x_1 - x_2$ phase plane, after solving the system equations, as exemplified in Figs. 2 and 3. Unknown parameter values have to be estimated, either based on previous reports or obtained by fitting the modeled $x_i(t)$ to the observed time course. Successful prediction of behaviors also serves to *validate* the assumed circuit architecture. From the ***stability analysis*** of the resulting behavior [151], generalization as to the ***dynamical robustness*** (low sensitivity to noise that cause $x(t)$ to randomly fluctuate) and ***structural robustness*** (preservation of similar dynamical behavior even if network architecture is slightly rewired by mutations) can be made [7,34]. Both types of robustness of the system shall not be confounded with the robustness which is sometimes encountered in the analysis of network topology where preservation of some graph properties (such as global connectedness) upon deletion of nodes or links is examined ("error tolerance") (as discussed in Sect. "Network Architecture").

Although in reality most genes and proteins are embedded in the larger, genome-wide network, small, idealized circuit models which implicitly accept the absence of many unknown links as well as inputs from the nodes in the global network outside the considered circuit often surprisingly well predict the observed kinetics of the variables of the circuit. This not only points to intrinsic structural robustness of the class of natural circuits, in that circuit architectures slightly different from that of the real system can generate the observed dynamics. But it also suggests that obviously, for some not well-understood reasons, local circuits are to some extent dynamically insulated from the larger network in which they are embedded although they are topologically not detached.

Such "functional modularity" may be a property of the particular architecture of the evolved complex GRNs. In fact, in models of complex networks (discussed in the next section), evidence for just such "functional modularity" has been found with respect to network dynamics [116]. In brief preview (see Sect. "Three Regimes of Behaviors for Boolean Networks"), work on random Boolean network models of GRN has revealed three "regimes" of dynamical behaviors: ordered, critical, and chaotic, as described in Sect. "Ordered and Chaotic Regimes of Network Behavior". In the ordered and critical regimes, many or most genes become "frozen" into "active" or "inactive" states, leaving behind *functionally isolated "islands" of genes* which, despite being connected to other islands through the interactions of the network, are free to vary their activities without impacting the behaviors of other functionally isolated islands of genes.

Complex Networks

Despite a recent spate of publications in which the temporal change of expression of individual genes have been predicted based on small circuit diagrams, such predictions do not provide understanding of the integrated cell behavior, such as the change of cell phenotype that may involve thousands genes in the core GRN. Thus, analysis of genome-wide network state is needed to understand the biological observable. In a first approximation, it is plausible that the state of a cell, such as the particular cell (pheno-)type in a multi-cellular organism, is defined by its genome-wide gene expression profile, or *transcriptome* $T = [x_1, x_2, \ldots, x_N]$ with $N = 25,000$. In fact, microarray analysis of various cells and tissues reveals globally distinct, tissue specific patterns of gene expression profiles that can easily be discerned as shown in Fig. 1f. As mentioned above (Sect. "Definition of the Subject"), the gene expression profile across the genome is governed by the core regulatory network of transcription factors (TFs) which enslave the rest of the genome. Thus, in our approximation the network state S of the core transcriptional network of 3000 or so genes essentially controls the entire (genome-wide) gene expression profile.

For clarity of formalization, it is important to note that one genome in principle encodes exactly one fixed network, since the network connections are defined by the specific molecular interactions between the protein structure of TFs and the DNA sequence motif of the cis-regulatory promoter elements they recognize. Both are encoded by the genomic sequence. The often encountered notion that "networks change during development" and that "every cell type has its own network" is in this strict formalism incorrect – the genes absent in one cell type must directly or indirectly have been repressed (and sometimes, continuously kept repressed) by other genes that are expressed. Thus, the genome (of one species) directly maps into one (time-invariant) network architecture which in turn can generate a variety of states $S(t)$. It is the state S that changes in time and is distinct in different cell types or in different functional states within one cell type. Only genetic mutations in the genome will "rewire" the network and change its architecture.

If the network state $S(t)$ of the core GRN directly maps into a state of a cell (the biological observable), then one question is: What is the nature of the integrated dynamics of S in complex, irregularly wired GRN and is it compatible with observable cell behavior?

The study of the dynamics of complex networks (Table 1, B) may at first glance appear to be impeded by our almost complete ignorance about the architecture and interaction modalities between the genes. However, we cannot simply extrapolate from the mindset of studying small circuits with rate equations to the analysis of large networks. This is not only impossible due to the lack of information about the detailed structure of the entire network – the function **F** in Eq. 1 is unknown – but it may also be numerically hard to do. Yet, despite our ignorance about the network architecture, much can be learned if we reset our focus plane to the larger picture of the network. In this regard, the study of the dynamics of complex network can have two distinct goals (see Table 1).

One line of research (Table 1, B2) overcomes the lack of information about the network architecture by taking an ensemble approach [112] and asks: *What is the typical behavior of a statistical ensemble of networks that is* *characterized by an architectural feature (e. g. average connectivity k_i, power-law exponent γ)*? This computationally intense approach typically entails the use of discrete-valued gene networks (Sect. "Boolean Networks as Model for Complex GRNs"). As will be discussed below, such analysis has led to the definition of three broad classes of behaviors: chaotic, critical and ordered.

The second approach (Table 1, B3) to the dynamics of complex GRN is closer to experimental biology and exploits the availability of gene expression profile measurements using DNA microarray technology. Such measurements provide snapshots of the state of the network $S(t)$ over N genes, covering almost the entire transcriptome, and thus, reveals the direct output of the GRN as a distributed control system. Monitoring $S(t)$ and its change in time during biological processes at the whole-cell level will reveal the constraint imposed on the dynamics of $S(t)$ by network interactions and can, in addition to providing data for the inference problem (Sect. "Network Inference"), expose particular dynamical properties of the transcriptome that can be correlated with the biological observable.

Cell Fates, Cell types: Terminology and Concepts

In order to appreciate the meaning of the network state S and how it maps to the biological observable, we will now present (to non-biologists) in more detail the most prosaic biological observable of gene network dynamics: cell fate determination during development.

Stem Cells and Progenitor Cells in Multi-cellular Organism

A hall-mark of multi-cellular organisms is the differentiation of the omnipotent zygote (fertilized egg) via *totipotent* and *pluripotent embryonic stem cells* and *multipotent tissue stem cells* into functionally distinct mature "cell types" of the adult body, such as red blood cell, skin cells, nerve cells, liver cells, etc. This is achieved through a branching (tree-like) scheme of successive specialization into lineages. If the fertilized egg is represented by the main trunk of the "tree of development", then think of cells at the branching points of developmental paths as the stem cells. One example of a multipotent stem cell is the hematopoietic stem cells (HSC) which is capable of differentiating into the entire palette of blood cells, such as red blood cells, platelets and the variety of white blood cells. The last branch points represent *progenitor* cells which have a lesser developmental potential but still can chose between a few cell types (e. g., the common granulocyte-macrophage progenitor (GMP) cell, Fig. 1f). Finally, the outmost branches of the tree represent the mature, terminally differentiated cell types of the body.

A cell that can branch into various lineages is said to be "multipotent". It is a "*stem cell*" when it has the potential to self-renew by cell division, maintaining its differentiation potential, and to create the large family of cells of an entire tissue (e. g., the hematopoietic stem cell). Thus, progenitor cells, which proliferate but cannot infinitively self-renew, are strictly not stem cells. The commitment to a particular cell phenotype (a next generation branch of the tree) is also referred to as a "cell fate" since the cell at the proximal branching point is "fated" to commit to one of its prospective cell types.

Development and Differentiation

The diversification of the embryonic stem cell to yield the spectrum of the thousands [94] or so cell types in the body occurs in a process of successive branching events, at which multipotent cells commit to one fate and which appear to be binary in nature. Thus, multipotent cells make an either-or decision between typically two lineages – although more complex schemes have been proposed [65]. Moreover, it is generally assumed that during natural development there is only ***diversification*** of developmental paths but no *confluence* from different lineages, although recently exceptions to this rule have been reported for the hematopoietic system [1].

As cells develop towards the outer branches of the "tree of development", they become more and more specialized and progressively lose their competence to proliferate and diversify ("potency"). They also develop the phenotype features of a mature cell type; for instance, in the case of red blood cells, they adopt the flat, donut-like shape and synthesize haemoglobin. This process is called ***differentiation***. Most cells then also loose their capacity to divide, that is, to enter into the proliferative state. Thus, mature, terminally differentiated cells are typically quiescent or "*post mitotic*".

The branching scheme of cell types imposes another fundamental property: cell types are *discrete* entities. They are distinct from each other, i. e., they are well separated in the "phenotype space" and are stable [171]. There is thus no continuum of phenotype. As Waddington, a prominent embryologist of the last century, recognized in the 1940s: Cell types are "well-recognisable" entities and "intermediates are rare" [198]. In addition to the (quasi-) discreteness between branches of the same level, discreteness between the stages within one developmental path is also apparent: a multipotent stem cell at a branching point is in a discrete stage and can be identified based on molecular markers, isolated and cultured as such. Hence, a "stem cell" is not just a snapshot of an intermediate stage within a continuous process of development, but a discrete metastable entity.

The flow down the developmental paths, from a stem cell to the terminally differentiated state is, despite the pauses at the various metastable stem and progenitor cell levels, essentially unidirectional and, with a few exceptions, irreversible. In some tissues, the mature cells, as is the case with liver, pancreas or endothelial cells, can upon injury revert to a phenotype similar to that of the last immature (progenitor) stage and resume proliferation to restore the lost cell population, upon which they return to the differentiated, quiescent state.

Biologists often speak in somewhat loose manner of cells "***switching***" their phenotype. This may refer to switching from a progenitor state to a terminally differentiated state (differentiation) or within a progenitor state from the quiescent to other functional states, such as the proliferative or the apoptotic state (apoptosis = programmed cell death). In any case, such intra-lineage switching between different functional states also represents discontinuous, quasi-discrete transitions of whole-cell behaviors. The balance between division, differentiation and death in the progenitor or stem cell compartment of a tissue thus consists of state transitions that entail all-or-none decisions. This balance is at the core of organismal development and tissue homeostasis.

Now we can come back to the network formalism: if the network state S maps directly into the biological observable, what are the properties of the network architecture that confer its ability to produce the properties of the biological observable outlined in this section: discreteness and robustness of cell types, discontinuity of transitions, successive binary diversification and directionality of these processes? Addressing these questions is the long-term goal of a theory of the multicellular organism. In the following we describe the status of research toward this goal.

History of Explaning Cell Types

Waddington's Epigenetic Landscape and Bistable Genetic Circuits

One of the earliest conceptualization of the existence of discreteness of cell types was the work of C. Waddington, who proposed "epigenetic regulation" in the 1940s, an idea that culminated in the famous figure of the "epigenetic landscape" (Fig. 2g). This metaphor, devoid of any formal basis, let alone relationship to gene regulation, captures the basic properties of discrete entities and the instability of intermediates. The term 'epigenetic' was coined by Waddington to describe distinct biological traits that arise from the interplay of the same set of genes and does not require the assumption of a distinct, "causal" gene to be explained [196]. The 1957 version of the epigenetic landscape [198] (Fig. 2g) also implies that multipotent cells are destined to make either-or decisions between two prospective lineages, as embodied in the "watershed" regions (Fig. 2g).

Almost at the same time as Waddington, in 1948 Max Delbrück proposed a generic concept of differentiation into two discrete states in a biochemical system that can be described by equations of the form (3), consisting of two mutual inhibiting metabolites, $x_1(t)$ and $x_2(t)$ that exhibits bistability [53] (For a detailed qualitative explanation, see Fig. 2). The dynamics of such a system is graphically represented in the two dimensional state space spanned by x_1 and x_2 (Fig. 2c-f). ***Bistable dynamics*** implies that there are two steady states S_1^* and S_2^* that satisfy $\mathrm{d}x_1/\mathrm{d}t = \mathrm{d}x_2/\mathrm{d}t = 0$ and are *stable* fixed-points of the system. For the system equations of Fig. 2b, this behavior is observed for a large range of parameters. In a nutshell, the mutual inhibition renders the balanced steady state $S_3^*(x_1 = x_2)$ unstable so that the system settles down in either the steady state $S_1^*(x_1 \gg x_2)$ or $S_2^*(x_1 \ll x_2)$ when kicked out of this unstable fixed point. These two stable steady states and their associated gene activity patterns are discretely separated in the $x_1 - x_2$ state space and have been postulated to represent the differentiated state of cells, thus, corresponding to Waddington's valleys. This was the first conceptualization of a cellular differentiated state as a stable fixed-point of a non-linear dynamical system. Soon after Monod and Jacob discovered the principle of gene regulation they also proposed a circuit of the same architecture as Delbrück [148], but consisting of two mutually suppressing genes instead of metabolites, to explain differentiation in bacteria as a bistable system.

Bistability, Tristability and Multistability

The central idea of bistability is that the very same system, in this case, a gene circuit composed of two genes x_1 and x_2, can under some conditions produce two distinct stable states separated by an unstable stationary-state, and hence, it can switch in almost discontinuous manner from one state (S_1^*) to another (S_2^*) ("toggle switch") (Fig. 2). Bistability is a special (the simplest) case of ***multi-stability***, an elementary (but not necessary) property of systems with non-linear interactions, such as those underlying the gene regulatory influences as detailed in Fig. 2b. Which stable state (in this case, S_1^* or S_2^*) a network occupies depends on the ***initial condition***, the position of $S(t=0)$ in the $x_1 - x_2$ state space (Fig. 2c). The two stable steady-states, S_1^* or S_2^*, are called "***attractors***" since the system in such states will return to the characteristic gene expression pattern in response to small ***perturbations*** to the system by enforced change of the values of x_1 or x_2. Similarly, after an external influence that places the network at an unstable initial state $S'(t=0)$ within the ***basin of attraction*** of attractor S_1^* (gray area in Fig. 2c), and hence cause the network to settle down in the stable state S_1^*, the network will stay there even after the causative influence that initially put it in the state S' has disappeared. Thus, attractor states confer memory of the network state. In contrast, larger perturbations beyond a certain threshold will trigger a transition from one attractor to another, thus explaining the observed discontinuous "switch-like" transitions between two stable states in a continuous system.

After Delbrück, Monod and Jacob, numerous theoretical [74] and, with the rise of systems biology, experimental works have further explored similar simple circuitries that produce bistable behavior (see ref. in [38]). Such circuits and the predicted switch-like behavior have been found in various biological systems, including in gene regulatory circuits in Escherichia coli [157], mammalian cell differentiation [43,99,127,168] as well as in protein signal transduction modules [12,64,205]. Artificial gene regulatory circuits have been constructed using simple recombinant DNA technology to verify model predictions [22,71, 123].

Circuit analyzes have been expanded to cover more complex circuits in mammalian development. It appears that there is a common theme in the circuits that govern cell differentiation (Sect. "Cell Fates, Cell Types: Terminology and Concepts"): interconnected pairs of mutually regulating genes that are often also self-regulatory, as shown in Fig. 3b [43,99,168]. Such circuit diagrams may be crucial in controlling the binary diversification at developmental branch points (Fig. 1f) [99]. In the case where the two mutually inhibiting genes are also are self-stimulatory, as summarized in Fig. 3b, an interesting modification of the bistable dynamics can be obtained. Assuming independent (additive) influence of the self-stimulatory and cross-inhibitory inputs, this circuit will convert the central unstable state (saddle) S_3^* (Fig. 2, 3a) that separate the two stable steady-states into a stable steady state, thus generating ***tristable*** behavior [99]. The third, central stable fixed point has, in symmetrical cases, the gene expression configuration $S_3^*[x_1 \sim x_2]$ (Fig. 3b).

The *promiscuous* expression of intermediate-low levels of x_1 *and* x_2 *in the locally stable state* S_3^* has been associated with a stem or progenitor cell that can differentiate into the cell represented by the attractors $S_1^*(x_1 \gg x_2)$ or $S_2^*(x_1 \ll x_2)$. In fact, the common progenitor cells (Fig. 1f) have been shown to express "promiscuous" expression of genes thought to be specific for either of the lineages in which it will have to commit to, so-to speak providing a "preview" or "multi-lineage priming" of the gene expression of its prospective cell fates [47,59,92]. For instance, the *common myeloid progenitor* (CMP, Fig. 1) which can commit to either the *erythroid* or the *myeloid* lineage, expresses both the erythroid-specific transcription factor GATA1 (= x_1) and the myeloid specific transcription factor PU.1 (= x_2) at intermediate levels (Fig. 3c). The metastable [GATA1~PU.1] configuration generates a state of *indeterminacy* or "suspense" [146] awaiting the signal, be it a biological instruction or stochastic perturbation, that resolves it to become either one of the more stable states [GATA1 $\gg$ PU.1] or [GATA1 $\ll$ PU.1] when cells differentiate into the erythroid or myeloid lineage, respectively. Thus, multi-potency and indeterminacy of a progenitor cell can be defined purely dynamically and does not require a much sought after "stemness" gene (again, a concept that arose from the gene-centered view) [195]. The metastable state also captures the notion of a "higher potential energy" [79] that drives development and hence, may account for the arrow of time in ontogenesis.

A Formalism for Waddington's Epigenetic Landscape Metaphor

Obviously, the valleys in Waddington's epigenetic landscape represent the stable steady states (attractors) while the hill-tops embody the unstable fixed-points, as shown in Fig. 2. How can Waddington's metaphor formally be linked to gene network dynamics and the state space structure? For a one dimensional system $\mathrm{d}x/\mathrm{d}t = f(x)$, this is easily shown with the following analogy: An "energy" landscape represents the cumulative "work" performed/received when "walking" in the state space against / along the vector field of the "force" $f(x)$ (Fig. 2c). Thus, the "potential energy" is obtained by integrating $f(x)$ (the right-hand side of the system equation, Eq. (1)) over the state space variables x.

$$V(x) = -\int f(x)\mathrm{d}x\,. \tag{3}$$

Here the state space dimension x is given the meaning of a physical space, as that pertaining to a landscape, and the integral $V(x)$ is the sum of the "forces" experienced by the network states $S(t) = x(t)$ over a path in x that drive $S(t)$ to the stable states (Fig. 2c). The negative sign establishes the notion of a potential in that the system loses energy as it moves towards the stable steady states which are in the valleys ("lowest energy"). Higher ($N > 1$) dimensional systems (Eq. 1) are in general non-integrable (unless there exists a continuously differentiable (potential) function $V(x_1, x_2, \dots, x_N)$ for which $f_1 dx_1 + f_2 dx_2 + \cdots + f_N dx_N \cdots = 0$ is the *exact total differential*, so that $-grad(V)=\mathbf{F}(\mathbf{x})$ with $\mathbf{F}(\mathbf{x}) = [f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_N(\mathbf{x})]^T$). Thus, there is in general no potential function that could represent a "landscape"; however, the idea of some sort of "potential landscape" is widely (and loosely) used, especially in the case of two-dimensional systems where the third dimension can be depicted as a cartographic elevation $V(x_1, x_2)$. An elevation function $V(x_1, x_2)$ can be obtained in stochastic systems where $\mathbf{x}(t)$ is subjected to random fluctuations due to gene expression noise [87]. Then $V(S)$ is related to the probability $P(S)$ to find the system in state $S = (x_1, x_2, \dots)$, e.g., $V(S) = -\ln(P(S)$ [118,177]. It should however be kept in mind that the "quasi-potential" V is not a true (conservative) potential, since the vector field is not a conservative field.

The above treatment of the dynamics of the gene regulatory circuit explains the valleys and hills of Waddington's landscape but still lacks the "directionality" of the overall flow on the landscape, depicted by Waddington as the slope from the back to the front of his landscape. (This *arrow or time of development* will briefly be discussed in the outlook Sect. "Future Directions and Questions").

In summary, the epigenetic landscape that Waddington proposed based on his careful observation of cell behavior and that he reshaped over decades [103,179,196,197,198], can now be given both a molecular biology correlate (the gene regulatory networks) and a formal framework (probability landscape of network states S). The landscape idea lies at the heart of the connection between molecular network topology and biological observable.

The Molecular Biology View: "Epigenetic" Marks of Chromatin Modification

Although it is intuitively plausible that stable steady states of the circuits of Delbrück and of Monod and Jacob may represent the stable differentiated state, this explanation of a biological observable in terms of a dynamical system was not popular in the community of experimental molecular biologists and was soon sidelined as molecular biology, and with it the gene-centered view, came to dominate biology. The success in identifying novel genes (and their mutated alleles) and the often straightforward explanation of a phenotype offered by the mere discovery of a (mutant) gene triggered a hunt for such "explanatory genes" to account for biological observables. Gene circuits had to give place to the one-gene-one trait concept, leading to an era in which a new gene-centered epistemological habit, sometimes referred to as "*genetic determinism*", prevailed [180]. Genetic determinism, a particular form of reductionism in biology, was to last for another fifty years after Delbrück's proposal of bistability. Only as the "low hanging fruits" of simple genotype-phenotype relationships seemed to have all been picked, and genome-wide gene expression measurements became possible was the path cleared for the rise of "system biology" and biocomplexity that we witness today.

In genetic determinism, macroscopic observables are reduced in a qualitative manner to the existence of genes or regulatory interactions which at best "form" a linear chain of events. Such "pathways", most lucidly manifest in the arrow-arrow schemes of modern cell biology papers, serve as a mechanistic explanation and satisfied the intellectual longing for causation. It is in light of this thinking that the molecular biologists' explanation of the phenomenon of cell type determination has to be seen. Absent a theory of cell fate diversification and in view of the stunning stability of cell types, a dogma thus came into existence according to which the type identity of cells, once committed to, is irreversibly carved in stone [161]. Rare transdifferentiation events (switch of cell lineages) were regarded as curiosities. The observation that cell types express type-specific genes was explained by the presence of cell-type specific transcription factors. For instance, red blood cells express haemoglobin because of the presence of GATA1 – a lineage specific transcription factor that not only promotes commitment to the erythroid lineage (as discussed above, Sect. "Bistability, Tristability and Multistability") but also controls haemoglobin expression [149]. Conversely, the absence of gene activity, for instance, non-expression of liver-specific genes in erythrocytes, was explained by the silencing of the not needed genes by covalent DNA methylation and histone modifications (methylation, acetylation, etc.) [13,65,69,117,122] which modify chromatin structure, and thereby, control the access of the transcription machinery to the regulatory sites on the DNA. But who controls the controller?

Chromatin modifications [117,122] are thought to confer discrete alterations of gene expression state that are stable and essentially irreversible. This idea of permanent marks on DNA represents the conceptual cousin of mutations (but without altering DNA sequence) and was thus in line with the spirit of genetic determinism. Accordingly, they were readily adopted as an explanation of the apparently irreversible cell type-specific gene inactivation and were given the attribute "epigenetic" to contrast them from the genetic changes that involve alteration of DNA sequences. But enzymes responsible for covalent DNA and chromatin modification are not gene-locus specific, leaving open how the cell type specific gene expression *pattern* is orchestrated.

It is important to mention here a disparity in the current usage of the term "epigenetics" [103]. In modern molecular biology, "epigenetics" is almost exclusively used to refer to DNA methylation and covalent histone modifications; this meaning is taken for granted even among authors who comment on the very usage of this term [13, 26,103], and are unaware that memory effects can arise purely dynamically without a distinct material substrate, as discussed in Sect. "Bistability, Tristability and Multistability". In contrast, biological physicists use "epigenetic" to describe precisely phenomena, such as multi-stability (Sect. "Bistability, Tristability and Multistability") that are found in non-linear systems – a usage that comes closer to Waddington's original metaphor for illustrating the discreteness and stability of cell types [197,198]. The use of Waddington's "epigenetic landscape" has recently seen a revival [75,165] in the modern literature in the context of chromatin modifications but remains loosely metaphoric and without a formal basis.

Rethinking the Histone Code

The idea of methylation and histone modifications as a second code beyond the DNA sequence ("histone code") that cells use to "freeze" their type-specific gene expression pattern relied on the belief that these covalent modifications act like permanent marks (only erased in the germline when an oocyte is formed). This picture is now beginning to change.

First, recent biochemical analysis suggest that the notion of a static, irreversible "histone code" is oversimplified, casting doubt on the view that histone modification is the molecular substrate of "epigenetic memory" [122,126,144,191]. With the accumulating characterization of chromatin modifying enzymes, notably those controlling histone lysine (de)methylation [122,126,144, 191], it is increasingly recognized that the covalent "epigenetic" modifications are bidirectional (reversible) and highly dynamic. Second, cell fate plasticity, most lucidly evident in the long-known but rarely observed transdifferentiation events, or in the artificial reprogramming of cells into embryonic stem cells either by nuclear transfer-mediated cloning [91] or genetic manipulation [143, 156,184,201], confirm that the "epigenetic" marks are reversible – given that the appropriate biochemical context is provided. If what was thought of as permanent molecular marks is actually dynamical and reversible – what then maintains lineage-specific gene expression patterns in an inheritable fashion across cell divisions?

In addition, as mentioned above, there is another, more fundamental question from a conceptual point of view: chromatin-based marking of gene expression status is a generic, not locus – specific process – the same enzymes can apply or remove the covalent marks on virtually any gene in the genome. They are dumb. So what smart system orchestrates the DNA methylation and histone modification machinery at the tens of thousands of loci in the genome so that the appropriate set of genes is (in)activated to generate the cell type-specific patterns of gene expression?

A system-level view avoids the conundrum caused by the mechanistic, proximal explanation [189] of the gene-centered view. A complex systems approach led to the idea that the genome-wide network of transcriptional regulation can under some conditions spontaneously orchestrate, thanks to self-organization, the establishment of lineage- specific gene expression profiles [114], as will be discussed below. In fact, the picture of chromatin modification as primum movens that operates "upstream" of the transcription factors (TFs), controlling their access to the regulatory elements in promoter regions, must be revised in light of a series of new observations. Evidence is accumulating that the controller itself is controlled – namely, by the TFs they are thought to control: TFs may actually take the initiative by recruiting the generic chromatin-modifying enzymes to their target loci [51,80,125, 144,145,182,185]. It is even possible that a mutual, cooperative dynamical interdependence between TFs and chromatin-modifying enzymes may establish locus-specific, switch-like behavior that commands "chromatin status" changes [56,132]. In fact, an equivalent of the indeterminacy state where both opposing lineage specific TFs balance each other (Sect. "Bistability, Tristability and Multistability", Fig. 3b) is found at the level of chromatin modification, in that some promoters exhibit "bivalent" histone modification in which activating and suppressing histone methylations coexist [25]. Such states in fact are associated with TFs expressed at low level – in agreement with the central attractor S_3^* of the tristable model (Fig. 3b). Thus, chromatin modification is at least in part "downstream" of TFs and may thus act to add additional stability to the dynamical states that arise from the network of transcriptional regulation. If correct, such a relationship will allow us to pass primary responsibility for establishing the observable gene expression patterns back to transcription factors. With its genome-wide regulatory connections the

GRN is predestined for the task of coordination and distributed information processing.

But under what conditions can a complex, apparently randomly wired network of 3000 regulators create, with such stunning reliability and accuracy, the thousands of distinct, stable, gene expression profiles that are associated with a meaningful biological state, such as a cell type? Studies of Boolean networks as toy models in the past 40 years have provided important insights.

Boolean Networks as Model for Complex GRNs

General Comment on Simplifying Models

The small-circuit model discussed in Sect. "Small Gene Circuits" represents arbitrarily cut-out fragments of the genome-wide regulatory network. A cell phenotype, however, is determined by the gene expression profile over thousands of genes. How can we study the entire network of 25,000 genes, or at least the core GRN with 3000 transcription factors even if most of the details of interactions remain elusive?

The use of random Boolean networks as a generic network model, independent of a specific GRN architecture of a particular species, was proposed by Kauffman in 1969 – at the time around which the very idea of small gene regulatory circuits were presented by Monod and Jacob [148]. In random Boolean networks the dynamics is implemented by assuming discrete-valued genes that are either ON (expressing the encoded protein) or OFF (silenced). The interaction function (Sect. "Introduction", and **F** in Sect. "Small Gene Circuits") that determines how the ON/OFF status of multiple inputs of a target gene map into its behavior (output status) is a logical (Boolean) function B, and the network topology is randomly-wired, with the exception of some deliberately fixed features. Thus, the work on random Boolean networks allowed the study of the generic behavior of large networks of thousands of genes even before molecular biology could deliver the actual connections and interaction logics of the GRN of living systems (for review, see [8]).

The lack of detailed knowledge about specific genes, their interaction functions and the formidable computational cost for modeling genome-wide networks has warranted a coarse-graining epitomized by the Boolean network approach. But more specifically, in the broader picture of system-wide dynamics, the discretization of gene expression level is also justified because (*i*) the above discussed steep sigmoidal shape of "transfer functions" (Fig. 2b) that describe the influence of one gene onto another's expression rate can be approximated by a step-function and/or (*ii*) the local dynamics produced by such small gene circuit modules is in fact characterized by discontinuous transitions between discrete states as shown in Sect. "Network Dynamics".

In addition, the Boolean network approach offers several advantages over the exhaustive, maximally detailed models favored by engineers who seek to understand a *particular instance* of a system rather than *typical* properties of a *class* of systems. The simplification opens a new vista onto fundamental principles that may have been obscured by the details since, as philosophers and physicists have repeatedly articulated, there is no understanding without simplification, and "less can be more" [11,30, 159]. An important practical advantage of the simplification in the Boolean network approach is the possibility to study *statistical ensembles* of ten thousands of network instances, i. e., entire classes of network architectures, and to address the question of how a particular architecture type maps into a particular type of dynamic behavior. Some of the results obtained in fact are valid for both discrete and continuous behavior of the network nodes [17].

Model Formalism for Boolean Networks

In the Kauffman model of random Boolean networks gene activity values are binary (1 = ON, and 0 = OFF) [111, 115,116] and time is also discretized. Thus, a Boolean network is a generalized form of cellular automata but without the aspect of physical space and the particular neighborhood relations. Then, in analogy to continuous systems, a network of N elements i ($i = 1, 2, \dots, N$), defines a network state S at any given discrete time step t: $\mathbf{S}(t) = [x_1(t), x_2(t), \dots, x_N(t)]$ where x_i is the activity status that now only takes the values 1 or 0. The principles are summarized in Fig. 4. The state space that represents the entire dynamics of the network is finite and contains 2^N states. However, again, not all states are equally likely to be realized and observed, since genes do not behave independently but influence each other's expression status.

Regulation of gene i by its incoming network connections is modeled by the Boolean function B_i that is associated with each gene i and maps the configuration of the activity status (1 or 0) of its input genes (upstream regulators of gene i) into the new value of x_i for the next time point. Thus, the argument of the Boolean function B_i is the input vector $\boldsymbol{R}_i(t) = [x_1(t), x_2(t), \dots, x_{ki}(t)]$, where k_i is the number of inputs that the gene i receives. At each time step, the value of each gene is updated: $x_i(t+1) = B_i[\boldsymbol{R}_i(t)]$. The logical function B_i can be formulated as a "truth table" which is convenient for large k's (Fig. 4a). In the widely studied case where each gene has exactly $k = 2$ inputs, the Boolean function can be one of

Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination, Figure 4

Principles of Boolean network models of GRN, exemplified on a $N = 4$ gene network. a From *architecture* to dynamics. The four genes i: A, B, C, D interact as indicated by the directed graph (*top left panel*), and each of the genes is assigned a Boolean function B_i as indicated, with the corresponding "truth table" shown below. A network state is a string of $N = 4$ binary variable, thus there are $2^N = 2^4 = 16$ possible *network states S*. They collectively establish the entire state space and can be arranged in a *state transition map* according to the state transitions imposed by the Boolean functions (*right panel*). The attractor states are colored *gray*. In the example, there are three point attractors and one limit cycle attractor (of period $T = 2$). The dotted lines in the state space denote the attractor boundaries. b Example for capturing the regulation at the promoter of the lactose operon as an "AND" Boolean function. Note that there are many ways to define what constitute an input – in the case shown, the allosteric ligands cAMP ("activator") and a β-galactoside ("inducer"), such as allolactose, give rise to a two-input Boolean function 'AND'

the set of $2^{(2\wedge k)} = 16$ classical Boolean operators, such as AND, OR, NOTIF, etc. [109,116]. Figure 4b shows the example of the well-studied lactose operon and how its regulatory characteristics can be captured as an AND Boolean function for the two inputs.

In the simplest model, all genes are updated in every time step. This synchrony is artificial for it assumes a central clock in the cell which is not likely to exist, although some gating processes from oscillations in the redox potential has been reported [120]. The idealization of synchrony, however, facilitates the study of large Boolean networks, and many of the results that have been found with synchronous Boolean networks carry over to networks with asynchrony of updating that has been implemented in various ways [40,72,81,119]. For synchronous networks the entire network state $\boldsymbol{S}$ can also be viewed as being updated by the updating function U: $\boldsymbol{S}(t+1) = U[\boldsymbol{S}(t)]$, where U summarizes all the N Boolean functions B_i. This facilitates some treatments and is represented in the ***state transition table*** that lists all possible network states in one column and its successor in a second column. This leads to a higher-level, directed graph that represents the entire dynamics of a network as illustrated below.

Dynamics in Boolean Networks

The state transition table captures the entire dynamical behavior of the network and can conveniently be depicted as a ***state transition map***, a directed graph in which a node represents one of the 2^N possible state $S(t)$ (a box with a string or 1, 0s in Fig. 4a. representing the gene expression pattern). Such diagrams are particularly illustrative only for N up to ~ 10, since they display all possible states S of the finite state space [204]. The states are connected by the arrows which represent individual state transitions and collectively depict the ***trajectories*** in the state space (Fig. 4a, right panel).

Since the Boolean functions are *deterministic*, a state $S(t)$ unambiguously transitions into *one* successor state $S(t+1)$. In contrast, a state can have multiple predecessors, since two or more different states can be updated into the same state. Hence, trajectories can converge but not diverge, i. e., there is no branching of trajectories emanating from one state. This property of "losing information about the ancestry" is essential to the robustness of the dynamics of networks.

In updating the network states over time, $S(t)$ can be represented as a walk on the directed graph of the state transition map. Because of the finiteness of the state space in discrete networks, $S(t)$ will eventually encounter an already visited state, and because of the absence of divergence, the set of successive states will be the same as in the previous encounter. Thus, no matter what the initial state is, the network will eventually settle down in either a set of cycling states (which form a *limit cycle*) or in a single stable state that updates onto itself. Accordingly, these states to which all the trajectories are "attracted" to are the ***attractors*** of the network. They are equivalent to stable oscillators or stable fixed-points, respectively, in the continuous description of gene circuits (Sect. "Bistability, Tristability and Multistability"). In other words, because of the regulatory interactions between the genes, the system cannot freely choose any gene expression configuration S. Again, most network states S in the state space are thus unstable and transition to other states to comply with the Boolean rules until the network finds an attractor. And as with the small, continuous systems (Sect. "Bistability, Tristability and Multistability") the set of states S that "drain" to an attractor state constitute its ***basin of attraction***.

However, unlike continuous systems, Boolean network dynamics do not produce unstable steady-states that can represent the indeterminacy of undecided cell states that correspond to stem cells about to make an either-or decision between two lineages (see Sect. "Bistability, Tristability and Multistability"). Instead, basins of attraction are "disjoint" areas of state space.

Attractors as Cell Types Kauffman proposed that the high-dimensional attractor states represent cell types in metazoan organisms – thus expanding the early notion of steady state in small circuits to networks of thousands of genes [111,116] (Sect. "Bistability, Tristability and Multistability"). This provides a natural explanation for the stability of the genome-wide expression profile that is characteristic of and defines a cell type as well as for the stable coordination of genome-wide gene expression oscillations in proliferating cells that undergo the cell division cycle [202]. The correspondence of attractors in large networks with the cell type specific transcriptome is a central hypothesis that links the theoretical treatment of the dynamics of complex networks with experimental cell biology.

Use of Boolean Networks to Model Real Network Dynamics Owing to their simple structure, Boolean networks have been applied in place of differential equations to model real-world networks for which a rudimentary picture of the topology with only few details about the interaction functions is known. Hereby, individual Boolean functions are assigned to the network nodes either based on best guesses, informed by qualitative descriptions from the experimental literature, or randomly. This approach has yielded surprisingly adequate recapitulation of biological behaviors, indicating that the topology itself accounts for a great deal of the dynamical constraints [4,49,60,62,95,130]. Such studies also have been used to evaluate the dynamical regime (discussed in the next section) of real biological networks [19].

Three Regimes of Behaviors for Boolean Networks

The simplicity and tractability of the Boolean network formalism has stimulated a broad stream of investigations that has led to important insights in the fundamental properties of the generic dynamics that large networks can generate [116] even before progress in genomics could even offer a first glimpse on the actual architecture of a real gene regulatory network [112].

Using the ensemble approach, the architectural parameters that influence the global, long-term behavior of complex networks with N up to 100,000 has been determined [114,116]. As mentioned in the introduction, based on the latest count of the genome size and the idea that the core transcriptional network essentially governs the global dynamics of gene expression profiles, networks of $N \sim 3000$ would have sufficed. Nevertheless, a striking result from the ensemble studies was that for a broad class of architectures, even a complex, irregular (randomly wired) network can produce 'ordered' dynamics with stable patterns of gene expression, thus potentially delivering the "biological observable". In general, the global behavior of ensembles of Boolean networks can be divided in three broad regimes [116]: an *ordered* and a *chaotic* regime, and a regime that represents behavior at their common border, the *critical* regime.

Ordered and Chaotic Regimes of Network Behavior

In networks in the ***ordered*** regime, two randomly picked initial states $S_1(t = 0)$ and $S_2(t = 0)$ that are closed to one another in state space as measured by the Hamming distance $H[H(t) = |S_1(t) - S_2(t)| \equiv$ the number of genes whose activities differ in the two states $S_1(t)$ and $S_2(t)]$ will exhibit trajectories that on average will quickly converge (that is, the Hamming distance between the two trajectories will on average decrease with time) [55]. The two trajectories will settle down in one fixed-point attractor or a limit cycle attractor that will have a small period T compared to N and thus, produce very stable system behaviors. Such networks in general have a small number of attractors with typically have small periods T and drain large basins of attraction [116]. Numerical analyzes of large ensembles suggest that the average period length scales with $\sqrt{N}$. The state transition map, as shown for $N = 4$ in Fig. 4a, will show that trajectories converge onto attractor states from many different directions and are in general rather short [Maliackal, unpublished] so that attractor basins appear as compact, with high rotational symmetry and hence, "bushy".

It is important to stress here that if a cell type is an attractor, then different cell types are different attractors, and, in the absence of the unstable steady states present in continuous dynamical systems (see Sect. "Bistability, Tristability and Multistability") differentiation consists in perturbations that move a system state from one attractor into the basin of another attractor from which it flows to the new attractor state that encodes the gene expression profile of the new cell type. Examination of the bushy basins in the ordered regime makes it clear, as do numerical investigations and experiments (Sect. "Are Cell Types Attractors?"), that multiple pathways can lead from one attractor to another attractor – a property that meets resistance in the community of pathway-centered biologists.

In contrast, in networks in the ***chaotic*** regime, two randomly placed initial states $S_1(t = 0)$ and $S_2(t = 0)$ that are initially close to one another (in terms of Hamming distance) will generate trajectories that on average will *diverge* and either end with high likelihood in two different attractors, or they may appear to "wander" aimlessly in state space. This happens because the attractor is a limit cycle attractor with very long period T – on the scale of 2^N so that in the worst case a trajectory may visit most if not all 2^N possible network configurations S. For a small network of just $N = 200$, this is a limit cycle in the order of length $2^{100} \approx 10^{30}$ time steps. As a point of comparison, the universe is some 10^{17} seconds old. Given the hyperastronomic size of this number, this "limit cycle" will appear as an aperiodic and endless stream of uncorrelated state transitions, as if the system is on a "permanent transient". Thus, networks in the chaotic regime are not stable, trajectories tend to diverge (at least initially), and their behavior is sensitive to the initial state. In the state transition map, the small attractors typically receive trajectories with long transients that arrive from a few state space directions and hence, in contrast to the bushy attractors of the ordered regime, the basins have long thin branches and appear "tree-like".

The definition of "chaos" for discrete networks given here is distinct from that of (deterministic) chaos in continuous systems, where time evolution of infinitesimally closed initial states can be monitored and shown to diverge. Nevertheless, the degree of chaos in discrete networks, as qualitatively outlined above, is well-defined and can be quantified based on the slope of the curve in the so-called Derrida plot which assesses how a large number of random pairs of initial states evolves in one time step [55].

More recently, it was shown that it is possible to determine the behavior class from the architecture, without simulating the state transitions and determining the Derrida plot, simply by calculating the expected *average sensitivity* from all the N Boolean functions B_i [173]. In addition, a novel distance measure that uses normalized compression distances (NCD) – which captures the complexity in the difference between two states $S(t)$ better than the Hamming distance used in the Derrida plot – has been proposed to determine the regime of networks [153].

Critical Networks: Life at Edge of Chaos?

Critical networks are those which exhibit a dynamical behavior just at the edge between that of the ordered and the chaotic regime, and have been postulated to be optimally poised to govern the dynamics of living cells [114, 116]. *Ordered* behavior would be too rigid, in that most perturbations of a stable attractor would be absorbed and the network would return to the same attractor state, minimizing the possibility for a network to change its internal equilibrium state in response to external signals (which are modeled as flipping individual genes from ON to OFF or vice versa). *Chaotic* behavior, on the other hand, would be too sensitive to such perturbations because trajectories diverge – so that the network would wander off in state space and fail to exhibit robust behavior. *Critical* networks may represent the optimal mix between stability and responsiveness, hence conferring robustness to random perturbations (noise) and adaptability in response to specific signals. Critical network have several remarkable features:

First, consider the need of cells to plausibly make the maximum number of reliable discriminations, and to act on them in the presence of noise with maximum reliability. Then 'deep' in the ordered regime, convergence of trajectories in state space is high, hence, as explained above (Sect. "Dynamics in Boolean Networks") information is constantly discarded. In this "lossy" regime, information about past discriminations is thus easily lost. Conversely, in the chaotic regime and with only a small amount of noise, the system will diverge and hence cannot respond reliably to external signals (perturbations). It seems plausible that optimal capacity to categorize and act reliably is found in critical networks, or networks slightly in the ordered regime.

Second, it has recently been shown that a measure of the correlation of pairs of genes with respect to their altering activities, called "***mutual information***" (MI) is maximized for critical networks [154]. The MI measures the mutual dependence of two variables (vectors), such as two genes based on their expression in a set of states $S(t)$. Consider two genes in a synchronous Boolean network, A and B. The mutual information between x_{A} and x_{B} is defined as $\mathrm{MI(A,B)} = H(x_{\mathrm{A}}) + H(x_{\mathrm{B}}) - H(x_{\mathrm{A}}, x_{\mathrm{B}})$. Here, $H(x)$ is the entropy of the variable x, and $H(x, y)$ is the joint entropy of x and y. Mutual information is 0 if either gene A or B is unchanging, or if A and B are changing in time in an uncorrelated way. Mutual information is greater than 0 and bounded by 1.0, if A and B are fluctuating in a correlated way. Thus, *critical networks maximize the correlated changing behavior of variables in the genetic network*. This new result strongly suggests, at least in the ensemble of random Boolean networks, that critical networks can coordinate the most complex organized behavior.

Third, the "basin entropy" of a Boolean network, which characterizes the way the state space is partitioned in to the disjoint basins of attraction of various sizes (Fig. 4a) also exposes a particular property of critical networks [124]. If the size or "weight", W_i, of a basin of attraction i is the fraction of all the 2^N states that flow to that attractor, then the basin entropy is defined as $\Sigma W_i \log(W_i)$. The remarkable result is that *only* critical networks have the property that this basin entropy continues to increase as the size of the network increases. By contrast, ordered and chaotic networks have basin entropies that first increase, but then stop increasing with network size [124]. If one thinks of basins of attraction and attractors not only as cell fates, or cell types, but as distinct specific cellular programs encoded by the network, then only critical networks appear to have the capacity to expand the diversity of what "a cell can do" with increasing network size. Again, this strongly suggests that critical networks can carry out the most complex coordinated behaviors. Thus, GRN may have evolved under natural selection (or otherwise – see Sect. "Evolution of Network Structure: Natural Selection or Natural Constraint?") to be critical.

Finally, it is noteworthy that while Boolean networks were invented to model GRNs, the variables can equally be interpreted as any kind of two-valued states of components in a cell, and the Boolean network becomes a *causal network* concerning events in a cell, including GRN as a subset of such events. This suggests that not only GRN but the entire network of processes in cells, including signal transduction and metabolic processes, that is, information, mass and energy flow, may optimally be coordinated if the network is critical.

If life is poised to be in the critical regime, then the questions follow: which architecture produces ordered, critical and chaotic behaviors, and are living cells in fact the critical regime?

Architectural Features of Large Networks and Their Dynamics

As outlined in Sect. "Network Architecture", the recent availability of data on gene regulation in real networks, although far from complete, has triggered the study of complex, irregular network topologies as static graphs. This line of investigation is now beginning to merge with the study of the dynamics of generic Boolean networks. Below we summarize some of the interesting architecture features and their significance for global dynamics in term of the three regimes. First, studies of generic dynamics in ensembles of Boolean networks have established the following major structure-dynamics relationships:

(1) *The average input connectivity per node, k.* Initial studies on Boolean networks by Kauffman assumed a homogenous distribution of inputs k. It was found

that $k = 2$ networks are in the ordered/critical regime (given other parameters, see below) [116]. Above a critical k_c value (which depends on other parameters, see below) networks behave chaotically. Analysis of continuous, linearized models also suggest that in general, sparsity of connections is more likely to promote ordered dynamics – or stability [142].

(2) The *distribution of the connectivity (degree)* over the individual network genes. As mentioned in Sect. "Network Architecture", the global topology of many complex molecular networks appears to have a connectivity distribution that approximates a power-law. For directed graphs such as the GRN, one needs to distinguish between the distribution of the input and output connectivities. Analyses of the dynamics of random Boolean networks with either scale-free input [66] or output connectivity distribution suggest that this property favors the ordered regime for a given value of the parameter p ("internal homogeneity", see below) [6]; Specifically, if the slope of the scale free distribution (power-law exponent γ) is greater than 2.5, the corresponding Boolean network is ordered, regardless of the value of the parameter p (see below). For values of p approaching 1.0, $\gamma > 2.0$ suffices to assure ordered dynamics.

(3) The nature of the Boolean functions is an important aspect of the network architecture that also influences the global dynamics. In the early studies, Kauffman characterized Boolean functions with respect to these two important features [116]:

(a) "*internal homogeneity* p". The parameter p $(0.5 < p < 1)$ is the proportion of either 1s or 0s in the output column of the truth table of the Boolean function (Fig. 4). Thus, a function with $p = 0.5$ has equal numbers of 1s and 0s for the output of all input configurations. Boolean functions with p-values close to 1 or 0 are said to exhibit high internal homogeneity.

(b) "*Canalizing function*". A Boolean function B_i of target gene i is said to be canalizing if at least one of its inputs has one value (either 1 or 0) that determines the output of gene i (1 or 0), independently of the values of the other components of the input vector. If the two values of the input j determines *both* output values of gene i [a "fully canalizing" function, e. g., if $x_j(t) = 1$ (or 0, respectively), then $x_i(t + 1) = 1$ (or 0, respectively)], then the other inputs have no influence on the output at all and the "*effective* input connectivity" of i, $k_{i\text{eff}}$ is smaller than the "*nominal*" k_i. For instance, for Boolean functions with $k = 2$, only two of the 16 possible functions, XOR and XNOR, are not canalizing. Four functions are "fully canalizing", i. e., are effectively $k = 1$ functions (TRANSFER, COMPLEMENT).

From ensemble studies it was found that both a high internal homogeneity p and a high proportion of canalizing functions contribute to ordered behavior [116].

Do Real Networks Have Architecture Features That Suggest They Avoid Chaos?

Only scant data is available for transcriptional networks, and it must be interpreted with due caution since new data may, given sampling bias and artefacts, especially for nearly scale-free distributions, affect present statistics. In any case, existing data indicate that in fact the average input connectivity of GRNs is rather low, and far from $k \sim N$ which would lead to chaotic behavior. Specifically, analysis of available (partial) transcriptional networks suggest that the *input* degrees approximates an *exponential* distribution while the *output* degree distribution seems to be *scale-free* although the number of nodes are rather small to reliably identify a power-law distribution [54,82].

GRN data from *E. coli*, for which the most complete, hand-curated maps of genome-wide gene regulation exists [169] and from partial gene interaction networks from yeast, obtained mostly by chromatin-precipitation/microarray (ChIP-chip) [128], indicate that the average input connectivity (which is exponentially distributed) is below 4 [82,134,188]. A recent work on the worm *C. elegans* using the Yeast-one-hybrid system on a limited set of 72 promoters found an average of 4 DNA-binding proteins per promoter [54]. Thus, while such analyzes await correction as coverage increase, clearly, real GRNs for microbial and lower metazoan are sparse, and hence more likely to be in or near the ordered regime.

In contrast to the input, the output connectivity appears to be power-law distributed for yeast and bacteria, and perhaps also for *C. elegans*, if the low coverage of the data available so far can be trusted [54,82]. The paucity of data points precludes reliable estimates of the power-law exponents. However, the scale-free property, if confirmed for the entire GRN, may well also contribute to avoiding chaotic and increasing the ordered or critical regime [6]. Nevertheless, It is reminded here that the deeper meaning of the scale-freeness per se and its genesis (natural selection due to functionality or not) are not clear – it may be an inevitable manifestation of fundamental statistics rather than evolved under natural selection (Sect. "Evolution of Network Structure: Natural Selection or Natural Constraint?").

As for the use of Boolean functions, analysis of a set of 150 experimentally verified regulatory mechanism of well-studied promoters revealed an enrichment for canalizing functions, again, in accordance with the architecture criteria associated with ordered dynamics [86]. Similarly, when canalizing functions were randomly imposed onto the published yeast protein–protein interaction network topology to create a architecture whose dynamics was then simulated, ordered behavior was observed [113].

In this conjunction it is interesting to mention ***microRNAs*** (miRNAs), a recently discovered class of non-coding RNA which act by inhibiting gene expression at the post-transcriptional level through sequence complementarity to mRNA [41,89]. Hence, they suppress a gene independent of the TF constellation at the promoter. Thus, miRNAS epitomize the most simple and powerful molecular realization of a canalizing function. Their existence may therefore shift the network behavior from the chaotic towards the critical or ordered regime. Interestingly, RNA-based gene regulation is believed to have appeared before the metazoan radiation 1000 million years ago, and microRNAs are thought to have evolved in ancestors of Bilateria [141]. In fact, many miRNA play key roles in cell fate determination during tissue specification of development of vertebrates [41,172], and a composite feedback loop circuit involving both microRNA and TFs has been described in neutrophil differentiation [63]. The shift of network behavior from the chaotic towards the critical or ordered regime may indeed enable the coordination of complex gene expression patterns during ontogeny of multicellular systems which requires maximal information processing capacity to ensure the coexistence of stability and diversity.

There are, as mentioned in Sect. "Analyzing Network Structures", many more global and local topological features that have been found in biomolecular networks that appear to be interesting, as defined in the sense in Sect. "Network Architecture" (enriched above some null model graph). It would be interesting to test how they contribute to producing chaotic, critical or ordered behavior. The impact of most of these topology features on the global dynamics, notably the three regimes of behaviors, remains unknown, since most functional interpretation of network motifs have focused on local dynamics [9,136]. The low quality and availability of experimental data of GRN architectures opens at the moment only a minimal window into the dynamical regimes of biological networks. The improvement with respect to coverage and quality of real GRNs, to be expected in the coming years, is mostly driven by a reductionist agenda whose intrinsic aim is to exhaustively enumerate all the "pathways" that may serve "predictive modeling" of gene behaviors, as detailed in Sect. "Small Gene Circuits". However, with the concepts introduced here, a framework now exists that warrants a deeper, genome-wide analysis of the relationship between structure and biological function. Such analysis should also address the fundamental dualism between inevitable self-organization (due to intrinsic constraints from physical laws) and natural selection (of random mutants for functional advantages) [46,93,203] to ask whether criticality is self-organized (see Sect. "Evolution of Network Structure: Natural Selection or Natural Constraint?").

Experimental Evidence from Systems Biology

The experimental validation of the central concepts that were erected based on theoretical analysis of network dynamics, notably the ensemble approach of Boolean networks, amounts to addressing the following two questions:

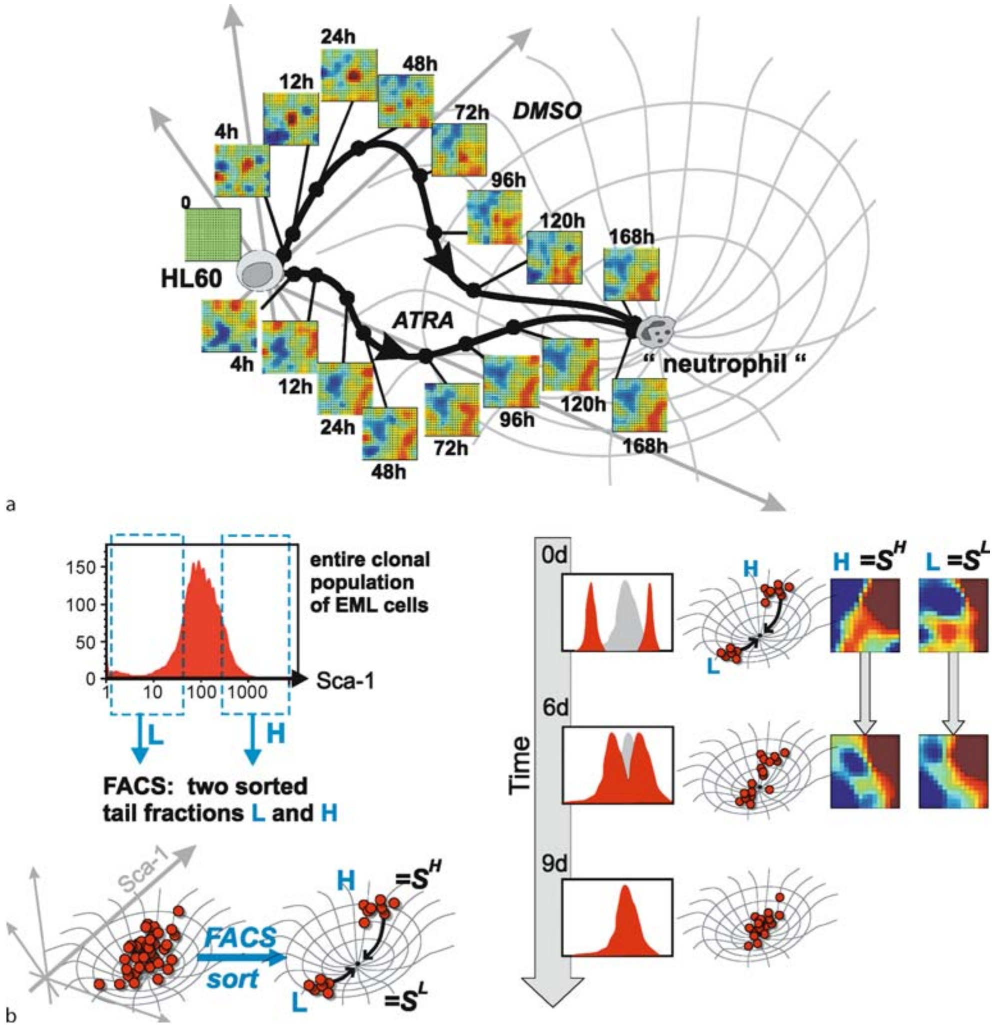
1. Are cell types attractors?
2. Is the dynamical behavior of the genomic GRN in the critical regime?

As experimental systems biology begins to reach beyond the systematic characterization of genes and their interactions it has already been possible to design experiments to obtain evidence to address these questions.

Are Cell Types Attractors?

Obviously, the observable gene expression profiles S^*, as shown in Fig. 1e, are stationary (steady) states and characteristic of a cell type. But "steady state" ($\mathrm{d}\mathbf{x}/\mathrm{d}t = 0$ in Eq. (1)) does not necessary imply a stable (self-stabilizing) attractor state that attracts nearby states. In the absence of knowledge of the architecture of the underlying GRN (we do not know the function **F** in Eq. (1)) we cannot perform the standard formal analysis, such as linear stability analysis around S^*, to determine whether a stationary state is stable or not; however, use of microarray-based expression profiling not to identify individual genes as in the gene-centered view, but in a novel integrated manner (Table 1, B3) for the analysis of $S(t)$ provides a way to address the question. The qualitative properties of an attractor offer a handle, in that a high-dimensional attractor state S^*, be it a fixed-point or a small limit cycle or even a strange attractor in the state space, requires that the volume of the states around it contracts to the attractor, i. e., $\mathrm{div}(\mathbf{F}) < 0$. [90].

Convergence of Trajectories Thus, one consequence is that trajectories emanating from states around (and near) S^* converge towards it from most (ideally, all) directions



Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination, Figure 5
Experimental evidence that a cell fate (differentiated state, cell type) is a high-dimensional stable attractor in gene expression state space. Evidence is based on convergence (**a**) from different directions of high-dimensional trajectories to the gene expression pattern of the differentiated state, or on the relaxation of states placed near the border of the basin of attraction back to the "center" of the attractor state (**b**). **a** Gene expression profile dynamics of HL60 cells treated with ATRA (all-trans retinoid acid) or DMSO (dimethylsulfoxide) at 0h to differentiate them into neutrophil-like cells. Selected gene expression profile snapshots along the trajectories shown as GEDI maps (as in Fig. 1), schematically placed along the state space trajectories. GEDI maps show the convergence of $N \sim 2800$ genes towards very similar patterns at 168h [98]. **b** Heterogeneity of a population of clonal (genetically identical) cells is exploited to demonstrate the relaxation towards the attractor state. The histogram (*top, left panel*) from flow cytometric measurement shows the inherent heterogeneity (spread) of cells with respect to stem cell marker Sca-1 expression in EML cells which cannot be attributed solely to measurement or gene expression noise but reflect metastable cell-individuality [37]. Two spontaneous "outlier" subfractions, expressing either low (L) or high (H) levels of the Sca-1, were sorted using FACS (fluorescence-activated cell sorting) and cultured independently. They represent "small perturbations" of the attractor state. Each sorted subpopulation will over a period of 5–9 days restore the parental distribution (*right panel, schematic*). Gene expression profiling (shown as as GEDI maps) reveal that the H and L subpopulations are distinct with respect not only to Sca-1 expression levels but also to that of multiple other genes. Thus, the two outlier cell fractions are at distinct states S^H and S^L in the high-dimensional state space of which Sca-1 is only one distinguishing dimension. The restoration of the parental distribution of Sca-1 is accompanied by the approaching of the two distinct gene expression profiles S^H and S^L of the spontaneously perturbed cells to become similar to each other (and to that of the parental population), indicating a high-dimensional attractor state

and in all dimensions of the state space. It is technically challenging to sample multiple high-dimensional initial states near the attractor states and demonstrate that they all converge towards S^*over time. However, the fact that the promyeloid precursor cells HL60 (a leukemic cell line) can be triggered to differentiate into mature neutrophil-like cells by an array of distinct chemical agents can be exploited [45]. This historical observation itself, without analysis of $S(t)$ by gene expression profiling, already suggests that the neutrophil state is an attractor, because it reflects robustness and means that the detailed history of how it is reached doesn't matter.

But the advent of microarray-based gene expression profiling technologies has recently opened up the possibility to show that (at least two) distinct trajectories converge towards gene expression profile of the neutrophil state S_{Neutr} if S_{Neutr} is an attractor state [98]. Thus, HL60 cells were treated with either one of two differentiation-inducing reagents, all-trans-retinoid acid (ATRA) and dimethyl sulfoxide (DMSO), two chemically unrelated compounds, and the changes of the transcriptome over time in response to either treatment were measured at multiple time intervals to monitor the two trajectories, $S^{\text{ATRA}}(t)$ and $S^{\text{DMSO}}(t)$, respectively (see Fig. 5a for details). In fact the two trajectories first diverged to an extent that the two state vectors lost most of their correlation (i. e. the two gene expression profiles $S^{\text{ATRA}}(24\,\text{h})$ and $S^{\text{DMSO}}(24\,\text{h})$ were maximally different at $t = 24$ hours after stimulation). But subsequently, they converged to very similar $S(t)$ values when the cells reached the differentiated neutrophil state for both treatments (Fig. 5a). The convergence was not complete, but quite dramatic relative to the maximally divergent state at 24 h, and was contributed by around 2800 of the 3800 genes monitored (for details see [98]). Thus, it appears that at least the artificial drug-induced differentiated neutrophil state is so stable that it can apparently orchestrate the expression of thousands of genes to produce the appropriate cell-type defining expression pattern S from quite distinct perturbed cellular states. Although only two trajectories have been measured rather than an entire state space volume, the convergence with respect to 2800 state space dimensions is strongly indicative of a high-dimensional attractor state.

Relaxation After Small Perturbations and the Problem of Cell Heterogeneity A second way to expose qualitative properties of a high-dimensional attractor S^* is to perform a weak perturbation of S^*, into a state S' near the edge of (but within) the basin of attraction (where S' should differ from S^* with respect to as many genes x_i as possible), and to observe its return of the network to S^*. This more intuitive property of an attractor state was difficult to measure because of a phenomenon often neglected by theorists and experimentalists alike: cell population heterogeneity due to "gene expression noise". Microarray measurements, as is the case with many biochemical analysis methods, require the material of millions of cells, thus the measured $S(t)$ is actually a population average. This can be problematic because the population is heterogeneous [33]: gene expression level of gene i can typically differ by as much as 100 or more fold between two individual cells within a clonal (genetically identical) population [37]. Thus, virtually all genes i exhibit a broad (log-normal) histogram (Fig. 5b, inset) when the expression level of an individual gene x_i is measured at the single-cell level across a population [38,101,129]. Such cell-to-cell variability is often explained by "gene expression noise" caused by random temporal fluctuations due to low copy numbers of specific molecules in the cell [108]. However, there may be other possibly deterministic sources that generate metastable variant cells [33,176]. Such non-genetic, enduring individuality of cells translates into the picture of a cell population forming a cloud of points in state space around the attractor S^*, in which each cell represents a single point. Application of a low dose perturbation intended to allow a system to relax back to the attractor state then will be interpreted by individual cells differently: Those positioned at the border of the cloud may be kicked out of the basin of attraction, and move to another attractor, thus masking the trajectory of relaxation. In fact, single-cell resolution measurements of the response to low dose stimulation in cell populations confirmed this picture of heterogeneity, in that a differentiation inducer given at low dose to trigger a partial response (weak perturbation) produced a bimodal distribution of gene expression of differentiation markers: Some cells differentiated, other did not [38].

However, the spontaneous heterogeneity eo ipso, consisting of transient but persistent variant cells within a population [37], allows us to demonstrate the relaxation to the attractor when single cell-level manipulation and analysis are performed: Physical isolation of the population fractions at two opposite the edge of the cloud (basin of attraction), based on one single state space dimension x_k can substitute for the weak perturbation that places cells to the border of a basin (see Fig. 5b for details). Indeed such "outlier" population fractions exhibited not only distinct levels of x_k expression but also globally distinct gene expression profiles (despite being members of the same clonal population). Cells of both outlier fractions eventually "flowed back" to populate the state space region around the attractor state and restored the original distribution (shape of the cloud) [37]. The time scale of this relaxation (>5 days) was similar to that for the HL60 cells to converge to the attractor of the differentiated neutrophils. This result is summarized in Fig. 5b. Again, the spontaneous regeneration of the distinct gene expression profile of a macroscopically observable cell phenotype, consisting of thousands of genes, supports the notion of a high-dimensional attractor in gene expression space that maps into a distinct, observable cell type.

Are Gene Regulatory Networks in Living Cells Critical?

The second central question we ask in this article is whether GRNs produce a global dynamics that is in the critical regime (Sect. "Three Regimes of Behaviors for Boolean Networks"). This question is not as straightforward to address experimentally. First, the notion of order, chaos and criticality are defined in the models as properties of network ensembles. Second, it is cumbersome to sample a large number of pairs of initial states and monitor their high-dimensional trajectories to determine whether they on average converge, diverge or stay "parallel".

As mentioned earlier (Sect. "Dynamics in Boolean Networks"), one approach for obtaining a first glimpse of an idea as to whether real networks are critical or not was recently proposed by Aldana and coworkers [19] and refs. herein): They "imposed" a dynamics onto real biological networks, for which only the topology but not the interaction functions are known, by treating them as Boolean networks, whereby the Boolean functions were guessed or randomly assigned according to some rules. Such studies suggest that these networks, given their assumed topologies, are in the critical regime.

To more directly characterize the observed dynamics of natural systems in terms of the three regimes, several indirect approaches have been taken. These strategies are based on novel measurable quantities computed from several schemes of microarray experiments that are now available but were not originally generated with an intention to answer this question. By first determining in simulated networks whether that quantity is associated also with criticality in silico, inference is then made as to what regime of system behavior the observed system resembles. Three such pieces of evidence provide a first hint that perhaps, living cells may indeed be in the critical regime:

(i) Gene expression profile changes during Hela cell cycle progression was compared with the detailed temporal structure of the updating of network states in Boolean networks. Tithe discretized real gene expression data of cells progressing in the cell cycle were compared with that of simulated state cycles of random Boolean networks in the three regimes in terms of the Lempev-Zip complexity of time series. This led to the conclusion that the dynamical behavior of thousands of genes was most consistent with either ordered or critical behavior, but not chaotic behavior [174].

(ii) A striking property predicted from analysis of simulated critical Boolean networks is that if a randomly selected gene is deleted and the number of other genes that change their expression as a consequence of that single-gene deletion ("avalanche size") is measured, and such single-gene deletion experiments is repeated many times, the avalanche-sizes will exhibit a power law distribution with a slope of $-\gamma = 1.5$. This specific behavior is only seen in critical networks. Analysis of just such data for over 200 single deletion mutants in yeast [163] from the experiments reported by Hughes et al. [100]was recently performed. It was found that the distribution of the avalanche sizes not only approached a power law, but that the slope was also -1.5 [163]. This result was insensitive to altering the criterion for defining a "change in gene activity" from two-fold to five fold in calculating the avalanche size.

(iii) A more direct determination of the regime of network dynamics was recently reported, in which an analogous analysis as the Derrida plot (see Sect. "Ordered and Chaotic Regimes of Network Behavior") was performed [153]. Macrophage gene expression profiles were measured at various time points in response to various perturbations (= stimulation of Toll-like receptors with distinct agents), offering a way to measure the time evolution of a large number of similar initial states. Here, instead of the Hamming distance the normalized compression distance NCD (as mentioned in Sect. "Ordered and Chaotic Regimes of Network Behavior") was used to circumvent the problems associated with Derrida curves. The results were consistent with critical dynamics, in that on average, for many pairs of initial states, their distance at time t and $t + \Delta t$ was on average equal, thus neither trajectory convergence nor divergence took place.

Future Directions and Questions

The ideas of a state space representing the dynamics of the network, and of its particular structure that stems from the constraints imposed by the regulatory interactions and can be epitomized as an 'epigenetic landscape', serve as a conceptual bridge linking network architecture with the observable biological behavior of a cell. In this framework, the attractors (valleys) are disjoint regions in the state space landscape and represent cell fates and cell types. One profound and bold hypothesis is that for networks to have a landscape with attractors that optimally convey cell lineage identity and robustness of their gene expression profile, yet allow enough flexibility for cell phenotype switches during development, the networks must be poised at the boundary between the chaotic and the ordered regime. Such critical networks may be a universal property of networks that have maximal information processing capacity. But what can we naturally do with this conceptual framework presented here? And what are the next questions to ask for the near future?

Clearly, new functional genomics analysis techniques will soon advance the experimental elucidation of the architecture of the GRN of various species, including that of metazoan organisms. This will drastically expand the opportunities for theoretical analysis of the architecture of networks and finally afford a much closer look at the dynamics without resorting to simulated network ensembles.

However, beyond network analysis in terms of mathematical formalisms, the concepts of integrated network dynamics presented here should also pave the way for a formal rather than descriptive understanding of tissue homeostasis and development as well as diseases, such as cancer. One corollary of the idea that cell types are attractors is that cancer cells are also attractors – which are lurking somewhere in state space (near embryonic or stem cell attractors) and are normally avoided by the physiological developmental trajectories. They become accessible in pathological conditions and trap cells in them, preventing terminal differentiation (this idea is discussed in detail in [33,96]).

Such biological interpretation of the concepts presented here will require that these concepts be expanded to embrace the following aspects of dynamical biological systems that are currently not well understood but can already be framed:

Attractor Transitions and Development

If cell fates are attractors, then development is a flow in state space trajectories which then represent the developmental trajectories. But how do cells, e. g., a progenitor cell committing to a particular cell fate, move from one attractor to another? Currently, two models are being envisioned for the "flow between attractors" that constitutes developmental paths in the generation of the multi-cellular organisms:

(i) In one model, stimulated by the studies in Boolean networks, the cell "jumps" from one attractor to another in response to a distinct perturbation (e. g., developmental signal) which is represented as the imposed alteration of the expression status of a set of genes ("bit-flipping" in binary Boolean networks). This corresponds to the displacement of the network state $S(t)$ by an external influence to a new position in the basin of another attractor.

(ii) The second model posits that the landscape changes, and has its roots in the classical modeling of nonlinear dynamical systems: For instance, the attractor of the progenitor cell (valley) may be converted into an unstable steady-state point (hill top) at which point the network (cell) will spontaneously be attracted by either of the two attractors on each side of the newly formed hill. This is exemplified in a model for fate decision in bipotent progenitor cells in hematopoiesis [99]. In this model, a change of the landscape structure ensues from a change in the network architecture caused by the slow alteration of the value of a system parameter that controls the interaction strength in the system equations (see Sect. "Small Gene Circuits"). Thus, the external signal that triggers the differentiation exerts its effect by affecting the system parameters. Increasing the decay rates of x_1 and x_2 in the example of Fig. 3b will lead to the disappearance of the central attractor and convert the tristable landscape of Fig. 3b to the bistable one of Fig. 3a [99]. Such qualitative changes that occur during the slow increase or decrease of a system parameter are referred to as a ***bifurcation***. Note that this second model takes a narrower view, assuming that the network under study is not the global, universal and fixed network of the entire genome, as discussed in Sect. "Complex Networks", but rather a subnetwork that can change its architecture based on the presence or absence of gene products of genes that are outside of the subnetwork.

Noisy Systems

In a bistable switching system, it is immediately obvious that random fluctuations in x_i due to "gene expression noise" may trigger a transition between the attractors and thus, explain the stochastic phenotype transitions, as has been recently shown for several micro-organismal systems and discussed for mammalian cell differentiation [87,97, 101,108]. The observed heterogeneity of cells in a nominally identical cell population,caused either by "gene expression noise" or other diversifying processes, such as the random partitioning of molecules at cell divisions, implies that cell states cannot be viewed as deterministic points and trajectories in the state space, but rather as moving "clouds" – held together by the attractors.

More recently, on the basis of such bistable switches, it has even been proposed and shown in synthetic networks that environmental bias in fluctuation magnitude may explicitly control the switch to the physiologically favorable attractor state – because gene expression noise may be higher (relative to the deterministically controlled expression levels) when cells are in the attractor that dictates a gene expression pattern that is incompatible with a given environment [110]. Such biased gene expression noise thus may drive the flow between the attractors, and hence, (on average) guide the system through attractor transitions to produce various cell fates in a manner that is commensurate with development of the tissue. On the other hand, it may also explain the local stochasticity of cell fate decisions observed for many stem and progenitor cells.

Directionality

The concepts of cell fates and cell types as attractors, as well as any mechanisms that explains attractor transitions during development and differentiation, do not explain the overall directionality of development, or the "*arrow of time*" in ontogenesis: Why is development essentially a one-way process, i. e., irreversible in time, given that the underlying regulatory events, the switching ON or OFF of genes, are fully reversible? Where does the overall slope (from back to front) in Waddington's epigenetic landscape (Fig. 2g) come from? One idea is that "gene expression noise" may play the role of thermal noise (heat) in thermodynamics in explaining the irreversibility of processes. Alternatively, the network could be specifically wired, perhaps through natural selection so that attractor transitions are highly biased for one direction.

Beyond Cell Autonomous Processes

To understand development we need of course to open our view beyond the cell autonomous dynamics of GRNs. Some of the genes expressed in particular states $S(t)$ encode secreted proteins that affect the gene expression hence, state $S(t)$ of neighboring cells. Such inter-cell communication establishes a network at a higher level, with its own constrained dynamics that need to be incorporated in the models of developmental trajectories in gene expression state space.

Evolution

As discussed several times in this article, when networks are studied in the light of evolution, a central question arises: how do mutations, which essentially rewire the network by altering the nature of regulatory interactions, give rise to the particular architecture of the GRN that we find today? What are the relative roles in shaping particular network architectures, of (*i*) constraints due to physical (graph-theoretical) laws and self-organization vs. that of (*ii*) natural selection for functionality? If selection plays a major role, can it select for such features as the global landscape structure, or even for criticality? Or can the latter even "self-organize" without adaptive selection [31]? Such questions go far beyond the current analysis of Darwinian mechanisms of robustness and evolvability of networks. They are at the heart of the quest in biocomplexity research for fundamental principles of life, of which the process of natural selection itself is a just subset.

Regulatory networks offer a accessible and formalizable object of study to begin to ask these questions.

Complexity in Earthquakes, Tsunamis, and Volcanoes, and Forecast, Introduction to

William H. K. Lee
US Geological Survey (Retired), Menlo Park, USA

Article Outline

This Introduction is intended to serve as a 'road map' for readers to navigate through the 42 Encyclopedia articles on earthquakes, tsunamis, and volcanoes. Selecting the topics and authors was somewhat subjective, as it is not possible to cover the vast existing literature with only 42 articles. They are, however, representative of the wide range of problems investigated in connection with these natural phenomena. I will introduce these articles by grouping them into sections and then into subsections. However, some articles belong to more than one section or one subsection, reflecting the inter-related nature of earthquakes, tsunamis and volcanoes. For the benefit of the readers, I will point to certain issues discussed in some of the articles which, in my view, have not been settled completely. I have also taken the liberty of quoting or paraphrasing sentences from many of these articles when introducing them, but I do not claim to be accurate. It is best for these articles to speak for themselves.

I wish to thank Bernard Chouet for helping me in planning and reviewing the manuscripts of the volcanoes section. I am grateful to Bernard Chouet, Edo Nyland, Jose Pujol, Chris Stephens, and Ta-liang Teng for their helpful comments that greatly improved this manuscript.

Introduction

Earthquakes, tsunamis, and volcanic eruptions are complex and often inter-related natural phenomena with disastrous impact to society rivaling those caused by the worst floods or storms. The 1556 Huaxian earthquake in the Shansi province of China claimed over 830,000 lives. The total economic loss of the 1995 Kobe earthquake in Japan was estimated at US $200 billion. The 2004 Indian Ocean tsunami (triggered by the Sumatra–Andaman earthquake of December 26) bought devastation thousands of miles away with fatalities exceeding 280,000. The 79 AD eruption of Mount Vesuvius near Naples, Italy buried the towns of Pompeii and Herculaneum. The 1902 eruption of Mount Pelée, Martinique, totally destroyed the town of St. Pierre.

Insurance companies classify major natural catastrophes as storms, floods, or earthquakes (including tsunamis, and volcanic eruptions). Since 1950, about 2.5 million people have died due to these catastrophes and overall economic losses have totaled about US $2 trillion in current dollar values. Earthquakes, tsunamis, and volcanic eruptions have accounted for about half of the fatalities and more than one third of the total economic losses. Geoscientists have attempted to predict these events, but with limited success. There are many reasons for such slow progress: (1) systematic monitoring of earthquakes, tsunamis and volcanoes requires large capital investment for instruments and very long-term support for operation and maintenance; (2) catastrophic earthquakes, tsunamis and volcanic eruptions occur rarely, and (3) politicians and citizens are quick to forget these hazards in the face of other more frequent and pressing issues. But with continuing rapid population growth and urbanization, the loss potential from these natural hazards in the world is quickly escalating.

With advances in nonlinear dynamics and complexity studies, geoscientists have applied modern nonlinear techniques and concepts such as chaos, fractal, critical phenomena, and self-organized criticality to the study of earthquakes, tsunamis and volcanoes. Here we sample these efforts, mainly in seismicity modeling for earthquake prediction and forecast, along with articles that review recent progress in studying earthquakes, tsunamis, and volcanoes. Although predictability is desirable, it is also possible to reduce these natural hazards with more practical approaches, such as early warning systems, hazard analysis, engineering considerations, and other mitigation efforts. Several articles in this Encyclopedia discuss these practical solutions.

Earthquakes

When a sudden rupture occurs in the Earth, seismic waves are generated. When these waves reach the Earth's surface, we may feel them as a series of vibrations, which we call an earthquake. Instrumental recordings of earthquakes have been made since the latter part of the 19th century by seismographic stations and networks from local to global scales. The observed data have been used, for example, (1) to compute the source parameters of earthquakes, (2) to determine the physical properties of the Earth's interior, (3) to test the theory of plate tectonics, (4) to map active faults, (5) to infer the nature of damaging ground shaking, (6) to carry out seismic hazard analyzes, and (7) to predict and forecast earthquakes. A satisfactory theory of the complex earthquake process has not yet been achieved, and realistic equations for modeling earthquakes do not exist at present. There is, however, good progress towards a physical foundation for the earthquake source process, partly as a result of research directed toward earthquake prediction.

Earthquake Monitoring, and Probing the Earth's Interior

Earthquakes are complex natural phenomena, and their monitoring requires an interdisciplinary approach, including using tools from other scientific disciplines and engineering. In ► Earthquake Monitoring and Early Warning Systems, W.H.K. Lee and Y.M. Wu presented a summary of earthquake monitoring, a description of the products derived from the analysis of seismograms, and a discussion of the limitations of these products. The basic results of earthquake monitoring are summarized in earthquake catalogs, which are lists of origin time, hypocenter location, and magnitude of earthquakes, as well as other source parameters. Lee and Wu describe the traditional earthquake location method formulated as an inverse problem. In ► Earthquake Location, Direct, Global-Search Methods, Lomax et al. review a different approach using direct-search over a space of possible locations, and discuss other related algorithms. Direct-search earthquake location is important because, relative to the traditional linearized method, it is both easier to apply to more realistic Earth models and is computational more stable. Although it has not been widely applied because of its computational demand, it shows great promise for the future as computer power is advancing rapidly.

The most frequently determined parameter after 'location' is 'magnitude', which is used to characterize the 'size' of an earthquake. A brief introduction to the quantification of earthquake size, including magnitude and seismic moment, is given in ► Earthquake Monitoring and Early Warning Systems by Lee and Wu. Despite its various limitations, magnitude provides important information concerning the earthquake source. Magnitude values have an immense practical value for realistic long-term disaster preparedness and risk mitigation efforts. A detailed review, including current practices for magnitude determinations, appears in ► Earthquake Magnitude by P. Bormann and J. Saul.

Besides computing earthquake source parameters, earthquake monitoring also provides data that can be used to probe the Earth's interior. In ► Tomography, Seismic, J. Pujol reviews a number of techniques designed to investigate the interior of the Earth using arrival times and/or waveforms from natural and artificial sources. The most common product of a tomographic study is a seismic velocity model, although other parameters, such as attenuation and anisotropy, can also be estimated. Seismic tomography generally has higher resolution than that provided by other geophysical methods, such as gravity and magnetics, and furnishes information (1) about fundamental problems concerning the internal structure of the Earth on a global scale, and (2) for tectonic and seismic hazard studies on a local scale.

In ► Seismic Wave Propagation in Media with Complex Geometries, Simulation of, H. Igel et al. present the state-of-the-art in computational wave propagation. They point to future developments, particularly in connection with the search for efficient generation of computational grids for models with complex topography and faults, as well as for the combined simulation of soil-structure interactions. In addition to imaging subsurface structure and earthquake sources, 3-D wave simulations can forecast strong ground motions from large earthquakes. In the absence of deterministic prediction of earthquakes, the calculation of earthquake scenarios in regions with sufficiently well-known crustal structures and faults will play an important role in assessing and mitigating potential damage, particularly those due to local site effects.

In addition to the classical parametrization of the Earth as a layered structure with smooth velocity perturbation, a new approach using scattered waves that reflect Earth's heterogeneity is introduced by H. Sato in his article on ► Seismic Waves in Heterogeneous Earth, Scattering of. For high-frequency seismograms, envelope characteristics such as the excitation level and the decay gradient of coda envelopes and the envelope broadening of the direct wavelet are useful for the study of small-scale inhomogeneities within the Earth. The radiative transfer theory with scattering coefficients calculated from the Born approximation and the Markov approximation for the parabolic wave equation are powerful mathematical tools for these analyzes. Studies of the scattering of high-frequency seismic waves in the heterogeneous Earth are important for understanding the physical structure and the geodynamic processes that reflect the evolution of the solid Earth.

Earthquake Prediction and Forecasting

A fundamental question in earthquake science is whether earthquake prediction is possible. Debate on this question has been going on for decades without clear resolution. Are pure observational methods without specific physical understanding sufficient? Earthquakes have been instrumentally monitored continuously for about 100 years (although not uniformly over the Earth), but reliable and detailed earthquake catalogs cover only about 50 years. Consequently, it seems questionable that earthquakes can be predicted solely on the basis of observed seismicity patterns, given that large earthquakes in a given region have recurrence intervals ranging from decades to centuries or longer. Despite progress made in earthquake physics, we are still not able to write down all the governing equations for these events and lack sufficient information about the Earth's properties. Nevertheless, many attempts have been and are being made to predict and forecast earthquakes. In this section, several articles based on empirical and physics-based approaches will be briefly introduced.

In ▶ Geo-complexity and Earthquake Prediction, V. Keilis-Borok et al. present an algorithmic prediction method for individual extreme events having low probability but large societal impact. They show that the earthquake prediction problem is necessarily intertwined with problems of disaster preparedness, the dynamics of the solid Earth, and the modeling of extreme events in hierarchical complex systems. The algorithms considered by Keilis-Borok et al. are based on premonitory seismicity patterns and provide alarms lasting months to years. Since the 1990s, these alarms have been posted for use in testing such algorithms against newly occurred large earthquakes. Some success has been achieved, and although the areas for the predicted earthquakes are very large and the predicted time windows are very long, such predictions can be helpful for the officials and the public to undertake appropriate preparedness.

Stochastic models are a practical way of bridging the gap between the detailed modeling of a complex system and the need to fit models to limited data. In ▶ Earthquake Occurrence and Mechanisms, Stochastic Models for, D. Vere-Jones presents a brief account of the role and development of stochastic models of seismicity, from the first empirical studies to current models used in earthquake probability forecasting. The author combines a model of the physical processes generating the observable data (earthquake catalogs) with a model for the errors, or uncertainties, in our ability to predict those observables.

D.A. Yuen et al. propose the use of statistical approaches and data-assimilation techniques to earthquake forecasting in their article on ▶ Earthquake Clusters over Multi-dimensional Space, Visualization of. The nature of the spatial-temporal evolution of earthquakes may be assessed from the observed seismicity and geodetic measurements by recognizing nonlinear patterns hidden in the vast amount of seemingly unrelated data. The authors endeavor to bring across the basic concept of clustering and its role in earthquake forecasting, and conclude that the clustering of seismic activity reflects both the similarity between clusters and their correlation properties.

In ▶ Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, G. Zoeller et al. present a combined approach to understanding seismicity and the emergence of patterns in the occurrence of earthquakes based on numerical modeling and data analysis. The discussion and interpretation of seismicity in terms of statistical physics leads to the concept of 'critical states', i. e. states in the seismic cycle with an increased probability for abrupt changes involving large earthquakes. They demonstrate that numerical fault models are valuable for understanding the underlying mechanisms of observed seismicity patterns, as well as for practical estimates of future seismic hazard.

D. Sornette and M.J. Werner in ▶ Seismicity, Statistical Physics Approaches to stress that the term 'statistical' in 'statistical physics' has a different meaning than as used in 'statistical seismology'. Statistical seismology has been developed as a marriage between probability theory, statistics, and earthquake occurrences without considerations of earthquake physics. In statistical physics approaches to seismicity, researchers strive to derive statistical models from microscopic laws of friction, damage, rupture, etc. Sornette and Werner summarize some of the concepts and tools that have been developed, including the leading theoretical physical models of the space-time organization of earthquakes. They then present several examples of the new metrics proposed by statistical physicists, underlining their strengths and weaknesses. They conclude that a holistic approach emphasizing the interactions between earthquakes and faults is promising, and that statistical seismology needs to evolve into a genuine physically-based statistical physics of earthquakes.

In ▶ Earthquake Networks, Complex, S. Abe and N. Suzuki discuss the construction of a complex earthquake network obtained by mapping seismic data to a growing stochastic graph. This graph, or network, turns out to exhibit a number of remarkable physical and mathematical behaviors that share common traits with many other complex systems. The scale-free and small-world natures are typical examples in complex earthquake networks.

Electromagnetic phenomena associated with earthquakes, such as earthquake light have been reported throughout almost all human history. Until rather recently, however, most such observations were unreliable and best described as folklore. In ▶ Earthquakes, Electromagnetic Signals of, S. Uyeda et al. summarize the scientific search for electromagnetic precursors for earthquake prediction. The presumption is that since earthquakes occur when slowly increasing tectonic stress in the Earth's crust reaches a critical level; the same stress may give rise to some electromagnetic phenomena. Research on possible relationships was initiated in several countries around the world in the 1980s. Two main approaches are (1) the monitoring of possible emissions from focal regions in a wide range of frequency from DC to VHF, and (2) the monitoring of possible anomalies in the transmission of man-made electromagnetic waves of various frequencies over focal regions. Despite much circumstantial evidence, earthquake-related electromagnetic signals, in particular those at a pre-seismic stage are not yet widely accepted to be associated with earthquakes.

Observational programs focused on searching for reliable precursory phenomena in seismicity, seismic velocities, tilt and strain, electromagnetic signals, chemical emissions and animal behavior, claim some successes but no systematic precursors have been identified. In ▶ Earthquake Forecasting and Verification, J.R. Holliday et al. stress that reliable earthquake forecasting will require systematic verification. They point out that although earthquakes are complex phenomena, systematic scaling laws such as the Gutenberg–Richter frequency-magnitude relation have been recognized. The Gutenberg–Richter relation is given by: $\log N(M) = a - bM$, where M is the earthquake magnitude, $N(M)$ is the number of earthquakes with magnitude greater than or equal to M, and a and b are constants. Since $b \approx 1$, this means that the number of earthquakes increase tenfold for each decrease of one magnitude unit. This suggests that *large* earthquakes occur in regions where there are large numbers of *small* earthquakes. On this basis, the regions where large earthquakes will occur can be forecast with considerable accuracy, but the Gutenberg–Richter relation provides no information about the precise occurrence times.

Earthquake Engineering Considerations and Early Warning Systems

Since seismic hazards exist in many regions of the world, three major strategies are introduced to reduce their societal impacts: (1) to avoid building in high seismic-risk areas, (2) to build structures that can withstand the effects of earthquakes, and (3) to plan for earthquake emergencies. The first strategy is not very practical because, with rapid population growth, many economically productive activities are increasingly located in high seismic-risk areas. However, by mapping active faults and by studying past earthquakes, we may estimate the risk potential from earthquakes and plan our land use accordingly. The second strategy depends on the skills of engineers, and also requires seismologists to provide realistic estimates of the ground motions resulting from expected earthquakes. The third strategy includes attempting to predict earthquakes reliably well in advance to minimize damage and casualties, and also requires the cooperation of the entire society. Although we are far from being able to predict earthquakes reliably, earthquake early warning systems can provide critical information to reduce damage and causalities, as well as to aid rescuing and recovery efforts.

Accurate prediction of the level and variability of near-source strong-ground motions in future earthquakes is one of the key challenges facing seismologists and earthquake engineers. The increasing number of near-source recordings collected by dense strong-motion networks exemplifies the inherent complexity of near-field ground shaking, which is governed by a number of interacting physical processes. Characterizing, quantifying, and modeling ground-motion complexity requires a joint investigation of (1) the physics of earthquake rupture, (2) wave-propagation in heterogeneous media, and (3) the effects of local site conditions. In ▶ Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, P.M. Mai discusses briefly the beginnings of strong-motion seismology and the recognition of ground-motion complexity. Using two well-recorded recent earthquakes, the author introduces the observational aspects of near-field ground shaking and describes the basic mathematical tools used in the computation of ground motion. The key elements for characterizing and modeling ground-motion complexity are also explained, supplemented by a concise overview of the underlying physical processes.

With increasing urbanization worldwide, earthquake hazards pose ever greater threats to lives, property, and livelihoods in populated areas near major active faults on land or near offshore subduction zones. Earthquake early-warning (EEW) systems can be useful tools for reducing the impact of earthquakes, provided that the populated areas are favorably located with respect to earthquake sources and their citizens are properly trained to respond to the warning messages. Under favorable conditions, an EEW system can forewarn an urban population of impending strong shaking with lead times that range from a few seconds to a few tens of seconds. A lead time is the time interval between issuing a warning and the arrival of the *S*- and surface waves, which are the most destructive due to their large amplitudes. Even a few seconds of advance warning is useful for pre-programmed emergency measures at various critical facilities, such as the deceleration of rapid-transit vehicles and high-speed trains, the orderly shutoff of gas pipelines, the controlled shutdown of some high-technological manufacturing operations, the safe-guarding of computer facilities, and bringing elevators to a stop at the nearest floor.

Recent advances in early warning methodologies are summarized by W.H.K Lee and Y.M. Wu in the second part of their article, ► Earthquake Monitoring and Early Warning Systems. In ► Earthquake Early Warning System in Southern Italy, A. Zollo et al. analyze and illustrate the main scientific and technological issues related to the implementation and management of the earthquake early warning system under development in the Campania region of southern Italy. The system is designed to issue alerts to distant coastal targets using data from a dense seismic network deployed in the Apennine belt region. The authors note that earthquake early warning systems can also help mitigate the effects of earthquake-induced disasters such as fires, explosions, landslides, and tsunamis. Earthquake early warning systems can be installed at relatively low cost in developing countries, where even moderate-size earthquakes can cause damage comparable to that caused by much larger earthquakes in developed countries.

Nonlinear problems in structural earthquake engineering deal with the dynamic response of meta-stable, man-made buildings subjected to strong earthquake shaking. During earthquakes, structures constructed on soft sediments and soils deform together with the underlying soil. Strong shaking forces the soil-structure systems to evolve through different levels of nonlinear response, with continuously changing properties that depend upon the time history of excitation and on the progression and degree of damage. In ► Earthquake Engineering, Non-linear Problems in, M.D. Trifunac first briefly discuss the literature on complex and chaotic dynamics of simple mechanical oscillators, and then introduces the dynamic characteristics and governing equations of the meta-stable structural dynamics in earthquake engineering. He describes the nature of the solutions of the governing equations in terms of both the vibrational and the wave representations. The author also addresses the dynamic instability, material and geometric nonlinearities, and complexities of the governing equations associated with nonlinear soil-structure interaction.

Structural health monitoring and structural damage detection refers to the processes of determining and tracking the structural integrity and assessing the nature of damage in a structure. An important and challenging problem is being able to detect the principal components of damage in structures (as they occur during or soon after the earthquake) before physical inspection. In the article, ► Earthquake Damage: Detection and Early Warning in Man-Made Structures, M.I. Todorovska focuses on global methods and intermediate-scale methods, which can point to the parts of the structure that have been damaged. Recently, structural identification and health monitoring of buildings based on detecting changes in wave travel time through the structure has received renewed attention and has proven to be very promising.

Earthquake Physics

Brittle deformation, which is the primary mode of deformation of the Earth's crust in response to tectonic stress, is manifested by faulting at the long timescale and by earthquakes at the short timescale. It is one of the best-known examples of a system exhibiting self-organized criticality. A full understanding of this system is essential for evaluating earthquake hazards, but our current understanding is sketchy. In ► Brittle Tectonics: A Non-linear Dynamical System, C.H. Scholz shows that an earthquake dynamic system has two characteristic length scales, W^* and W^{**}. An earthquake nucleates within the seismogenic zone and initially propagates in all directions along its perimeter, acting as a 3D crack. When its dimension exceeds W^*, the rupture is restricted to propagating in the horizontal direction, acting as a 2D crack. Thus a symmetry breakage occurs at the dimension W^*. *Small* earthquakes, with dimensions smaller than W^*, are not self-similar with *large* earthquakes, those with lengths larger than W^*. The same occurs for suprafaults at the dimension W^{**} (a suprafault is the shear relaxation structure that includes a fault and its associated ductile shear zone).

Earthquake prediction is desirable for reducing seismic hazards, but we lack an understanding of how and why earthquakes begin and grow larger or stop. Theoretical and laboratory studies show that a quasi-static rupture growth precedes dynamic rupture. Thus, detecting the quasi-static rupture growth may lead to forecasting the subsequent dynamic rupture. In ► Earthquake Nucleation Process, Y. Iio reviews studies that analyze the early portions of observed waveforms, and summarizes what we presently understand about earthquake nucleation process. An earthquake initiates over a small patch of a fault, and then their rupture fronts expand outward until they stop. Some large earthquakes have a rupture extent greater than 1000 km, while fault lengths of small microearthquakes range over only a few meters. Surprisingly, the concept that earthquakes are self-similar is widely accepted despite fault length ranging over 6 orders of magnitude. One example of such similarity is the proportionality of average fault slip to fault length, which implies a constant static stress drop, independent of earthquake size.

The self-similarity law raises a fundamental question, namely what is the difference between large and small earthquakes? One end-member model represents earthquakes as ruptures that grow randomly and then terminate at an earlier stage for smaller earthquakes, but continue longer for larger earthquakes. This type of model has been proposed mainly to explain the frequency–magnitude distribution of earthquakes (the Gutenberg–Richter relation), but it implies that it is impossible to forecast the final size of an earthquake at the time the rupture initiates. However, the other end-member model predicts that larger earthquakes have a larger 'seed' than smaller earthquakes, and that large and small earthquakes are different even at their beginnings.

Geoscientists have long sought an understanding of how earthquakes interact. Can earthquakes trigger other earthquakes? The answer is clearly yes over short time and distance scales, as in the case of mainshock–aftershock sequences. Over increasing time and distance scales, however, this question is more difficult to answer. In ▶ Earthquakes, Dynamic Triggering of, S.G. Prejean and D.P. Hill explore the most distant regions over which earthquakes can trigger other earthquakes. This subject has been the focus of extensive research over the past twenty five years, and offers a potentially important key to improving our understanding of earthquake nucleation. In this review, the authors discuss physical models and give a description of documented patterns of remote dynamic triggering.

Models of the earthquake source have been successfully used in predicting many of the general properties of seismic waves radiated from earthquakes. These general properties can be derived from a simple omega-squared spectral shape. In ▶ Earthquake Scaling Laws, R. Madariaga derives general expressions for energy, moment and stress in terms of measured spectral parameters, and shows that earthquake sources can be reduced to a single family with the three parameters of moment, corner frequency and radiated energy. He suggests that most of the properties of the seismic spectrum and slip distribution can be explained by a simple crack model. Whether an earthquake is modeled as a simple circular crack or as a complex distribution of such cracks, the result is the same.

In ▶ Earthquake Source: Asymmetry and Rotation Effects, R. Teisseyre presents a consistent theory describing an elastic continuum subjected to complex internal processes, considers all the possible kinds of the point-related motions and deformations, and defines a complex rotation field including spin and twist. Also included in the discussion is a new description of the source processes, including the role of rotation in source dynamics, an explanation of co-action of the slip and rotation motions, and a theory of seismic rotation waves. Rotational seismology is an emerging field, and a progress report is provided in the Appendix in ▶ Earthquake Monitoring and Early Warning Systems by W.H.K. Lee and Y.M. Wu.

Some New Tools to Study Earthquakes

The Global Positioning System (GPS) is a space-based Global Navigation Satellite System. Using signals transmitted by a constellation of GPS satellites, the positions of ground-based receivers can be calculated to high precision, making it possible to track relative movements of points on the Earth's surface over time. Unlike older geodetic surveying methods (which involved periodically but infrequent measuring angles, distances, or elevations between points), GPS can provide precise 3-D positions over a range of sampling rates and on a global scale. GPS equipment is easy to use and can be set up to collect data continuously. Since its early geophysical applications in the mid-1980s, this versatile tool, which can be used to track displacements over time periods of seconds to decades, has become indispensable for crustal deformation studies, leading to many important insights and some surprising discoveries. In ▶ GPS: Applications in Crustal Deformation Monitoring, J. Murray-Moraleda focuses on applications of GPS data to the studies of tectonic, seismic, and volcanic processes. The author presents an overview of how GPS works and how it is used to collect data for geophysical studies. The article also describes a variety of ways in which GPS data have been used to measure crustal deformation and investigate the underlying processes.

The concept of a seismic cycle involves processes associated with the accumulation and release of stress on seismogenic faults, and is commonly divided into three intervals: (1) the coseismic interval for events occurring during an earthquake, (2) the postseismic interval immediately following an earthquake, and (3) the interseismic period in between large earthquakes. In ▶ Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, R. Lohman explores how we can draw conclusions about fault zone slip at depths far greater than are directly accessible to us, based on how the Earth's surface deforms during, before, and after earthquakes.

Atmospheric sound can be radiated by the displacement or rupture of the Earth's surface induced by earthquakes, tsunamis, and volcanoes, and by the flow and excitation of fluids during volcanic eruptions. These complex and potentially cataclysmic phenomena share some common physics, yet represent different ways of converting energy into atmospheric sound. In ▶ Infrasound from Earthquakes, Tsunamis and Volcanoes, M. Garces and A. LePichon discuss some of the signal features unique to earthquakes, tsunamis, and volcanoes captured by the present generation of infrasound arrays. They also discuss contemporary methods for the analysis, interpretation, and modeling of these diverse signals, and consider some of the associated geophysical problems that remain unsolved.

Tsunamis

Tsunamis are oceanic gravity waves generated by seafloor deformation due to earthquakes, volcanic eruptions, landslides, or asteroid impacts. Earthquake tsunamis, such as the 2004 Indian Ocean tsunami (caused by the Sumatra–Andaman earthquake of December 26), are the most frequent type of tsunamis. However, large volcanic eruptions, such as the 1883 Krakatau eruption (in the Sunda strait between the islands of Java and Sumatra) also cause ocean-wide tsunamis. Landslides (which are often triggered by earthquakes) cause large tsunamis locally, but their effects are usually limited to the immediate vicinity of the source.

Modeling: Forward and Inverse Approaches

Forward-modeling of a tsunami starts from given initial conditions, computes its propagation in the ocean, and calculates the tsunami arrival times and/or water run-up heights along the coasts. Once the initial conditions are provided, the propagation and coastal behavior can be numerically computed for an actual bathymetry. These calculations are useful for early tsunami warning and for detailed hazard estimations. However, the initial conditions associated with tsunami generation processes are still poorly known, because large tsunamis are rare and the tsunami generation in the open ocean is not directly observable. Currently, the tsunami source is estimated indirectly, mostly on the basis of seismological analysis, but a more direct estimation of the tsunami source is essential to better understand the tsunami generation process and to more accurately forecast the effects of a tsunami along the coasts.

In ▶ Tsunamis, Inverse Problem of, K. Satake reviews inverse methods used in the quantification of tsunami sources from the observations. The author describes the tsunami generation by earthquakes, with an emphasis on the fault parameters and their effects on tsunami propagation, including shallow water theory and numerical computation. The author then summarizes the tsunami observations, including instrumental sea-level data and run-up height estimates for modern, historical and prehistoric tsunamis. He also describes methods for modeling and quantifying a tsunami source, and for analyzing tsunami travel times, amplitudes and waveforms. He concludes with an estimation of earthquake fault parameters derived from waveform inversion of tsunami data, and a discussion of heterogeneous fault motion and its application for tsunami warning.

Tsunami inundation is the one of the final stages of tsunami evolution, when the wave encroaches upon and floods dry land. It is during this stage that a tsunami is most destructive and takes the vast majority of its victims. To gauge the near-shore impact of tsunami inundation, engineers and scientists rely primarily on three different methods: (1) field survey of past events, (2) physical experimentation in a laboratory, and (3) numerical modeling. In ▶ Tsunami Inundation, Modeling of, P.J. Lynett focuses on numerical simulations. He reviews tsunami generation and open ocean propagation, and discusses the physics of near-shore tsunami evolution, hydrodynamic modeling of tsunami evolution, moving shoreline algorithms, and effect of topographical features on inundation.

Tsunami Forecasting and Warning

The original definition of 'tsunami earthquake' was given by H. Kanamori (Phys Earth Planet Inter 6:346–359, 1972) as "an earthquake that produces a large-size tsunami relative to the value of its surface wave magnitude (M_S)". The true damage potential that a tsunami earthquake represents may not be recognized by conventional near real-time seismic analysis methods that utilize measurements of relatively high-frequency signals, and thus the threat may only become apparent upon the arrival of the tsunami waves on the local shores. Although tsunami earthquakes occur relatively infrequently, the effect on the local population can be devastating, as was most recently illustrated by the July 2006 Java tsunami earthquake, which was quickly followed by tsunami waves two to seven meters high, traveling as far as two kilometers inland and killing at least 668 people.

It is important to note that the definition of 'tsunami earthquake' is distinct from that of 'tsunamigenic earthquake'. A tsunamigenic earthquake is any earthquake that excites a tsunami. Tsunami earthquakes are a specific subset of tsunamigenic earthquakes. In ▶ Tsunami Earthquakes, J. Polet and H. Kanamori describe the characteristics of tsunami earthquakes and the possible factors involved in the anomalously strong excitation of tsunamis by these events. They also discuss a possible model for these infrequent, but potentially very damaging events.

Tsunamis are among nature's most destructive hazards. Typically generated by large, underwater shallow earthquakes, tsunamis can cross an ocean basin in a matter of hours. Although difficult to detect, and not dangerous while propagating in open ocean, tsunamis can unleash awesome destructive power when they reach coastal areas. With advance warning, populations dwelling in coastal areas can be alerted to evacuate to higher ground and away from the coast, thus saving many lives.

Tsunami travels at about the same speed of a commercial airliner, however, seismic waves can travel at speeds more than 40 times greater. Because of this large disparity in speed, scientists rely on seismic methods to detect the possibility of tsunami generation and to warn coastal populations of an approaching tsunami well in advance of its arrival. The seismic P-wave for example, travels from Alaska to Hawaii in about 7 min, whereas a tsunami will take about 5.5 hours to travel the same distance. Although over 200 sea-level stations reporting in near-real time are operating in the Pacific Ocean, it may take an hour or more, depending on the location of the epicenter, before the existence (or not) of an actual tsunami generation is confirmed. In other ocean basins where the density of sea-level instruments reporting data in near real-time is less, the delay in tsunami detection is correspondingly longer. However, global, regional, and local seismic networks, and the infrastructure needed to process the large amounts of seismic data that they record, are well in place around the world. For these reasons, tsunami warning centers provide initial tsunami warnings to coastal populations based entirely on the occurrence of a large shallow offshore earthquake. It is well-known, however, that large shallow offshore earthquakes may or may not be tsunamigenic.

In ► Tsunami Forecasting and Warning, O. Kamigaichi discusses the complexity problem in tsunami forecasting for large local events, and describes the Tsunami Early Warning System in Japan. Tsunami disaster mitigation can be achieved effectively by the appropriate combination of software and hardware countermeasures. Important issues for disaster mitigation includes: (1) improving people's awareness of the tsunami hazards, (2) imparting the necessity of spontaneous evacuation when people notice an imminent threat of tsunami on their own (feeling strong shaking near the coast, seeing abnormal sea level change, etc), (3) giving clear directions on how to respond to the tsunami forecast, and (4) conducting tsunami evacuation drills. The author notes that in tsunami forecasting, a trade-off exists between promptness and accuracy/reliability.

In ► Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, B. Hirshorn and S. Weinstein describe the basic method used by the Pacific Tsunami Warning Center (PTWC) mainly for large teleseismic events. Software running at the PTWC processes in real time seismic signals from over 150 seismic stations worldwide provided by various seismic networks. Automatic seismic event detection algorithms page the duty scientists for any earthquake occurring worldwide over about Magnitude 5.5. Other automatic software locates these events, and provides a first estimate of their magnitude and other source parameters in near real time. Duty scientists then refine the software's automated source parameter estimates and issue a warning if necessary. The authors also describe their ongoing efforts to improve estimates of earthquake source parameters.

Wedge Mechanics, Submarine Landslides and Slow Earthquakes

A study of the mechanics of wedge-shaped geological bodies, such as accretionary prisms in subduction zones and fold-and-thrust belts in collision zones, is interesting because they enable us to use the observed morphology and deformation of these bodies to constrain properties of the thrust faults underlying them. The fundamental process described in wedge mechanics is how gravitational force, in the presence of a sloping surface, is balanced by basal stress and internal stress. The internal state of stress depends on the rheology of the wedge. The most commonly assumed wedge rheology for geological problems is perfect Coulomb plasticity, and the model based on this rheology is referred to as the Coulomb wedge model.

The connection between wedge mechanics and great earthquakes and tsunamis at subduction zones is an emerging new field of study. In their article, ► Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Wang et al. cover the topics of stable and critical Coulomb wedges, dynamic Coulomb wedge, stress drop and increase in a subduction earthquake, and tsunamigenic coseismic seafloor deformation. Better constraints are needed to quantify how stresses along different downdip segments of the subduction fault evolve with time throughout an earthquake cycle and how the evolution impacts wedge and seafloor deformation. Submarine monitoring in conjunction with land-based monitoring at subduction zones that are currently in different phases of earthquake cycles will allow us to better understand the evolution of fault and wedge stresses during the interseismic period. In this regard, cabled seafloor monitoring networks including borehole observatories being designed or implemented at different subduction zones will surely yield valuable data in the near future.

The term 'submarine landslide' encompasses a multitude of gravitational mass failure features at areal scales from square meters to thousands of square kilometers. The term ‘slow earthquake’ describes a discrete slip event that produces millimeter to meter-scale displacements identical to those produced during earthquakes but without the associated seismic shaking. Recently, a GPS network on the south flank of Kilauea volcano, Hawaii, recorded multiple slow earthquakes on the subaerial portion of a large landslide system that extends primarily into the submarine environment. Since catastrophic failure of submarine landslides can cause a tsunami they represent significant hazards to coastal zones. Because submarine landslide systems are among the most active as well as spatially confined deforming areas on Earth, they are excellent targets for understanding the general fault failure process. In ► Submarine Landslides and Slow Earthquakes: Monitoring Motion with GPS and Seafloor Geodesy, B.A. Brooks et al. present a review of this interdisciplinary topic of interest in geodesy, seismology, tsunamis, and volcanology.

Volcanoes

About 1,500 volcanoes have erupted one or more times during the past 10,000 years, and since A.D. 1600, volcanic disasters have killed about 300,000 people and resulted in property damage and economic loss exceeding hundreds of millions of dollar. Articles in this section are intended to summarize recent research in: (1) volcano seismology, (2) physical processes involved in volcanoes, and (3) modeling volcanic eruptions and hazards warning.

Volcano Seismology

Magma transport in a volcano is episodic due to the inherent instability of magmatic systems at all time scales. This episodicity is reflected in seismic activity, which originates in dynamic interactions between gas, liquid and solid along magma transport paths that involve complex geometries. The description of the flow processes is governed by the nonlinear equations of fluid dynamics. In volcanic fluids, further complexity arises from the strong nonlinear dependence of magma rheology on temperature, pressure, and water and crystal content, and nonlinear characteristics of associated processes underlying the physico-chemical evolution of liquid-gas mixtures constituting magma.

In ► Volcanoes, Non-linear Processes in, B. Chouet presents a brief review of volcano seismology and addresses basic issues in the quantitative interpretation of processes in active volcanic systems. Starting with an introduction of the seismic methodology used to quantify the source of volcano seismicity, the author then focuses on sources originating in the dynamics of volcanic fluids. A review of some of the representative source mechanisms of Long-Period (LP) and Very Long-Period (VLP) signals is followed by a description of a mesoscale computational approach for simulating two-phase flows of complex magmatic fluids. Refined understanding of magma and hydrothermal transport dynamics therefore requires multidisciplinary research involving detailed field measurements, laboratory experiments, and numerical modeling. Such research is fundamental to monitoring and interpreting the subsurface migration of magma that often leads to eruptions, and thus would enhance our ability to forecast hazardous volcanic activity.

Volcano seismicity produces a wide variety of seismic signals that provide glimpses of the internal dynamics of volcanic systems. Quantitative approaches to analysis and interpret volcano-seismic signals have been developed since the late 1970s. The availability of seismic equipments with wide frequency and dynamic ranges since the early 1990s has revealed a variety of volcano-seismic signals over a wide range of periods. Quantification of the sources of volcano-seismic signals is crucial to achieving a better understanding of the physical states and dynamics of magmatic and hydrothermal systems. In ► Volcano Seismic Signals, Source Quantification of, H. Kumagai provides the theoretical basis for a quantification of the sources of volcano-seismic signals. The author focuses on the phenomenological representation of seismic sources, waveform inversion to estimate source mechanisms, spectral analysis based on an autoregressive model, and physical properties of fluid-solid coupled waves.

Among various eruptive styles, Strombolian activity is easier to study because of its repetitive behavior. Since Strombolian activity offers numerous interesting seismic signals, a growing attention has been devoted to the application of waveform inversion for imaging conduit geometry and retrieving eruption dynamics from seismological recordings. Quantitative models fitting seismological observations are a powerful tool for interpreting seismic recordings from active volcanoes. In ► Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, L. D’Auria and M. Martini discuss the mechanism of generation of Very-Long Period (VLP) signals accompanying Strombolian explosions. This eruptive style, occurring at many basaltic volcanoes worldwide, is characterized by the ascent and the bursting of large gas slugs. The mechanism of formation, ascent and explosion of bubbles and slugs and their relation with eruptive activity has been studied theoretically and by analogue simulations. The authors report results from numerical simulations, focusing on the seismic signals generated by pressure variations applied to the conduit walls.

Physical Processes in Volcanoes

The dynamics of solid-liquid composite systems are relevant to many problems, including how melts or aqueous fluids migrate through the mantle and crust toward the surface, how deformation and fracture in these regions are influenced by the existence of fluids, and also how these fluids can be observed in seismic tomographic images. In ▶ Earth's Crust and Upper Mantle, Dynamics of Solid–Liquid Systems in, Y. Takei introduces a general continuum mechanical theory for macroscopic dynamics of solid-liquid composite systems, and emphasizes on how such interactions with pore geometry can be studied. The author then discusses the determinability of porosity and pore geometry from seismic tomographic images, and presents a practical method to assess porosity and pore geometry from tomographic V_P and V_S images.

A volcano consists of solids, liquids, gases, and intermediate materials of any two of these phases. Mechanical and thermodynamical interactions between these phases are essential in the generating a variety of volcanic activities. In particular, the gas phase is mechanically distinct from the other phases and plays an important role in dynamic phenomena in volcanoes. In ▶ Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, M. Ichihara and T. Nishimura discuss several bubble dynamics phenomena from the viewpoint that a bubbly fluid acts as an impulse generator of observable signals, such as earthquakes, ground deformations, airwaves, and an eruption itself. The authors focus on the notion that the impulse is excited by non-linear coupling between internal processes in a bubbly fluid and an external perturbation. The importance of these processes has recently become noticed as a possible triggering mechanism of eruptions, earthquakes, and inflation of a volcano.

Our capability to mitigate volcano hazards relies in large part on forecasting explosive events, a process which requires a high degree of understanding of the physicochemical factors operating during explosive volcanism. The approaches taken to gain an understanding of explosive volcanism have relied on a combination of field observations, theoretical models and laboratory models of materials and mechanisms. In ▶ Volcanic Eruptions, Explosive: Experimental Insights, S.J. Lane and M.R. James first review aspects of the volcanic materials literature, with the aim of illustrating the nature of molten rock, the complexity of which underpins most explosive volcanic processes. Experimental modeling of these processes can then build on the materials understanding. Such experiments involve investigation of the behavior of natural volcanic products at laboratory time and length scales, including the response of magma samples to rapid changes in pressure and temperature, the fall behavior of silicate particles in the atmosphere, and the generation and separation of electrostatic charge during explosive eruptions.

In ▶ Volcanic Eruptions: Cyclicity During Lava Dome Growth, O. Melnik et al. consider the process of slow extrusion of very viscous magma that forms lava domes. Dome-building eruptions are commonly associated with hazardous phenomena, including pyroclastic flows generated by dome collapses, explosive eruptions, and volcanic blasts. These eruptions commonly display fairly regular alternations between periods of high and low or no activity with time scales from hours to years. Usually hazardous phenomena are associated with periods of high magma discharge rate. Hence, understanding the causes of pulse activity during extrusive eruptions is an important step towards forecasting volcanic behavior, and especially the transition to explosive activity when magma discharge rate increases by a few orders of magnitude. In recent years the risks have escalated because the population density in the vicinity of many active volcanoes has increased.

Modeling Volcanic Eruptions and Hazards Warning

While a wide range of complex deterministic models exists to model various volcanic processes, these provide little in the way of information about future activity. Being the (partially) observed realization of a complex system, volcanological data are inherently stochastic in nature, and need to be modeled using statistical models. In ▶ Volcanic Eruptions: Stochastic Models of Occurrence Patterns, M.S. Bebbington considers models of eruption occurrence, omitting techniques for forecasting the nature and effect of the eruption. As the track record of a potentially active volcano provides the best method of assessing its future long-term hazards, the author first briefly reviews the provenance and characteristics of the data available, and then discusses various taxonomies for stochastic models. The examples of Mount Etna and Yucca Mountain are selected for more detailed examination partly because many, somewhat contradictory, results exist. Different models make different assumptions, and vary in how much information they can extract from data. In addition, the data used often varies from study to study, and the sensitivity of models to data is important, but too often ignored.

In ▶ Volcanic Hazards and Early Warning, R.I. Tilling highlights the range in possible outcomes of volcano unrest and reviews some recent examples of the actual outcomes documented for several well-monitored volcanoes. The author also discusses the challenge for emergency-management authorities, as well as challenges in achieving refined predictive capability. To respond effectively to a developing volcanic crisis, timely and reliable early warnings are absolutely essential; they can be achieved only by a greatly improved capability for eruption prediction. This in turn depends on the quantity and quality of volcano-monitoring data and the diagnostic interpretation of such information.

Discussions

The terms 'Prediction' and 'forecasting' are often used interchangeably. However, the commonly accepted definition of an 'earthquake prediction' is a concise statement, in advance of the event, of the time, location, and magnitude of a future earthquake. To be practically useful to the society, the time window must be short (in days or months), the location extent small (within tens of kilometers), and the magnitude precise (± 0.5 unit). A 'forecast', on the other hand, is more loosely defined as the probability of an occurrence of a large earthquake in a given region (e. g., southern California) during the coming decades or centuries. The broader time intervals associated with forecasts allows society to consider and implement mitigation efforts over a large region.

As an observational seismologist and on a personal note, I am skeptical that earthquakes can be reliably predicted before (1) we have collected accurate data of their occurrences over a sufficiently long period of time, and (2) we have a good understanding of the physical processes that create them. Although earthquakes have been known from antiquity, accurate earthquake catalogs exist only since about the 1960s. Since the recurrence of a damaging earthquake in a given area is often more than 100 years (some even thousands of years), it is obvious that we lack the necessary observed data. C. Lanczos (*Linear Differential Operators*, Van Nostrand-Reinhold, 1961) said it well in general: "a lack of information cannot be remedied by any mathematical trickery". Nevertheless, we must apply new concepts and tools to extract as much useful information as possible from the existing data. Indeed, we must thank many pioneers for enlightening us with many interesting and tentative results about earthquakes, tsunamis and volcanoes that they managed to extract from inadequate and insufficient data.

Because most tsunamis are generated by earthquakes, successes in predicting tsunamis depend on predicting earthquakes and recognizing them as tsunamigenic. Predicting a volcanic eruption is a little easier, as the location is known and there are often some observable phenomena preceding it. However, the exact time and the intensity and extent of an eruption are difficult to predict because the volcanic processes are very complex involving gas, liquid and solid phases.

Fortunately, earthquake, tsunami and volcano hazards can be reduced by employing sound engineering practices, early warning systems, and hazard analysis, using many of the tools and concepts that were developed for prediction. Since fatalities and economic loss from a single catastrophic event can reach 100,000 or more, and $100 billion or more, respectively, it is imperative that governments should support long-term monitoring with modern instruments and research, including complexity studies of earthquakes, tsunamis and volcanoes.

Complexity and Non-linearity in Autonomous Robotics, Introduction to

WARREN E. DIXON
Department of Mechanical and Aerospace Engineering,
Gainesville, USA

Historically, robotic systems have played a key role in manufacturing, hazardous material handling, exploration and surveillance, search and rescue, and military applications. For most of these applications, single robot systems with traditional sensing and actuation are able to execute predetermined tasks in a well defined environment. The ability to develop a robotic system capable of executing tasks in an environment that is not well defined or is dynamic has been a daunting task. The development of such a capability has been limited by the complexity required in sensing, cognitive decision making, new actuation capabilities, and robustness and responsiveness of the control system. The complexity of these challenges increases when groups of robots are required to interact with each other or with people in a social or physical manner. This volume of work is a collection of recent and emerging efforts at the dawn of a new millennium to develop enabling technologies for new frontiers where robots are able to execute tasks in dynamic and unstructured environments.

Sensing is a fundamental requirement for an autonomous system to efficiently interact with its environment. Vision is arguably the primary environmental sensor used by human beings and many other animals to understand how to interact with dynamic and unstructured environments. While traditional sensor modalities will continue to be an integral part of emerging robotic systems, new research efforts will be driven by the desire for human-like interpretation and reaction to image information. However, the use of image-based feedback adds complexity and new challenges. One challenge is how an autonomous system can find and track objects of interest in an image of dense, cluttered environments (see ▶ Motion Prediction for Continued Autonomy). Once a target(s) of interest is determined, how can a robot use a set of two dimensional images to interpret its relative position and orientation with respect to different objects (see ▶ Image Based State Estimation). Another challenge is how to use reconstructed and estimated information from an image to develop a stable closed-loop error system (see ▶ Adaptive Visual Servo Control).

Given feedback from vision sensors, traditional sensors (e. g., sonar, radar, lidar, encoders), or a fusion of these sensors, another complexity is how to best exploit sensor and other information discovered during the execution of a plan, including autonomous selection of which behavior(s) to invoke, in what sequence, and by what method. The ability to organize and apply situational knowledge to macro-level planning and decision-making can be enabled through a scaffolding provided by a computer architecture that provides interfaces for different sources of information (see ▶ Software Architectures for Autonomy). As robotic systems operate in increasingly more complicated environments, more intelligence is required by the autonomous system. The ultimate goal for an autonomous system is to enable a level of cognition with human-like intelligence in perception, motor control, and high-level cognition. Beyond sensing and reaction, cognition enables a robotic system to reason about an environment without direct interaction, enabling the capability to plan for selecting between competing goals, coping with multiple sensory inputs, and completing multiple tasks (see ▶ Cognitive Robotics). Computer architectures that provide a backbone for organizing and interfacing with different sensing and actuation components and the ability for autonomous systems to exhibit increasing levels of intelligence are especially important as robotics move from behind chained off work cells in an assembly line to direct emotional and physical interaction with people (see ▶ Human Robot Interaction).

In addition to new frontiers in sensing, computer architectures, and autonomous reasoning, advances are also required in the construction and actuation of an autonomous robotic system. For example, since people spend a significant portion of their time inside buildings, the building itself could be designed as a morphing robot surface that is articulated, programmable, and embedded with integrated digital technologies (see ▶ Continuum Robots). Or, as robots are forecasted to take an increasing role for in-home care, robots will need new methods of physically interacting with people and the environment. For example, many biological systems have shown that significant articulation can be achieved through tongues, trunks, and tentacles. Robots inspired by these systems could also morph their shape to their environment to access difficult-to-reach areas, and to perform adaptive grasping using whole arm manipulation (see also ▶ Continuum Robots).

New actuation and manipulation methods place new challenges on control systems. One challenge includes the lack of precise mathematical models of the environment and its interaction with the robot through actuators and sensors. As autonomous robots interact with people, the robot may be required to interpret events that a person describes using linguistic terms. These challenges motivate the need for new control designs that may be inspired by the way that humans tend to work with vague or imprecise concepts (see ▶ Neuro-fuzzy Control of Autonomous Robotics).

Given the complexity that arises from developing a single autonomous system capable of interacting with uncertain and dynamic environments, motivation exists to develop technologies for groups of robotic systems. Distributed robotics hold the promise to enable groups of robots to collaborate to solve complex tasks such as monitoring a vast environment, manipulating large objects, or building advanced structures. One challenge to enable groups of robots to collaborate efficiently is how to develop path planning and motion coordination methods so that teams of autonomous mobile robots can share the same workspace while avoiding interference with each other, and/or while achieving group motion objectives (see ▶ Multiple Mobile Robot Teams, Path Planning and Motion Coordination in). Obtaining an optimal solution for the coordination of multiple robot vehicles is a challenge because an integrated approach for designing communication, sensing, and control systems must all be considered as constraints on the system performance (see ▶ Distributed Controls of Multiple Robotic Systems, An Optimization Approach). The design of a single robot requires the balancing of many factors (e. g., cost, sensing, processing capabilities), many of which are conflicting. In addition to these factors, distributed robotics adds the complexity of multiple robots. For example, there are different advantages and disadvantages to designing a homogeneous versus a heterogeneous team (see ▶ Distributed Robotic Teams: A Framework for Simulated and Real–World Modeling).

Despite different design tradeoffs for teams of robots, some advanced teams hold the potential for unprecedented versatility and robustness at a low cost. For example, modular self-reconfigurable (MSR) robot teams are composed of a large number of repeated modules that can rearrange their connectedness to form a large variety of structures to suit the task (see ▶ Modular Self-Reconfigurable Robots). In contrast to self-reconfigurable robotics, self-replication utilizes an original unit to actively assemble an exact copy of itself from passive components. This has the potential to result in an exponential growth in the number of robots available to perform a job, thus drastically shortening the original unit's task time (see ▶ Self--replicating Robotic Systems). To enable self replication, a robot must exploit resources in the environment such as raw materials and energy. Insights to address this challenge can be provided from nature, where biological systems must forage for resources. Foraging robots are mobile robots capable of searching for and, when found, transporting objects to one or more collection points. Foraging robots may be single robots operating individually, or multiple robots operating collectively (see ▶ Foraging Robots).

New technologies are emerging in sensing, actuation, reasoning, and control. As these technologies mature, new levels of autonomy are made possible. As robotic systems are able to operate in increasingly more dynamic and uncertain environments, an exciting new era for robotics is evident.

Complexity in Systems Level Biology and Genetics: Statistical Perspectives

David A. Stephens
Department of Mathematics and Statistics,
McGill University, Montreal, Canada

Article Outline

Glossary

Systems biology The holistic study of biological structure, function and organization.

Probabilistic graphical model A probabilistic model defining the relationships between variables in a model by means of a graph, used to represent the relationships in a biological network or pathway.

MCMC Markov chain Monte Carlo – a computational method for approximating high-dimensional integrals using Markov chains to sample from probability distributions, commonly used in Bayesian inference.

Microarray A high-throughput experimental platform for collecting functional gene expression and other genomic data.

Cluster analysis A statistical method for discovering subgroups in data.

Metabolomics The study of the metabolic content of tissues.

Definition of the Subject

This chapter identifies the challenges posed to biologists, geneticists and other scientists by advances in technology that have made the observation and study of biological systems increasingly possible. High-throughput platforms have made routine the collection vast amounts of structural and functional data, and have provided insights into the working cell, and helped to explain the role of genetics in common diseases. Associated with the improvements in technology is the need for statistical procedures that extract the biological information from the available data in a coherent fashion, and perhaps more importantly, can quantify the certainty with which conclusions can be made. This chapter outlines a biological hierarchy of structures, functions and interactions that can now be observed, and detail the statistical procedures that are necessary for analyzing the resulting data. The chapter has four main sections. The first section details the historical connection between statistics and the analysis of biological and genetic data, and summarizes fundamental concepts in biology and genetics. The second section outlines specific mathematical and statistical methods that are useful in the modeling of data arising in bioinformatics. In sections three and four, two particular issues are discussed in detail: functional genomic via microarray analysis, and metabolomics. Section five identifies some future directions for biological research in which statisticians will play a vital role.

Introduction

The observation of biological systems, their processes and inter-reactions, is one of the most important activities in modern science. It has the capacity to provide direct insight into fundamental aspects of biology, genetics, evolution, and indirectly will inform many aspects of public health. Recent advances in technology – high-throughput measurement platforms, imaging – have brought a new era of increasingly precise methods of investigation. In parallel to this, there is an increasingly important focus on statistical methods that allow the information gathered to be processed and synthesized. This chapter outlines key statistical techniques that allow the information gathered to be used in an optimal fashion.

Although its origin is dated rather earlier, the term *Systems Biology* (see, for example, [1,2,3]) has, since 2000, been used to describe the study of the operation of biological systems, using tools from mathematics, statistics and computer science, supplanting *computational biology* and *bioinformatics* as an all-encompassing term for quantitative investigation in molecular biology. Most biological systems are hugely complex, involving chemical and mechanical processes operating at different scales. It is important therefore that information gathered is processed coherently, according to self-consistent rules and practices, in the presence of the uncertainty induced by imperfect observation of the underlying system. The most natural framework for coherent processing of information is that of probabilistic modeling.

Statistical Versus Mathematical Modeling

There is a great tradition of mathematical and probabilistic modeling of biology and genetics; see [4] for a thorough review. The mathematization of biology, evolution and heredity began at the end of the nineteenth century, and continued for the first half of the twentieth century, by far pre-dating the era of molecular biology and genetics that culminated at the turn of the last millennium with the human genome project. Consequently, the mathematical models of, say, evolutionary processes that were developed by Yule [5] and Fisher and Wright [6,7,8], and classical models of heredity, could only be experimentally verified and developed many years after their conception. It could also be convincingly argued that through the work of F. Galton, K. S. Pearson and R. A. Fisher, modern statistics has its foundation in biology and genetics.

In parallel to statistical and *stochastic* formulation of models for biological systems, there has been a more recent focus on the construction of *deterministic* models to describe observed biological phenomena. Such models fall under the broad description *Mathematical Biology*, and have their roots in applied mathematics and dynamical systems; see, for example, [8,9] for a comprehensive treatment. The distinction between stochastic and deterministic models is important to make, as the objectives and tools used often differ considerably. This chapter will restrict attention to stochastic models, and the processing of observed data, and thus is perhaps more closely tied to the immediate interests of the scientist, although some of the models utilized will be inspired by mathematical models of the phenomena being observed.

Fundamental Concepts in Biology and Genetics

To facilitate the discussion of statistical methods applied to systems biology, it is necessary to introduce fundamental concepts from molecular biology and genetics; see the classic text [10] for full details. Attention is restricted to eukaryotic, organisms whose cells are constructed to contain a nucleus which coding information is encapsulated.

- The cell nucleus is a complex architecture containing several nuclear domains [11] whose organization is not completely understood, but the fundamental activity that occurs within the nucleus is the production and distribution of proteins.
- Dioxyribonucleic acid (DNA) is a long string of nucleotides that encodes biological information, and that is copied or *transcribed* into ribonucleic acid (RNA), which in turn enables the formation of proteins. Specific segments of the DNA, genes, encode the proteins, although non-coding regions of DNA – for example, promoter regions, transcription factor binding sites – also have important roles. Genetic variation at the nucleotide level, even involving a single nucleotide, can disrupt cellular activity. In humans and most other complex organisms, DNA is arranged into chromosomes, which are duplicated in the process of mitosis. The entire content of the DNA of an organism is termed the *genome*.
- Proteins are macromolecules formed by the *translation* of RNA, comprising amino acids arranged (in primary structure) in a linear fashion, comprising domains with different roles, and physically configured in three dimensional space. Proteins are responsible for all biological activities that take place in the cell, although proteins may have different roles in different tissues at different times, due to the *regulation* of transcription.
- Proteins interact with each other in different ways in different contexts in interaction networks that may be dynamically organized. Genes are also regarded as having indirect interactions through gene regulatory networks.
- Genetic variation amongst individuals in a population is due to mutation and selection, which can be regarded as stochastic mechanisms. Genetic information in the form of DNA passes from parent to offspring, which

promulgates genetic variation. Individuals in a population are typically related in evolutionary history. Similarly, proteins can also thought to be related through evolutionary history.

- Genetic disorders are the result of genetic variation, but the nature of the genetic variation can be large- or small-scale; at the smallest scale, variation in single nucleotides (*single nucleotide polymorphisms* (SNPs)) can contribute to the variation in observed traits.

Broadly, attention is focused on the study of *structure* and *function* of DNA, genes and proteins, and the nature of their *interactions*. It is useful, if simplistic, to view biological activities in terms of an organizational hierarchy of inter-related chemical reactions at the level of DNA, protein, nucleus, network and cellular levels. A holistic view of mathematical modeling and statistical inference requires the experimenter to model simultaneously actions and interactions of all the component features, whilst recognizing that the component features cannot observed directly, and can only be studied through separate experiments on often widely different platforms. It is the role of the bioinformatician or systems biologist to synthesize the data available from separate experiments in an optimal fashion.

Mathematical Representations of the Organizational Hierarchy

A mathematical representation of a biological system is required that recognizes, first, the complexity of the system, secondly, its potentially temporally changing nature, and thirdly the inherent uncertainties that are present. It is the last feature that necessitates the use of probabilistic or stochastic modeling.

An aphorism commonly ascribed to D.V. Lindley states that "*Probability is the language of uncertainty*"; probability provides a coherent framework for processing information in the presence of imperfect knowledge, and through the paradigm of Bayesian theory [12] provides the mathematical template for statistical inference and prediction. In the modeling of complex systems, three sorts of uncertainty are typically present:

- *Uncertainty of Structure:* Imperfect knowledge of the connections between the interacting components is typically present. For example, in a gene regulatory network, it may be possible via the measurement of gene co-expression to establish which genes interact within the network, but it may not be apparent precisely how the organization of regulation operates, that is which genes regulate the expression of other genes.
- *Uncertainty concerning Model Components:* In any mathematical or probabilistic model of a biological system, there are model components (differential equations, probability distributions, parameter settings) that must be chosen to facilitate implementation of the model. These components reflect, but are not determined by, structural considerations.
- *Uncertainty of Observation:* Any experimental procedure carries with it uncertainty induced by the measurement of underlying system, that is typically subject to random measurement error, or noise. For example, many biological systems rely on imaging technology, and the extraction of the level of signal of a fluorescent probe, for a representation of the amount of biological material present. In microarray studies (see Sect. "Microarrays"), comparative hybridization of messenger RNA (mRNA) to a medium is a technique for measuring gene expression that is noisy due to several factors (imaging noise, variation in hybridization) not attributable to a biological cause.

The framework to be built must handle these types of uncertainty, and permit inference about structure and model components.

Models Derived from Differential Equations

A deterministic model reflecting the dynamic relationships often present in biological systems may be based on the system of ordinary differential equations (ODEs)

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{g}(\boldsymbol{x}(t)) \qquad (1)$$

where $\boldsymbol{x}(t) = (x_1(t), \dots, x_d(t))^{\mathsf{T}}$ represent the levels of d quantities being observed $\dot{\boldsymbol{x}}(t)$ represents time derivative, and $\boldsymbol{g}$ is some potentially non-linear system of equations, that may be suggested by biological prior knowledge or prior experimentation. The model in Eq. (1) is a classical "Mathematical Biology" model, that has been successful in representing forms of organization in many biological systems (see, for example [13] for general applications). Suppressed in the notation is a dependence on system parameters, $\boldsymbol{\theta}$, a k-dimensional vector that may be presumed fixed, and "tuned" to replicate observed behavior, or estimated from observed data. When data representing a partial observation of the system are available, inferences about $\boldsymbol{\theta}$ can be made, and models defined by ODE systems are of growing interest to statisticians; see, for example, [15,16,17].

Equation (1) can be readily extended to a *stochastic differential equation* (SDE) system

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{g}(\boldsymbol{x}(t)) + \boldsymbol{dz}(t) \qquad (2)$$

where $\boldsymbol{z}(t)$ is some stochastic process that renders the solution to Eq. (2) a stochastic process (see, for example, [18] for a comprehensive recent summary of modeling approaches and inference procedures, and a specific application in [19]). The final term $\boldsymbol{dz}(t)$ represents the infinitesimal stochastic increment in $\boldsymbol{z}(t)$. Such models, although particularly useful for modeling activity at the molecular level, often rely on simplifying assumptions (linearity of $\boldsymbol{g}$, Gaussianity of $\boldsymbol{z}$) and the fact that the relationship structure captured by $\boldsymbol{g}$ is known. Inference for the parameters of the system can be made, but in general require advanced computational methods (Monte Carlo (MC) and Markov chain Monte Carlo (MCMC)).

Probabilistic Graphical Models

A simple and often directly implementable approach is based on a *probabilistic graphical model*, comprising a graph $\mathcal{G} = (\mathcal{N}, \mathcal{E})$, described by a series of nodes $\mathcal{N}$, edges $\mathcal{E}$, and a collection of random variables $\boldsymbol{X} = (X_1, \dots, X_d)^\mathsf{T}$ placed at the nodes, all of which may be dynamically changing. See, for example [20] for a recent summary, [14] for mathematical details and [22] for a biological application.

The objective of constructing such a model is to identify the joint probability structure of $\boldsymbol{X}$ given the graph $\mathcal{G}$, which possibly is parametrized by parameters $\boldsymbol{\phi}$, $f_{\boldsymbol{X}}(\boldsymbol{x}|\boldsymbol{\phi}, \mathcal{G})$. In many applications, $\boldsymbol{X}$ is not directly observed, but is instead inferred from observed data, $\boldsymbol{Y}$, arising as noisy observations derived from $\boldsymbol{X}$. Again, a k-dimensional parameter vector $\boldsymbol{\theta}$ helps to characterize the stochastic dependence of $\boldsymbol{Y}$ on $\boldsymbol{X}$ by parametrize the conditional probability density $f_{\boldsymbol{Y}|\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{\theta})$. The joint probability model encapsulating the probabilistic structure of the model is

$$f_{\boldsymbol{X},\boldsymbol{Y}}(\boldsymbol{x}, \boldsymbol{y}|\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G}) = f_{\boldsymbol{X}}(\boldsymbol{x}|\boldsymbol{\phi}, \mathcal{G}) f_{\boldsymbol{Y}|\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{\theta}) \tag{3}$$

The objectives of inference are to learn about $\mathcal{G}$ (the uncertain structural component) and parameters $(\boldsymbol{\theta}, \boldsymbol{\phi})$ (the uncertain model parameters and observation components).

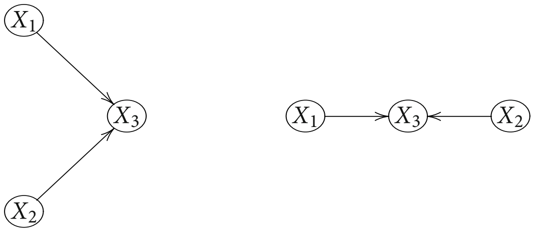
The graph structure $\mathcal{G}$ is described by $\mathcal{N}$ and $\mathcal{E}$. In holistic models, $\mathcal{G}$ represents the interconnections between interacting modules (genomic modules, transcription modules, regulatory modules, proteomic modules, metabolic modules etc.) and also the interconnections within modules in the form of sub graphs. The nodes $\mathcal{N}$ (and hence $\boldsymbol{X}$) represent influential variables in the model structure, and the edges $\mathcal{E}$ represent dependencies. The edge connecting two nodes, if present, may be *directed* or *undirected* according to the nature of the influence; a directed edge indicates the direction of *causation*, an undirected edge indicates a *dependence*.

Causality is a concept distinct from dependence (association, co-variation or correlation), and represents the influence of one node on one or more other nodes (see, for example, [23] for a recent discussion of the distinction with examples, and [24,25] for early influential papers discussing how functional dependence may be learned from real data). A simple causal relationship between three variables X_1, X_2, X_3 can be represented

which encodes a *conditional independence relationship* between X_1 and X_3 given X_2, and a factorization of the joint distribution

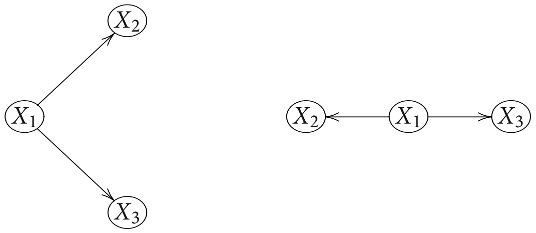
$$p(x_1, x_2, x_3) = p(x_1)p(x_2|x_1)p(x_3|x_2).$$

Similarly, the equivalent graphs



encode $\quad p(x_1, x_2, x_3) = p(x_1)p(x_2)p(x_3|x_1, x_2)$

whereas the graphs for conditional independence of X_2 and X_3 given X_1 are



encoding $\quad p(x_1, x_2, x_3) = p(x_1)p(x_2|x_1)p(x_3|x_1). \quad (4)$

Such simple model assumptions are the building blocks for the construction of highly complex graphical representations of biological systems. There is an important difference between analysis based purely on simultaneous observation of all components of the system, which can typically on yield inference on *dependencies* (say, covariances measured in the joint probability model $p(\boldsymbol{x})$ – see, for example [26,27,28] and analysis based on *interventions*-genomic knock–out experiments, chemical or biological challenges, transcriptional/translational perturbation such as RNA interference (RNAi) – that may yield information on casual links; see, for example [29,30].

Bayesian Statistical Inference

Given a statistical model for observed data such as Eq. (3), inference for the parameters $(\boldsymbol{\theta}, \boldsymbol{\phi})$ and the graph structure $\mathcal{G}$ is required. The optimal coherent framework is that of *Bayesian statistical inference* (see for example [31]), that requires computation of the *posterior distribution* for the unknown (or *unobservable*) quantities given by

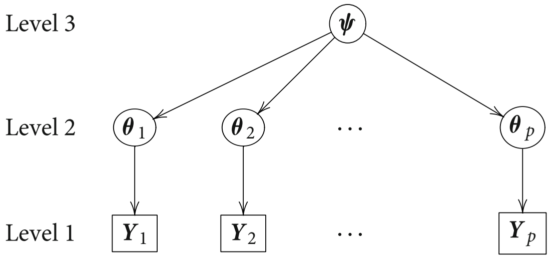
$$\begin{aligned}\pi(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G}|\boldsymbol{x}, \boldsymbol{y}) &\propto f_{X,Y}(\boldsymbol{x}, \boldsymbol{y}|\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G})p(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G}) \\ &= L(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G}|\boldsymbol{x}, \boldsymbol{y})p(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G}) \qquad (5)\end{aligned}$$

a probability distribution from which can be computed parameter estimates with associated uncertainties, and predictions from the model. The terms $L(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G}|\boldsymbol{x}, \boldsymbol{y})$ and $p(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G})$ are termed *likelihood* and *prior probability distribution* respectively. The likelihood reflects the observed data, and the prior distribution encapsulates biological prior knowledge about the system under study. If the graph structure is known in advance, the prior distribution for that component can be set to be degenerate. If, as in many cases of probabilistic graphical models, the $\boldsymbol{x}$ are unobserved, then the posterior distribution incorporates them also,

$$\pi(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G}, \boldsymbol{x}|, \boldsymbol{y}) \propto f_{Y|X}(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{\theta}) f_X(\boldsymbol{x}|\boldsymbol{\phi}, \mathcal{G}) p(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G}) \quad (6)$$

yielding a *latent* or *state-space* model, otherwise interpreted as a *missing data* model.

The likelihood and prior can often be formulated in a hierarchical fashion to reflect believed causal or conditional independence structures. If a graph $\mathcal{G}$ is separable into two sub graphs $\mathcal{G}_1, \mathcal{G}_2$ conditional on a connecting node η, similar to the graph in Eq. (4), then the probability model also factorizes into a similar fashion; for example, X_1 might represent the amount of expressed mRNA of a gene that regulates two separate functional modules, and X_2 and X_3 might be the levels of expression of collections of related proteins. The hierarchical specification also extends to parameters in probability models; a standard formulation of a Bayesian hierarchical model involves specification of conditional independence structures at multiple levels of within a graph. The following three-level hierarchical model relates data $\boldsymbol{Y} = (\boldsymbol{Y}_1, \ldots, \boldsymbol{Y}_p)$ at level 1, to a population of parameters $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_p)^{\mathsf{T}}$ at level 2, to hyper parameters $\boldsymbol{\psi}$ at level 3



(7)

yielding the factorization of the Bayesian full joint distribution as

$$\begin{aligned}&f_{X,Y,\boldsymbol{\psi},\boldsymbol{\theta}}(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{\theta}, \boldsymbol{\psi}) \\ &\qquad = p(\boldsymbol{\psi}) \left\{ \prod_{i=1}^{p} p(\boldsymbol{\theta}_i|\boldsymbol{\psi}) \right\} \left\{ \prod_{i=1}^{p} p(\boldsymbol{Y}_i|\boldsymbol{\phi}_i) \right\} .\end{aligned}$$

Bayesian Computation

The posterior distribution is, potentially, a high-dimensional multivariate function on a complicated parameter space. The proportionality constant in Eq. (5) takes the form

$$f_{X,Y}(\boldsymbol{x}, \boldsymbol{y}) = \int f_{X,Y}(\boldsymbol{x}, \boldsymbol{y}|\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G})p(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G})\,\mathrm{d}\boldsymbol{\theta}\,\mathrm{d}\boldsymbol{\phi}\,\mathrm{d}\mathcal{G} \qquad (8)$$

and in Eq. (6) takes the form

$$f_Y(\boldsymbol{y}) = \int f_{X,Y}(\boldsymbol{x}, \boldsymbol{y}|\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G})p(\boldsymbol{\theta}, \boldsymbol{\phi}, \mathcal{G})\,\mathrm{d}\boldsymbol{\theta}\,\mathrm{d}\boldsymbol{\phi}\,\mathrm{d}\mathcal{G}\,\mathrm{d}\boldsymbol{x} \quad (9)$$

and is termed the *marginal likelihood* or *prior predictive distribution* for the *observable* quantities $\boldsymbol{x}$ and $\boldsymbol{y}$. In formal Bayesian theory, it is the representation of the distribution of the observable quantities through the paradigm of *exchangeability* that justifies the decomposition in Eq. (8) into likelihood and prior, and justifies, via asymptotic arguments, the use of the posterior distribution for inference (see Chaps. 1–4 in [13] for full details). It is evident from these equations that exact computation of the posterior distribution necessitates high-dimensional integration, and in many cases this cannot be carried out analytically.

Numerical Integration Approaches Classical numerical integration methods, or analytic approximation methods are suitable only in low dimensions. Stochastic numerical integration, for example Monte Carlo integration, approximates expectations by using empirical averages of functional of samples obtained from the target distribution; for probability distribution $\pi(\boldsymbol{x})$, the approximation of $\mathrm{E}_\pi[g(\boldsymbol{X})]$,

$$\mathrm{E}_\pi[g(\boldsymbol{X})] = \int g(\boldsymbol{x})\pi(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x} < \infty$$

is achieved by randomly sampling $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N$ (N large) from $\pi()$, and using the estimate

$$\widehat{\mathrm{E}}_\pi[g(\boldsymbol{X})] = \frac{1}{N}\sum_{i=1}^{n} g(\boldsymbol{x}_i).$$

An adaptation of the Monte Carlo method can be used if the functions g and π are not "similar" (in the sense that g is large in magnitude where π is not, and *vice versa*); *importance sampling* uses the representation

$$\mathrm{E}_\pi[g(\boldsymbol{X})] = \int g(\boldsymbol{x})\pi(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x} = \int \frac{g(\boldsymbol{x})\pi(\boldsymbol{x})}{p(\boldsymbol{x})}p(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x}$$

for some pdf $p()$ having common support with π, and constructs an estimate from a sample $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N$ from $p()$ of the form

$$\widehat{\mathrm{E}}_\pi[g(\boldsymbol{X})] = \frac{1}{N}\sum_{i=1}^{n} \frac{g(\boldsymbol{x}_i)\pi(\boldsymbol{x}_i)}{p(\boldsymbol{x}_i)}.$$

Under standard regularity conditions, the corresponding estimators converge to the required expectation. Further extensions are also useful:

- *Sequential Monte Carlo:* Sequential Monte Carlo (SMC) is an adaptive procedure that constructs a sequence of improving importance sampling distributions. SMC is a technique that is especially useful for inference problems where data are collected sequentially in time, but is also used in standard Monte Carlo problems (see [32]).
- *Quasi Monte Carlo:* Quasi Monte Carlo (QMC) utilizes uniform **but not random** samples to approximate the required expectations. It can be shown that QMC can produce estimators with lower variance than standard Monte Carlo.

Markov Chain Monte Carlo Markov chain Monte Carlo (MCMC) is a stochastic Monte Carlo method for sampling from a high-dimensional probability distribution $\pi(\boldsymbol{x})$, and using the samples to approximate expectations with respect to that distribution. An ergodic, discrete-time Markov chain is defined on the support of π in such a way that the stationary distribution of the chain exists, and is equal to π. Dependent samples from π are obtained by collecting realized values of the chain after it has reached its stationary phase, and then used as the basis of a Monte Carlo strategy.

The most common MCMC algorithm is known as the *Metropolis–Hastings* algorithm which proceeds as follows. If the state of the d-dimensional chain $\{\boldsymbol{X}_t\}$ at iteration t is given by $\boldsymbol{X}_t = \boldsymbol{u}$, then a candidate state $\boldsymbol{v}$ is generated from conditional density $q(\boldsymbol{u}, \boldsymbol{v}) = q(\boldsymbol{v}|\boldsymbol{u})$, and accepted as the new state of the chain (that is, $\boldsymbol{X}_{t+1} \overset{\mathrm{def}}{=} \boldsymbol{v}$) with probability $\alpha(\boldsymbol{u}, \boldsymbol{v})$ given by

$$\alpha(\boldsymbol{u}, \boldsymbol{v}) = \min\left\{1, \frac{\pi(\boldsymbol{v})q(\boldsymbol{v}, \boldsymbol{u})}{\pi(\boldsymbol{u})q(\boldsymbol{u}, \boldsymbol{v})}\right\}.$$

A common MCMC approach involves using a *Gibbs sampler strategy* that performs iterative sampling with updating from the collection of *full conditional* distributions

$$\begin{aligned}\pi(\boldsymbol{x}_j|\boldsymbol{x}_{(j)}) &= \pi(\boldsymbol{x}_j|\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{j-1}, \boldsymbol{x}_{j+1}, \boldsymbol{x}_d) \\ &= \frac{\pi(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_d)}{\pi(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{j-1}, \boldsymbol{x}_{j+1}, \boldsymbol{x}_d)}, \quad j = 1, \ldots, d\end{aligned}$$

rather than updating the components of $\boldsymbol{x}$ simultaneously. There is a vast literature on MCMC theory and applications; see [33,34] for comprehensive treatments.

MCMC re-focuses inferential interest from computing posterior analytic functional forms to producing posterior samples. It is an extremely flexible framework for computational inference that carries with it certain well-documented problems, most important amongst them being the assessment of *convergence*. It is not always straightforward to assess when the Markov chain has reached its stationary phase, so certain monitoring steps are usually carried out.

Bayesian Modeling: Examples

Three models that are especially useful in the modeling of systems biological data are *regression models*, *mixture models, and state-space models*. Brief details of each type of model follow.

Regression Models Linear regression models relate an observed response variable Y to a collection of predictor variables $X_1, X_2, \ldots, X_d$ via the model for the ith response

$$Y_i = \beta_0 + \sum_{j=1}^{d} \beta_j X_{ij} + \epsilon_i = \boldsymbol{X}_i^{\mathsf{T}}\boldsymbol{\beta} + \epsilon_i$$

say, or in vector form, for $\boldsymbol{Y} = (Y_1, \ldots, Y_n)^{\mathsf{T}}$,

$$\boldsymbol{Y} = \boldsymbol{X}\boldsymbol{\beta} + \epsilon$$

where $\boldsymbol{\beta} = (\beta_0, \beta_1, \ldots, \beta_d)^\mathsf{T}$ is a vector of real-valued parameters, and ϵ is a vector random variable with zero-mean and variance-covariance matrix Σ. The objective in the analysis is to make inference about $\boldsymbol{\beta}$, to understand the influence of the predictors on the response, and to perform prediction for Y. The linear regression model (or General Linear Model) is extremely flexible: the design matrix $\boldsymbol{X}$ can be formed from arbitrary, possibly non-linear *basis* functions of the predictor variables. By introducing a covariance structure into Σ, it is possible to allow for dependence amongst the components of $\boldsymbol{Y}$, and allows for the possibility of modeling repeated measures, longitudinal or time-series data that might arise from multiple observation of the same experimental units.

An extension that is often also useful is to *random effect* or *mixed* models that take into account any repeated measures aspect to the recorded data. If data on an individual (person, sample, gene etc) is $\boldsymbol{Y}_i = (Y_{i1}, \ldots, Y_{id})^\mathsf{T}$, then

$$\boldsymbol{Y}_i = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{Z}\boldsymbol{U}_i + \epsilon_i \tag{10}$$

where $\boldsymbol{Z}$ is a $d \times p$ constant design matrix, and $\boldsymbol{U}_i$ is a $p \times 1$ vector of *random effects* specific to individual *i*. Typically the random effect vectors are assumed to be drawn from a common population. Similar formulations can be used to construct semi-parametric models that are useful for flexible modeling in regression.

Mixture Models A mixture model presumes that the probability distribution of variable $\boldsymbol{Y}$ can be written

$$f_{\boldsymbol{Y}|\boldsymbol{\theta}}(\boldsymbol{y}|\boldsymbol{\theta}) = \sum_{k=1}^{K} \omega_k f_k(\boldsymbol{y}|\theta_k) \tag{11}$$

where $f_1, f_2, \ldots, f_K$ are distinct component densities indexed by parameters $\theta_1, \ldots, \theta_K$, and for all k, $0 < \omega_k < 1$, with

$$\sum_{k=1}^{K} \omega_k = 1 .$$

The model can be interpreted as one that specifies that with probability ω_k, $\boldsymbol{Y}$ is drawn from density f_k, for $k = 1, \ldots, K$. Hence the model is suitable for modeling in cluster analysis problems.

This model can be extended to an *infinite mixture model*, which has close links with *Bayesian non-parametric* modeling. A simple infinite mixture/Bayesian non-parametric model is the *mixture of Dirichlet processes* (MDP) model [35,36]: for parameter $\alpha > 0$ and distribution function F_0, an MDP model can be specified using the following hierarchical specification: for a sample of size n, we have

$$\begin{aligned} Y_i|\theta_i &\sim f_{Y|\theta}(y|\theta_i) \quad i = 1, \ldots, n \\ \theta_1, \ldots, \theta_n &\sim DP(\alpha, F_0) \end{aligned}$$

where $DP(\alpha, F_0)$ denotes a *Dirichlet process*. The $DP(\alpha, F_0)$ model may be sampled to produce $\theta_1, \theta_2, \ldots, \theta_n$ using the *Polya-Urn* scheme

$$\begin{aligned} \theta_1 &\sim F_0 \\ \theta_k|\theta_1, \ldots, \theta_{k-1} &\sim \frac{\alpha}{\alpha + k - 1} F_0 + \frac{1}{\alpha + k - 1} \sum_{j=1}^{k-1} \delta_{\theta_j} \end{aligned}$$

where δ_x is a point mass at x. For θ_k, conditional on $\theta_1, \ldots, \theta_{k-1}$, the Polya-Urn scheme either samples θ_k from F_0 (with probability $\alpha/(\alpha + k - 1)$), or samples $\theta_k = \theta_j$ for some $j = 1, \ldots, k-1$ (with probability $1/(\alpha + k - 1)$). This model therefore induces *clustering* amongst the θ values, and hence has a structure similar to the finite mixture model – the distinct values of $\theta_1, \ldots, \theta_n$ are identified as the cluster "centers" that index the component densities in the mixture model in Eq. (11). The degree of clustering is determined by α; high values of α encourage large numbers of clusters.

The MDP model is a flexible model for statistical inference, and is used in a wide range of applications such as density estimation, cluster analysis, functional data analysis and survival analysis. The component densities can be univariate or multivariate, and the model itself can be used to represent the variability in observed data or as a prior density. Inference for such models is typically carried out using MCMC or SMC methods [32,33]. For applications in bioinformatics and functional genomic, see [37,38].

State-Space Models A state-space model is specified through a pair of equations that relate a collection of *states*, $\boldsymbol{X}_t$, to *observations* $\boldsymbol{Y}_t$ that represent a system and how that system develops over time. For example, the relationship could be model led as

$$\begin{aligned} \boldsymbol{Y}_t &= f(\boldsymbol{X}_t, \boldsymbol{U}_t) \\ \boldsymbol{X}_{t+1} &= g(\boldsymbol{X}_t, \boldsymbol{V}_t) \end{aligned}$$

where f and g are vector-valued functions, and $(\boldsymbol{U}_t, \boldsymbol{V}_t)$ are random error terms. A *linear state-space model* takes the form

$$\begin{aligned} \boldsymbol{Y}_t &= A_t\boldsymbol{X}_t + \boldsymbol{c}_t + \boldsymbol{U}_t \\ \boldsymbol{X}_{t+1} &= B_t\boldsymbol{X}_t + \boldsymbol{d}_t + \boldsymbol{V}_t \end{aligned}$$

for deterministic matrices A_t and B_t and vectors $\boldsymbol{c}_t$ and $\boldsymbol{d}_t$. The $\boldsymbol{X}_t$ represent the values of unobserved states, and the second equation represents the evolution of these states through time (see [39]).

State-space models can be used as models for scalar, vector and matrix-valued quantities. One application is evolution of a covariance structure, for example, representing dependencies in a biological network. If the network is dynamically changing through time, a model similar to those above is required but where $\boldsymbol{X}_t$ is a square, positive-definite matrix. For such a network, therefore, a probabilistic model for positive-definite matrices can be constructed from the Wishart/Inverse Wishart distributions [40]. For example, we may have for $t = 1, 2, \ldots,$

$$\begin{aligned} \boldsymbol{Y}_t &\sim \text{Normal}(0, \boldsymbol{X}_t) \\ \boldsymbol{X}_{t+1} &\sim \text{InverseWishart}(\nu_t, \boldsymbol{X}_t) \end{aligned}$$

where degrees of freedom parameter ν_t is chosen to induce desirable properties (stationary, constant expectation etc.) in the sequence of $\boldsymbol{X}_t$ matrices.

Transcriptomics and Functional Genomics

A key objective in the study of biological organization is to understand the mechanisms of the transcription of genomic DNA into mRNA that initiates the production of proteins and hence lies at the center of the functioning of the nuclear engine. In a cell in a particular tissue at a particular time, the nucleus contains the entire mRNA profile (*transcriptome*) which, if it could be measured, would provide direct insight into the functioning of the cell. If this profile could be measured in a dynamic fashion, then the patterns of gene regulation for one, several or many genes could be studied. Broadly, if a gene is “active” at any time point, it is producing mRNA transcripts, sometimes at a high rate, sometimes at a lower rate, and understanding the relationships between patterns of up- and down-regulation lies at the heart of uncovering pathways, or networks of interacting genes. *Transcriptomics* is the study of the entirety of recorded transcripts for a given genome in a given condition. *Functional genomics*, broadly, is the study of gene function via measured expression levels and how it relates to genome structure and protein expression.

Microarrays

A common biological problem is to detect *differential expression* levels of a gene in two or more tissue or cell types, as any differences may contribute to the understanding of the cellular organization (pathways, regulatory networks), or may provide a mechanism for discrimination between future unlabeled samples. An important tool for the analysis of these aspects of gene function is the *microarray*, a medium onto which DNA fragments (or *probes*) are placed or etched. Test sample mRNA fragments are tagged with a fluorescent marker, and then allowed to bond or *hybridize* with the matching DNA probes specific to that nucleotide sequence, according to the usual biochemical bonding process. The microarray thus produces a measurement of the mRNA content of the test sample for each of the large number of DNA sequences bound to the microarray as probes. Microarrays typically now contain tens of thousands of probes for simultaneous investigation of gene expression in whole chromosomes, or even whole genomes for simple organisms. The hybridization experiments are carried out under strict protocols, and every effort is made to regularize the production procedures, from the preparation stage through to imaging. Typically, replicate experiments are carried out.

Microarray experiments have made the study of gene expression routine; instantaneous measurements of mRNA levels for large numbers of different genes can be obtained for different tissue or cell types in a matter of hours. The most important aspects of a statistical analysis of gene expression data are, therefore, twofold; the analysis should be readily implementable for large data sets (large numbers of genes, and/or large numbers of samples), and should give representative, robust and reliable results over a wide range of experiments.

Since their initial use as experimental platforms, microarrays have become increasingly sophisticated, allowing measurement of different important functional aspects. Arrays containing whole genomes of organisms can be used for investigation of function, copy-number variation, SNP variation, deletion/insertion sites and other forms of DNA sequence variation (see [41] for a recent summary). High-throughput technologies similar in the form of printed arrays are now at the center of transcriptome investigation in several different organisms, and also widely used for genome-wide investigation of common diseases in humans [42,43]. The statistical analysis of such data represents a major computational challenge. In the list below, a description of details of *first* and *second* generation microarrays is given.

- **First Generation Microarray Studies**
  From the mid 1990s, comparative hybridization experiments using microarrays or gene-chips began to be widely used for the investigation of gene expression. The two principal types of array used were cDNA arrays and oligonucleotide arrays:
  - **cDNA microarrays**: In cDNA microarray competitive hybridization experiments, the mRNA levels of a genes in a target sample are compared to the

mRNA level of a control sample by attaching fluorescent tags (usually red and green respectively for the two samples) and measuring the relative fluorescence in the two channels. Thus, in a test sample (containing equal amounts of target and control material), differential expression **relative** to the control is either in terms of *up-regulation* or *down-regulation* of the genes in the target sample. Any genes that are up-regulated in the target compared to the control and hence that have larger amounts of the relevant mRNA, will fluoresce as predominantly red, and any that are down-regulated will fluoresce green. Absence of differences in regulation will give equal amounts of red and green, giving a yellow fluor. Relative expression is measured on the log scale

$$y = \log \frac{x_{\mathrm{TARGET}}}{x_{\mathrm{CONTROL}}} = \log \frac{x_{\mathrm{R}}}{x_{\mathrm{G}}} \tag{12}$$

where x_{R} and x_{G} are the fluorescence levels in the RED and GREEN channels respectively.

- **Oligonucleotide arrays:** The basic concept oligonucleotide arrays is that the array is produced to interrogate specific target mRNAs or genes by means of a number of oligo probes usually of length no longer than 25 bases; typically 10-15 probes are used to hybridize to a specific mRNA, with each oligo probe designed to target a specific segment of the mRNA sequence. Hybridization occurs between oligos and test DNA in the usual way. The novel aspect of the oligonucleotide array is the means by which the **absolute** level of the target mRNA is determined; each *perfect match* (PM) probe is paired with a *mismatch* (MM) probe that is identical to the prefect match probe **except** for the nucleotide in the center of the probe, for which a mismatch nucleotide is substituted, as indicated in the diagram below.

$$\mathrm{PM:\ ATGTATACTATT}\boxed{\mathrm{A}}\mathrm{TGCCTAGAGTAC}$$
$$\mathrm{MM:\ ATGTATACTATT}\boxed{\mathrm{C}}\mathrm{TGCCTAGAGTAC}$$

The logic is that the target mRNA, which has been fluorescently tagged, will bind perfectly to the *PM* oligo, and not bind at all to the *MM* oligo, and hence the absolute amount of the target mRNA present can be obtained as the difference $x_{PM} - x_{MM}$ where x_{PM} and x_{MM} are the measurements of for the *PM* and *MM* oligos respectively.

- **Second Generation Microarrays**
In the current decade, the number of array platforms has increased greatly. The principle of of hybridization of transcripts to probes on a printed array is often still the fundamental biological component, but the design of the new arrays is often radically different. Some of the new types of array are described below (see [44] for a summary).
  - **ChiP-Chip:** ChIP-chip (*chromatin immunoprecipitation* chip) arrays are *tiling* array with genomic probes systematically covering whole genomes or chromosomes that is used to relate protein expression to DNA sequence by mapping the binding sites of transcription factor and other DNA-binding proteins. See [45] for an application and details of statistical issues.
  - **ArrayCGH:** Array comparative genome hybridization (ArrayCGH) is another form of tiling array that is used to detect *copy number variation* (the variation in the numbers of repeated DNA segments) in subgroups of individuals with the aim of detecting important variations related to common diseases. See [46,47].
  - **SAGE:** Serial Analysis of Gene Expression (SAGE) is a platform for monitoring the patterns of expression of many thousands of transcripts in one sample, which relies on the sequencing of short cDNA tags that correspond to a sequence near one end of every transcript in a tissue sample. See [48,49,50].
  - **Single Molecule Arrays:** Single Molecule Arrays rely on the binding of single mRNA transcripts to the spots on the array surface, and thus allows for extremely precise measurement of transcript levels: see [51]. Similar technology is used for precise protein measurement and antibody detection. See [52].

Statistical Analysis of Microarray Data

In a microarray experiment, the experimenter has access to expression/expression profile data, possibly for a number of replicate experiments, for each of a (usually large) number of genes. Conventional statistical analysis techniques and principles (hypothesis testing, significance testing, estimation, simulation methods/Monte Carlo procedures) are used in the analysis of microarray data. The principal biological objectives of a typical microarray analysis are:

- **Detection of differential expression:** up- or down-regulation of genes in particular experimental contexts, or in particular tissue samples, or cell lines at a given time instant.
- **Understanding of temporal aspects of gene regulation:** the representation and modeling of patterns of changes in gene regulation over time.

- **Discovery of gene clusters:** the partitioning of large sets of genes into smaller sets that have common patterns of regulation.
- **Inference for gene networks/biological pathways:** the analysis of co-regulation of genes, and inference about the biological processes involving many genes concurrently.

There are typically several key issues and models that arise in the analysis of microarray data: such methods are described in detail in [53,54,55,56]. For a Bayesian modeling perspective, see [57].

- **Array normalization:** Arrays are often imaged under slightly different experimental conditions, and therefore the data are often very different even from replicate to replicate. This is a systematic experimental effect, and therefore needs to be adjusted for in the analysis of differential expression. A misdiagnosis of differential expression may be made purely due to this systematic experimental effect.
- **Measurement error**: The reported (relative) gene expression levels models are only in fact proxies for the true level gene expression in the sample. This requires a further level of variability to be incorporated into the model.
- **Random effects modeling**: It may be necessary to use *mixed* regression models, where gene specific *random-effects* terms are incorporated into the model.
- **Multivariate analysis**: The covariability of response measurements, in time course experiments, or between PM and MM measurements for an oligonucleotide array experiment, is best handled using multivariate modeling.
- **Testing:** One- and two-sample hypothesis testing techniques, based on parametric and non-parametric testing procedures can be used in the assessment of the presence of differential expression. For detecting more complex (patterns of) differential expression, in more general structured models, the tools of analysis of variance (ANOVA) can be used to identify the chief sources of variability.
- **Multiple testing/False discovery**: In microarray analysis, a classical statistical analysis using significance testing needs to take into account the fact that a very large number of tests are carried out. Hence significance levels of tests must be chosen to maintain a required *family-wise error rate*, and to control the *false discovery rate***.**
- **Classification:** The genetic information contained in a gene expression profile derived from microarray experiments for, say, an individual tissue or tumor type may be sufficient to enable the construction of a *classification rule* that will enable subsequent classification of new tissue or tumor samples.
- **Cluster analysis:** Discovery of subsets of sets of genes that have common patterns of regulation can be achieved using the statistical techniques of *cluster analysis* (see Sect. "Clustering").
- **Computer-intensive inference**: For many testing and estimation procedures needed for microarray data analysis, simulation-based methods (bootstrap estimation, Monte Carlo and permutation tests, Monte Carlo and MCMC) are often necessary, especially when complex Bayesian models are used.
- **Data compression/feature extraction:** The methods of principal components analysis and extended linear modeling via *basis functions* can be used to extract the most pertinent features of the large microarray data sets.
- **Experimental design**: Statistical experimental design can assist in determining the number of replicates, the number of samples, the choice of time points at which the array data are collected and many other aspects of microarray experiments. In addition, power and sample size assessments can inform the experimenter as to the statistical worth of the microarray experiments that have been carried out.

Typically, data derived from both types of microarrays are highly noise and artefact corrupted. The statistical analysis of such data is therefore quite a challenging process. In many cases, the replicate experiments are very variable. The other main difficulty that arises in the statistical analysis of microarray data is the dimensionality; a vast number of gene expression measurements are available, usually only on a relatively small number of individual observations or samples, and thus it is hard to establish any general distributional models for the expression of a single gene.

Clustering

Cluster analysis is an unsupervised statistical procedure that aims to establish the presence of identifiable subgroups (or *clusters*) in the data, so that objects belonging to the same cluster resemble each other more closely than objects in different clusters; see [58,59] for comprehensive summaries.

In two or three dimensions, clusters can be visualized by plotting the raw data. With more than three dimensions, or in the case of dissimilarity data (see below), analytical assistance is needed. Broadly, clustering algorithms fall into two categories:

- **Partitioning Algorithms:** A partitioning algorithm divides the data set into K clusters, where and the algorithm is run for a range of K-values. Partitioning methods are based on specifying an initial number of groups, and iteratively reallocating observations between groups until some equilibrium is attained. The most famous algorithm is the *K-Means* algorithm in which the observations are iteratively classified as belonging to one of K groups, with group membership is determined by calculating the centroid for each group (the multidimensional version of the mean) and assigning each observation to the group with the closest centroid. The K-means algorithm alternates between calculating the centroids based on the current group memberships, and reassigning observations to groups based on the new centroids. A more robust method uses mediods rather than centroids (that is, medians rather than means in each dimension, and more generally, any distance-based allocation algorithm could be used.
- **Hierarchical Algorithms:** A hierarchical algorithm yields an entire hierarchy of clustering for the given data set. *Agglomerative methods* start with each object in the data set in its own cluster, and then successively merges clusters until only one large cluster remains. *Divisive methods* start by considering the whole data set as one cluster, and then splits up clusters until each object is separated. Hierarchical algorithms are discussed in detail in Sect. "Hierarchical Clustering".

Data sets for clustering of N observations can either take the form of an $N \times p$ data matrix, where rows contain the different observations, and columns contain the different variables, or an $N \times N$ dissimilarity matrix, whose (i,j)th element is d_{ij}, the distance or dissimilarity between observations i and j that obeys the usual properties of a metric. Typical data distance measures between two data points i and j with measurement vectors $\mathbf{x}_i$ and $\mathbf{x}_j$ are the L_1 and L_2 Euclidean distances, and the grid-based *Manhattan distance* for discrete variables, or the *Hamming distance* for binary variables. For *ordinal* (ordered categorical) or *nominal* (label) data, other dissimilarities can be defined.

Hierarchical Clustering Agglomerative hierarchical clustering initially places each of the N items in its own cluster. At the first level, two objects are to be clustered together, and the pair is selected such that the potential function increases by the largest amount, leaving $N-1$ clusters, one with two members, the remaining $N-2$ each with one. At the next level, the optimal configuration of $N-2$ clusters is found, by joining two of the existing clusters. This process continuous until a single cluster remains containing all N items. At each level of the hierarchy, the merger chosen is the one that leads to the smallest increase in some objective function.

Classical versions of the hierarchical agglomeration algorithm are typically used with *average*, *single* or *complete* linkage methods, depending on the nature of the merging mechanism. Such criteria are inherently heuristic, and more formal *model-based* criteria can also be used. Model-based clustering is based on the assumption that the data are generated by a mixture of underlying probability distributions. Specifically, it is assumed that the population of interest consists of K different sub populations, and that the density of an observation from the the sub population is for some unknown vector of parameters. Model-based clustering is described in more detail in Sect. "Model–Based Hierarchical Clustering".

The principal display plot for a clustering analysis is the *dendrogram* which plots all of the individual data objects linked by means of a binary "tree". The dendrogram represents the structure inferred from a hierarchical clustering procedure which can be used to partition the data into subgroups as required if it is cut at a certain "height" up the tree structure. As with many of the aspects of the clustering procedures described above, it is more of a heuristic graphical representation rather than a formal inferential summary. However, the dendrogram is readily interpretable, and favored by biologists.

Model-Based Hierarchical Clustering Another approach to hierarchical clustering is *model-based clustering* (see for example [60,61]), which is based on the assumption that the data are generated by a mixture of K underlying probability distributions as in Eq. (11). Given data matrix $\boldsymbol{y} = (\boldsymbol{y}_1, \ldots, \boldsymbol{y}_N)^{\mathsf{T}}$, let $\gamma = (\gamma_1, \ldots, \gamma_N)$ denote the cluster labels, where $\gamma_i = k$ if the ith data point comes from the kth sub-population. In the classification procedure, the maximum likelihood procedure is used to choose the parameters in the model.

Commonly, the assumption is made that the data in the different sub-populations follow multivariate normal distributions, with mean u_k and covariance matrix Σ_k for cluster k, so that

$$\begin{aligned} f_{Y|\boldsymbol{\theta}}(\boldsymbol{y}|\boldsymbol{\theta}) &= \sum_{k=1}^{K} \omega_k f_k(\boldsymbol{y}|u_k, \Sigma_k) \\ &= \sum_{k=1}^{K} \omega_k \frac{1}{(2\pi)^{d/2}} \frac{1}{|\Sigma_k|^{1/2}} \\ &\qquad \exp\left\{-\frac{1}{2}(\boldsymbol{y}-u_k)^{\mathsf{T}} \Sigma_k^{-1} (\boldsymbol{y}-u_k)\right\} \end{aligned}$$

where $\Pr[\gamma_i = k] = \omega_k$. If $\Sigma_k = \sigma^2 \boldsymbol{I}_p$ is a $p \times p$ matrix, then maximizing the likelihood is the same as minimizing the sum of within-group sums of squares and corresponds to the case of hyper-spherical clusters with the same variance. Other forms of Σ_k yield clustering methods that are appropriate in different situations. The key to specifying this is the singular value or eigen decomposition of Σ_k, given by eigenvalues $\lambda_1, \ldots, \lambda_p$ and eigen vectors $\mathbf{v}_1, \ldots, \mathbf{v}_p$, as in Principal Components Analysis [62]. The eigen vectors of Σ_k, specify the orientation of the kth cluster, the largest eigenvalue λ_1 specifies its variance or size, and the ratios of the other eigenvalues to the largest one specify its shape. Further, if $\Sigma_k = \sigma_k^2 \boldsymbol{I}_p$, the criterion corresponds to hyper spherical clusters of different sizes, and by fixing the eigenvalue ratios $\alpha_j = \lambda_j/\lambda_1$ for $j = 2, 3, \ldots, p$ across clusters, other cluster shapes are encouraged.

Model-Based Analysis of Gene Expression Profiles

The clustering problem for vector-valued observations can be formulated using models used to represent the gene expression patterns via the *extended linear model*, that is, a linear model in non-linear basis functions; see, for example, [63,64] for details.

Generically, the aim of the statistical model is to capture the behavior of the gene expression ratio y_t as a function of time t. The basis of the modeling strategy would be to use models that capture the characteristic behavior of expression profiles likely to be observed due to different forms of regulation. A regression framework and model can be adopted. Suppose that Y_t is model led using a linear model

$$Y_t = \boldsymbol{X}_t \boldsymbol{\beta} + \varepsilon_t$$

where $\boldsymbol{X}_t$ is (in general) a $1 \times p$ vector of specified functions of t, and $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector. In vector representation, the gene expression profile over times $t_1, \ldots, t_T$ can be written $\boldsymbol{Y} = (Y_1, \ldots, Y_T)$,

$$\boldsymbol{Y} = \boldsymbol{X}\boldsymbol{\beta} + \varepsilon\,. \tag{13}$$

The precise form of design matrix $\boldsymbol{X}$ will be specified to model the time-variation in signal. Typically the random error terms $\{\varepsilon_t\}$ are taken as independent and identically distributed Normal random variables with variance σ^2, implying that the conditional distribution of the responses $\boldsymbol{Y}$ is multivariate normal

$$\boldsymbol{Y}|\boldsymbol{X}, \boldsymbol{\beta}, \sigma^2 \sim N\left(\boldsymbol{X}\boldsymbol{\beta}, \sigma^2 \boldsymbol{I}_T\right) \tag{14}$$

where now $\boldsymbol{X}$ is $T \times p$ where $\boldsymbol{I}_T$ is the $T \times T$ identity matrix.

In order to characterize the underlying gene expression profile, the parameter vector $\boldsymbol{\beta}$ must be estimated. For this model, the maximum likelihood/ordinary least squares estimates of $\boldsymbol{\beta}$ and σ^2 are

$$\widehat{\boldsymbol{\beta}}_{\text{ML}} = \left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{X}\right)^{-1} \boldsymbol{X}^{\mathsf{T}}\boldsymbol{y} \qquad \widehat{\sigma}^2 = \frac{1}{T-p}\left(\boldsymbol{y} - \widehat{\boldsymbol{y}}\right)^{\mathsf{T}}\left(\boldsymbol{y} - \widehat{\boldsymbol{y}}\right)$$

for fitted values $\widehat{\boldsymbol{y}} = \boldsymbol{X}\widehat{\boldsymbol{\beta}}_{\text{ML}} = \boldsymbol{X}\left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{X}\right)^{-1} \boldsymbol{X}^{\mathsf{T}}\boldsymbol{y}$.

Bayesian Analysis in Model–Based Clustering In a Bayesian analysis of the model in (13) a joint prior distribution $\pi\left(\boldsymbol{\beta}, \sigma^2\right)$ is specified for $\left(\boldsymbol{\beta}, \sigma^2\right)$, and a posterior distribution conditional on the observed data is computed for the parameters. The calculation proceeds using Eq. (5) (essentially with $\mathcal{G}$ fixed).

$$\pi\left(\boldsymbol{\beta}, \sigma^2|\boldsymbol{y}, \boldsymbol{X}\right) = \frac{L\left(\boldsymbol{y}; \boldsymbol{X}, \boldsymbol{\beta}, \sigma^2\right)\pi\left(\boldsymbol{\beta}, \sigma^2\right)}{\int L\left(\boldsymbol{y}; \boldsymbol{X}, \boldsymbol{\beta}, \sigma^2\right)\pi\left(\boldsymbol{\beta}, \sigma^2\right) \mathrm{d}\boldsymbol{\beta}\, \mathrm{d}\sigma^2}$$

where $L\left(\boldsymbol{y}; \boldsymbol{X}, \boldsymbol{\beta}, \sigma^2\right)$ is the likelihood function. In the linear model context, a conjugate prior specification is used where

$$\begin{aligned} \pi\left(\boldsymbol{\beta}|\sigma^2\right) &\equiv \text{Normal}\left(\boldsymbol{v}, \sigma^2 \boldsymbol{V}\right) \\ \pi\left(\sigma^2\right) &\equiv \text{IGamma}\left(\frac{\alpha}{2}, \frac{\gamma}{2}\right) \end{aligned} \tag{15}$$

($\boldsymbol{v}$ is $p \times 1$, $\boldsymbol{V}$ is $p \times p$ positive-definite and symmetric, all other parameters are scalars) and IGamma denotes the inverse Gamma distribution. Using this prior, standard Bayesian calculations show that conditional on the data

$$\begin{aligned} \pi\left(\boldsymbol{\beta}|\boldsymbol{y}, \sigma^2\right) &\equiv \text{Normal}\left(\boldsymbol{v}^*, \sigma^2 \boldsymbol{V}^*\right) \\ \pi\left(\sigma^2|\boldsymbol{y}\right) &\equiv \text{IGamma}\left(\frac{T+\alpha}{2}, \frac{c+\gamma}{2}\right) \end{aligned} \tag{16}$$

where

$$\begin{aligned} \boldsymbol{V}^* &= \left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{X} + \boldsymbol{V}^{-1}\right)^{-1} \\ \boldsymbol{v}^* &= \left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{X} + \boldsymbol{V}^{-1}\right)^{-1}\left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{y} + \boldsymbol{V}^{-1}\boldsymbol{v}\right) \\ c &= \boldsymbol{y}^{\mathsf{T}}\boldsymbol{y} + \boldsymbol{v}^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{v} - \left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{y} + \boldsymbol{V}^{-1}\boldsymbol{v}\right)^{\mathsf{T}} \\ &\qquad \left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{X} + \boldsymbol{V}^{-1}\right)^{-1}\left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{y} + \boldsymbol{V}^{-1}\boldsymbol{v}\right) \end{aligned} \tag{17}$$

In regression modeling, it is usual to consider a centered parametrization for $\boldsymbol{\beta}$ so that $\boldsymbol{v} = 0$, giving

$$\begin{aligned} \boldsymbol{v}^* &= \left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{X} + \boldsymbol{V}^{-1}\right)^{-1} \boldsymbol{X}^{\mathsf{T}}\boldsymbol{y} \\ c &= \boldsymbol{y}^{\mathsf{T}}\boldsymbol{y} - \boldsymbol{y}^{\mathsf{T}}\boldsymbol{X}^{\mathsf{T}}\left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{X} + \boldsymbol{V}^{-1}\right)^{-1} \boldsymbol{X}^{\mathsf{T}}\boldsymbol{y} \\ &= \boldsymbol{y}^{\mathsf{T}}\left(\boldsymbol{I}_T - \boldsymbol{X}\left(\boldsymbol{X}^{\mathsf{T}}\boldsymbol{X} + \boldsymbol{V}^{-1}\right)^{-1} \boldsymbol{X}^{\mathsf{T}}\right)\boldsymbol{y} \end{aligned}$$

A critical quantity in a Bayesian clustering procedure is the marginal likelihood, as in Eq. (8), for the data in light of the model:

$$f_Y(\boldsymbol{y}) = \int f_{Y|\boldsymbol{\beta},\sigma^2}\left(\boldsymbol{y}|\boldsymbol{\beta},\sigma^2\right)\pi\left(\boldsymbol{\beta}|\sigma^2\right)\pi\left(\sigma^2\right)\mathrm{d}\boldsymbol{\beta}\,\mathrm{d}\sigma^2 . \tag{18}$$

Combining terms above gives that

$$f_Y(\boldsymbol{y}) = \left(\frac{1}{\pi}\right)^{T/2}\frac{\gamma^{\alpha/2}\Gamma\left(\frac{T+\alpha}{2}\right)}{\Gamma\left(\frac{\alpha}{2}\right)}\frac{|\boldsymbol{V}^*|^{1/2}}{|\boldsymbol{V}|^{1/2}}\frac{1}{\{c+\gamma\}^{(T+\alpha)/2}} \tag{19}$$

This expression is the marginal likelihood for a single gene expression profile. For a collection of profiles belonging to a single cluster, $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_N$, Eq. (19) can again be evaluated and used as the basis of a dissimilarity measure as an input into a hierarchical clustering procedure. The marginal likelihood in Eq. (19) can easily be re-expressed for clustered data. The basis of the hierarchical clustering method outlined in [64] proceeds by agglomeration of clusters from N to 1, with the two clusters that lead to the **greatest increase** marginal likelihood score at each stage of the hierarchy. This method works for profiles of arbitrary length, potentially with different observation time points, however it is computationally most efficient when the time points are the same for each profile.

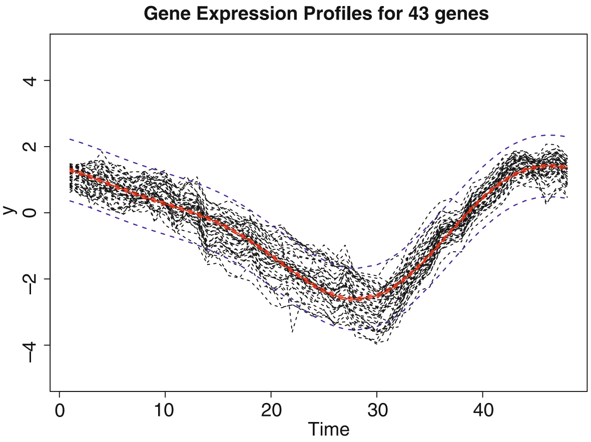
The design matrix $\boldsymbol{X}$ is typically expressed via non-linear basis functions, for example truncated polynomial splines, Fourier bases or wavelets. For T large, it is usually necessary to use a projection through a lower number of bases; for example, for a single profile, $\boldsymbol{X}$ becomes $T \times p$ and $\boldsymbol{\beta}$ becomes $p \times 1$, for $T > p$. Using different designs, many flexible models for the expression profiles can be fitted. In some cases, the linear mixed effect formulation in Eq. (10) can be used to construct the spline-based models; in such models, some of the β parameters are themselves assumed to be random effects (see [65]).

For example, in *harmonic regression*, regression in the Fourier bases is carried out. Consider the extended linear model

$$Y_t = \sum_{j=0}^{p} \beta_j g_j(t) + \varepsilon_t$$

where $g_0(t) = 1$ and

$$g_j(t) = \begin{cases}\cos(\phi_j t) & j \text{ odd}\\ \sin(\phi_j t) & j \text{ even}\end{cases}$$



Complexity in Systems Level Biology and Genetics: Statistical Perspectives, Figure 1

Cluster of gene expression profiles obtained using Bayesian hierarchical model-based clustering: data from the intraerythrocytic developmental cycle of protozoa *Plasmodium falciparum*. Clustering achieved using harmonic regression model with $k = 2$. Solid red line is posterior mean for this cluster, dotted red lines are point wise 95% credible intervals for the cluster mean profile, and dotted blue lines are point wise 95% credible intervals for the observations

where p is an even number, $p = 2k$ say, and $\phi_j, j = 1, 2, \ldots, k$ are constants with $\phi_1 < \phi_2 < \cdots < \phi_k$. For fixed t, $\cos(\phi_j t)$ and $\sin(\phi_j x)$ are also fixed and this model is a linear model in parameters

$$\boldsymbol{\beta} = (\beta_0, \beta_1, \ldots, \beta_p)^{\mathsf{T}} .$$

This model can be readily fitted to time-course expression profiles. The plot below is a fit of the model with $k = 2$ to a cluster of profiles extracted using the method described in [64] from the malaria protozoa *Plasmodium falciparum* data set described in [66].

One major advantage of the Bayesian inferential approach is that any biological prior knowledge that is available can be incorporated in a coherent fashion. For example, the data in Figure 1 illustrate periodic behavior related to the cyclical nature of cellular organization, and thus the choice of the Fourier bases is a natural one.

Choosing the Number of Clusters: Bayesian Information Criterion A hierarchical clustering procedure gives the sequence by which the clusters are merged (in agglomerative clustering) or split (in divisive clustering) according the model or distance measure used, but does not give an indication for the number of clusters that are present in the data (under the model specification). This is obviously an important consideration. One advantage of the model-based approach to clustering is that it allows the use of statistical model assessment procedures to assist in the choice of the number of clusters. A common method is to use approximate *Bayes factors* to compare models of different orders (i. e. models with different numbers of clusters), and gives a systematic means of selecting the parametrization of the model, the clustering method, and also the number of clusters (see [67]).

The Bayes factor is the posterior odds for one model against the other assuming neither is favored a priori. A reliable approximation to twice the log Bayes factor called the *Bayesian Information Criterion* (BIC), which, for model M fitted to n data points is given by

$$\mathrm{BIC}_M = -2 \log L_M(\widehat{\boldsymbol{\theta}}) + d_M \log n$$

where L_M is the Bayesian marginal likelihood from Eq. (18), $L_M(\widehat{\boldsymbol{\theta}})$ is the maximized log likelihood of the data for the model M, and d_M is the number of parameters estimated in the model. The number of clusters is not considered a parameter for the purposes of computing the BIC. The smaller (more negative) the value of the BIC, the stronger the evidence for the model.

Classification via Model–Based Clustering Any clustering procedure can be used as the first step in the construction of *classification* rules. Suppose that it, on the basis of an appropriate decision procedure, it is known that there are C clusters, and that a set of existing expression profiles $y_1, \ldots, y_N$ have been allocated in turn to the clusters. Let $z_1, \ldots, z_N$ be the cluster allocation labels for the profiles. Now, suppose further that the C clusters can be decomposed further into two subsets of sizes C_0 and C_1, where the subsets represent perhaps clusters having some common, known biological function or genomic origin. For example, in a cDNA microarray, it might be known that the clones are distinguishable in terms of the organism from which they were derived. A new objective could be to allocate a novel gene and expression profile to one of the subsets, and one of the clusters within that subset.

Let y_{ijk}, for $i = 0, 1,\ j = 1, 2, \ldots, C_i,\ k = 1, 2, \ldots, N_{ij}$ denote the kth profile in cluster j in subset i. Let y^* denote a new profile to be classified, and ξ^* be the binary classification-to-subset, and z^* the classification-to-cluster variable for y^*. Then, by Bayes Rule, for $i = 1, 2$,

$$P\left[\xi^* = i | y^*, y, z\right] \propto p\left(y^* | \xi^* = i, y, z\right) P\left[\xi^* = i | y, z\right] \tag{20}$$

The two terms in Eq. (20) can be determined on the basis of the clustering output.

Metabolomics

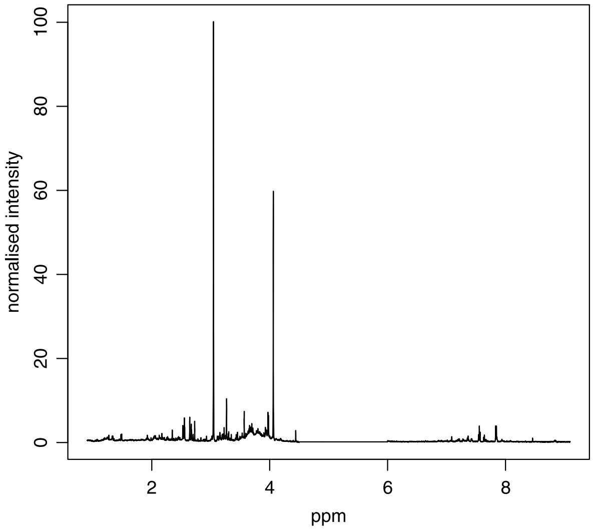
The term *metabolome* refers to the total metabolite content of an organic sample (tissue, blood, urine etc) obtained from a living organism which represents the products of a higher level of biological interaction than that which occurs within the cell. *Metabolomics* and *metabonomics* are the fields in biomedical investigation that combines the application of nuclear magnetic resonance (NMR) *spectroscopy* with multivariate statistical analysis in studies of the composition of the samples. Metabonomics is often used in reference to the static chemical content of the sample, whereas metabolomics is used to refer to the dynamic evolution of the metabolome. Both involve the measurement of the metabolic response to interventions – see for example [68] – and applications of metabolomics include several in public health and medicine [69,70].

Statistical Methods for Spectral Data

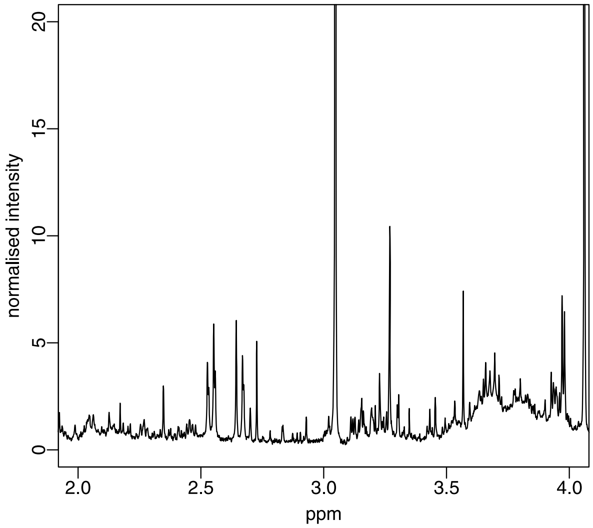
The two principal spectroscopic measurement platforms, NMR and Mass Spectrometry (MS) yield alternative representations of the metabolic spectrum. They produce spectra (or profiles) that consist of several thousands of individual measurements at different resonances or masses. There are several phases of processing of such data; preprocessing using smoothing, alignment and de-noising, peak separation, registration and signal extraction. For an extensive discussion, see [62].

An NMR spectrum consists of measurements of the intensity or frequency of different biochemical compounds (metabolites) represented by a set of *resonances* dependent upon the chemical structure, and can be regarded as a linear combination of peaks (nominally of various widths) that correspond to singletons or multiple peaks according to the neighboring chemical environment. A typical spectrum extracted from rat urine is depicted in Fig. 2 see [71]. Two dominant sharp peaks are visible.

Features of the spectra that require specific statistical modeling include multiple peaks for a single compound, variation in peak shape, and chemical shifts induced by variation in experimental pH Signals from different metabolites can be highly overlapped and subject to peak position variation due primarily to pH variations in the samples, and there are many small scale features (see Fig. 3). Statistical methods of pre-processing NMR spectra for statistical analysis which address the problems outlined above, using, for example, dynamic time warping to achieve alignment of resonance peaks across replicate spectra as a form or spectral registration form part of the necessary holistic Bayesian framework.



Complexity in Systems Level Biology and Genetics: Statistical Perspectives, Figure 2
A normalized rat urine spectrum. The ordinate is parts per million, the abscissa is intensity after standardization



Complexity in Systems Level Biology and Genetics: Statistical Perspectives, Figure 3
Magnified portion of the spectrum showing small scale features

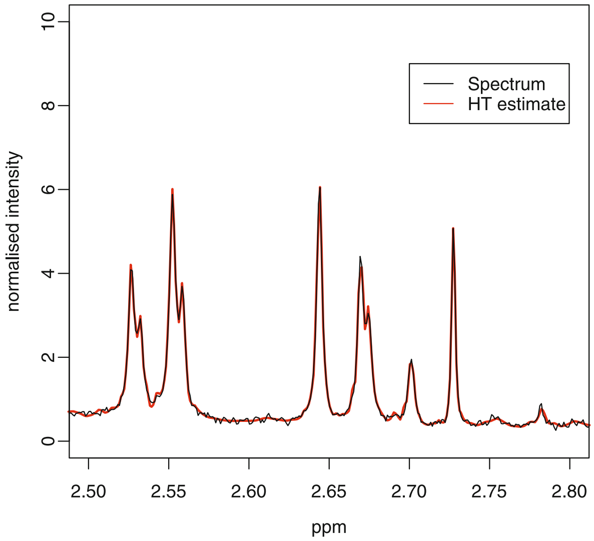
Classical statistical methods for metabolic spectra include the following:

- **Principal Components Analysis (PCA) and Regression:** a linear data projection method for dimension reduction, feature extraction, and classification of samples in an unsupervised fashion, that is, without reference to labeled cases.
- **Partial Least Squares (PLS):** a non-linear projection method similar to PCA, but implemented in a supervised setting for sample discrimination.
- **Clustering:** Clusters of spectra, or peaks within spectra, can be discovered using similar techniques to those described in Sect. "Clustering".
- **Neural Networks:** Flexible non-linear regression models constructed from simple mathematical functions that are learned from the observation of cases, that are ideal models for classification. The formulation of an neural network involves three levels of interlinked variables; *outputs*, *inputs*, and *hidden variables*, interpreted as a collection of unobserved random variables that form the hidden link between inputs and outputs.

Bayesian Approaches

The Bayesian framework is a natural one for incorporating genuine biological prior knowledge into the signal reconstruction, and typically useful prior information (about fluid composition, peak location, peak multiplicity) is available. In addition, a hierarchical Bayesian model structure naturally allows construction of plausible models for the spectra across experiments or individuals.

- **Flexible Bayesian Models:** The NMR spectrum can be represented as a noisy signal derived from some underlying and biologically important mechanism. Basis-function approaches (specifically, wavelets) have been much used to represent non-stationary time-varying signals [65,71,72,73]. The sparse representation of the NMR spectrum in terms of wavelet coefficients makes them an excellent tool in data compression, yet these coefficients can still be easily transformed back to the spectral domain to give a natural interpretation in terms of the underlying metabolites.
  Figure 4 depicts the reconstruction of the rat urine spectrum in the region between 2.5 and 2.8 ppm using wavelet methods; see [71].
- **Bayesian Time Series Models for Complex Non-stationary Signals:** See for example [74]. The duality between semi-parametric modeling of functions and latent time series models allows a view of the analysis of the underlying NMR spectrum not as a set of point wise evaluations of a function, but rather as a (time-ordered) series of correlated observations with some identifiable latent structure. Time series models, computed using dynamic calculation (filtering), provide a method for representing the NMR spectra parsimoniously.
- **Bayesian Mixture Models:** A reasonable generative model for the spectra is one that constructs the



Complexity in Systems Level Biology and Genetics: Statistical Perspectives, Figure 4

Wavelet reconstruction of a region of the spectrum results under the "Least Asymmetric wavelet" with four vanishing moments using the hard thresholding (HT)

> spectra from a large number of symmetric peaks of varying size, corresponding to the contributions of different biochemical compounds. This can be approximated using a finite mixture model, where the number, magnitudes and locations, of the spectral contributions are unknown. Much recent research has focused on the implementation of computational strategies for Bayesian mixtures, in particular Markov chain Monte Carlo (MCMC) and Sequential Monte Carlo (SMC) have proved vital. The reconstruction of NMR spectra is a considerably more challenging area than those for which mixture modeling is conventionally used, as many more individual components are required. Flexible semi-parametric mixture models have been utilized in [75,76], whilst fully non-parametric mixture models similar to those described in Sect. "Mixture Models" can also be used [73].

A major advantage of using the fully Bayesian framework is that, once again, all relevant information (the spectral data itself, knowledge of the measurement processes for different experimental platforms, the mechanisms via which multiple peaks and shifts are introduced) can be integrated in a coherent fashion. In addition, prior knowledge about the chemical composition of the samples can be integrated via a prior distribution constructed by inspection of the profiles for training samples. At a higher level of synthesis, the Bayesian paradigm offers a method for integrating metabolomic data with other functional or structural data, such as gene expression or protein expression data. Finally, the metabolic content of tissue changes temporally, so dynamic modeling of the spectra could also be attempted.

Future Directions

Biological data relating to structure and function of genes, proteins and other biological substances are now available from a wide variety of platforms. Researchers are beginning to develop methods for coherent combination of data from different experimental processes to get an entire picture of biological cause and effect. For example, the effective combination of gene expression and metabonomic data will be of tremendous utility. A principal challenge is therefore the fusion of expression data derived from different experimental platforms, and seeking links with sequence and ontological information available. Such fusion will be critical in the future of statistical analysis of large scale systems biology and bioinformatics data sets.

In terms of public health impact of systems biology and statistical genomics, perhaps the most prominent is the study of common diseases through high-throughput genotyping of single nucleotide polymorphisms (SNPs). In genome wide association studies, SNP locations that correlate with disease status or quantitative trait value are sought. In such studies, the key statistical step involves the selection of informative predictors (SNP or genomic loci) from a large collection of candidates. Many such genome wide studies have been completed or are ongoing (see [42,43,77,78]). Such studies represent huge challenges for statisticians and mathematical modelers, as the data contain many subtle structures but also as the amount of information is much greater than that available for typical statistical analysis.

Another major challenge to the quantitative analysis of biological data comes in the form of image analysis and extraction. Many high throughput technologies rely on the extraction of information from images, either in static form, or dynamically from a series of images. For example it is now possible to track the expression level of mRNA transcripts in real-time ([79,80,81]), and to observe mRNA transcripts moving from transcription sites to translation sites (see for example [82]). Imaging techniques can also offer insights into aspects of the dynamic organization of nuclear function by studying the positioning of nuclear compartments and how those compartments reposition themselves in relation to each other through time. The challenges for the statistician are to develop real-time analysis methods for tracking and quantifying the nature and content of such images, and tools from spatial modeling and time series analysis will be required.

Finally, *flow cytometry* can measure characteristics of millions of cells simultaneously, and is a technology that offers many promises for insights into biological organization and public health implications. However, quantitative measurement and analysis methods are only yet in the early stages of development, but offer much promise (see [83,84]).

Article Outline

Glossary

Directed/Undirected graph A set of vertices connected by directed or undirected edges. A directed edge is one-way ($A \to B$), while an undirected edge is two-way or symmetric: $A - B$.

Network For our purposes, a network is defined identically to a graph: it is an abstract object composed of vertices (nodes) joined by (directed or undirected) edges (links). Hence we will use the terms 'graph' and 'network' interchangeably.

Graph topology The list of nodes i and edges (i, j) or $(i \to j)$ defines the topology of the graph.

Graph structure There is no single agreed definition for what constitutes the "structure" of a graph. To the contrary: this question has been the object of a great deal of research—research which is still ongoing.

Node degree distribution One crude measure of a graph's structure. If n_k is the number of nodes having degree k in a graph with N nodes, then the set of n_k is the node degree distribution—which is also often expressed in terms of the frequencies $p_k = n_k/N$.

Small-worlds graph A "small-worlds graph" has two properties: it has short path lengths (as is typical of random graphs)—so that the "world" of the network is truly "small", in that every node is within a few (or not too many) hops of every other; and secondly, it has (like real social networks, and *unlike* random graphs) a significant degree of *clustering*—meaning that two neighbors of a node have a higher-than-random probability of also being linked to one another.

Graph visualization The problem of displaying a graph's topology (or part of it) in a 2D image, so as to give the viewer insight into the structure of the graph. We see that this is a hard problem, as it involves both the unsolved problem of what we mean by the structure of the graph, and also the combined technological/psychological problem of conveying useful information about a (possibly large) graph via a 2D (or quasi-3D) layout. Clearly, the notion of a good graph visualization is dependent on the use to which the visualization is to be put—in other words, on the information which is to be conveyed.

Section Here, a 'bookkeeping' definition. This article introduces the reader to all of the other articles in the Section of the Encyclopedia which is titled "Complex Networks and Graph Theory". Therefore, whenever the word 'Section' (with a large 'S') is used in this 'roadmap' article, the word refers to that Section of the Encyclopedia. To avoid confusion, the various subdivisions of this roadmap article will be called 'parts'.

Definition of the Subject

The basic network concept is very simple: objects, connected by relationships. Because of this simplicity, the concept turns up almost everywhere one looks. The study of networks (or equivalently, graphs), both theoretically and empirically, has taken off over the last ten years, and shows no sign of slowing down. The field is highly interdisciplinary, having important applications to the Internet and the World Wide Web, to social networks, to epidemiology, to biology, and in many other areas. This introductory article serves as a reader's guide to the 13 articles in the Section of the Encyclopedia which is titled "Complex Networks and Graph Theory". These articles will be discussed in the context of three broad themes: network structure; dynamics of network structure; and dynamical processes running over networks.

Introduction

In the past ten years or so, the study of graphs has exploded, leaving forever the peaceful sanctum of pure mathematics to become a fundamental concept in a vigorous, ill-defined, interdisciplinary, and important field of study. The most common descriptive term for this field is the "study of complex networks". This term is distinguished from the older, more mathematically-bound term "graph theory" in two ways. First – and perhaps most important – this new field is not just theoretical; to the contrary, the curious researcher finds that there is an enormous variety of empirically obtained graphs/networks (we use the terms interchangeably here) available as datasets on the Web. That is, one studies real, measured graphs; and not surprisingly, this empirical connection gives the endeavor much more of an applied flavor also.

The second distinction is perhaps not well motivated by the words used; but the "study of complex networks" typically means studying networks whose structure deviates in important ways from the "classical random graphs" of Erdős and Rényi [10,11]. We note that these two points are related: as one turned to studying real networks [18], one found that they were not described by classical random graphs [24,25]; hence one was forced to look at other kinds of structures.

This article is a reader's guide to the other articles in the Section entitled "Complex Networks and Graph Theory". The inclusion of both terms was very deliberate: graph theory gives the mathematical foundation for the more messy endeavor called "complex networks"; and the two fields have a strong and fruitful interaction. In this article I will describe the 13 other articles of this Section.

These 13 articles amply document the interdisciplinary nature of this exciting field: we find represented mathematics, biology, the Web and the Internet, software, epidemiology, and social networks (with the latter field also having its own Section in the Encyclopedia). For this reason, I will not define the parts of this article by field of study, but rather by general *themes* which run through essentially all studies of networks (at least in principle, and often in fact). In each part of this article I will point out those articles which represent that part's theme to a significant degree. Hence these themes are meant to tie together all of the articles into a simple framework.

In the next part "Graphs, Networks, and Complex Networks", I will concisely present the basic terminology which is in use. Then in entitled part the "Structure of Networks" I discuss the knotty question of the *structure* of a graph; this problem is the first theme, and it is very much unfinished business. In part "Dynamical Network Structures" we look at network topologies (and structures) which are *dynamic* rather than static. This is clearly an important theme, since (i) real empirical networks are necessarily dynamic (on some – often short – time scale), and (ii) the study of how networks grow and evolve can be highly useful for understanding how they have the structure we observe today. Then in part "Dynamical Processes on Networks" we look at the very large question of dynamical processes which take place *over* networks. Examples which illustrate the importance of this topic are epidemic spreading over social and computer networks, and the activation/inhibition processes going on over gene (or neural) networks. Clearly the progress of such dynamical processes may be strongly dependent on the underlying network structure; hence we see that all of these themes (parts "Structure of Networks"–"Dynamical Processes on Networks") are tightly related.

In part "Graph Visualization" we look briefly at an important but somewhat 'orthogonal' theme, namely, the problem of *graph visualization:* given a graph's topology, how can one best present this information visually to a human viewer? Finally, part "Future Directions" offers a very brief, modest, and personal take on the very large question of "future directions" in research on complex networks.

Graphs, Networks, and Complex Networks

Graphs

One of the earliest applications of graph theory may be found in Euler's solution, in 1736, of the problem called 'The seven bridges of Königsberg'. Euler considered the problem of finding a continuous path crossing each of the seven bridges of Königsberg exactly once, and solved the problem by representing each connected piece of land as a vertex (node) of a graph, and each bridge as an undirected (two-way) link. (For a nice presentation of this problem, see http://mathforum.org/isaac/problems/bridges2.html.) This little problem is an excellent example of the power of mathematics to extract understanding via abstraction: the lay person may stare at the bridges, islands etc, and try various ideas—but reducing the entire problem to an abstract graph, composed only of nodes and links, aids the application of pure reason, leading to a final and utterly convincing solution.

To study graphs is to study discrete objects and the relationships between them. Hence graph theory may be regarded as a branch of combinatorics. Erdős and Rényi [10,11] founded the study of "classical random graphs". These graphs are specified by the node number N (which typically is assumed to grow large), and by links laid down at random between these nodes, subject to various constraints. One such constraint is that every node have exactly k links—giving a (k—) *regular random graph*. A more relaxed constraint is simply to specify m links in total (so that the average node degree is $\langle k \rangle = m/N$). Further relaxing of this constraint gives that every possible link, out of the set of

$$\begin{bmatrix} N \\ 2 \end{bmatrix} = N(N-1)/2$$

possible links, is included with probability p. This gives the average node degree (now averaged over many graphs) as $\langle k \rangle = \langle m \rangle / N = p(N-1)/2$. While all of these types of classical random graphs are similar "in spirit", those with the fewest constraints are those for which it is easiest to prove things.

We are fortunate to have in our Section the article ► Random Graphs, A Whirlwind Tour of by Fan Chung. In this article, the reader is given a good introduction to classical random graphs, along with a thorough presentation of the more modern theory of random graphs with a new, and more realistic, type of constraint—namely that they should, on average, have a given *node degree distribution*. This new theory makes the study of random graphs extremely relevant for today's empirically-anchored research: many empirical graphs are characterized by their node degree distribution, and many of these in fact have a *power-law degree distribution*, such that the number n_k of nodes having degree k varies with k by a power law: $n_k \sim k^{-\beta}$. This work is useful, precisely because a random graph with a given node degree distribution is the "most typical" graph of the set of graphs with that degree distribution. Hence, statements about such random graphs are statements about typical graphs with the same degree distribution—unless and until we know more about the empirical graphs.

Networks

As noted earlier in this introduction, we consider the terms 'network' and 'graph' to be interchangeable. Nevertheless there is a bit more to be said about the term. The 'network' concept motivates and infuses a vigorous and lively research activity that has more or less exploded since (roughly) the work of Watts and Strogatz [24,25]. Much of their work was motivated by the 'small worlds problem'. The latter dates back to the work of Milgram [18] (and even earlier). Milgram posed the question: how far is it from Kansas (or Nebraska) to Boston, Massachusetts—when the distance is measured in 'hops' between people who know one another? Modern language would rephrase this question as follows: is the US acquaintanceship network a 'small world'? Milgram's answer was 'yes': after disregarding the chains (of letters—that was the mechanism for a 'hop') that never reached the target, the average path length was roughly 5–6 hops—a 'small world'.

The explosion of interest in the last 10 years is well documented in the set of references in "Books and Reviews" (below).

We also include in this part an introductory discussion of directed graphs. Directed graphs have directed links: it no longer suffices to say "i and j are linked", because there is a *directionality* in the linking: $(i \to j)$ or $(j \to i)$ (or both). Some of the mathematical background for understanding directed graphs is provided in the article in this Section by Berman and Shaked-Monderer (► Non-negative Matrices and Digraphs). One quickly finds, upon coming in contact with directed graphs, that one is in a rather different world—the mathematics has changed, the structures are different, and one's intuition often fails.

Directed graphs are however here to stay, and well worth study. We cite two classic examples to demonstrate the extreme relevance of directed graphs. First, there is early and pioneering work by Stuart Kauffman [14,15] on genetic regulatory networks. These form directed graphs, because the links express the fact that gene $G1$ regulates gene $G2$ $(G1 \to G2)$—a relationship which is by no means symmetric. Understanding gene regulation and expression is a fundamental problem in biology—and we see that the problem may be usefully expressed as one of understanding *dynamics on a directed graph*. The article in this Section by Huang and Kauffman (► Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination) brings us up to date on this exciting problem.

A more well known directed graph, which plays a role for many of us in our daily lives, is the *Web graph* [1,2,8]. We navigate among Web pages using hyperlinks—one-way pointers taking us (e.g.) from page A to page B $(A \to B)$. The utility of the Web as a source of information—and as a platform for interaction—is enormous. Hence the Web is well worth intense study, both intellectually and practically.

Hyperlinks are useful, not only for navigation, but also to aid in *ranking* Web pages. This utility was clearly pointed out in two early papers on Web link analysis [7,17]. "Web link analysis" may be viewed most simply as a process which takes (all or part of) the Web graph as input, and which gives 'importance scores' for each Web page as output. The PageRank approach to link analysis of Brin and Page [7] has almost certainly played a significant role in the meteoric rise of the Web search company Google. Hence there is both practical and commercial value in understanding the Web graph. We have two complementary papers in this Section which treat this important area: that by Adamic on ► World Wide Web, Graph Structure, and that by Bjelland et al. on ▶ Link Analysis and Web Search.

Complex Networks

Now we come to the last substantial word in the title of this Section: 'complex'. This is a word that (as yet) lacks a precise scientific meaning. There are in fact too many definitions; in other words, there is no generally-agreed precise definition. For a good overview of work on this thorny problem we refer the reader to [4].

Fortunately, for the purposes of this Section, we need only a very simple definition: 'complex networks' are those which are *not* well modeled by classical random graphs (described above, and in the article by Fan Chung). The use of the term 'complex networks' is very widespread—while examples which give a clear definition are less common. We note that the definition given here is also cited by Dorogovtsev in his article in this Section (▶ Growth Models for Networks).

Structure of Networks

We have noted already that there is no single, simple answer to the question "what is the structure of this graph"? With this caveat in mind, we offer the reader a guide to the articles in this Section which address the structure of networks.

Undirected Graphs

We have already noted the article by Fan Chung (▶ Random Graphs, A Whirlwind Tour of), giving an up-to-date overview of the properties of random graphs with a given node degree distribution—with the well-studied case being power-law graphs. She cites a number of experimental results which indicate that the experimental exponents β (taken from the power-law degree distributions) fall in one range ($2 < \beta < 3$) for social and technological networks, and another, rather distinct range ($\beta < 2$) for biological networks. This may be regarded as a (quantitative) structural difference between these two types of network; Chung offers an explanation based on qualitatively distinct growth mechanisms (see the next part of this article).

Fortunato and Castellano (▶ Community Structure in Graphs) offer an excellent overview of another broad approach to network structure. Here the idea is to understand structure in terms of substructure (and sub-substructure, etc). That is: here is a network. Can we identify subgraphs—possibly overlapping, possibly disjoint—of this network that in some sense "belong together"? In other words: how can one identify the *community structure* of a graph? The review of Fortunato and Castellano is on the one hand very thorough—and on the other hand makes clear that there is no one agreed answer to this question. There are indeed almost as many answers as there are theoretical approaches; and this problem has received a lot of attention. Fortunato and Castellano note that there is currently a "favorite" approach, defined by finding subgraphs with high *modularity* [21]. Roughly speaking, a subgraph with high modularity has a higher density of internal links than that found for the same subgraph in a randomized 'null model' for the same graph. Fortunato and Castellano give a careful discussion of the strengths and weaknesses of this approach to community detection, as well as of many others.

Since the work of Watts and Strogatz [24,25], the definition of a 'small-world graph' has included two criteria. First, one must have the short average path length which Milgram found in his experiments, and which gives rise to the term 'small worlds'. However, one also insists that a 'true' small-world graph should locally resemble a real social network, in that there is a significant degree of *clustering*. Roughly speaking, this means that the probability that two of my acquaintances know each other is higher than random. More mathematically, to say that a graph G has high clustering means that the incidence of *closed triangles* of links in G is higher than expected in a randomized 'null model' for G.

A closed triangle is a small, simply defined subgraph, and in studying clustering one studies the statistics of the occurrence of this small subgraph. A more general term for this type of small subgraph is a *motif* [19]. Much as with clustering and triangles, one defines a set of motifs, and then generates a *significance profile* for any given network, comparing the frequency of each motif in the profile to that of a corresponding random graph. Valverde and Solé (▶ Motifs in Graphs) offer a stimulating overview of the study of motifs in networks of many types—both directed and undirected. They point out a remarkable consistency of motif significance profiles across networks with very different origins—for example, a software graph and the gene network of a bacterium—and argue that this consistency is best understood in terms of historical accident, rather than in terms of functionality.

The article by Liljeros (▶ Human Sexual Networks) looks at empirical human sexual networks. He addresses the evidence for and against the notion that such networks are power-law (also known as "scale free"). This question is important for understanding epidemic spreading over networks—especially in the light of the results of Pastor-Satorras and Vespignani [23], which showed that epidemic spreading on power-law networks is more difficult to stop than was predicted by earlier models using the well-mixed (all-to-all) approximation. Liljeros examines carefully what is known about the structure of human sexual networks, noting the great difficulty inherent in gathering extensive and/or reliable data.

The article by He, Siganos, and Faloutsos (▶ Internet Topology) looks at a very different empirical network, namely the physical Internet, composed (at the lowest level) of routers and cables. The naïve newcomer might assume that the Internet, being an engineered system, is fully mapped out, and hence its topology should be readily "understood". The article by He et al. presents the reality of the Internet: it is largely self-organized (especially at the higher level of organization, the 'Autonomous System' or AS level); it is far from trivial to experimentally map out this network—even at the AS level; and there is not even agreement on whether or not the AS-graph is a power-law graph—which is after all a rather crude measure of structure of the network. He et al. describe recent work which offers a neat resolution of the conflicting and ambiguous data on this question. They then go on to describe more imaginative models for the structure of the Internet, going beyond simply the degree distribution, and having names like 'Jellyfish' and 'Medusa'.

Directed Graphs

A generic directed graph is immediately distinguished from its undirected counterparts in that a natural unit of substructure is obvious, and virtually always present. That is the 'strongly connected component' or SCC (termed 'class' by Berman and Shaked-Monderer). That is, even when a directed graph is connected, there are node pairs which cannot reach one another by following directed paths. An SCC C is then a maximal set of nodes satisfying the constraint that every node in C is reachable, via a directed path, from every other node in C. The SCCs then form disjoint sets (equivalence classes), and every node is in one SCC. In short, the very notion of 'reachability' is more problematic in directed graphs: all nodes in the same SCC can reach one another, but otherwise, all bets are off!

Lada Adamic (▶ World Wide Web, Graph Structure) gives a good overview of what is known empirically about the structure of the *Web graph*—that abstract and yet very real object in which a node is a Web page, and a link is a (one-way) hyperlink. The Web graph is highly dynamic, in at least two ways: pages have a finite lifetime, with new ones appearing while old ones disappear; also, many Web pages are dynamic, in that they generate new content when accessed—and can in principle represent an infinite amount of content. Also, of course, the Web is huge. Lada Adamic presents the problems associated with '*crawling*' the Web to map out its topology. The reader will perhaps not be surprised to learn that the Web graph obeys a power law—both for the indegree distribution and for the outdegree distribution. Adamic discusses several other measures for the structure of the Web graph, including its gross SCC structure (the 'bow tie'), its diameter, reciprocity, clustering, and motifs. The problem of path lengths and diameter is less straightforward for directed graphs, since the unreachability problem produces infinite or undefined path length for many pairs.

A nice bonus in the article by Adamic is the discussion of some popular and well studied *subgraphs* of the Web graph—query connection graphs, Weblogs, and Wikipedia. Query connection graphs are subgraphs built from a hit list, and can give useful information about the query itself, and the likelihood that the hit list will be satisfactory. Weblogs and Wikipedia are well known to most Web-literate people; and it is fascinating to see these daily phenomena subjected to careful scientific analysis.

The article by Bjelland et al. (▶ Link Analysis and Web Search) has perhaps the closest ties to the mathematical presentation of Berman and Shaked-Monderer (▶ Non-negative Matrices and Digraphs). This is because Web link analysis tends to focus on the *principal eigenvector* of the graph's adjacency matrix (or of some modification of the adjacency matrix), while Berman and Shaked-Monderer discuss in some detail the spectral properties of this matrix, and give some results about the principal eigenvector. The latter yields *importance* or *authority scores* for each page. These scores are the principal output of Web link analysis; and in fact Berman and Shaked-Monderer cite PageRank as an outstanding example of an application of the theory [22]. Bjelland et al. explain the logic leading to the choice of the principal eigenvector, as a way of 'harvesting' information from the huge set of 'collective recommendations' that the hyperlinks constitute. They also present the principal approaches to link analysis (the 'big three'), and place them in a simple logical framework which is completed by the arrival of a new, fourth approach. In addition, Bjelland et al. discuss a number of technical issues related to Web link analysis—which is, after all, a practical and commercial field of endeavor, as well as an object for research and understanding.

Jennifer Dunne (▶ Food Webs) presents a rather special type of directed graph taken from biology: the food web. She offers a very concise definition of this concept in her glossary, which we reproduce here: "the network of feeding interactions among diverse co-occurring species in a particular habitat". We note that most feeding interactions are one-way: bird B eats insect I, but insect I does not eat bird B. However, food webs are rather special among empirical directed graphs, in that they have a lower incidence of loops than that found in typical directed graphs. Early work indicated (or even assumed) that a food web is loop-free; but this has been shown not to be strictly true. (A simple, but real example of a loop is cannibalism: A eats A; but much longer loops also exist.) The field faces (as many do) a real problem in getting good empirical data, and empirically obtained food webs tend to be small. For example, Table 1 of Dunne presents data for 16 empirical food webs, ranging in size from 25 nodes to 172.

Our second biological application of directed graphs is presented by Huang and Kauffman (▶ Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination). This article presents gene regulatory networks (GRN). The directed link ($G1 \rightarrow G2$) in a GRN expresses the fact that gene $G1$ regulates (by inhibition or activation) the expression of gene $G2$, via intermediate proteins (typically transcription factors). The links are thus inherently one way, although reciprocal links ($G1 \leftrightarrow G2$) do occur. The article of Huang and Kauffman is very comprehensive: the structure of a GRN is only their starting point, as they seek to understand and model the *dynamical development process*, in which the set of on/off states of the cell genome moves towards an *attractor* (a steady or quasi-steady state), which represents a mature and stable cell type.

Returning to structure (of GRNs), we again face a severe data-extraction problem, which is compounded by the fact that the 'interaction modality' (activation or inhibition, plus or minus) of each link must also be known before one can study dynamical development of gene expression over the GRN. In short: one needs to know more than just the presence and direction of the links; one needs their type. Huang and Kauffman give a thorough discussion of these problems, and argue for studies using an "ensemble approach". This is much like the random graph approach, in that it takes a set of statistical constraints which are empirically determined, and then studies (often via simulation) a randomly generated ensemble of graphs which satisfy the statistical constraints. In short, the ensemble approach takes the structure as determined by these constraints (node degree distribution, etc), and then studies random graphs with this structure. Note that both the graph topology and the interaction modalities of the links are randomized in this ensemble approach.

Dynamical Network Structures

We have already had a lot to say about the structure of networks—and yet we have left out one important dimension, namely *time*. Empirical networks change over time, so that most measurements that map out such a network are taking a snapshot. Now we will look explicitly at studies addressing the dynamical evolution of networks.

One classic study is the paper by Barabasi and Albert [5]. Here the preferential-attachment (or "rich get richer") model was introduced as an explanation for the ubiquitous power-law degree distributions. In other words, a *growth* (developmental) model was used to explain properties of *snapshots* of "mature" networks. In the preferential-attachment model, new nodes which join a network link to existing nodes with a biased probability distribution—so that the probability of linking to an existing node of degree k is proportional to k.

This simple model indeed gives (after long time) a power-law distribution; and the ideas in [5] stimulated a great interest in various growth models for networks. We are fortunate to have, in this Section of the Encyclopedia, the article by Sergey Dorogovtsev entitled ▶ Growth Models for Networks. This article is of course very short compared to the volume [9]—but it offers a good overview of the field, and a thorough updating of that volume, covering a broad range of questions and ideas, including the simple linear preferential attachment model, and numerous variations of it. Also, a distinctly different class of growth models, termed "optimization based models", is presented, and compared to the class of models involving forms of preferential attachment. In optimization based models, new nodes place links so as to optimize some function of the resulting network properties.

We also mention, in the context of growth models, the article by Fan Chung (▶ Random Graphs, A Whirlwind Tour of). As noted above, she has pointed out a tendency for biological networks to have significantly smaller exponents than technological networks; and she includes a good discussion of both preferential attachment (which tends to give the larger, technological, exponents) and duplication models. The latter involve new nodes "copying" or duplicating (probabilistically) the links of existing nodes. Chung observes that such duplication mechanisms do exist in biology, and also shows that they can give exponents in the appropriate range.

Huang and Kauffman (▶ Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination) also offer a limited discussion of evolution of the genome—not so much as a topic in itself, but because (again) understanding genome evolution can help in understanding—and even determining—the structure of today's genome. They mention both duplication and preferential attachment. Also, it is quite interesting to note the parallels between their discussion and that of Valverde and Solé (▶ Motifs in Graphs)—in that Huang and Kauffman also argue that many observed structures may be due, not to selection pressure or enhanced functionality, but simply to physical constraints on the evolutionary process, and/or to historical accident. The duplication mechanism in fact turns up again in the article by Valverde and Solé, who argue that this growth mechanism can largely account for the high frequency of occurrence of some motifs.

Finally, we note that growth is not the only dynamical process operative in networks. Just as the mature body is constantly shedding and regenerating cells, many mature networks are subject to constant small topology changes. One interesting class of non-growth dynamics is the *attack*. That is: how robust is a given network against a systematic attack which deletes nodes and/or links? A classic study in this direction is [3], which studied the attack tolerance of scale-free networks. There are many reasons to believe that such networks are very well connected, and this study added more: attacking random nodes had little effect on the functionality of the network (as crudely measured by the network diameter, and by the size of the largest surviving component). Thus such networks may be termed "robust"—but only with regard to this kind of "uninformed" attack. The same study showed that a "smart" attack, removing the nodes in descending order of node degree (i. e., highest degree first), caused the network to break down much more rapidly—thus highlighting once again the crucial role played by the 'hubs' in power-law networks.

Jennifer Dunne (▶ Food Webs) reports some studies of the robustness of food webs to attack—where here the 'attack' is extinction of a node (species). The dynamics is slightly different from that in the previous paragraph, however, because of the phenomenon of secondary extinction: removal of one species can cause another (or several others) to go extinct as well, if they are dependent on the first for their food supply. Also, food webs are not well modeled by power-law degree distributions. Nevertheless, the cited studies indicate that removing high-degree species again causes considerably more damage (as measured by secondary extinctions and web fragmentation) than removing low-degree species. Dunne also reports studies seeking to simulate the effects of "ecologically plausible" extinction scenarios; here we find that the studied food webs are in fact very robust to such extinction scenarios—a result which (perhaps) confirms our prejudice, that today's ecosystems are here because they are robust.

Dynamical Processes on Networks

Our next theme is also about dynamics—not *of* the network topology, however, but *over* it. That is, it is often of interest to study *processes* which occur on the nodes (changing their state), and which transmit something (information) over the links, so that a change in one node's state induces a change in other nodes' states.

We can render these ideas less abstract by considering the concrete example of epidemic spreading. The nodes can be individuals (or computers, or mobile phones), and the network is then a network of social contacts (or a computer or phone network). The elementary point that the disease is spread via contact is readily captured by the network model. A classic study in this regard, which strongly underscored the value of network models, was that (mentioned earlier) of Pastor-Satorras and Vespignani [23]. Here it was shown that classical threshold thinking about epidemic spreading fails when the network is scale-free: the effective threshold is *zero*. This study, in yet another way, revealed that such networks are extremely well connected—and it stimulated a great deal of thought about prevention strategies.

We have already mentioned the article by Liljeros (▶ Human Sexual Networks) in this Section, with its evidence for power-law, or nearly power-law, degree distributions in human sexual networks. Liljeros offers a sober and careful discussion of the implications of the theoretical result just cited, for understanding and preventing the spread of sexually transmitted diseases on finite networks. One consequence of a power-law node degree distribution—that a few individuals will have an *extremely* high number of contacts—may seem at first glance implausible or even impossible; and yet, as Liljeros points out, careful empirical studies have tended to support this prediction.

The human sexual network is of course not static; people change partners, and in fact people with many partners tend to change more often. Hence, the dynamics of the network topology must be considered, including how it affects the dynamics of the epidemic spreading process going on over the topology. A term which captures this interplay is "concurrence"—which tells, not how many partners you have, but how many partners you have "simultaneously"—i. e., within a time window which allows the passing of the disease from one contact to another. Considering concurrence leads to another type of graph, termed a 'line graph'—a structure in which contact relationships become nodes, which are linked when they are concurrent.

The reader will not be surprised to hear that epidemic spreading over directed graphs is qualitatively different from the same process over undirected graphs. The topic has real practical interest, because—as pointed out by Kephart and White [16] and by Newman, Forrest and Balthrop [20]—the effective network over which computer viruses propagate is typically directed. We invite the interested reader to consult these sources—and to note the striking similarities between the picture of the 'email address graph' in [20] and the gross structure of the Web graph [8] (and Figure 1 of Adamic).

Another classic study of dynamical processes on networks is that by Duncan Watts [24,25] on synchronization phenomena over networks. Our Section includes a thorough and up-to-date survey of this problem, primarily from the theoretical side, by Chen et al. (▶ Synchronization Phenomena on Networks). The field is large, as there exists a wide variety of dynamical processes on nodes, and types of inter-node coupling, which may (or may not) lead to synchronization over the network. Chen et al. focus on three main themes which neatly summarize the field. First, there is the synchronization process itself, and the theory which allows one to predict when synchronization will occur. Next comes the question of how the network structure affects the tendency to synchronization. The third theme is a logical followup to the second: if we know something about how structure affects synchronization, can we not find design methods which enhance the tendency to synchronize? This latter theme includes a number of ingenious methods for 'rewiring' the network in order to enhance its synchronizability. For example: it is found that a very strong community structure (recall the article by Castellano and Fortunato) will inhibit synchronization; and so one has studied networks called *'entangled networks'*, which are systematically rewired so as to have essentially no community structure, and so are optimally synchronizable.

Dunne (▶ Food Webs) discusses dynamics of species number over food webs. That is, the links telling "who eats who" also mediate transfers of biomass—a simple dynamical process. And yet—as we know from the dynamics of the simple two-species Lotka–Volterra equations [13]—simple nonlinear rules can give rise to complex behavior. Dunne reports that the behavior does not get more simple as one studies larger networks; one finds the same types of asymptotic behavior—equilibrium, limit cycle, and chaotic dynamics. It is a nontrivial task to study nonlinear dynamical models over tens or hundreds of nodes, and at the same time anchor the theory and simulation in reality. One approach to doing this has been to insist that the resulting model satisfy certain stability criteria (hence conforming to reality!); these criteria are framed in terms of 'species persistence' (not too many extinctions) and/or 'population stability' (limited fluctuations in species mass for all species).

A dynamical process also plays a central role in the discussion of Huang and Kauffman (▶ Complex Gene Regulatory Networks – from Structure to Biological Observables: Cell Fate Determination). In a simplified but highly nontrivial model, the state of the gene network is modeled by a vector $\boldsymbol{S}(t)$, which takes binary values (0 or 1, i. e., 'off' or 'on') at each node in the network, at each time t. Also, the interactions between genes are modeled by Boolean truth tables—i. e., a given gene's (binary) output state is some Boolean function of all of its input states. The resulting 'Boolean network model' is at once very simple (discrete time, discrete binary states), and yet very complex, in the sense that it is impossible to predict the behavior of such models without simulating them. Huang and Kauffman describe the three regimes of dynamical behavior found: an 'ordered' regime, a 'chaotic' regime, and an intermediate 'critical' regime. While the ordered regime gives stable behavior, Huang and Kauffman argue that biology favors the critical regime. One gets the flavor of their argument if one recalls that the same genome must be able to converge to many different cell types—so its dynamics cannot be *too* stable—and yet those same cell types must be 'stable enough'. The discussion of the latter point includes a remarkable recent experimental study which graphically shows the return of two cell populations to the same 'preferred' stable attractor, after two distinct perturbations, via two distinct paths in state space.

Valverde and Solé (▶ Motifs in Graphs) also discuss dynamical processes, in terms of motifs. They give a clear picture for the simple test case of the three-node motif called 'Feed Forward Loop' or FFL. Here again—as for the GRNs of Huang and Kauffman—the modality (activation/inhibition) of the three links must be considered, and the resulting possibilities are either 'coherent' (non-conflicting) or 'incoherent'. It is interesting to note that the FFL motif has been studied both via simulation, and experimentally, in real gene networks. Valverde and Solé also make contact with the article of Chen et al. (▶ Synchronization Phenomena on Networks) by briefly discussing the connection between network synchronizability and the distribution of motif types.

Graph Visualization

The problem of graph visualization is a marvelous mixture of art and science. To produce a good graph visualization is to translate the science—what is known factually and analytically about the graph—into a 2D (or quasi-3D) image that the human brain can appreciate. Here the word 'appreciate' can include both understanding and the experience of beauty. Both of these aspects are present in great quantities in the many figures of this Section. We invite the reader interested in visualization to visit and compare the following figures: Figure 2 in Fan Chung's article; Figures 1 and 3 in Dunne; Figures 2 and 5 in Liljeros; Figure 17 in Chen et al.; and Figures 1, 2, and 6b in Valverde and Solé.

Graph visualization is included in the articles of this Section because it is a vital tool in the study of networks, and also an unfinished research challenge. The article by Vladimir Batagelj (▶ Complex Networks, Visualization of) offers a fine overview of this large field. This article in fact has a very broad scope, touching upon many visualization problems (molecules, Google maps) which may be called "information visualization". The connection to networks (no pun intended) is that information is readily understood in terms of connections between units—i. e., as a network.

We note that one natural way of 'understanding' a graph is in terms of its *communities*; and since community substructure offers a way (perhaps even hierarchical) of 'coarse-graining' the network, methods for defining communities often lead naturally to methods for graph visualization. One example of this may be found in Figure 10 of Fortunato and Castellano (▶ Community Structure in Graphs); for other examples, see [12] and [6]. Batagelj describes a wide variety of graph visualization methods; but a careful reading of his article shows that many methods which are useful for large graphs are dependent on finding and exploiting some kind of community structure. The terms used for approaches in this vein include 'multilevel algorithms', 'clustering', 'block modeling', coarse graining, partitions, and hierarchies.

The lessons learned from Fortunato and Castellano are brought home again in the article by Batagelj: there is no 'magic bullet' that gives a universally satisfying answer to the problem of visualizing large networks. To quote Batagelj in regard to an early graph visualization: "Nice as a piece of art, but with an important message: there are big problems with visualization of dense and/or large networks." A more recent example is a 2008 visualization of the Internet: here there is a 'natural' unit of coarse graining, namely the autonomous system or AS level (recall the article by He et al. on Internet Topology), so that the network of almost 5 million nodes reduces to 'only' about 18 000 ASes. Yet the resulting visualization (Figure 4 of Batagelj) clearly reveals that 18 000 nodes is still 'large' relative to human visual processing capacity.

For other beautiful and mystifying examples of this same point, I recommend figures 5 and 7 in the same article. The difficulty of visualizing large networks is perhaps most succinctly captured in the outline of Batagelj's stimulating article. Besides the normal introductory parts, we find only two others: 'Attempts' and 'Perspectives'. Yet the article is by no means discouraging—it is rather fascinating and inspiring, and I encourage the reader to read and enjoy it.

Future Directions

The many articles related to "Complex Networks and Graph Theory" have each offered their own view of 'Future directions' for the corresponding field of study. Therefore it would be both redundant and presumptuous for me to attempt the same task for all of these fields. Instead I will offer a very short and entirely personal assessment of the 'Future' for the broad field of complex networks and graph theory.

I view the field somewhat as a living organism: it is highly dynamic, and still growing vigorously. New ideas continue to pop up—many of which could not be covered in this Section, simply due to practical limitations. Also, there is a fairly free flow of ideas across disciplines. The reader has perhaps already gotten a feeling for this cross-boundary flow, by seeing the same basic ideas crop up in many articles, on problems coming for distinctly different traditional disciplines. In short, I feel that the interdisciplinarity of this field is real, it is vigorous and healthy, and it is exciting.

Another aspect contributing to the excellent health of the field is its strong connection to empiricism. Network studies thrive on getting access to real, empirically-obtained graphs—we have seen this over and over again in discussion of the articles in this Section. From the Web graph with its tens of billions of nodes, to food webs with perhaps a hundred nodes, the science of networks is stimulated, challenged, and enriched by a steady influx of new data.

Finally, the study of complex networks is eminently practical. The path to direct application can be very short. Again we cite the Web graph and Google's PageRank algorithm as an example of this. The study of gene networks is somewhat farther from immediate application; but the possible benefits from a real understanding of cell and organism development can be enormous. The same holds for the problem of epidemic spreading. These examples are only picked out to illustrate the point; all of the articles, and topics represented by them, are not far removed from practical application.

In short: the field is exciting, vigorous, and interdisciplinary, and offers great practical benefits to society. The study of graphs and networks shows no signs of becoming moribund. Hence I will hazard a guess about the future: that the field will continue to grow and inspire excitement for many years to come. It is my hope that many readers of this Section will be infected by this excitement, and will choose to join in the fun.

Article Outline

Glossary

For basic notions on graphs and networks, see the articles by Wouter de Nooy: ► Social Network Analysis, Graph Theoretical Approaches to and by Vladimir

Batagelj: ► Social Network Analysis, Large-Scale in the Social Networks Section. For complementary information on graph drawing in social network analysis, see the article by Linton Freeman: ► Social Network Visualization, Methods of.

***k*-core** A set of vertices in a graph is a k-core if each vertex from the set has an internal (restricted to the set) degree of at least k and the set is maximal – no such vertex can be added to it.

Network A network consists of vertices linked by lines and additional data about vertices and/or lines. A network is large if it has at least some hundreds of vertices. Large networks can be stored in computer memory.

Partition A partition of a set is a family of its nonempty subsets such that each element of the set belongs to exactly one of the subsets. The subsets are also called classes or groups.

Spring embedder is another name for the energy minimization graph drawing method. The vertices are considered as particles with repulsive force between them, and lines as springs that attract or repel the vertices if they are too far or too close, respectively. The algorithm is a means of determining an embedding of vertices in two or three dimensional space that minimizes the 'energy' of the system.

Definition of the Subject

The earliest pictures containing graphs were magic figures, connections between different concepts (for example the Sephirot in Jewish Kabbalah), game boards (nine men's morris, pachisi, patolli, go, xiangqi, and others) road maps (for example Roman roads in Tabula Peutingeriana), and genealogical trees of important families [33].

The notion of the graph was introduced by Euler. In the eighteenth and nineteenth centuries, graphs were used mainly for solving recreational problems (Knight's tour, Eulerian and Hamiltonian problems, map coloring). At the end of the nineteenth century, some applications of graphs to real life problems appeared (electric circuits, Kirchhoff; molecular graphs, Kekulé). In the twentieth century, graph theory evolved into its own field of discrete mathematics with applications to transportation networks (road and railway systems, metro lines, bus lines), project diagrams, flowcharts of computer programs, electronic circuits, molecular graphs, etc.

In social science the use of graphs was introduced by Jacob Moreno around 1930 as a basis of his sociometric approach. In his book *Who shall survive?* [36], a relatively large network *Sociometric geography of community – map III* (435 individuals, 4350 lines) is presented. Linton Freeman wrote a detailed account of the development of social network analysis [20] and the visualization of social networks [19]. The networks studied in social network analysis until the 1990s were mostly small – some tens of vertices.

Introduction

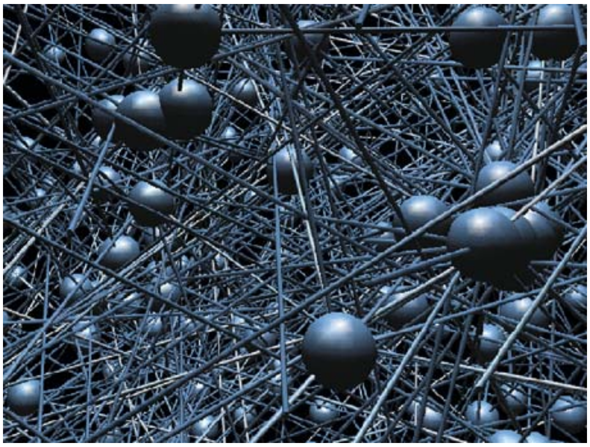
Through the 1980s, the development of information technology (IT) laid the groundwork for the emerging field of computer graphics. During this time, the first algorithms for graph drawing appeared:

- Trees: Wetherell and Shannon [45].
- Acyclic graphs: Sugiyama [42].
- Energy minimization methods (spring embedders) for general graphs: Eades [17], Kamada and Kawai [30], Fruchterman and Reingold [21].

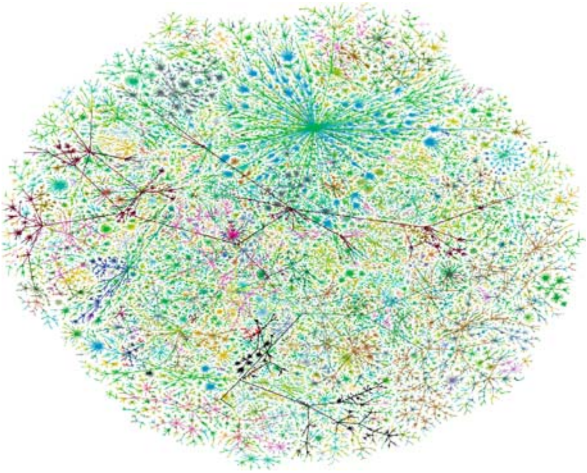
In energy minimization methods, vertices are considered as particles with repulsive force between them and lines as springs that attract or repel the vertices if they are too far or too close, respectively. The algorithms provide a means of determining an embedding of vertices in two or three dimensional space that minimizes the 'energy' of the system.

As early as 1963, William Tutte proposed an algorithm for drawing planar graphs [43] and Donald E. Knuth put forth an algorithm for drawing flowcharts [31].

A well known example of an early graph visualization was produced by Alden Klovdahl using his program View_Net – see Fig. 1. As nice a piece of art as it was, it held an important message: there are big problems with the visualization of dense, large graphs.



Complex Networks, Visualization of, Figure 1
Klovdahl: Social links in Canberra, Australia



Complex Networks, Visualization of, Figure 2
Network of traceroute paths for 29 June 1999

These developments led to the emergence of a new field: graph drawing. In 1992 a group of computer scientists and mathematicians (Giuseppe Di Battista, Peter Eades, Michael Kaufmann, Pierre Rosenstiehl, Kozo Sugiyama, Roberto Tamassia, Ioannis Tollis, and others) started the conference *International Symposium on Graph Drawing* which takes place each year. The proceedings of the conference are published in the *Lecture Notes in Computer Science* series by Springer [24]. To stimulate new approaches to graph drawing, a *graph drawing contest* accompanies each conference. Many papers on graph drawing are published in the *Journal of Graph Algorithms and Applications* [79].

Most of the efforts of the graph drawing community were spent on problems of drawing special types of graphs (trees, acyclic graphs, planar graphs) or using special styles (straight lines, orthogonal, grid-based, circular, hierarchical) and deriving bounds on required space (area) for selected types of drawing.

In the 1990s, further development of IT (GUI, multimedia, WWW) made large graph analysis a reality. For example, see the studies of large organic molecules (PDB [51]), the Internet (Caida [52]), and genealogies (White and Jorion [46], FamilySearch [60]). In chemistry, several tools for dynamic three-dimensional visualization and inspection of molecules were developed (Kinemage [48], Rasmol [87], MDL Chime [82]).

One of the earliest systems for large networks was SemNet (see Fairchild, Poltrock, Furnas [18]), used to explore knowledge bases represented as directed graphs.

In 1991 Tom Sawyer Software [91] was founded – the premier provider of high performance graph visualization,

layout, and analysis systems that enable the user to see and interpret complex information to make better decisions.

In 1993 at AT&T, the development of GraphViz tools for graph visualization began (dot, neato, dotty, tcldot, libgraph) [69]. Becker, Eick and Wilks developed a SeeXYZ family of network visualization programs [8].

In 1996 Vladimir Batagelj and Andrej Mrvar started the development of *Pajek* – a program for large network analysis and visualization [5].

In 1997 at La Sepienza, Rome, the development of GDToolkit [63] started as an extension of LEDA (Library of Efficient Data types and Algorithms) to provide implementations of several classical graph-drawing algorithms. The new version, GDT 4.0 (2007), produced in collaboration with University of Perugia, is LEDA independent.

Graham Wills, a principal investigator at Bell Labs (1992–2001), built the Nicheworks system for the visual analysis of very large weighted network graphs (up to a million vertices).

In the summer of 1998 Bill Cheswick and Hal Burch started work on the *Internet Mapping Project* at Bell Labs [53]. Its goal was to acquire and save Internet topological data over a long period of time. This data has been used in the study of routing problems and changes, distributed denial of service (DDoS) attacks, and graph theory. In the fall of 2000 Cheswick and Burch moved to a spin-off from Lucent/Bell Labs named Lumeta Corporation. Bill Cheswick is now back at AT&T Labs. Figure 2 shows a network obtained from traceroute paths for 29 June 1999 with nearly 100 000 vertices.

In the years 1997–2004, Martin Dodge maintained his *Cybergeography Research* web pages [58]. The results were published in the book *The Atlas of Cyberspace* [14]. A newer, very rich, site on information visualization is *Visual complexity* [95], where many interesting ideas on network visualizations can be found. These examples, and many others, can also be accessed from the Infovis *1100+ examples of information visualization* site [77]. An interesting collection of graph/network visualizations can be found also on the CDs of Gerhard Dirmoser. The collection also contains many artistic examples and other pictures not produced by computers.

In 1997 Harald Katzmair founded FAS research in Vienna, Austria [61], a company providing network analysis services. FAS emphasizes the importance of nice-looking final products (pictures) for customers by using graphical tools to enhance the visual quality of results obtained from network analysis tools. In Fig. 3, a network of Austrian research projects is presented. A similar company, Aguidel [49], was founded in France by Andrei Mogoutov, author of the program Réseau-Lu.

Every year (from 2002) at the INSNA Sunbelt conference [78], the *Viszards group* has a special session in which they present their solutions – analysis and visualizations of selected networks or types of networks. Most of the selected networks are large (KEDS, Internet Movie Data Base, Wikipedia, Web of Science).

Attempts

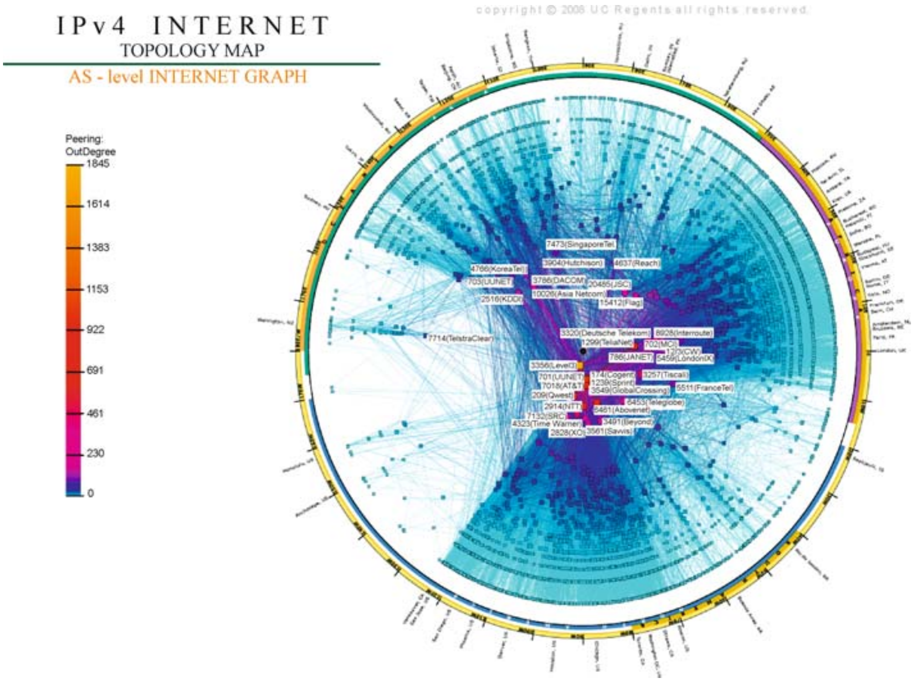
The new millennium has seen several attempts to develop programs for drawing large graphs and networks. Most of the following descriptions are taken verbatim from the programs' web pages.

Stephen Kobourov, with his collaborators from the University of Arizona, developed two graph drawing systems: GRIP (2000) [22,70] and Graphael (2003) [66]. GRIP – *Graph dRawing with Intelligent Placement* was designed for drawing large graphs and uses a multi-dimensional force-directed method together with fast energy function minimization. It employs a simple recursive coarsening scheme – rather than being placed at random, vertices are placed intelligently, several at a time, at locations close to their final positions.

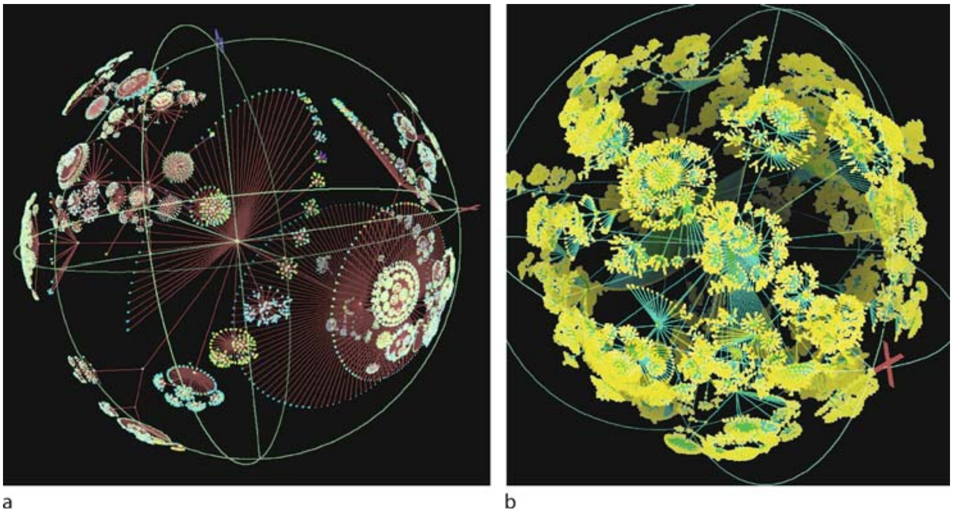
The Cooperative Association for Internet Data Analysis (CAIDA) [52], co-founded in 1998 by kc claffy, is an independent research group dedicated to investigating both the practical and theoretical aspects of the Internet to promote the engineering and maintenance of a robust, scalable, global Internet infrastructure. They have been focusing primarily on understanding how the Internet is evolving, and on developing a state-of-the-art infrastructure for data measurement that can be shared with the entire research community.

Figure 4 represents a macroscopic snapshot of the Internet for two weeks: 1–17 January 2008. The graph reflects 4 853 991 observed IPv4 addresses and 5 682 419 IP links. The network is aggregated into a topology of Autonomous Systems (ASes). The abstracted graph consists of 17 791 ASes (vertices) and 50 333 peering sessions (lines).

Walrus is a tool for interactively visualizing large directed graphs in three-dimensional space. It is best suited to visualizing moderately sized graphs (a few hundred thousand vertices) that are nearly trees. Walrus uses three-dimensional hyperbolic geometry to display graphs under a fisheye-like magnifier. By bringing different parts of a graph to the magnified central region, the user can examine every part of the graph in detail. Walrus was developed by Young Hyun at CAIDA based on research by Tamara Munzner. Figure 5 presents two examples of visualizations produced with Walrus.



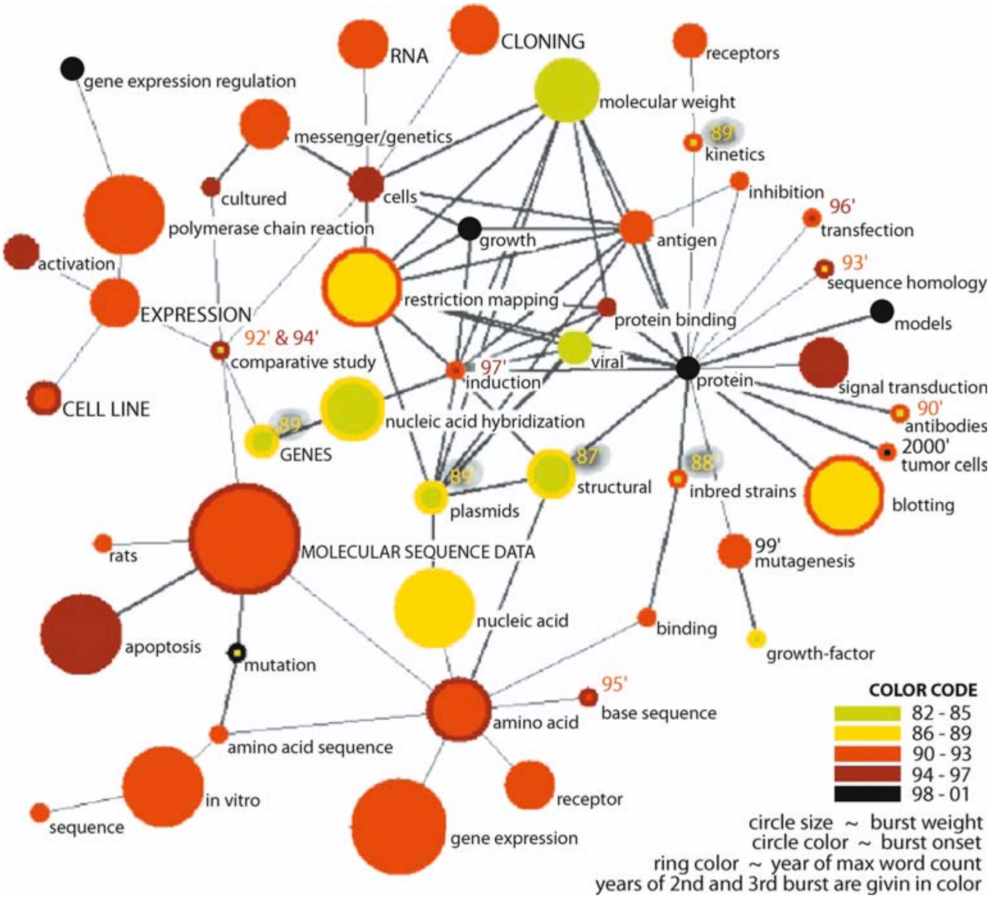
Complex Networks, Visualization of, Figure 4
CAIDA: AS core 2008



Complex Networks, Visualization of, Figure 5
Walrus

Some promising algorithms for drawing large graphs have been proposed by Ulrik Brandes, Tim Dwyer, Emden Gansner, Stefan Hachul, David Harel, Michael Jünger, Yehuda Koren, Andreas Noack, Stephen North, Christian Pich, and Chris Walshaw [11,16,23,25,26,32,39,44]. They are based either on a multilevel energy minimization approach or on an algebraic or spectral approach that reduces to some application of eigenvectors.

The multilevel approach speeds-up the algorithms. *Multilevel algorithms* are based on two phases: a *coarsening phase*, in which a sequence of coarse graphs with decreasing sizes is computed, and a *refinement phase*, in which successively finer drawings of graphs are computed, using the drawings of the next coarser graphs and a variant of a suitable force-directed single-level algorithm [25]. The fastest algorithms combine the multilevel approach



Complex Networks, Visualization of, Figure 6
Katy Börner: Text analysis

with fast approximation of long range repulsive force using nested data structures, such as quadtree or kd-tree.

Katy Börner from Indiana University, with her collaborators, produced several visualizations of scientometric networks such as Backbone of Science [9] and Wikipedia [73]. They use different visual cues to produce information-rich visualizations – see Fig. 6. She also commissioned the *Map of Science* based on data (800 000 published papers) from Thomson ISI and produced by Kevin Boyack, Richard Klavans and Bradford Paley [9].

Yifan Hu from AT&T Labs Information Visualization Group developed a multilevel graph drawing algorithm for visualization of large graphs [29]. The algorithm was first implemented in 2004 in Mathematica and released in 2005. For demonstration he applied it to the *University of Florida Sparse Matrix collection* [56] that contains over 1500 square matrices. The results are available in the *Gallery of Large Graphs* [74]. The largest graph (vanHeukelum/cage15) has 5 154 859 vertices and 47 022 346 edges. In Fig. 7, selected pictures from the gallery are presented.

From the examples that we have given, we can see that, in some cases, graph drawing algorithms can reveal symmetries in a given graph and also a 'structure' ((sub)trees, clusters, planarity, etc.). Challenges remain in devising ways to represent graphs with dense parts.

For dense parts, a better approach is to display them using matrix representation. This representation was used in 1999 by Vladimir Batagelj, Andrej Mrvar and Matjaž Zaveršnik in their partitioning approach to visualization of large graphs [7] and is a basis of systems such as *Matrix Zoom* by James Abello and Frank van Ham, 2004 [1,2], and *MatrixExplorer* by Nathalie Henry and Jean-Daniel Fekete, 2006 [27]. A matrix representation is determined by an ordering of vertices. Several algorithms exist that can produce such orderings. A comparative study of them was published by Chris Mueller [37,84]. In Fig. 8 three orderings of the same matrix are presented. Most ordering al-

Examples from the Gallery of Large Graphs

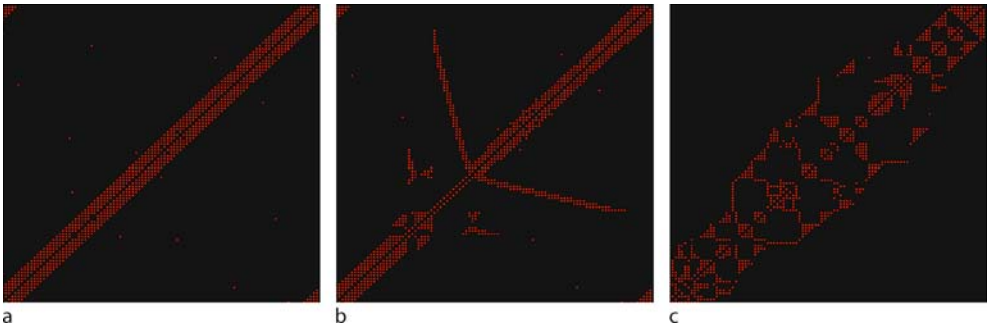
gorithms were originally designed for applications in numerical, rather than data, analysis. The orderings can also be determined using clustering or blockmodeling methods [15].

An important type of networks are *temporal networks*, where the presence of vertices and lines changes through time. Visualization of such networks requires special approaches (Sonia [88], SVGanim [90], TecFlow [75]). An interesting approach to visualization of temporal networks was developed by Ulrik Brandes and his group [12].

Perspectives

In this section, we present a collection of ideas on how to approach visualization of large networks. These ideas are only partially implemented in different visualization solutions.

While the technical problems of graph drawing strive for a single 'best' picture, network analysis is also a part of data analysis. Its goal is to gain insight not only into the structure and characteristics of a given network, but also



Complex Networks, Visualization of, Figure 8
Matrix representations

Complex Networks, Visualization of, Figure 9
Big picture, V. Batagelj, AE'04

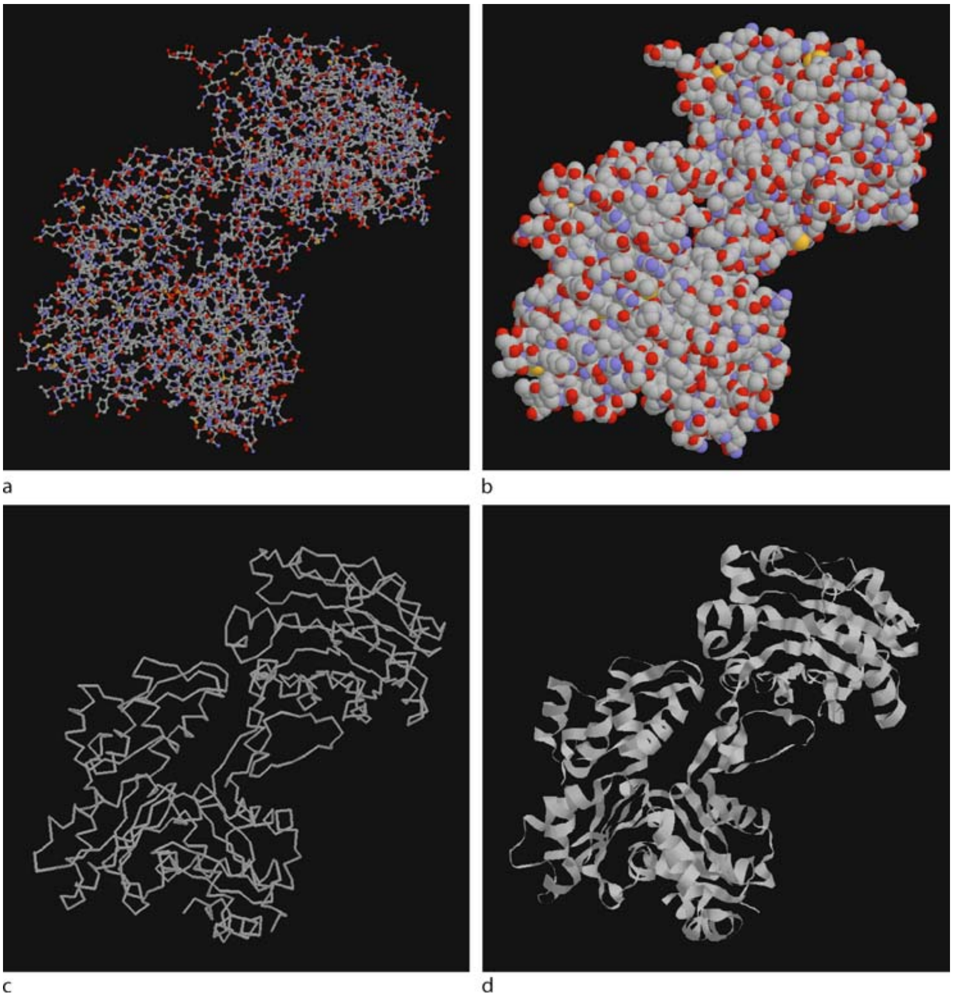
into how this structure influences processes going on over the network. We usually need several pictures to present the obtained results.

Small graphs can be presented in their totality and in detail within a single view. In a comprehensive view of large graphs, details become lost – conversely a detailed view can encompass only a part of a large graph.

The literature on graph drawing is dominated by the 'sheet of paper' paradigm – the solutions and techniques are mainly based on the assumption that the final result is a static picture on a sheet of paper. In this model, to present a large data set we need a large 'sheet of paper' – but this has a limit. Figure 9 presents a visualization of a symmetrized subnetwork of 5952 words and 18 008 associations from the *Edinburgh Associative Thesaurus* [59] prepared by Vladimir Batagelj on a 3 m × 5 m 'sheet of paper' for Ars Electronica, Linz 2004 *Language of networks* exhibition.

The main tool for dealing with large objects is abstraction. In graphs, abstraction is usually realized using a hierarchy of partitions. By shrinking selected classes of a partition we obtain a smaller reduced graph. The main operations related to abstraction are:

- Cut-out: Display of only selected parts (classes of partition) of a graph;



Complex Networks, Visualization of, Figure 10
Glasses: Rasmol displays – BallStick, SpaceFill, Backbone, Ribbons

- Context: Display details of selected parts (classes) of a graph and display the rest of the graph in some reduced form;
- Model: Display the reduced graph with respect to a given partition;
- Hierarchy: Display the tree representing the nesting of graph partitions.

In larger, denser networks there is often too much information to be presented at once. A possible answer is an interactive layout on a computer screen where the user controls what (s)he wants to see.

The computer screen is a medium which offers many new possibilities: parallel views (global and local); brushing and linking; zooming and panning; temporary elements (additional information about the selected elements, labels, legends, markers, etc.); highlighted selections; and others. These features can and should be maximally leveraged to support data analytic tasks; or repeating Shneiderman's mantra: overview first, zoom and filter, then details on-demand (extended with: Relate, history and extract) [40].

When interactively inspecting very large graphs, a serious problem appears: how does one avoid the "lost within the forest" effect? There are several solutions that can help the user maintain orientation:

- Restart option: Returns the user to the starting point;
- Introduction of additional orientation elements: Allows elements to be switched on and off.
- Multiview: Presents at least two views (windows):

- Map view: Shows an overall global view which contains the current position and allows 'long' moves (jumps). For very large graphs, a map view can be combined with zooming or fish-eye views.
- Local view: Displays a selected portion of the graph.

Additional support can be achieved by implementing trace, backtrack, and replay mechanisms and guided tours.

An interactive dynamic visualization of a graph on the computer screen need not be displayed in its totality. Inspecting a visualization, the user can select which parts and elements will be displayed and in what way. See, for example, TouchGraph [92].

Closely related to the multiview concept are the associated concepts of glasses, lenses and zooming. Glasses affect the entire window, while lenses affect only selected region or elements.

By selecting different glasses, we can obtain different views on the same data supporting different visualization aims. For example, in Fig. 10 four different glasses (ball and stick, space-fill, backbone, ribbons) were applied in the program Rasmol to the molecule 1atn.pdb (deoxyribonuclease I complex with actin).

Another example of glasses is presented in Fig. 11. The two pictures were produced by James Moody [35]. The graph pictured was obtained by applying spring em-

bedders. It represents the friendships among students in a school. The glasses are the coloring of its vertices by different partitions: an age partition (left picture) and a race partition (right picture). This gives us an explanation of the four groups in the resulting graph picture, characterized by younger/older and white/black students.

Figure 12 shows a part of the big picture presented in Fig. 9. The glasses in this case are based on ordering the edges in increasing order of their values and drawing them in this order – stronger edges cover the weaker. The picture emphasizes the strongest substructures; the remaining elements form a background.

There are many kinds of glasses in representation of graphs, for example, fish-eye views, matrix representation, using application field conventions (genealogies, molecules, electric circuits, SBGN), displaying vertices only, selecting the type of labels (long/short name, value), displaying only the important vertices and/or lines, size of vertices determined by core number or "betweenness".

Zoom, glasses, lenses, navigation: Grokker

An example of lens is presented in Fig. 13 – contributions of companies to various presidential candidates from *Follow the Oil Money* by Greg Michalec and Skye Bender-deMoll [62]. When a vertex is selected, information about that vertex is displayed. Another possible use of a lens would be to temporarily enhance the display of neighbors of a selected vertex [94] or to display their labels. The "shaking" option used in *Pajek* to visually identify all vertices from a selected cluster is also a kind of lens; so are the matrix representations of selected clusters in NodeTrix [72].

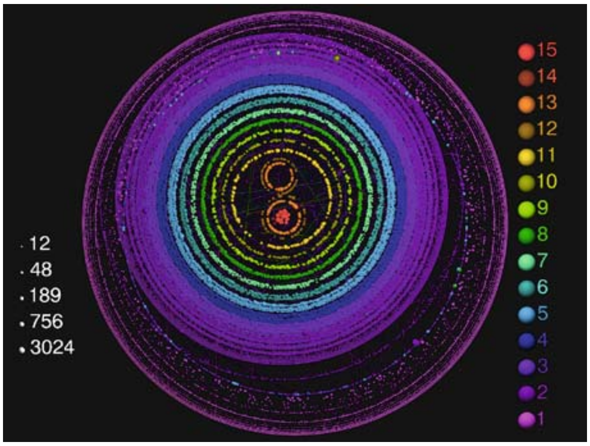
Additional enhancement of a presentation can be achieved by the use of support elements such as labels, grids, legends, and various forms of help facilities.

An important concept connected with zooming is the level of detail, or LOD – subobjects are displayed differently depending on the zoom depth.

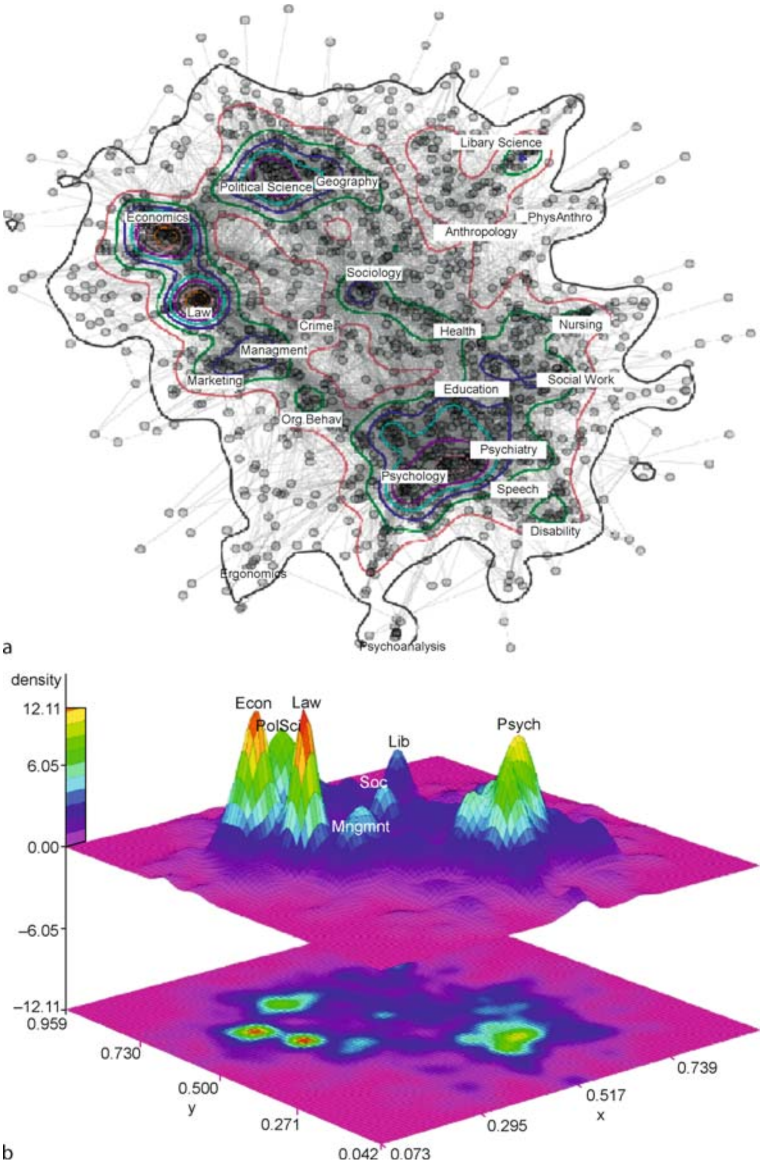
A nice example of a combination of these techniques is the Google Maps service [65] – see Fig. 14. It combines zooming, glasses (Map, Satellite, Terrain), navigation (left, right, up, down) and lenses (info about points). The maps at different zoom levels provide information at different levels of detail and in different forms.

A similar approach could be used for inspection of a large graph or network by examining selected hierarchical clusterings of its vertices. To produce higher level 'maps,' different methods can be used: *k*-core representation [4], density contours [83], generalized blockmodeling [15], clustering [71] (Fig. 15), preserving only important vertices and lines, etc. In visualizing 'maps,' new graphical elements (many of them still to be invented) can be used (see [13,80], p. 223 in [15]) to preserve or to indicate information about structures at lower levels.

The *k*-core representation [4,81] is based on *k*-core decomposition of a network [6,7] and was developed by Alessandro Vespignani and his collaborators [54]. Fig-



Complex Networks, Visualization of, Figure 16
***k*-core structure of a portion of the web at the .fr domain**



Complex Networks, Visualization of, Figure 17
Density structure

ure 16 shows a portion of the web at the .fr domain with 1 million pages. Each node represents a web page and each edge is a hyperlink between two pages.

Density contours were introduced by James Moody in 2006. First, a spring embedder layout of a (valued) network is determined. Next, vertices and lines are removed and replaced by density contours. Figure 17 shows this process applied to the case of a social science co-citation network. The left side shows the network layout and the right bottom part presents the corresponding density contours.

The basic steps in graph/network visualization are:

$$\text{graph/network} \to \boxed{\text{analysis}} \to \text{layouts}$$
$$\to \boxed{\text{viewer}} \to \text{pictures}\,.$$

Development of different tools can be based on this scheme, depending on the kind of users (simple, advanced) and the tasks they address (reporting, learning, monitoring, exploration, analysis). In some cases, a simple viewer will be sufficient (for example SVG viewer, X3D viewer, or a special graph layout viewer), in others a complete network analysis system is needed (such as Geomi [3,64], ILOG [76], Pajek [50], Tulip [93], yFiles [96]).

To visualize a network, layouts are obtained by augmenting network data with results of analysis and users' decisions. In *Pajek*'s input format, there are several layout elements from *Pajek*'s predecessors (see *Pajek*'s manual, pp. 69–73 in [50]). As in typesetting

$$\text{text} \ + \ \text{formatting} \ = \ \text{formatted text}$$

so in network visualization

$$\text{network} \ + \ \text{layout} \ = \ \text{picture}\,.$$

It would be useful to define a common layout format (an extension of GraphML [68]?) so that independent viewer modules can be developed and combined with different layout algorithms. Some useful ideas can be found in the nViZn ("envision") system [89]. To specify layouts we can borrow from typesetting the notion of *style*.

Article Outline

Glossary

Correlations is the degree, to which events at different positions and at different times depend on or influence each other, is measured by correlation functions. If two events are statistically independent, the correlation between them is zero. The opposite is not necessarily the case, but one will often expect that if correlations decay, the mutual dependence does likewise.

Correlation function describes correlations between two quantities and depends on their separation in time and space.

Complex systems consist of a large number of interacting components. The interactions give rise to emergent hierarchical structures. The components of the system and properties at systems level typically change with time. A complex system is inherently open and its boundaries often a matter of convention.

Equilibrium In statistical mechanics the prototype equilibrium system consists of a "small" system in thermal contact with another system, the latter being big enough to act as a heat bath. A heat bath is defined as a system so big that when it exchanges energy with the small system the temperature of the heat bath remains the same. The statistical properties of equilibrium systems are independent of time.

Generalized rigidity is a term introduced by P.W. Anderson [1] to describe the situation, when a many component system acts as a globally connected unit, in the sense that if one apply a force at one point, the effect can be transmitted across the system. Ice has rigidity, if we push at one point, the entire piece of ice will start moving. If the ice, on the other hand melts to water, a force applied locally will only have an effect locally.

Hamiltonian expresses the energy of a system as a function of the degrees of freedom, in terms of which the system is defined at the considered level of description. Emergence in physical systems can sometimes be understood in terms of lumping degrees of freedom, in the Hamiltonian, together in sets of effective degrees of freedom, e. g. the center of mass of a solid body.

Non-equilibrium systems is a term used to describe any system that is not in equilibrium. Needless to say this is a characterization of limited value, since there are many very different types of systems included in this category.

Order parameter is a quantity that allows one to discriminate between two phases of a physical system. The order parameter changes from zero to non-zero as one passes from one phase to the other. To identify the relevant order parameter is often non-trivial and, is in itself, a first important step.

Renormalization group analysis is a systematic mathematical procedure that enables a derivation of the emergent behavior at the macroscopic systems level. The behavior at long length and time scales is obtained from the underlying microskopic short length scales and fast dynamics.

Statistical mechanics seeks to understand how properties at systems level emerge from the level of the system-components and their interactions. This often involves the application of probability theory, and a number of mathematical techniques. Throughout, we draw a distinction between statistical mechanics and statistical physics. The latter is mainly concerned with the microscopic foundation of thermodynamics and, e. g., phenomena such as phase transitions and superconductivity.

Definition of the Subject

Matter in the universe is organized in a hierarchical structure. At the bottom (if there is one) we have elementary particles, atoms and molecules from which we get macro molecules like proteins and DNA, these are the building blocks of organelles, which together form the cells. From cells we get organs, which put together form organisms: animals and plants of a great variety of species. One level of structure emerges from the level below. Is it possible to scientifically describe, let alone, predict emergence. Sometimes emergence is described as a phenomena beyond analysis. The perplexity with which this concept is sometimes met, is well illustrated by the following quote from a recent call for participation in a meeting, held by the British research council EPSRC, to look at ways to explore emergence in complex systems. Emergence is described in the following words: "For the first time since the enlightenment in the western tradition we have started to understand that there are non-causal systems in which some things just "are". The concept of emergence by whisch patterns of possibility arise through interactions of agents over time, accepts that even with the same starting conditions the same pattern would not necessarily repeat." Another attitude is represented by Lord Roberts May's statement in a recent lecture that "when people say something is an emergent property, it just means they don't understand the phenomena".

In this brief article we will argue that emergence is neither an empty concept nor a mysterious non-causal enigma. On the contrary, emergence is central to scientific enquiry. Emergence occurs when many components interact and combine to form an identifiable system. In philosophy this is the observation that quantitative changes accumulate and give rise to new qualitative changes. A proposition that can be traced from the ancient Greek philosophers through Hegel to Dialectical Materialism. In physics Phil Anderson famously summed the fact that new levels of organization need new types of description, up in the phrase "More is Different" [2]. By following the tradition of statistical mechanics it is sometimes possible to reduce significantly the confusion surrounding what emergence is, and how it can be investigated and described. Kenneth Wilson got the 1982 Nobel prize for his Renormalization Group theory, which is a particular beautiful method for extracting certain emergent properties with great mathematical detail and precision [3].

Introduction

Statistical mechanics is concerned with the interaction of many components. From interactions between the components at one given level the aim is to understand the collective coherent behavior, which emerges as many components are put together. It is through the interactions of the components at one level that the next level emerges. We consider a collection of *interacting* atoms and the outcome is, say, a transistor. In some cases the microscopic details of the properties of the *individual* building blocks are not so crucial. It happens that the collective behavior is controlled by general properties of the *interactions* between the components more than by the intrinsic properties of the components. A number of methods have been developed to bridge the gap between the individual components comprising a system and the collective whole. This often involves predictions of the asymptotic behavior at long distances and at long times. In particular the philosophy and technique of the Renormalization Group have been successful in a number of cases in doing this. Many other approaches exist, some in which a coarse grained description is sought similar to the one used in fluid dynamics, other times the collective systems level behavior is generated by use of Individual Based Agent models typically simulated on computers. The latter method goes beyond traditional statistical mechanics, nevertheless it is reasonable to consider simulations of agent based models as part of statistical mechanics since they are very similar in spirit to traditional statistical mechanics simulations starting from the microscopic degrees of freedom, as e. g. extensively done for the celebrated Ising model used in studies of magnetic systems, melting and many other phenomena.

In this article we will discuss a number of examples of how statistical mechanics is able to deal with emergent phenomena. Our first example is from the theory of equilibrium properties of magnetic materials. In the model the microscopic magnetic moments – or spin – combine to form macroscopic coherent vortices. The vortices are bound in pairs at low temperature. When the temperature is increased, the biggest pairs are able to unbind, or fall apart. This is a subtle collective effect caused by the smaller pairs weakening the binding force between the vortices in the biggest pairs. We use this case to describe in some detail how the statistical mechanics formalism of Boltzmann and Gibbs allows us to identify the macroscopic excitations. These macroscopic excitations are what constitute the macroscopic "components" of the system, once they are identified we can calculate the unbinding of the vortex pairs. This discussion focuses on spatial aspects. The mathematical description developed from this model has applications to a range of very different phenomena, such as melting, superconductivity, superfluidity, electrical charges in two-dimensional space and crystal growth. This is a good typical example of how the mathematical formalism of statistical mechanics is able to deliver understanding, and a description, transcending the particular and unify apparently disconnected phenomena.

Many-component systems also often exhibit emergent temporal behavior that is caused by the interactions and ensuing collective motion of the components. For example, one typically see very persistent correlations, or long time memory, in the macro-dynamics of many-component systems. A particular version of this phenomena is called $1/f$ fluctuations, and we explain below what this is, and how it is related to long time correlations or long memory effects. To make the discussion concrete we will present the details of a very simple model of diffusing particles. The model might be related to motorway traffic.

To go beyond models taken from physics we will finish by a discussion of models inspired by the observed collective behavior of social insects. Aspects of trail formation and mound building of ants and termites have been reproduced in computer simulations. Often the models consider "agents" with a tendency to perform random walks and picking up and laying down material. The agents deviate from random walking when they come across traces of smell – pheromones – laid down by other ants. This indirect interaction can lead to the formation of surprisingly intricate structures of trails and mounds.

Since essentially any activity within statistical mechanics is concerned with a description of emerging phenomena a very large literature exists and we list here only a few books of particular relevance to the view point of the present article [1,4,5,6,7,8,9,10,11,12,13] and some more specialized papers as we go along.

Equilibrium Averages

To describe how statistical mechanics is able to identify structures emerging at the macroscopic level we briefly recall how macroscopic (or systems level) quantities are obtained through averaging procedures. The reason equilibrium systems can be analyzed in particular detail is that the situation, where the systems of interest can be considered as in thermal equilibrium with a heat bath, allows for the determination of the probability weights of the individual micro-states. One starts out with the following fundamental hypothesis concerning isolated or closed systems:

- **Micro Canonical Ensemble**. For a closed system it is assumed that *all* micro-states, consistent with the macroscopic constraints, occur with *equal* probability.

The macroscopic constraints can, for example, be the total energy E (which is constant for a closed system) and the volume V. Denote by $\Omega(E, V)$ the total number of micro-states possible under these constrains. Meaning the components or particles of the system have to be located within the given volume V, and that when we add all the energies of the particles the sum must equal E. The probability $p(s)$ that the system is in a particular state s is then

$$p(s) = \frac{1}{\Omega(E, V)} \, . \tag{1}$$

Closed systems are not very interesting in the sense that one is unable to interact with them. A much more interesting situation is when the system **S** under consideration is brought in contact with a heat bath **B** or heat reservoir. The heat bath is a system so big that even when it exchanges energy with the small system of experimental interest, the heat bath remains unchanged. Say a cup of tea in contact with the Pacific Ocean. The heat bath is characterized by its temperature T. We can now use the fundamental hypothesis above to determine the probabilistic weights for the states of **S**. Since the combined system $\mathbf{B}+\mathbf{S}$ is closed the weights for the combined system is given by the Micro Canonical Ensemble, i. e. all micro-states of the combined system are equally likely. The number of micro-states for the combined system of total energy $E_{\text{Tot}} = E_{\mathbf{B}} + E_{\mathbf{S}}$ will be a product

$$\Omega_{\text{Tot}}(E_{\text{Tot}}) = \Omega_{\mathbf{B}}(E_{\mathbf{B}})\Omega_{\mathbf{S}}(E_{\mathbf{S}}) \,. \tag{2}$$

Here one neglects the interactions between the heat bath and the system. Now focus on one particular micro-state s of **S** of energy $E_{\mathbf{s}}$. Since we have a particular state, s, in mind we have $\Omega_{\mathbf{S}}(s) = 1$. This state can be combined in many ways with states of the bath **B** as long as those fulfill the constraint $E_{\text{Tot}} = E_{\mathbf{B}} + E_s$. So the probability, $p(s)$, for finding the system **S** in s, when **S** is in equilibrium with the bath, is proportional to $\Omega_{\mathbf{B}}(E_{\text{Tot}} - E_s)$. Namely

$$p(s) = \frac{\Omega_{\mathbf{B}}(E_{\text{Tot}} - E_s)}{\sum_{\text{state}} \Omega_{\mathbf{B}}(E_{\text{Tot}} - E_{\text{state}})}, \tag{3}$$

the denominator ensures normalization. In order to introduce the temperature into the mathematical formalism it turns out that we should consider the logarithm of $p(s)$. We have

$$\ln[p(s)] = \text{constant} + \ln[\Omega_{\mathbf{B}}(E_{\text{Tot}} - E_s)] \tag{4}$$

$$= \text{constant} + \ln[\Omega_{\mathbf{B}}(E_{\text{Tot}})] - \frac{\partial \ln[\Omega_{\mathbf{B}}(E_{\text{Tot}})]}{\partial E_{\text{Tot}}} E_s \tag{5}$$

$$= \text{constant} - \frac{1}{k_{\text{B}} T} E_s \,. \tag{6}$$

Here we Taylor expanded to linear order to obtain the first equality. The second equality follows, because it can be shown by use of the first and second law of thermodynamics that the temperature is given by

$$\frac{1}{k_{\text{B}} T} = \frac{\partial \ln[\Omega_{\mathbf{B}}(E_{\text{Tot}})]}{\partial E_{\text{Tot}}} \,. \tag{7}$$

This is obtained in the following way. The first and second law of thermodynamics lead to the following thermodynamic identity $\mathrm{d}E = T\mathrm{d}S - p\mathrm{d}V$ where the entropy $S = k_{\text{B}} \ln[\Omega(E)]$. Since the thermodynamic identity takes the form of an exact differential we conclude that $\partial E/\partial S = T$ from which Eq. (7) follows. We now conclude

$$p(s) = \frac{\mathrm{e}^{-\frac{E_s}{k_{\text{B}} T}}}{Z} \,, \tag{8}$$

where the constant Z is obtained from the normalization condition

$$\sum_{\text{states}} p(s) = 1 \,, \tag{9}$$

to be given by

$$Z = \sum_{\text{states}} = \mathrm{e}^{-\frac{E_s}{k_{\text{B}} T}} \,. \tag{10}$$

We conclude that the probabilistic weights, needed to calculate the average macroscopic behavior of a system in contact with a heat bath at temperature T, is given by the (Boltzmann) weights in Eq. (8). And we mention that a large number of average quantities can be calculated from the sum in Eq. (10). This important sum is called the *partition function* or partition sum. Some states, or configurations of the microscopic degrees of freedom, will contribute more to the partition sum than others, such configurations can sometimes be identified as macroscopic collective excitations. These may possess a degree of robustness and stability and can in such cases be identified as macroscopic emergent objects with specific properties that can be considered essential building blocks. Perhaps it is instructive to have the following picture in mind. Think of a pool table. To describe the motion of the balls we can either follow the trajectories of all the individual molecules making up 15 colored balls or we can notice that some of the molecules move together in a coordinated way and thereby form each of the 15 balls. We can therefore instead simply follow the trajectories of the center of mass (COM) of each of the balls. Obviously we lose a lot of information since we can't go from the COM of the balls to the motion of all the molecules; whereas we can drive the COM motion if we know the motion of all the molecules. Hence we note that emergence involves a loss of information. We will discuss in detail an important and illustrative example in the next section.

The Two-Dimensional *XY*-Model

Here we describe how the averaging procedure described in the previous section can be structured in a way that allows the introduction of new effective collective degrees of freedom. These describe macroscopic excitations created by the coherent motion of a huge number of microscopic variables. When the collective degrees have been identified information concerning the detailed motion of the microscopic variables can be neglected, and one is in this way able to reduce the computational effort needed and at the same time identify the essential emergent structures. A particular clear example of this procedure consists of the physics of systems modeled by the so-called two-dimensional XY-model.

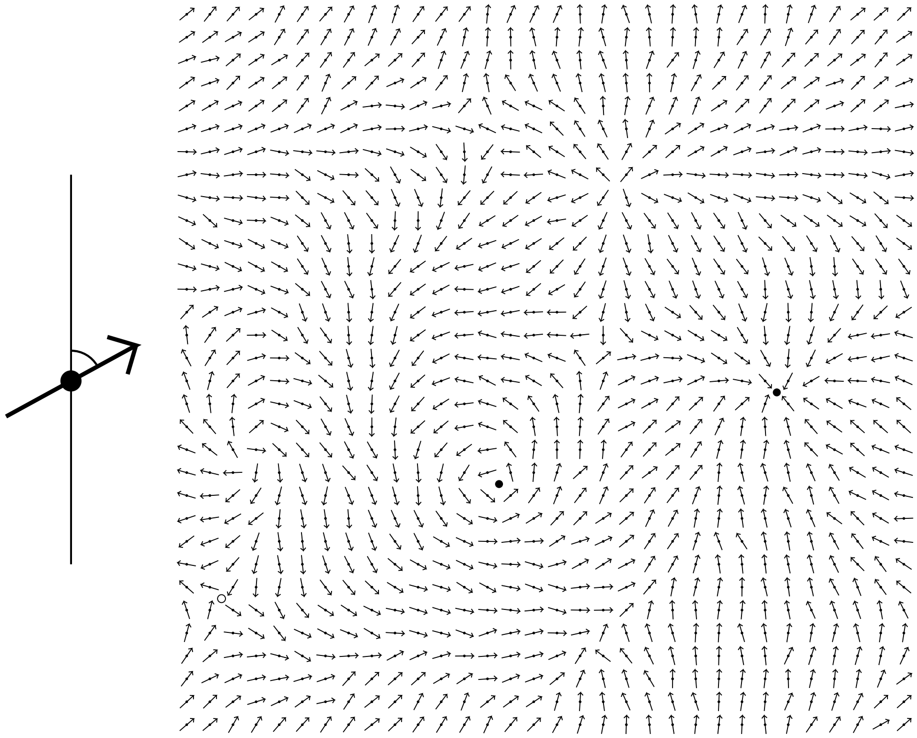
We start our discussion by considering the formation of vortices in the sea of two-dimensional magnetic moments. The individual microscopic magnetic moments sit on the sites of a two-dimensional square lattice and the direction of the moments are confined to two dimensions, see Fig. 1 (A beautiful online interactive simulation can be found on Hans Weber's web page at http://www.mt.luth.se/~weber/). Each magnetic moment can be thought of as a magnetic needle, or an arrow, confined to two dimensions and pointing in a specific direction described by the angle θ. The magnetic moment number i is given by the vector $\mathbf{S}_i = (\cos(\theta_i), \sin(\theta_i))$.

We will use it as our reference model. We think of the model as consisting of planar rotors of unit length arranged on a two-dimensional square lattice. The Hamiltonian of the system is given by

$$H = -J \sum_{\langle i,j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j = -J \sum_{\langle i,j \rangle} \cos(\theta_i - \theta_j) \,. \qquad (11)$$

Here J is the coupling constant between the magnetic moments, $\langle i, j \rangle$ denotes summation over all nearest neighbor sites in the lattice, and θ_i denotes the angle of the rotor on site i with respect to some (arbitrary) polar direction in the two-dimensional vector space containing the rotors.

We shall see below how the components, the rotors, work together to form certain collective coherent structures: topological defects or topological charges. In Fig. 1 these excitations are depicted. Each consists of a whirl or vortex in the configuration of the rotors. There are vortices of opposite sign. As one moves around in a positive direction along a contour encircling the center of a vortex (black circle) the rotors perform a full rotation in the positive direction as well. When we move around one of the anti-vortices (white circle) in a similar way, the rotors undergo a full rotation in the negative direction. Although these charges are here seen as arising from rotors or magnetic moments, the impressive fact is that these topological charges also represent Coulomb charges in two dimensions, or dislocations in two-dimensional crystals, or vortices in two-dimensional superconductors or a large number of other collective excitations. The interaction between



Complex Systems and Emergent Phenomena, Figure 1
Rotor configuration of the *XY*-model. Vortices (*black circle*) and anti-vortices (*white circle*) are clearly seen. The configuration is neutral, i. e. there is an equal number of vortices and anti-vortices; but only one white circle is indicated. The reader may find it amusing to try to locate the missing anti-vortex

the topological charges depends in all cases logarithmically on the spatial separation and this leads to some very general collective behavior, most spectacular the logarithmic dependence on separation causes a certain type of phase transition: the Kosterlitz–Thouless transition [14].

If we assume that the direction of the rotors varies smoothly from site to site, we can approximate $\cos(\theta_i - \theta_j)$ by the first two terms $1 - 1/2(\theta_i - \theta_j)^2$ in the Taylor expansion of cos. The sum over the nearest neighbors corresponds to the discrete Laplace operator, which we can express in terms of partial derivatives through $\theta_i - \theta_j = \partial_x \theta$ for two sites i and j which differs by one lattice spacing in the x-direction. This leads to the continuum Hamiltonian

$$H = E_0 + \frac{J}{2} \int \mathrm{d}\mathbf{r} (\nabla\theta)^2 \, . \tag{12}$$

Here $E_0 = 2JN$ is the energy of the completely aligned ground state of N rotors.

The thermodynamics of the system is obtained from the partition function

$$Z = \mathrm{e}^{-\beta E_0} \int D[\theta] \exp\left\{ -\beta \frac{J}{2} \int \mathrm{d}\mathbf{r} (\nabla\theta)^2 \right\} \, , \tag{13}$$

a functional integral over all possible configurations of the director field $\theta(\mathbf{r})$. Not all configurations will be of the same importance. By focusing on the terms in the sum that contribute most, we can identify the configurations that may be used as building blocks at the next level of description. Since the energy appears in the exponential with a negative sign in front, the most significant contributions will be those with the smaller energy – thus we have to pick out the local minima. We therefore divide the integral over $\theta(\mathbf{r})$ into a sum over the local minima θ_{vor} of $H[\theta]$ plus fluctuations θ_{sw} around the minima

$$\begin{aligned} Z = \mathrm{e}^{-\beta E_0} \sum_{\theta_{\mathrm{vor}}} \int D[\theta_{\mathrm{sw}}] \exp \Bigg\{ & -\beta (H[\theta_{\mathrm{vor}}] \\ & + \frac{1}{2} \int \mathrm{d}\mathbf{r}_1 \int \mathrm{d}\mathbf{r}_2 \theta_{\mathrm{sw}}(\mathbf{r}_1) \frac{\delta^2 H}{\delta\theta(\mathbf{r}_1)\delta\theta(\mathbf{r}_2)} \theta_{\mathrm{sw}}(\mathbf{r}_2)) \Bigg\} \, . \end{aligned} \tag{14}$$

The field configurations corresponding to local minima of H are solutions to the extremal condition

$$\frac{\delta H}{\delta\theta(\mathbf{r})} = 0 \;\Rightarrow\; \nabla^2\theta(\mathbf{r}) = 0 \, . \tag{15}$$

There are two types of solutions to this equation. The first consists of the ground state $\theta(\mathbf{r}) =$ constant. The second type of solutions consist of vortices in the director field (see Fig. 1) and are obtained by imposing the following set of boundary conditions on the circulation integral of $\theta(\mathbf{r})$:

1) For all closed curves encircling the position $\mathbf{r}_0$ of the center of the vortex

$$\oint \nabla\theta(\mathbf{r}) \cdot \mathrm{d}\mathbf{l} = 2\pi n \, , \quad n = 1, 2, \ldots \, . \tag{16}$$

2) For all paths that don't encircle the vortex position $\mathbf{r}_0$

$$\oint \nabla\theta(\mathbf{r}) \cdot \mathrm{d}\mathbf{l} = 0 \, . \tag{17}$$

Condition 1) imposes a singularity in the director field. Note the circulation integral *must* be equal to an integer times 2π since we circle a closed path and therefore $\theta(\mathbf{r})$ has to point in the same direction after traversing the path as it did when we started.

We can estimate the energy of a vortex in the following way. The problem is spherical symmetric, hence the vortex field θ_{vor} must be of the form $\theta(\mathbf{r}) = \theta(r)$. The dependence on r can be found from Eq. (16). We calculate the circulation integral along a circle of radius r centered at the position $\mathbf{r}_0$ of the vortex

$$2\pi n = \oint \nabla\theta(\mathbf{r}) \cdot \mathrm{d}\mathbf{l} = 2\pi r |\nabla\theta| \, . \tag{18}$$

We solve and obtain $|\nabla\theta(r)| = n/r$. Substitute this result into the Hamiltonian Eq. (12)

$$E_{\mathrm{vor}} - E_0 = \frac{J}{2} \int \mathrm{d}\mathbf{r} [\nabla\theta(\mathbf{r})]^2 \tag{19}$$

$$= \frac{Jn^2}{2} \int_0^{2\pi} \mathrm{d}\phi \int_a^L r \, \mathrm{d}r \frac{1}{r^2} \tag{20}$$

$$= \pi n^2 J \ln \frac{L}{a} \, . \tag{21}$$

Here a denotes the lattice constant and L is the linear size of the considered lattice. The circulation condition Eq. (16) creates a distortion in the phase field $\theta(\mathbf{r})$ that persists infinitely far from the center of the vortex. $|\nabla\theta|$ decays only as $1/r$ leading to a logarithmic divergence of the energy. Hence we need to take into account that the integral over r in Eq. (20) is cut-off for large r-values by the finite system size L and for small r-values by the lattice spacing a. We recall that our continuum Hamiltonian is an approximation to the lattice Hamiltonian in Eq. (11). A vortex with the factor n in Eq. (16) larger than one is called multiple charged. We notice that the energy of the vortex is quadratic in the charge. In a macroscopically large system even the energy of a single charge vortex will be large, and therefore we do not expect individual vortices to be thermally induced.

Consider now a pair consisting of a single charged vortex and a single charged anti-vortex. When we encircle the vortex, we pick up $\oint \mathrm{d}\mathbf{l} \cdot \nabla\theta = 2\pi$ and when we encircle the anti-vortex, we pick up $\oint \mathrm{d}\mathbf{l}\cdot\nabla\theta = -2\pi$. Hence, if we choose a path large enough to enclose both vortices, we pick up a circulation of the phase equal to $2\pi + (-2\pi) = 0$. I. e. the distortion of the phase field $\theta(\mathbf{r})$ from the vortex-anti-vortex pair is able to cancel out at distances from the center of the two vortices large compared to the separation R between the vortex and the anti-vortex, see Fig. 1. This explains why the energy of the vortex pair is of the form [15,16,17]

$$E_{2\mathrm{vor}}(R) = 2E_c + E_1 \ln(R/a) \,. \tag{22}$$

Where E_c is the energy of a vortex core and E_1 is proportional to J. In detail, the phase field $\theta_{2\mathrm{vor}}(\mathbf{r})$ of a vortex located at $\mathbf{r} = (-a, 0)$ and an anti-vortex located at $\mathbf{r} = (a, 0)$ is given by [15]

$$\theta_{2\mathrm{vor}}(\mathbf{r}) = \mathrm{arctg}\left(\frac{2ay}{a^2 - r^2}\right) \,. \tag{23}$$

Significant aspects of the macroscopic behavior of the XY-model can be understood by treating the vortices as particles characterized by their position and their charge and ignoring the underlying sea of rotors. Indication of this follows from the expression for the energy of a pair of vortices in Eq. 22. This energy is given in terms of the relative position of the two vortices, no reference is needed to the microscopic rotor field given in Eq. 23. The pairs of vortices have dramatic effects on the macroscopic behavior of the XY-model. At low temperature the vortices are organized in fairly small bound pairs, as the temperature is increased and more thermal energy is available the separation between paired up vortices grow and at a certain temperature the pairs break apart with the effect that the individual vortices now can move freely around as they are no longer kept in check by their partner of the opposite charge. The result is the Kosterlitz–Thouless transition which manifests itself in various ways in different realizations of the XY-model. Before we discuss this transition we will look at the average ordering of the rotors. This quantity – the magnetization – is usually able to monitor if a dramatic change in the macroscopic behavior occurs as a function of temperature. But not so in the 2d XY-model. To understand this makes it clearer how important it is to identify correctly the emergent excitations of a many component system.

Lack of Ordering in Two Dimensions

In order to highlight the peculiarity of two dimensions we consider the d-dimensional XY-model. We imagine a d-dimensional cubic lattice. Each lattice site contains a planar rotor or a phase. In the continuum limit the Hamiltonian is still given by Eq. (12) except the integral over $\mathbf{r}$ is now a d-dimensional integral and therefore the factor J is replaced by Ja^{2-d}. The average size of the projection of the rotors along, say, the x-direction in $\mathbf{S}$ space, i. e. the magnetization, is

$$\langle S_x\rangle = \langle\cos\theta(\mathbf{r})\rangle \tag{24}$$

$$= \langle\cos\theta(0)\rangle \,. \tag{25}$$

Note that we might as well have chosen the y-direction. The model is isotropic and the x and the y directions are equivalent. When $\langle S_x\rangle \neq 0$ a preferred direction is singled out in the sense that on average $\mathbf{S}$ points in the direction given by $\langle S_x\rangle$. In this case we say that the rotor field possesses order. In contrast if $\langle S_x\rangle = 0$ we also have $\langle S_y\rangle = 0$, since the model is isotropic. The zero projection comes about because the rotors circulate around and on average point equally much in all directions. So we say that the rotor field is disordered or does not possess any ordering.

First we neglect the singular vortex contributions (which is perfectly safe at low temperature) and Fourier transform the phase field

$$\theta(\mathbf{r}) = \int \frac{\mathrm{d}\mathbf{k}}{(2\pi)^d}\hat{\theta}(\mathbf{k})\mathrm{e}^{-i\mathbf{k}\cdot\mathbf{r}} \tag{26}$$

$$\theta(0) = \int \frac{\mathrm{d}\mathbf{k}}{(2\pi)^d}\hat{\theta}(\mathbf{k}) \tag{27}$$

$$\int \mathrm{d}\mathbf{r}(\nabla\theta)^2 = \int \frac{\mathrm{d}\mathbf{k}}{(2\pi)^d} k^2\theta(\hat{\mathbf{k}})\hat{\theta}(-\mathbf{k}) \,. \tag{28}$$

These equations are substituted into the expression

$$\begin{aligned}\langle S_x\rangle &= \frac{\int D[\theta]\cos(\theta(0))\mathrm{e}^{-\beta H}}{\int D[\theta]\mathrm{e}^{-\beta H}}\\ &= Re\left(\frac{\int D[\theta]\mathrm{e}^{-\beta H + i\theta(0)}}{Z}\right) \,.\end{aligned} \tag{29}$$

After some algebra one obtains the following expression

$$\langle S_x\rangle = \exp\left(-\frac{T}{2Ja^{2-d}}S_d\int_{\pi/L}^{\pi/a}\mathrm{d}k k^{d-3}\right) \,. \tag{30}$$

The behavior of $\langle S_x\rangle$ is controlled by the integral

$$I(L) = \int_{\frac{\pi}{L}}^{\frac{\pi}{a}} \mathrm{d}k k^{d-3} \,. \tag{31}$$

The behavior of $I(L)$ strongly depends on the dimension d. For $d < 2$ we have $I(L) \sim L^{2-d} \to \infty$ as $L \to \infty$. Hence,

$\langle S_x \rangle = 0$ in the limit of large systems for dimensions less than 2. For $d > 2$ we have that

$$I(L) \to A = \frac{1}{d-2}\left(\frac{\pi}{a}\right)^{d-2} \tag{32}$$

and therefore

$$\langle S_x \rangle = \exp\left(-\frac{S_d}{2Ja^{2-d}} AT\right) > 0\,. \tag{33}$$

Finally for $d = 2$ the integral $I(L)$ is logarithmically divergent $I(L) = \ln(L/a)$ which is sufficient to force $\langle S_x \rangle$ to zero for any non-zero temperature.

We conclude that there is no ordered phase according to the behavior of $\langle S_x \rangle$ at low temperature for $d \le 2$. For $d < 2$ this means that there is no phase transition. The same was for a while thought to be the case for $d = 2$. Since the thermal motion included in the calculation of $\langle S_x \rangle$ is able to prevent a preferred direction and hence ensure $\langle S_x \rangle = 0$ for $T > 0$ including other types of excitations, such as vortices, can surely not make $\langle S_x \rangle$ different from zero. So it is safe to conclude that the rotors are unable to order along a common direction for any non-zero temperature and it was accordingly expected that a phase transition in the 2d YX-model was excluded. This conclusion was reached since in magnetic systems the average of the local magnetic moment, i. e. $\langle S_x \rangle$ is the order parameter and the phase transition takes place at the temperature where the order parameter changes from zero to a non-zero value. It turned out that by identifying the vortices as emergent collective excitations and by understanding their physical effects, a phase transition of a new kind was discovered in the 2d XY-model.

Vortex Unbinding

An indication of the importance of vortices as the temperature is increased can be obtained from the following simple and heuristic argument. We estimate the free energy of a single vortex. The Helmholtz free energy is given by the difference between the energy and the entropy multiplied by the temperature $F = E - TS$. The energy is given by Eq. (21). We estimate the entropy from the number of places where we can position the vortex center, namely on each of the $(L/a)^2$ plaquette of the square lattice, i. e., $S = k_B \ln(L^2/a^2)$. Accordingly, the free energy is given by

$$F = E_0 + (\pi J - 2k_B T)\ln(L/a)\,. \tag{34}$$

For $T < \pi J/2k_B$ the free energy will diverge to plus infinity as $L \to \infty$. At temperatures $T > \pi J/2k_B$ the system can lower its free energy by producing vortices: $F \to -\infty$ as $L \to \infty$. This simple heuristic argument points to the fact that the logarithmic dependence on system size of the energy of the vortex combines with the logarithmic dependence of the entropy to produce the subtleties of the vortex unbinding transition. Assume a different dependence of the energy on system size and one will either have thermal activation of vortices at all temperatures (in case $E_{\text{vor}} \to \text{const.} < \infty$) or vortices will not be activated at any temperature (in case $E_{\text{vor}} \sim (L/a)^b$ with $b > 0$). It is the logarithmic size dependence of the 2d vortex energy that allows the outcome of the competition between the entropy and the energy to change qualitatively at a certain finite temperature T_{KT}.

In reality it is not single vortices of the same sign that proliferate at a certain temperature. What happens is that the larger vortex pairs which are bound together for temperatures below T_{KT} unbind at T_{KT}. This is a collective effect that can be treated quantitatively by use of a special Renormalization Group method design by Kosterlitz [18]. The vortex pairs induced as one approaches T_{KT} disturb the phase field so much that the effective value of the vortex binding term E_1 in the vortex pair free energy, that is Eq. (22) generalized to non-zero temperature, is driven to zero for large vortex separations. In the next section we shall see in detail how this happens.

The Spin Wave Stiffness

As our concern in this article is with emergent entities, we will now briefly discuss how a focus on, and an understanding of, the vortex degrees of freedom makes it possible to identify and describe the previously "hidden" phase transition in the 2d XY-system.

The effect of the thermally activated vortex pairs is describe by the temperature dependent *spin wave stiffness* ρ_s^R. This is an example of what Philip W. Anderson calls a generalized rigidity [1]. The spin wave stiffness describes how much free energy it costs to apply a twist, or gradient, to the rotors (also called spins):

$$\theta(\mathbf{r}) = \theta_0(\mathbf{r}) + \mathbf{v}_{\text{ex}} \cdot \mathbf{r}\,, \tag{35}$$

here $\theta_0(\mathbf{r})$ is allowed to vary according to the canonical ensemble. The increase in the free energy is given by

$$F(\mathbf{v}_{\text{ex}}) - F(0) = \frac{1}{2} V \rho_s^R v_{\text{ex}}^2\,. \tag{36}$$

A number of comments concerning the notation are illuminating. The notation $\mathbf{v}_{\text{ex}}$ for the gradient applied to the phase field $\theta(\mathbf{r})$ has its origin in the fact that the same physics, as we describe here, applies to superfluid films and superconducting films. In these cases the field $\theta(\mathbf{r})$ is the phase of the complex order parameter, the wave function of the super-fluid. Being the phase of a quantum mechanical wave function the gradient of $\theta(\mathbf{r})$ is related to a probability current and thereby to the velocity field of the superfluid. The notation ρ_s^R is meant to remind one that this phase rigidity, is determined by the **density** of superfluid in the case of a superfluid or a superconductor. The superscript R in ρ_s^R indicates that thermal excitations renormalize the quantity. It follows immediately from the Hamiltonian in Eq. (12) that at zero temperature $\rho_s^R = J = \rho_s$. The spin wave stiffness is similar to the shear constant of a material. The shear constant determines how the (free) energy increase when a shear deformation is imposed. As temperature is increased the shear constant decreases and drops abruptly to zero when the solid melts into a liquid.

To obtain ρ_s^R one calculates the left hand side of Eq. (36). Details can be found in the wonderful book by Chaikin and Lubensky [9]. The phase field is split into two parts

$$\theta_0(\mathbf{r}) = \theta_s(\mathbf{r}) + \theta_v(\mathbf{r}) \,, \tag{37}$$

where the first term describes smooth spin waves and the second term contains the singular vortex contribution. The free energy is obtained from $F = k_B T \ln Z$ and the partition function is given by Eq. (13). To calculate Z introduce Fourier transforms of the phase field. After quite a bit of algebra one arrives at the following simple expression

$$\rho_s^R = \rho_s - \frac{1}{2}\frac{\rho_s^2}{T} \lim_{k\to 0} \frac{\langle \hat{n}(\mathbf{k})\hat{n}(-\mathbf{k})\rangle_0}{k^2} \,, \tag{38}$$

which expresses the renormalized stiffness in terms of the correlation function of the Fourier transform of the vortex density function

$$n(\mathbf{r}) = \sum_\alpha n_\alpha \delta(\mathbf{r} - \mathbf{r}_\alpha) \,, \tag{39}$$

for a collection of vortices of charge n_α (see Eq. (16)) with centers located at positions $\mathbf{r}_\alpha$. The vortices are now described entirely by their position exactly like if they were ordinary particles. So what started out as a complex configuration in the field of rotors is now possible to treat as point particles. The effect of the extended disturbance of the rotor field is taken care of by the interaction energy between two vortices. The thermodynamic average in Eq. (38) is over the canonical ensemble with no twist imposed, hence the subscript 0. Eq. (38) can be used to determine how the spin wave stiffness behaves at large distances as a function of temperature. We will discuss how in the next section.

The KT Transition

Let us first summarize the phenomenology of the Kosterlitz–Thouless transition. As the temperature is increased more and more vortex pairs are thermally activated. This makes ρ_s^R decrease, see Eq. (38). This corresponds to a decrease in the increment of the free energy induced by a certain twist $\mathbf{v}_{ex}$. We can understand the effect from the fact that the phase field $\theta(\mathbf{r})$ becomes more and more distorted as the temperature is increased, hence the extra perturbation caused by $\mathbf{v}_{ex}$ becomes relatively less important. Quantitatively one finds

$$\rho_s^R = \begin{cases} \rho_s^R(T_{KT}^-)[1 + \text{const.}(T_{KT} - T)^{1/2}] & \text{for } T < T_{KT} \\ 0 & \text{for } T > T_{KT} \,. \end{cases} \tag{40}$$

Here, T_{KT} is the Kosterlitz–Thouless temperature at which vortex pairs unbind. The value of T_{KT} differs from one system to another. In the 2d XY-model $T_{KT}/J \simeq 0.893 \pm 0.002$ [19]. The remarkable thing is, that the ratio

$$\rho_s^R(T_{KT}^-)/T_{KT} = 2/\pi \tag{41}$$

is universal for all systems that undergoes a KT-transition. Since $\rho_s^R(T_{KT}^+) = 0$ Eq. (41) is referred to as the universal jump. The correlation length $\xi(T)$ behaves in a very unusual way as one approaches T_{KT} from above. We are used to a relatively slow algebraic divergence of the correlation length as the critical temperature is approached. For the KT-transition the divergence is, however, much faster

$$\xi(T) \sim \exp\left(\frac{\text{const.}}{(T - T_{KT})^{1/2}}\right) \quad \text{for} \quad T > T_{KT} \,. \tag{42}$$

Can we in a simple way understand this exponential divergence? Yes, we can. The phase field is significantly distorted by unbound vortices, since these vortices are not screened by a nearby anti-vortex. I. e. the phases $\theta(\mathbf{r})$ can remain correlated over distances shorter than the typical distance $D = 1/\sqrt{n_{ub}}$ between unbound vortices of density n_{ub} [20]. Or in other words, we expect the correlation length $\xi \sim D$. The vortices are thermally induced and therefore their density is expected to depend on the temperature through a Boltzmann factor $\exp(-E_{vor}/T)$. The situation described here is exactly what happens in the one-dimensional so-called ϕ^4 model. This model supports thermally activated solitons. The correlation length is set by the inverse of the soliton density and diverges exponentially as the temperature goes to zero [21]. The same thing, in a slightly simpler version, also happens in the one-dimensional Ising model. This argument can indicate the cause of the exponential dependence of ξ. But it is no more than an indication since the exponential dependence in Eq. (42) is significantly different from a simple Boltzmann factor. This difference is due to corrective renormalization effects.

Continuous phase transitions are accompanied by divergences in thermodynamic quantities caused by the divergence of the correlation length as the critical temperature T_c is approached. The singular part of the free energy density f can be estimated as the amount of thermal energy T_c within a correlated volume ξ^d, which gives $f \sim T_c/\xi^d$. The specific heat c_V is given by the second derivative of the free energy $c_V = -T\partial^2 f/\partial T^2 \sim \partial^2 \xi^{-d} \partial T^2$. For the KT-transition the exponential divergence of $\xi(T)$ in Eq. (42) is so rapid and occur over such a narrow temperature range that the divergence in c_V cannot be resolved in simulations or in experiment. This is another reason why the vortex unbinding transition remained unnoticed for so long. It doesn't leave any dramatic signature in the thermodynamic quantities. However, as mentioned above, the macroscopic rigidity clearly changes at the transition.

The Vortex Unbinding Transition in Other Systems

We have above mentioned that not only the XY-model exhibits the Kosterlitz–Thouless vortex unbinding transition [22]. Any two-dimensional system that supports thermally induced "charges" or topological defects that interact logarithmically will undergo this transition. The $U(1)$ symmetry of the phase field $\theta(\mathbf{r})$ of the XY-model is also present in the Ginzburg–Landau free energy of superfluids and of superconductors. The topological excitations in the case of a superfluid consist of vortices in the flow of the superfluid. Vortices like those observed when one empties a bath tub. In thin superfluid helium film such vortices destruct the superfluid phase with increasing temperature according to the scenario of the KT-transition [23,24].

The situation is slightly more complicated in superconductors. Because the superfluid in this case is charged (the superconducting pairs of electrons), screening effects play a role [9,10,22]. However, for thin superconducting films of thickness δ the effective screening length is given by $\lambda_{\text{eff}} = \lambda^2/\delta$, which can easily become a macroscopic length. In this case the loss of superconductivity is caused by the unbinding of vortex pairs according to the KT-transition. The broken pairs can move freely when they respond to an applied electric current. As they move they cause phase slips in the superconducting order parameter. These phase slips induce a voltage drop according to the Josephson relation. The superconductor is now unable to support an electric current without a voltage drop, i. e. it is not a superconductor any longer [25,26,27,28].

Dislocations in two-dimensional crystals interact through the strain field. Two edge dislocations of opposite sign correspond to an extra row of atoms inserted along the line connecting the location of the two dislocation cores. The extra line of atoms produces strain and leads to an increase in the energy which is logarithmic in the separation between the two dislocations. Thus, the situation is very similar to the one encountered in the XY-model. When the dislocations unbind, free dislocations are produced. A shear applied to the system can now be accommodated by the mobile dislocations without an increase in the (free) energy. I. e., the shear constant has dropped to zero and the system is melted. The 2d melting theory of Kosterlitz–Thouless–Halperin–Nelson–Young predicts that melting occurs in two stages. At the first stage dislocations unbind and make the shear constant drop to zero. The dislocations are topological defects, their effect on the order of the lattice are, however, not very dramatic. Before the unbinding of dislocations, the translational and the orientational order of the lattice are both described by correlation functions that depend algebraically on distance. When the dislocations unbind the translational correlation function becomes exponential but the orientational correlations remain algebraic. At a somewhat higher temperature topological defects called disclinations unbind with the effect that the orientational order becomes exponential. Details can be found in Chaikin and Lubensky [9].

There are many other cases where the logarithmic vortex interaction and the KT-transition play a role. For instance, the shape of surfaces in three dimensions may undergo a transition from smooth to rough [29]. Assume that the surface energy of the two-dimensional surface is proportional to the area of the surface. And assume that the surface is defined in terms of its height $h(x, y)$ above the xy-plane, i. e. no over hangs. In other words the points on the surface have the coordinates $(x, y, h(x, y))$. The Hamiltonian for the surface is then

$$H = \sigma \int \mathrm{d}x \int \mathrm{d}y \sqrt{1 + (\nabla h)^2} \,. \tag{43}$$

Here σ is a measure of the surface tension. If the height only varies slowly as a function of (x, y) we can assume $|\nabla h| \ll 1$ and then expand the square root. In this approximation the Hamiltonian in Eq. (43) can be written as

$$H = \sigma L^2 + \frac{1}{2} \int \mathrm{d}x \int \mathrm{d}y (\nabla h)^2 \,, \tag{44}$$

(L is the linear size of the system in the xy-plane) which is equivalent to Eq. (19), and we expect the same physical phenomenology to apply to the surface as we found for the XY-model.

Non-Equilibrium Systems

The Boltzmann probabilities cannot be used to calculate the macroscopic properties when we deal with situations that have no equivalence among systems in contact with a heat bath. At present there is no general procedure for the determination of the probability weights of the individual microstates. This doesn't mean that statical mechanics can't describe how macroscopic properties emerge in systems out of equilibrium. Indeed approaches of broad interest exist. Here we will briefly introduce the use of Langevin equations and algorithmic models through two concrete simplistic models. The first is inspired by the very long memory or correlation times often observed in complex systems. We will discuss slow flowing motorway traffic. The other is concerned with the emergence of self-organized structures among interacting living organisms. Specifically we will think of the formation of ant trails.

1/f Fluctuations – a Langevin Approach

In this section we describe an example of emergence in time. We will assume that interaction between the components of our system forces these to diffuse around, rather than to move around in a ballistic manner. The result is a time signal that contains very strong correlations and is characterized by what is denoted a $1/f$ power spectrum [30].

We want to study correlations in a time signal $f(t)$. We measure the signal again and again at two times separated by T time units. To make life simple we will *neglect* the normalization factor in the empirical averages, i. e. we don't divide by the number of terms in the sum in Eq. (45) below. A justification for this is that we are interested in the functional dependence of the correlations on the time interval T and not so much interested in the actual specific value of the correlation coefficient. Since the correlation coefficient will depend on T we talk about the correlation function. Moreover, since we are correlating the signal with itself we talk about the autocorrelation function given by:

$$\begin{aligned} C(T) &= \sum_t [f(t) - \langle f(t)\rangle][f(t+T) - \langle f(t+T)\rangle] \\ &= \int \mathrm{d}t [f(t) - \langle f(t)\rangle][f(t+T) - \langle f(t+T)\rangle] \\ &= \int \mathrm{d}t [f(t) - \langle f(t)\rangle][f(t+T) - \langle f(t)\rangle] \,. \end{aligned} \tag{45}$$

In the last equality we made use of the fact that the average of value $f(t)$ and $f(t+T)$ are identical.

The autocorrelation function is an important object for the study of memory effects or causality effects in a signal. The correlation function is equivalent to the *power spectrum*. The power spectrum of the signal $f(t)$ is defined as

$$S_f(\omega) = |\hat{f}(\omega)|^2 \,. \tag{46}$$

That is the absolute value squared of the Fourier transform of the signal and the power spectrum is related to the Fourier transform of the autocorrelation function:

$$S_f(\omega) = \hat{C}(\omega) \,. \tag{47}$$

This relation explains why power spectra that approximately depend inversely proportional on the frequency

$$S_f(\omega) \propto 1/\omega^\beta \,, \tag{48}$$

with $\beta \simeq 1$, are of special interest [31,32,33]. Namely, at a somewhat heuristic level, we can substitute Eq. (48) into Eq. (47) and then into

$$C(T) = \int_{-\infty}^{\infty} \mathrm{d}\omega \hat{C}(\omega) \mathrm{e}^{-i\omega t} \,, \tag{49}$$

to obtain

$$C(T) = \int_{-\infty}^{\infty} \mathrm{d}\omega \omega^{-\beta} \mathrm{e}^{-i\omega T} \tag{50}$$

$$= T^{1-\beta} \int_{-\infty}^{\infty} \mathrm{d}u u^{-\beta} \mathrm{e}^{u} \,. \tag{51}$$

We made the substitution $u = \omega T$ and note that the integral in the above equation now is independent of T. So when $\beta \simeq 1$, the correlation function $C(T)$ depends very weakly on T meaning very slow decay of correlations. This indicates the particular interest in power spectra that approximately decays as one over the frequency – called $1/f$ noise. The way we carried the argument through is slightly dangerous due to possible divergent integrals; the conclusion is, however, sound.

Transport by Diffusion

For concreteness imagine a piece of motorway stretching from $x = -\infty$ to $x = \infty$. At $x = 0$ vehicles can enter or leave at an intersection. We will develop a model for the time evolution of the density of cars $n(x, t)$ at position x at time t. Since the cars – particles – only can leave or enter our system at $x = 0$, at all other positions, $x \neq 0$, changes during a brief time interval δ in the number of particles in a small interval $[x, x+\delta x]$ about x

$$\delta n(x,t) = n(x,t+\delta t)\delta x - n(x,t)\delta x \tag{52}$$

will be caused by a difference during the time δt between the number of particles leaving the section $[x, x+\delta x]$ at $x+\delta x$ and the number of particles entering the section at x. Let $J(x,t)$ denote the particle current (number of particles crossing the position x at time t per time unit). We can then write

$$\delta n(x,t) = J(x+\delta x,t)\delta t - J(x,t)\delta t\,. \tag{53}$$

Substituting Eq. (53) into Eq. (52) we obtain

$$\begin{gathered} n(x,t+\delta t)\delta x - n(x,t)\delta x = -J(x+\delta x,t)\delta t + J(x,t)\delta t \\ \Downarrow \end{gathered} \tag{54}$$

$$\frac{\partial n(x,t)}{\partial t} = -\frac{\partial J(x,t)}{\partial x}\,. \tag{55}$$

The last equation follows in the limit $\delta x \to 0$ and $\delta t \to 0$.

This equation is exact and only assumes conservation of the particles. To obtain a closed equation for $n(x,\ t)$ we need to relate $J(x,\ t)$ to $n(x,\ t)$. And to do so we need to make assumptions concerning the nature of how the particles, or cars, move along the line. Let us imagine that congestion makes it impossible for cars to move freely. On the contrary assume that the drivers are forced to effectively perform random walks; i. e. diffuse along the motorway.

We emphasize that it is through this assumption that the cars, or particles, are made to interact. Here we assume that the diffusion is a result of over-crowding and interaction amongst the cars. Obviously particles might perform diffusive motion as a result of other interactions. Pollen in water diffuses because it is bombarded by large numbers of water molecules. In any case some sort of complex interaction is always responsible for diffusive motion since the particles otherwise would move around according to Newton's laws. The model might in fact be more relevant to small particles (pollen, say) suspended in a long narrow strip of water – or something else.

To model the jamming and resulting diffusive motion, we will assume that the net particle current (at coarse grained level) is from high particle density to low particle density, and linear in the density difference. We express this as

$$J(x,t) = -\gamma\frac{\partial n(x,t)}{\partial x}\,. \tag{56}$$

We combine Eq. (55) and Eq. (56) to obtain a closed form of dynamical equation for $n(x,t)$:

$$\frac{\partial n(x,t)}{\partial t} = \gamma\frac{\partial^2 n(x,t)}{\partial x^2}\,. \tag{57}$$

This is the well-known diffusion equation. It describes how inhomogeneities in the density $n(x,\ t)$ relaxes by diffusion. The equation describes a closed system. Next we include the particles that might be added or removed at a certain rate $g(x,\ t)$ at position x at time t. According to the description above we have in particular in mind that $g(x,\ t)$ must describe cars leaving and entering at $x=0$. We will later return to how this particular requirement can be imposed on $g(x,\ t)$. We now have our final equation of motion for $n(x,\ t)$

$$\frac{\partial n(x,t)}{\partial t} = \gamma\frac{\partial^2 n(x,t)}{\partial x^2} + g(x,t)\,. \tag{58}$$

This is an inhomogeneous partial differential equation and we solve it easily by Fourier transformation

$$n(x,t) = \int_{-\infty}^{\infty}\frac{\mathrm{d}k}{2\pi}\int_{-\infty}^{\infty}\frac{\mathrm{d}\omega}{2\pi}\hat{n}(k,\omega)\mathrm{e}^{i(kx+\omega t)}\,. \tag{59}$$

Substitute into Eq. (58) to obtain an expression for $\hat{n}(k,\omega)$ in terms of the Fourier transform of the drive $\hat{g}(k,\omega)$

$$\hat{n}(k,\omega) = \frac{\hat{g}(k,\omega)}{i\omega+\gamma k^2}\,. \tag{60}$$

Now substitute Eq. (60) into Eq. (59):

$$n(x,t) = \int_{-\infty}^{\infty}\frac{\mathrm{d}k}{2\pi}\int_{-\infty}^{\infty}\frac{\mathrm{d}\omega}{2\pi}\frac{\hat{g}(k,\omega)}{i\omega+\gamma k^2}\mathrm{e}^{i(kx+\omega t)}\,. \tag{61}$$

Next we want to focus on the density fluctuations at a specific position $x_0 > 0$. Therefore we define

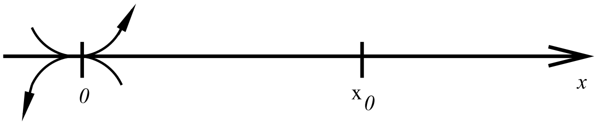
$$N(t) \equiv n(x_0,t) - \langle n(x_0,t)\rangle_t\,, \tag{62}$$

where we have subtracted the temporal averaged density. We will determine the power spectrum of $N(t)$ and for this purpose need the Fourier transform

$$\hat{N}(\omega) = \int_{-\infty}^{\infty}\mathrm{d}tN(t)\mathrm{e}^{-i\omega t} \tag{63}$$

$$= \int_{-\infty}^{\infty}\mathrm{d}t\ n(x_0,t)\mathrm{e}^{-i\omega t} - \langle n(x_0,t)\rangle_t \int_{-\infty}^{\infty}\mathrm{d}t\ \mathrm{e}^{-i\omega t} \tag{64}$$

$$= \int_{-\infty}^{\infty}\frac{\mathrm{d}k}{2\pi}\frac{\hat{g}(k,\omega)}{i\omega+\gamma k^2}\mathrm{e}^{ikx_0} - \langle n(x_0,t)\rangle_t\delta(\omega)\,. \tag{65}$$



Complex Systems and Emergent Phenomena, Figure 2
Cars/particles diffusing up and down a motorway stretching from $x = -\infty$ to $x = \infty$. At $x = 0$ an intersection allows the vehicles to enter or leave the motor way. At $x = x_0$ a traffic warden is monitoring the number of vehicles, $N(t)$, in front of him

That is how far we can go without further assumptions concerning the nature of the drive $g(x, t)$. Since this source term is meant to represent vehicles entering and leaving at position $x = 0$ we will now use

$$g(x,t) = \delta(x)\chi(t) \Rightarrow \hat{g}(\omega) = \hat{\chi}(\omega)\,. \tag{66}$$

We then have that for $x \neq 0$ the source $g(x,t) = 0$ and at $x = 0$ the temporal variation in the flow onto and away from the "motorway" is given by $\chi(t)$. From Eq. (65) we get

$$\hat{N}(\omega) = \hat{\chi}(\omega)\int_{-\infty}^{\infty} \mathrm{d}k \frac{\mathrm{e}^{ikx_0}}{i\omega + \gamma k^2}\,. \tag{67}$$

The power spectrum is finally calculated as the absolute value square of $\hat{N}(\omega)$

$$|\hat{N}(\omega)|^2 = \frac{|\hat{\chi}(\omega)|^2}{4\gamma\omega}\mathrm{e}^{-\sqrt{\frac{2\omega}{\gamma}}x_0}\,. \tag{68}$$

The power spectrum of the density fluctuations is clearly influenced by the power spectrum of $\chi(t)$. Let us assume that vehicles enter and leave at the intersection in a totally uncorrelated manner (perhaps not a totally realistic assumption) which translates into $|\hat{\chi}(\omega)|^2 =$ constant. In this case

$$|\hat{N}(\omega)|^2 \propto \frac{1}{\omega}\mathrm{e}^{-\sqrt{\frac{2\omega}{\gamma}}x_0}\,. \tag{69}$$

For frequencies so small that $\sqrt{(2\omega)/\gamma}x_0 < 1$ we have $\exp(-\sqrt{(2\omega)/\gamma}x_0) \simeq 1$ and therefore

$$|\hat{N}(\omega)|^2 \propto \frac{1}{\omega} \quad \text{for} \quad \omega < \frac{\gamma}{2x_o^2} \equiv \frac{1}{2T_{\text{diff}}}\,. \tag{70}$$

Where we introduced the time scale $T_{\text{diff}} = x_o^2/\gamma$. This is the characteristic time it takes for particles, under going diffusion with a diffusion constant γ, to move from $x = 0$ to $x = x_0$.

Very long temporal correlations, as indicated by the $1/f$ behavior of the power spectrum, is observed in very many and diverse situations: the light intensity from quasars, the ocean current, the pitch or pressure fluctuations in speech and music, the flow of traffic, the fluctuations in the resistivity of a conductor, and many more [31, 32]. Is the model we have sketched above able to explain the observed $1/f$ correlations in all these many different systems? No, probably not. Surface driven diffusion doesn't seem to be central to all these situations. The question whether a general explanation for $1/f$ exists is still an open one.

We have considered $1/f$ fluctuations here for mainly two reasons. It is a fascinating problem which is often encountered in complex systems and our discussion illustrates how one can use stochastic differential equations to go beyond equilibrium statistical mechanics to analyze temporal emergent behavior.

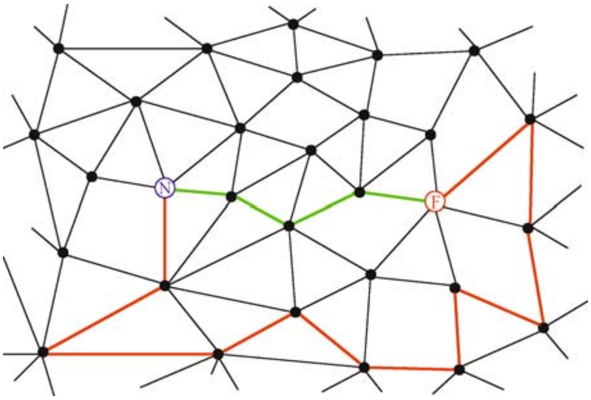
Self-organized Structure Formation – Ant Trails

As our next example of non-equilibrium statistical mechanics and emergence in complex systems we will briefly consider an algorithmic model inspired by ant trail formation. The model is schematic, simplistic and its relevance to the actual mechanism involved when real ants form trails is not known in detail. Nevertheless, the model is an interesting example of how emergent structures can appear from a dynamical algorithm.

The model describes how the path selected by ants gradually converge towards the *shortest* path between the nest and a location of food, as a result of ants' tendency to walk around at random combined with a preference for following the smell (the pheromone trail) left behind by preceding ants [12,13]. The model discussed here is presented by Danilo Benzatti at http://ai-depot.com/CollectiveIntelligence/Ant.html; but a rich literature on individual based models of formation of patterns by social insects exists [12,13,34,35,36].

We imagine a network of possible paths around the ant nest (see Fig. 3).

The nest is located at one node. Around the nest many edges connect a system of nodes. The ants can only move along the edges and in this way travel from node to node. At some of the nodes food is present. Often more than one



Complex Systems and Emergent Phenomena, Figure 3
A network of possible paths the ants can choose between as they travel from the nest at *N* to the food at *F*. The *green* short path will maintain a high level of pheromones, and will continue to attract ants, while the longer *red* path will gradually sustain a high level of pheromones and will therefore cease to attract ants

possible route will lead from the nest to the food. How do ants, with no global overview and no sophisticated means of measuring traveled distance, identify the shortest route from the nest to a food position? The assumption is that all what an individual ant is able to do is:

(1) **Ant Motion:** Perform random walks.
(2) **Effect of ant on path:** Lay down a unit of pheromone when traversing an edge.
(3) **Feedback:** Feel attracted to pheromones deposited on the edges. The more pheromones the more an ant is attracted to an edge; and the more likely it is that the ant chooses to walk along that edge.
(4) **Return to nest:** When food is found the ant follows its own pheromone trail back to the nest.

The reason this algorithm can converge towards the shortest path, is that the shortest path between the nest and the location of the food will have more ants traveling along its edges per time, and therefore will have a higher pheromone concentration than the longer paths.

The details of the algorithm is as follows. Let the nodes be enumerated by $i = 1, 2, \dots, N$. Let edges between node number i and node number j be labeled E_{ij}. Each edge carries a time-dependent pheromone weight $\phi(E_{ij},\ t)$. When an ant traverses an edge it deposits one unit of pheromone leading to

$$\phi(E_{ij}, t) \mapsto \phi(E_{ij}, t+1) = \phi(E_{ij}, t) + 1\ . \qquad (71)$$

At each node the ants chose probabilistically between the edges sprouting from the node. The probability $p(E_{ij},\ t)$ that an ant chooses a certain edge E_{ij} among all the edges connected to a specific node number i is given by

$$p(E_{ij}, t) = \frac{\phi(E_{ij}, t)}{\sum_l \phi(E_{il}, t)}\ . \qquad (72)$$

At the start of the simulation all ants are in the nest. Next they begin their random exploration of the network. When an ant locates the food, it picks up a unit of food and returns to the nest along the path it followed on its way out. On the return journey pheromones are also laid down, reinforcing this specific path. Finally it is assumed that the pheromones evaporate at a constant rate, say,

$$\phi(E_{ij}, t) \mapsto \phi(E_{ij}, t+1) = \phi(E_{ij}, t) - \nu\Theta(E_{ij}, t)\ . \quad (73)$$

(Note the Θ-function [defined as $\Theta(x) = 1$ for $x > 0$ and $\Theta(x) = 0$ for $x \le 0$] ensures that the evaporation stops when there are no more pheromones on an edge, i. e. when $\phi(E_{ij} = 0.)$ Thus, paths rarely used will lose their pheromone signature and will not be attractive to the ant, whereas the pheromone level will be maintained along the more often used paths. Thus, the shorter paths with a more frequent ant-traffic will prevail over the longer paths, since the ants on the latter paths visit the individual edges less frequently.

The collective effect of this algorithm is to find the shortest path between nest and food, although the individual ant doesn't need to know that this is what is going on. For more detail see [37] and for modeling of emergent collective intelligence and pattern formation amongst social insects see [12,13,34,35,36]. It is still an open question how to represent algorithmic models, like the one described in this section, in a precise way.

Summary and Future Directions

We have described a specific example where one can follow in great detail the steps from one level of structure to the next in the hierarchical order of matter. Topological defects arise as coherent structures of the "atoms" at one level and can be considered as (composite) particles at the next level. Their interaction can be derived from the behavior of the constituent "atoms". Many different systems may support composite particles that interact in the same way. We looked in particular at vortex physics, where the Kosterlitz–Thouless transition is caused by the logarithmic interaction between the topological defects. The one most important fact in determining the KT-transition is that both energy and entropy depend logarithmically on length scale for the two-dimensional topological charges. This example is hoped to make clear that within equilibrium statistical mechanics emergent phenomena can be described and analyzed in great quantitative detail.

When we move to systems out of equilibrium, which of course by far constitute the majority, no universally applicable formalism exists so far. We illustrated, however, by two very different examples that emergent collective behavior produced by interactions between components can also in non-equilibrium situations be modeled either by use of various mathematical techniques or through the application of computer simulations.

I will finish by suggesting the following *conclusion*. There is nothing mysterious about emergent phenomena. They are a wonderful thing – but they are not of new character, something science never has seen or dealt with before. On the contrary, I will claim that understanding emergent phenomena is exactly what all science is aimed at. Often this is not so explicitly clear as in the examples discussed above where the emphasis is explicitly on the macroscopic, or systems level, effects of the interactions between the components constituting the system. Nevertheless, even when one studies, say, atomic physics (as in contrast to statistical physics), one is dealing with the effect of interacting components. An atom consists after all of interacting protons, neutrons and electrons and the properties of the atom are the emergent result of the interactions between these particles.

Notwithstanding, the focus of the statistical mechanics approach is towards generality. As illustrated by our discussion of the XY-model and the Kosterlitz–Thouless transition, the same phenomenology can be observed in many very different systems with very different types of components (magnetic moments, atoms in a lattice, superfluids etc.), if the interactions between the components possess equivalence at a mathematical level. It is this generality that leads people to suggest that even simple model studies may sometimes be of relevance to seemingly much more complicated situations. In the future we are bound to see the statistical mechanics approach to emergent phenomena being applied to a much broader range of problems than was traditionally the case. We see attempts in fields like biology and economics, but also in linguistics, to develop pertinent statistical mechanics models. Examples include phenomena ranging from gene regulation to the social behavior of insect colonies and from stock market fluctuations to management of logistics. So far statistical mechanics has mainly been developed under the influence of physics and methods like the Renormalization Group arose. It will be very interesting to follow how statistical mechanics broadens its arsenal of tools as emergent phenomena in other fields are approached from the view point of statistical mechanics.

Acknowledgments

I am deeply grateful to many people with whom I have collaborated and learnt from during many years concerning matters relevant to the topic of the present article. In particular it is a pleasure to mention Hans Fogedby, Peter Minnhagen, and Hans Weber.

Article Outline

Glossary

Biocomposite Biological composite materials made through biological processes usually in living organisms. Biocomposites formed through biomineralization processes are referred to as biomineral composites

Biomimetics Also known as biomimicry, is the study of biological systems with the aim of applying the methods and processes in these systems to the design of engineering materials and systems to produce engineering devices and structures with superior or comparable functionalities.

Biomineralization Mineralization carried out through biological processes to convert organic materials to inorganic materials to form biominerals. Biomineral composites are composed of inorganic minerals formed through biomineralization processes by living organisms in organic matrices of proteins and polysaccharides.

Composite A combination of two or more monophase materials arranged into a material (or "material structure") to produce one or more particular properties that are superior to the same properties exhibited by the individual component materials.

Multifunctionality This is the ability of a material or device to perform two or more functions simultaneously or consecutively.

Self healing The ability of a structure to repair damage without external intervention. For example, a small cut on a human skin will be repaired automatically by the body. Man-made structures with such ability are under early development.

Definition of the Subject

A composite material is a combination of two or more monophase materials arranged into a single entity material (or "material structure") to produce one or more particular properties that are superior to the same properties exhibited by the individual component materials. Until recently, most composites were designed with a single function in mind, most commonly focusing on improving strength or durability of the material. Many high performance composites have been developed and are performing excellently in this respect. For example, carbon fiber reinforced epoxy is now commonly used in many engineering applications. Carbon fibers have high theoretical strength and high stiffness, but are brittle and therefore readily break if a very small flaw is initiated. By embedding the fiber in epoxy, which is relatively ductile (less flaw sensitive) compared to the carbon fiber, the composite structure combines the strength and stiffness of the carbon fibers with the ductility of the epoxy. A natural extension of this concept is to develop materials that are optimized for engineering applications in conditions that demand more than one function being performed by a single material. For example, a material acting as a structural support may as well function as a thermal sensor at the same time.

A multifunctional composite, therefore, is a composite material that is capable of performing two or more functions simultaneously or consecutively. The need for improved performance in current engineering application and in entirely new areas of application has been the major driving force behind the design and development of multifunctional composites. Multifunctionality is achieved in a composite by deliberately and purposefully engineering the microsructures of the component materials and the composite as a whole usually at the micro- and nano-range levels (that is at the length scales of μm and nm). When the reinforcement scale is in the nano-region the resulting composites are commonly referred to as *nanocomposites*, which is a new frontier in materials science and engineering. Today, much effort is being geared towards research and development of multifunctional composites at various materials research departments and institutions across the world.

Introduction

Multifunctional composites are designed, through microstructural modification, to enhance or introduce new material properties in order to improve or increase the functionalities of a structure, with respect to a broad range of properties. This can include various combinations of magnetic, electronic, electrical, optical, chemical, thermal and mechanical properties. In other words, a multifunctional composite provides two or more functionalities simultaneously or sequentially with improved performance, with less complexity, cost and weight compared to a structure where these functions are provided by individual components. In many cases, a multifunctional composite is the only means by which the combination of the desired functions can be achieved.

Requirements for high performance, durability, conservation of natural resources, low cost, and in many applications miniaturization have led to research and development of multifunctional composites with high specific properties, e. g., high strength per unit weight. These have especially been the driving forces for applications in space exploration, aerospace, information technology and energy production and transmission. Thus, materials science is a critical tool to bring together different materials as composites that can perform more than one function. Such composites are designed and engineered at various scales, ranging from the atomic level and up. For example, load-bearing composites have been developed to simultaneously act as thermal sensors by utilizing carbon nanotube reinforced polymers [109].

A very important multifunctional composite group that has been researched over the past two decades is the group of carbon nanotube composites because of the remarkable mechanical, electrical, thermal and structural properties exhibited by the fiber-like carbon nanotubes reinforcing component of the composites [35]. Carbon nanotubes are added to polymeric matrices to form carbon nanotube polymer composites with excellent mechanical and electrical properties [105]. With the nanotubes the scale of reinforcement is now in the nano region hence these composites are termed nanocomposites, and will be discussed in Sect. "Functionalized Carbon Reinforced Polymer Matrix Composites".

Living organisms are made up of multifunctional materials. An example is the human skin that functions as a container and protector for all internal organs and the human structure. It also serves as a heat sensor, touch sensor, and an outlet for sweat and oil. The human skin, made up of various cells and layers of cells consisting of blood vessels, sensory receptors, glands, and hair follicles, is therefore a natural multifunctional composite. Moreover, human skin has the amazing ability of self healing. Consequently, nature serves as an inspiration for the development of multifunctional materials. A second class of multifunctional natural composites is the biomineralized materials found in living organisms. Biomineral composites are natural materials, a group of bioceramic-biopolymer composites, produced through cell-mediated processes [40]. They are composed of inorganic nano- or micro-scale amorphous or crystalline minerals formed through biologically induced or biologically controlled mineralization processes by living organisms in organic matrices of proteins and polysaccharides [42,116]. Their functions include structural support, mechanical protection, movement, grinding, and gravity or magnetic field sensing. This class of multifunctional composites is of importance in biomimetics and is of interest to both biologists and materials scientists. They are tough materials combining high hardness with high fracture resistance. Examples are bone, dentine, enamel, shells, scales, eggshells and sponge silica skeletons. There are many other biocomposites that are not organic-inorganic such as skin, wood and leaf – these are organic and are also multifunctional.

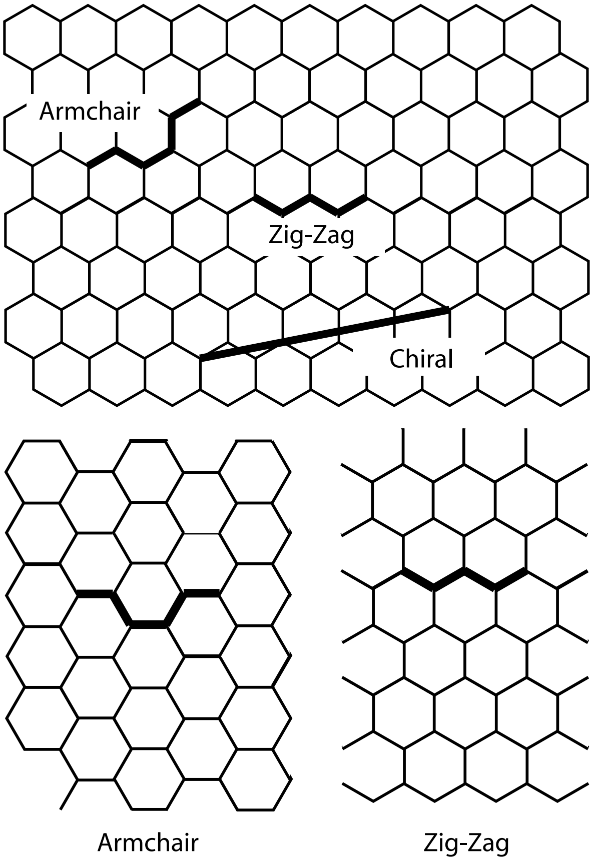
Many other types of composite materials are now being developed aiming towards multifunctional composites as demands are increasing for smaller, lightweight but smarter products. Reinforcing components could be particles (0-dimensional), fibers (1-dimensional) or plates (2-dimensional). The orientation of these reinforcing components in a matrix could be random, unidirectional or bidirectional, and could be laminar. They are in the form of distinct phases in the matrix with sizes varying from macrophases to nanophases. When the size of the reinforcement is in the nano-range, the composite is referred to as a nanocomposite. When the nanoreinforcements are composed of a functional nanophase the composite is then a multifunctional nanocomposite in which the nanophase provides an advanced functional behavior through enhanced properties such as mechanical, chemical, biological, electrical, magnetic, optical properties.

A Short Note on Carbon

Carbon is a critical, enabling material and consequently an important component of many multifunctional composites. We will, therefore, outline some of the key properties for this element.

Carbon is one on the most common elements found on earth. It appears in three major forms: diamond, graphite, and as various forms of "fullerenes" and "carbon nanotubes." The two former versions occur naturally, whereas the latter is typically artificially produced. Diamond, with a cubic crystal structure where the atoms are arranged in a tetrahedral configuration, is the hardest material found in nature. It is an electric insulator. In graphite, the atoms are arranged in hexagonal planes that are stacked parallel to each other. This layered nature of the structure makes graphite anisotropic and relatively soft, since fracture easily occurs along these layers. In this form, carbon is electrically conductive.

A third form of carbon was categorized in 1985 [54] (even though earlier work indicated their existence) and will play a key role in functionalizing composite materials. This third form is a variant of graphite, where one layer of graphite is wrapped to form a sphere or cylinder. The initial form described was a 60-carbon atom sphere, where the carbon atoms are arranged in 20 hexagons and 12 pentagons on the surface of the sphere. Soon after this discovery, variants of the 60-atom sphere were found, where, in particular, the tubular form, carbon nanotube (CNT) have provided an exciting new research field [50]. There are endless variants of how CNTs can be assembled, but the major categories can be summarized as single- and multi-wall tubes along with their major division by the atomic structure (armchair or zigzag; if arbitrary direction "chiral" see Fig. 1). CNTs are one of the most promising materials for functionalizing composites, due to their unique properties. For example, the armchair styled CNT are metallic, but the other versions are semiconductors. In particular, single CNTs are excellent conductor, and can therefore serve as nano-sized electrical wires. CNTs also have excellent mechanical properties, for example as high as 1 TPa elastic modulus has been reported [48,60]. Multiwalled CNTs consist of either single walled tubes layered



Composites, Multifunctional, Figure 1
Illustration of the various atomic configurations a carbon nanotube can assume. A carbon atom is located in each of the corners of the hexagons

over each other ("Russian doll-style"), or as a continuous, rolled sheet forming a wrapped layered sheet (parchment-style). There are several interesting review papers discussing CNT tubes, for example by Thostenson et al. [106] focusing on mechanical properties, by Gooding [43] focusing on electrochemistry and by Bandaru [5], discussing electrical properties of CNTs. Two recent review papers on theoretical aspects of the thermomechanical properties of carbon nanotubes can be found in [20,21].

Functionalized Carbon Reinforced Polymer Matrix Composites

Carbon reinforced, polymer matrix composite are now commonly used in engineering applications, due to their relatively high strength and low weight. The carbon fibers give the composite their strength and stiffness, for which the structures traditionally have been optimized. However, recent developments make it possible to utilize the ability of carbon fibers to be electrically conductive. This opens up a broad range of opportunities for functionalizing carbon reinforced polymer matrix composites.

Electromagnetic Shielding

Electromagnetic interference (EMI) is caused by electromagnetic radiations emitted from sources that carry electrical current. A common source for EMI is an electronic device, but natural sources such as the Northern Lights and the Sun can also cause EMI. EMI results in anything from annoying "sound sparkles" on the television or cell phone to a malfunction of a device or a system (e. g., an aircraft). In warfare, EMI can be used to disrupt communications by the hostile side. Thus, it is important to shield aircrafts and communication devices from EMI. Carbon reinforced polymer matrix composites can readily be designed to shield EMI. Since carbon is electrically conducting, the carbon fibers can be used to reflect the radiations. By adding conductive fillers into the polymer matrix, the composite material can work efficiently as an EMI shield. It is now commonly used in many consumer products to shield them from EMI, both for protecting the machine and from spreading EMI the machine is generating. For example Bagwell et al. [4] added short copper fibers to increase EMI. A review of EMI shielding can be found in reference [27] and a review of conducting polymer composites that are primarily optimized for EMI shield is found in [101].

Electrified Carbon Fiber Polymer Matrix Composites

Interestingly, research from the groups of Sierakowski and Zhupanska have shown that the material properties in a carbon fiber polymer matrix composite may change when subjected to an electromechanical field [97,98,121]. Early work [98] indicated that the strength, in particular the resistance to fracture and delamination, increases when the composite is subjected to an electric current. Several factors contributes to this, including that (i) the mechanical and electromagnetic fields are coupled when mechanical and electromagnetic loads are imposed simultaneously; (ii) the heat generated in the conducting carbon fibers are transferred to the polymer matrix; and possibly that (iii) the failure mechanisms change when the structure is subjected to an electromagnetic field. Recent work [97,121] where the impact resistance was investigated, show that the gains are short-term. The impact resistance initially can increase as much as 30%, but for a structure subjected to long-term exposure to an electromagnetic field, the gain is reduced back to the initial properties. The losses appear to be caused by the increasing temperature of the polymer due to the heating of the carbon fibers. Nevertheless, a structure can temporarily be strengthened by imposing an electromagnetic field. Moreover, the heat generated in the carbon fibers could potentially be used to activate self healing mechanisms (self healing mechanisms are discussed in Sect. "Self-healing Composites")

Functionalized Composites with Carbon Nanotubes

As discussed in the introductory section of carbon, carbon nanotubes are probably one of the single most promising materials to functionalize composites. The possibilities appear to be endless and a few limited examples will be discussed here.

Single-walled carbon nanotubes (SWNTs) have great promise for functionalizing composite materials. They are light weight and have high mechanical strength, high thermal and electric conductivity and unique optoelectronic properties. They are also light weight, with a small diameter and high aspect ratio. However, these properties may be compromised when incorporated into a polymer matrix. This is primarily caused by the SWNT not being compatible with the polymer matrixes. This results in the SWNTs tending to agglomerate into clusters. When the SWNT are not bonded properly to the polymer matrix and/or appear in clusters, their unique properties may not be transferred to the composite materials. Therefore, significant efforts are being aimed towards improving the dispersion and bonding.

Chen et al. [19] suggest that molecular engineering is a viable approach to achieve good mechanical strength and retain the electric conductivity of CNT. They pointed out that the problem with dispersion and bonding is due to the smooth surface of the SWNT. In a mix of SWNT and a polymer matrix, the mechanical load can be transferred though mechanical interactions between the SWNT and the polymer matrix, via van der Waals' interactions or covalent bonds, or via special non-covalent bonds, such as hydrogen bonding. The covalent bonding is in general the strongest type of bonding. However, when this is implemented, the electrical and thermal properties are often seriously challenged since these bonds tend to interfere with the SWNT structure [19].

CNTs can be used for energy absorption, which have been shown by Chen and co-workers [22,45,86]. In their work, they developed a solid-liquid composite which combines a non-wetting liquid with a hydrophobic nanoporous solid. The basic premise is that a liquid is absorbed into nanopores (such as the inside of a CNT) when a pressure is applied on the system. They showed that this infiltration absorbs and converts mechanical work into solid-liquid interface energy, with high energy absorption (10–100 J/g). Due to the ultra-high specific surface area of the nanopores, this is several orders of magnitude higher than conventional energy absorption materials. Moreover, by varying the interface energy, the energy absorption performance may be adjusted in a wide range, suitable for damping protections, vibration proof, or blast resistance. The interfacial energy can be changed by using chemical admixtures, or using viscous liquid. If the load rate can be controlled, this can also change the interfacial energy. In addition, by using functional liquids (such as electrolytes), the ion density at the nanopore-liquid interface may be perturbed by external mechanical or thermal fields. Thus, the multifunctional solid-liquid nanocomposite may harvest thermal and mechanical energies into electricity [46,87].

Polyaniline (PANi) is formed by polymerizing aniline (phenylamine, aminobenzene) which is an aromatic amine with the formula $C_6H_5NH_2$. PANi is a conductive polymer, and consequently has great potential to be a useful material component in multifunctional composites. When aniline is polymerized with the presence of multi-walled carbon nanotubes (MWNT), to form a polyaniline-carbon nanotube composite, the MWNT are coated with PANi and form a three-dimensional network within a matrix of PANi. This results in a composite with excellent electro-optical properties [90]. Preliminary work has shown that PANi can also work as a biological sensor [61]. Here the SWNT was wrapped with a single-stranded DNA and mixed with a self-doped polyaniline, poly(anilineboronic acid). The composite is able to detect nanomolar concentration of dopamine (a naturally occurring hormone). The sensitivity for detecting dopamine was increased with a factor of four by adding the SWNT compared to the self-doped polyaniline [61].

Polypyrrole (PPy) is formed from synthesized (connected) pyrrole, where pyrrole is a heterocyclic aromatic organic compound, C_4H_4NH. PPy have been used for corrosion protection of metals, discussed in Sect. "Multifunctional Coatings". In a similar manner as PANi, PPy is conducting. An interesting application is to use PPy with MWNT, where supercapacitive properties have been measured [49]. To achieve this, the MWNTs must be aligned and then coated by an appropriate layer of PPy. Alignment of the MWNTs can be obtained by growing them on a quartz glass under appropriate conditions, described for example by Hughes et al. [49]. Measurement of the charge storage capacity of the aligned-MWNT-PPy composite film show several times charge storage than either PPy or MWNT alone (e. g., 2.55 F/cm^2 for the composite film compared to 0.62 F/cm^2 for pure PPy film) [49]. Thus, aligned MWNTs coated with PPy have potential applications for supercapacitors and batteries, as well as sensors.

Composites as Actuators and Sensors

Ionic polymers have received significant attention during the last decade, based on their ability to work as electromechanical transducer and potentials to work as sensors and/or actuators, and also as electrolytes in polymer fuel cells. Today, the preferred polymer materials are perfluorosulfonic acid (PFSA) polymers, a class of fluoropolymers consisting of a hydrophobic polytetrafluoroethylene (PTFE) backbone attached to hydrophilic sulfonic acid groups (SO_3^-) or carboxylate groups via the fluorocarbon polymer side chains. Upon water uptake, the hydrophobic groups ionize and attach to the hydronium ions (H_3O^+) to provide a conductive path for proton transport, while the polymer network maintains the overall structure of the membrane. Commercial material products include Nafion®[1] membranes and Flemion®[2] membranes. These membranes are also used as the proton exchange membranes (PEM) for fuel cell applications. A PEM functions as a "filter" (an electrolyte), letting protons through the polymer membrane, whereas the electrons are forced to take a path outside the PEM. From the path of the electrons, electric energy can be harvested.

Actuators and sensors can be made by an ionic polymer metal composite (IPMC) [3,8,9,56,57,74,75,76,89],

[1] Nafion® is a registered trademark of E.I. DuPont De Nemours & Co.

[2] Flemion® is a registered trademark of Asahi Glass Group in Japan.

Adapted from [47,67,76,95]

with a potential application as artificial muscles [3,8,9,10, 56,57,67,76,94,95,112,114]. In this case, the ionic polymer is sandwiched between two metallic electrodes. The ionic polymer is hydrated, typically with water or ionic liquids such as salts [3], to achieve its functionality. The metal electrodes are flexible layers, resulting in a soft and flexible actuator which can perform large dynamic deformation if placed in an alternating electric field, see Fig. 2.

Currently, platinum (Pt) and gold (Au) are the preferred electrode materials, which defuses into the ionic polymer membrane, resulting in a material gradient over the thickness of the IPMC. The actuation is governed by the mobile cations (positively charged) moving towards the fixed cathode (negatively charged), resulting in a biased morphology and consequently a bending of the membrane as indicated in Fig. 2. When the current is switched, the location of the cathode is reversed and the cations will consequently move towards the other side, causing the actuator to move in the reverse. Alternatively, the IPMC can work as a sensor, where it generates a voltage if it is suddenly bent.

Nafion® polymer based IPMCs relaxes (reduces its deflection), whereas Flemion® polymer based IPMCs slowly increases its deflection under constant voltage. This is attributed to the mobile cations initially repelling the sulfonic acid groups in Nafion® polymer (which gives a fast actuation), but when the polarization is held constant, the cations relocates slowly, relaxing the IPMC. The carboxylate in Flemion® polymers are weaker in polarizing the structure, and therefore the relaxation is not observed [75,76].

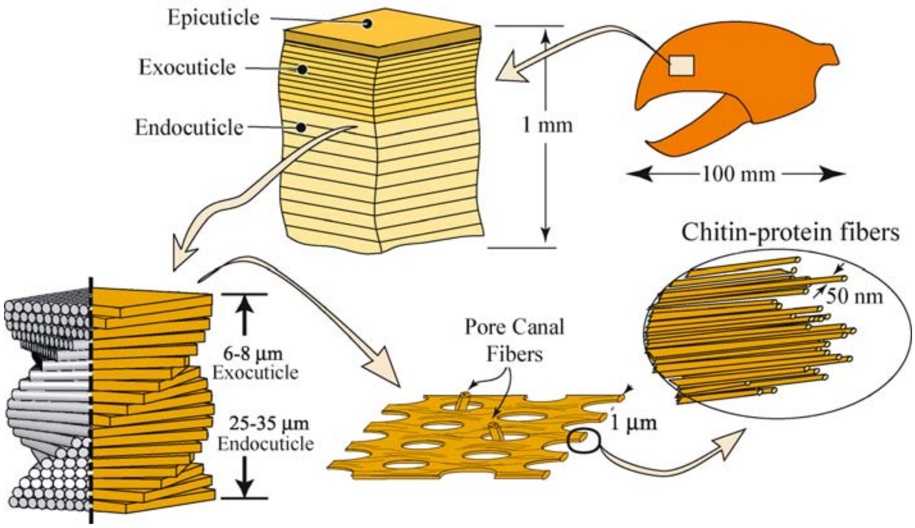
These actuators can strain up to 3% for voltages less than 7 V [67]. This induces a significant bending, where stresses up to 30 MPa are reported [67]. Future research efforts are focused on reducing the negative effect of dehydration (an ionizing liquid is needed for the function), as well as addressing the reduced efficiency over time. Current applications range from fins to robotic fish to artificial eyes [67].

Biomineral Composites

Nature has presented us with a variety of biological composites (biocomposites) such as skin, bone, shell, leaf and wood, which are all multifunctional in living organisms. Some are organic in nature, e. g. leaf and wood, whereas some are organic-inorganic, e. g. bone. Attempting to mimic nature, the design of these biocomposites are now intensely studied, including the structure and microstructure and the physical, chemical, electrical, magnetic and even optical properties. For example, using a biomimetics process M. C. Chang and co-workers have been able to develop a synthetic bone [17,18].

Biocomposites formed through a biomineralization process are referred to as biomineral composites. Examples of biomineral composites include bone, dentine, enamel, mollusk shells, crustacean exoskeletons, eggshells, sponge silica skeletons, and a variety of transition metal minerals produced by different bacteria (see references in references [42] and [33]). The functions of the biomineral composites include structural support, mechanical protection and movement, anchoring (to another body or to ocean floor) grinding, filtering, gravity or magnetic field sensing, optical and piezoelectric [33]. Biomineral composites are composed of an organic matrix of proteins, lipids and polysaccharides. The structure consist of a nano- or micro-scale amorphous or crystalline minerals formed by a biologically induced or controlled mineralization processes, through complex chemical interactions between organic and inorganic matrices [2,42,91,116]. The structure is usually complex with the organic and the mineral components tightly interwoven at the nanoscale level, highly ordered and hierarchical to give high strength, rigidity along with mechanical and chemical stability, that are superior to synthetic materials made from the same materials. Biomineral composites are normally designed to function under a narrow range of environmental conditions, such as narrow temperature regimes and restricted mechanical loads. However, the compositions of biocomposites can be altered over time when a gradual change in environmental conditions occurs, to achieve necessary properties for the survival of the organisms [63]. Mollusks and sponges are known to make use of sophisticated biomineralization mechanisms to obtain structures that exhibit attractive combinations of strength, stiffness, resilience, and energy absorbing capabilities [63]. Even though the mechanisms of biomineralization are yet to be fully understood [69], biomineral composites are of much interest to warrant in-depth studies by biologists and chemists as well as material scientists. The structures of a few biomineral composites that are multifunctional are briefly described below.

The crustacean exoskeleton is a layered structure made up of the epicuticle layer, which is the topmost layer, the exocuticle layer and the endocuticle layer, which is the innermost [25]. The epicuticule is a relatively thin layer of about 2–4 μm. It is waxy, acting as a diffusion barrier [77]. The exocuticle is about 150–180 μm in *Homarus americanus* (American lobster) claw with the endocuticle 3–4 times this thickness. As a comparison, for the *Callinected sapidus* (Atlantic blue crab) claw, the exocuticle is about 40–50 μm and the endocuticle 6–8 times thicker [25]. The exocuticle and the endocuticle are the major load bearing structures of the exoskeleton and are made up of multiple fibrous layers arranged parallel to the surface. The fibrous layer consists of chitin-protein (chitin is a biological polysaccharide with the generic formula $(C_8H_{13}O_5N)_n$) fibrils bonded by a matrix of minerals and other proteins. Each of these fibrous layers is rotated by a small angle relative to the next layer in parallel, building up to a band of



Composites, Multifunctional, Figure 3

The cross-section (*top*) of the exoskeleton of a Homarus americanus (American lobster) taken from the claw (*top right*). The outer layer (epicuticle) acts as a diffusion barrier while the exocuticle and endocuticle layers are load bearing structures built of mineralized fibrous chitin protein. The helicoidal nature of the arrangement of the fibrous layers of the exocuticle and the endocuticle layers is shown on the *left*. The pore canals and the pore canal fibers in a layer are shown (*bottom*). Each layer is composed of chitin protein fibers (*bottom right*). Note that the exocuticle layer is denser than the endocuticle layer

layers that is twisted by 180° to form a helicoidal architecture (Fig. 3). The exoskeleton has through-the-thickness holes, *pore canals*, through which chitin-protein macrofibrils fibers, *pore canal fibers* run perpendicularly to the layers. Even though some disagreement exists in the literature, the pore canal fibers appear to run from the bottom of the endocuticle to the top of the exocuticle [25,28]. The pore canals and the pore canal fibers fill important functions in building the exoskeleton after molting. Moreover, Cheng et al. [25] showed that the pore canal fibers are important for strength of the exoskeleton. In all, the multiscaled structure of the exoskeleton, a biomineral composite, provide the crustacean with a strong structural support, an impervious defense covering for the body of the crustacean, and also serve as a carrying, holding and tearing tool in case of attack or feeding.

Nacre is another natural biomineral nanocomposite; it is also known as mother-of-pearl. It is the iridescent lining on the inside of the shells of many sea-going bivalves and gastropods such as oysters, mussels and abalones. Like many other biomineral composites, nacre has a hierarchical structure. It is composed of about 95% inorganic hexagonal platelets of aragonite (a crystallographic form of $CaCO_3$) 5 to 8 μm wide and 0.2 to 0.5 μm thick [6], arranged in a continuous parallel lamina in 5% organic matrix composed of elastic biopolymers (such as chitin, lustrin and silk-like proteins and polysaccharides). The organic biopolymer is typically 5 to 20 nm thick. Nacre has received significant attention in recent years due to its high ductility, enhanced toughness and fracture strength, along with its low weight, resulting in excellent specific properties. Its fracture resistance is about 1000 to 3000 times greater than that of its component aragonite crystals [30,31]. Its high toughness is as a result of the ductility of the organic matrix in connection with the repeated unfolding of the protein molecules. The nanostructure resembles a brickwork arrangement with a significant overlap of the platelets and the organic matrix serving as the mortal [15]. This architecture is a critical factor that is responsible for the high fracture strength observed in nacre [6,41]. In addition, Li et al. [59] showed that the rotation of the nano-sized grain during loading is a key contributor to the high ductility. Many studies have been carried out on nacre using various experimental and modeling techniques to study its formation, its structure and morphology, and its deformation and properties, especially the mechanical properties [6,16,52,55,62,63,65,73,85].

Mimicking this material is of interest in the design of high performance materials such as impact resistance armor [7,55,92]. Using layer by layer assembly technique, Podsiadlo et al. [84] have been able to prepare a nanostructured analogue of nacre from nanometer sized sheets of montmorillonite clay and a polyelectrolyte. Artificial nacre has also been synthesized [103]. Mimicking nacre in creating one nano-layer of material at a time, Nicholas Kotov and his team have evolved a process that allows the creation of materials one nano-layer at a time. They use this process to produce a new material from clay nanosheets and a water-soluble polymer that shares chemistry with white glue. The material is transparent, very strong, yet lighter in weight [64].

Animal skeletons are made up of bones which are hard and rigid tissues. Bone is self-healing and can continuously regenerate itself. Moreover, bone is relatively stiff and tough, and can withstand and adapt over time to local stresses. These properties make bone a reliable biological structural material. Bone is considered as a nanocomposite of minerals and proteins [18,26]: It is composed of a matrix impregnated with calcium carbonate, calcium sulphate and small amounts of sodium and magnesium. The matrix, consist of collagen fibers impregnated with crystals of hydroxyapatite, $Ca_5(PO_4)_3(OH)$, and water. Among the functions of the bone is support, locomotion, protection for soft and delicate organs (like the skull protecting the brain), manufacturing of blood cells and homeostasis. An example of bone is the femur; it has a covering of a tough, strong membrane, called periosteum which is richly supplied with blood vessels. Next to the periosteum is a layer of compact bone and bone forming cells (osteoblasts), arranged in concentric layers (lamellae) with round small interconnecting canals (the Haversian canals) that contain blood vessels, nerves and lymph vessels. Embedded in this hard bone matrix are osteocytes, which are associated with bone deposition and bone remodeling. Inside the compact bone is a thin soft membrane known as the endosteum that encloses the marrow cavity that contains soft tissues, the yellow marrow [88,108]. The growth and strengthening of bone is stimulated by mechanical stresses through strain detection. This function is carried out by specialized cells within the bone that are sensitive to and respond to strains. In the absence of mechanical stresses bone becomes weak and less developed. Thus, the more the bone performs its intended functions the stronger it becomes. Mimicking this ability will produce excellent synthetic engineering materials for structural or load-bearing applications.

In a study of the sponge *Euplectella sp.*, Aizenberg et al. [2] described the structure of its skeleton as being hierarchical in nature. It has a layered arrangement that gives it a high resistance to crack propagation. The skeleton is thus composed of a layered biocomposite material. The structure is described in Fig. 4, after Aizenberg et al. [2]. The microstructure is made up of consolidated hydrated silica nanoparticles forming sets of concentric rings glued together by an organic matrix to form spicules. This layer approach provides toughness and resistance to crack propagation. These spicules are then assembled in parallel into bundles within a silica matrix to form struts. The struts are arranged to make the cylindrical cage with the ability to resist tensile and shearing stresses and a significant capacity for recovery after deformation of the skeleton.

Aizenberg et al. [1] showed that the tunic spicules of the ascidian *P. pachydermatina* are a biocomposite material with well-defined domains of both amorphous and crystalline calcium carbonates, separated by an insoluble organic layer. The crystalline calcium carbonate is polycrystalline calcite, and it forms around the amorphous calcium carbonate which serves as the core. The calcium carbonate layers contain magnesium and proteins with a higher content in the amorphous than in the crystalline. The amino acid compositions of macromolecules associated with the two mineral phases are also quite different.

Wood is a natural biocomposite material with a multifunctional capability. It differs from the above mentioned bicomposites in that it is *not* a biomineral composite. Wood is a naturally hard and tough biocomposite material that forms the trunk or stem of trees. The material consists essentially of elongated hollow cells that carry nutrients from the roots to the leaves. The cells make up the cellulose fibers that are arranged generally in the grain direction, parallel to the surface of the trunk. Cellulose, with a generic chemical formular $(C_6H_{10}O_5)_n$, is one of the major chemical constituents of wood, others are hemicellulose and lignin. It is a linear polymer with thousands of mers in a single molecule and it constitutes about 40 to 50% of wood. The cross section of wood is composed of several layers: the outer bark, the inner bark, the cambium, the sapwood, the heartwood, and the pitch. The thickness of each layer depends on the age of the tree, the species to which it belongs, and on the particular tree. The cambium layer is microscopically thin and it grows by cell division to increase the diameter of the trunk. The tree trunk increases in diameter by addition of new peripheral growth layers that constitute the growth rings. The sapwood layer conducts moisture, minerals, oxygen, and nitrogen. As the stem (or trunk) grows in diameter, the sapwood progressively forms the heartwood. The heartwood is the thickest of the layers and it is the one that provides the structural strength. It is usually darker in color because of the mineral deposits, gums and resins that are present in it. Cutting across these layers horizontally are tissues called wood rays radiating out from the center outward. They help in storing and transferring nutrients. Botanically, woods are classified as softwoods and hardwoods depending on their basic cellular structure and on how moisture moves within

the living tree. Softwoods are mainly made up of long cells of between 3 and 5 mm called tracheids. Hardwoods, on the other hand, are mainly made up of two kinds of cells, wood fibers (0.7 to 3 mm long) and vessel elements (with wide ranging lengths).

The important physical properties of wood are moisture content, permeability, shrinkage, density. These give it the multifunctional capability such as serving as a super-structure, acting as a nutrient storage and transport medium, the ability to withstand harsh weather, and self-healing. The properties, however, vary greatly across species and also depend on factors such as the age of the tree, stem form, type of soil and climate. Wood is anisotropic with the mechanical properties varying across the growth rings and along the height up the tree. The mechanical, electrical and thermal characteristics of wood make it a popular excellent engineering material over ages.

Leaf is an organic biocomposite that is flat, broad and thin. It is a plant organ in which photosynthesis is carried out. The upper surface of the leaf is waxy for the purpose of water-proofing. It performs functions such as converting sunlight to chemical energy in the mesophyll, transporting glucose, water and minerals through out the plant by the vascular bundle; it is water-proof and provides shade for the tree. The cross-section is made up of different layers in this order from the top: upper cuticle, upper epidermis, palisade mesophyll, spongy mesophyll, lower epidermis and lower cuticle. Embedded in the mesophyll layers is the vascular bundle (phloem and xylem) and air spaces for the supply of air (carbon dioxide) and moisture that comes in through the stomata that dotted the lower epidermis through the lower cuticle. The broadness of leaf allows it to gather as much sunlight as possible as a supply of the energy needed for photosynthesis. Leaf provides a system that could be mimicked in designing materials for energy conversion and at the same time distributes the product.

Biocomposites materials produced by nature have properties that could be beneficial when reproduced in synthetic materials. The design, manufacture from simple raw materials, economical use of raw materials and energy, multifunctionality and degradability of biocomposites are inspirational to biomimetics or biomimicry in the design and manufacture of synthetic engineering materials. Another inspiration from nature is the building from bottom up, from atomic or molecular level to the macro structural level. This provides for efficient use of raw materials. A thorough study of nature's biocomposite materials could, therefore, yield viable procedures and techniques for the design and manufacture of synthetic engineering materials with excellent combination of properties that will provide for multifunctionality in them.

Self-healing Composites

Biological systems have an outstanding ability in self-healing; that is, automatically detecting and repairing damaged tissue. The repair is made by a material similar to the original (causing a scar tissue), or identical tissue (leaving the damage area undetectable after repair). For humans, the latter can for example be observed in bone, whereas the former on skin. Moreover, biological systems can adapt to new conditions. Humans build more muscles and bones if we increase our daily exercise regime and a tree grows branches to find the most sunlight.

Man-made structures traditionally do not have these features. If damage occurs, damage will continue to accumulate until it is detected via human intervention or until the structures fails. Today, there are many sophisticated means of detecting failures. Even though tremendous advances have been made towards detecting and repairing damage in structures, *self-healing materials* would significantly improve the reliability of structures. During the last decade, significant advances have been made towards developing self-healing composites. The current approaches results in a "scar tissue" in the sense that the original material is not exactly reproduced, but that the structure will function satisfactory. Two materials systems will be discussed here; (i) ceramic matrix composites and (ii) polymer matrix composites.

Ceramic materials typically have high strength and stiffness, and retain their strength even at high temperatures. Since they are brittle and therefore are considered unreliable (tend to break without warning signs that metals exhibit, such as plastic deformations, especially under tensile stresses) their uses have been limited. To negotiate the brittle response, ceramics can be reinforced. Most commonly, ceramics are reinforced with a second ceramic, forming a ceramic matrix composite (CMC). The bonding between the reinforcement and the matrix is a key parameter that governs the toughness of the CMC. By controlling the interface material, referred to as "interphase", the interfacial bonding can be optimized, allowing for the load transfer between the matrix and the fibers, deflects matrix cracking and serve as a barrier towards diffusion. When considering the strength of the interface material, it must be optimized to be "just right," not too strong and not too weak.

Self-healing of CMCs can be achived through high temperature oxidation in silicon carbide based CMCs. Silicon carbide (SiC) reinforced with SiC fiber (SiC/SiC composites) or carbon fibers (SiC/C composites) is mechanically durable up to 1500°C and is therefore considered a promising composite for high temperature applications such as engines and gas turbines [70]. Even though the fibers are brittle in a similar manner as the matrix, the fibers and matrix work synergistically to create a ductile material. Micro-cracks develop during loading, but these micro-cracks are stopped by the microstructural features, simulating a non-linear response paralleling yielding in metals. When silicon is subjected to elevated temperatures, it quickly forms a protective coating of silica (SiO_2). Unfortunately, the micro-cracks that are associated with the CMC become pathways for oxygen to penetrate into the structure, causing internal oxidation. This can weaken the structure. By coating the fibers with carefully selected materials, the oxidation can be controlled and result in self-healing of the micro-cracks. Graphitic carbons ("pyrocarbons," "PyC") and boron nitride (BN) have emerged as the most prominent interphase [39,44,70,71,72]. When oxygen diffuses through the micro-cracks, a fluid oxide is formed due to the oxidation, filling the cracks, Fig. 5. These glassy oxides that form can be optimized through the interphase. For example, when a borosilica glass is used as an additional coating on the fibers, no loss in composite strength was observed after 200 h at elevated temperatures [39]. Thus, a self-healing mechanism in silicon carbide (SiC) matrix composite reinforced with SiC or carbon fibers has been observed, which is caused by oxidation at high temperatures. The oxidation occurs at temperatures above 800°C. The self-healing can continue until the reducing material has been consumed.

Polymer composites might be the most promising systems where self-healing mechanisms can be developed. There are several reasons for this. Polymer based systems are in general less expensive than ceramic based systems, and tends to be easier to work with. All self-healing ceramic systems are based on activating the healing process through subjecting the material structure to heat. Even though some self-healing polymer systems are based on heating, the temperature regime for healing polymer is significantly lower than for ceramics, thus simplifying the process. Furthermore, many self-healing approaches to polymer systems are not dependent on heating. Lastly, several different approaches for self-healing of polymer have been developed so far, thus inviting alternative approaches for self-healing.

One simple concept of healing a damaged structure is to subject the material to elevated temperatures as was

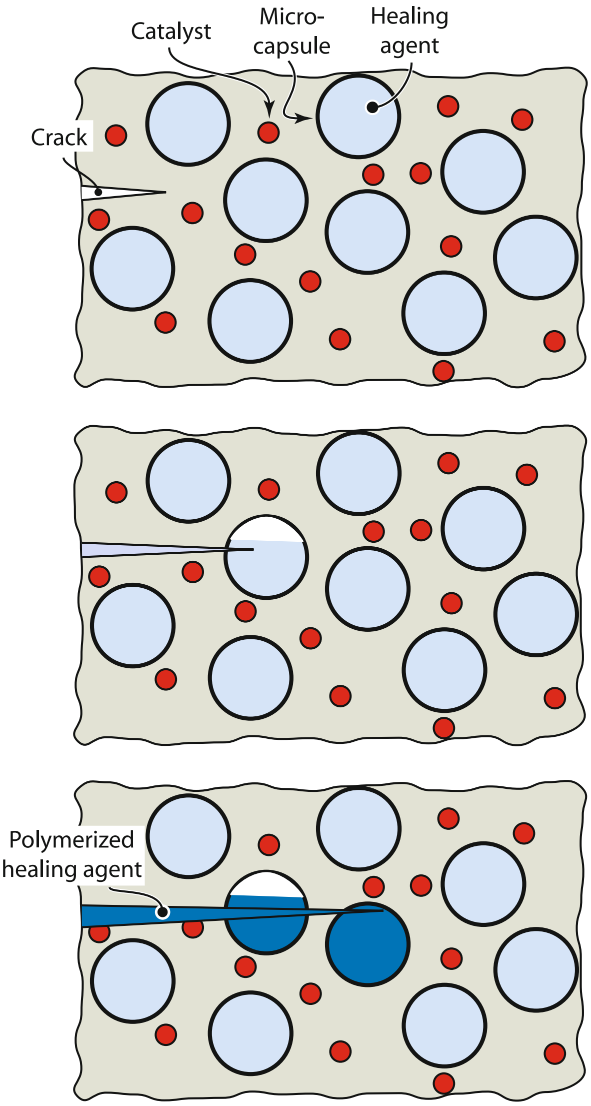
seen for ceramics. This idea is based on that the elevated temperature activates a chemical process that results in healing. For example, by utilizing a particular thermally reversible reaction (e. g., a selected Diels–Alder reaction) for cross linking linear polymer chains, a fractured material can be healed, as demonstrated by Chen and coworkers [23,24]. For one material system investigated, after fracture and subsequent heat treatment, the original strength was regained. In this case, the polymer (a furan-based monomer synthesized with 1.8-bis(maleimido)-3.6-dioxaoctane) was subjected to mechanical testing leading to fracture followed by heat treatment at 130°C for 30 min. In this case, there was no loss in the original strength when the structure was re-tested [24]. This approach to self-healing has the clear advantage that no additional material is needed to be added: the material is intrinsically self-healing. However, only a very limited set of materials that can self-heal by cross-linking the polymer chains upon reheating. An alternative approach for healing via heating utilizes an additional material phase incorporated into the original material. When subjected to sufficient heating, this additional material is activated, and can mend the damage structure. For example, a composite made of glass fiber reinforced epoxy retained its stiffness after the heated repair [120]. By adding a heat-activated material to the composite structure, a design engineer would not be strictly limited to a narrow set of materials. However, a major disadvantage with both of these heat activated healing methods is that the healing is not automatic; rather, the structure needs to be treated in a separate process. (This may be differentiated from the ceramic self-healing that was discussed above. The ceramic is operating at the temperature at which oxidation occurs, but this polymer operates at temperature lower than where self-healing appears.) Nevertheless, depending on the application, this approach can be quite useful.

A more convenient approach to self-healing of a structure compared to the heat activated systems described above is a system that heals itself without active interference. Most approaches aiming to achieve this are based on introducing one or more phases into the composite material. These additional material phases are automatically activated when damage occurs. A successful approach have been developed by White, Sottos and co-workers, where spherical microcapsules containing a "healing agent" and a second phase containing a catalyst are embedded in a polymer matrix composite [12,13,14,53,115]. When a crack propagates, the micro capsules in the crack path burst and release their healing agent into the crack, Fig. 6. As the healing agent fills the crack, it will eventually contact the catalysts. When this occurs, the healing agent will polymerize, filling the crack and effectively healing the crack. In the work by White, Sottos and co-workers, the agent was a dicyclopentadiene (DCPD) monomer and the catalyst a bis(tricyclohexylphoshine)benzylidine rethenum (IV) dichloride (a Grubbs' catalyst) [12,13, 14,53,115]. This results in a ring-opening metathesis polymerization (ROMP) of the DCPD, resulting in a highly cross-linked polymer. When stabilized with 100–200 ppm p-tert-butylcatechol, the DCPD has a long life and healing can be achieved even for aging structures. The micro capsules containing the DCPD ranged from 40–240 μm and were made with poly-ureaformaldehyde. In early work, curing for 48 h was required to retain 45% of the initial strength (if the curing occurred at 80°C, up to 80% of initial strength was achieved) [12,115]. Subsequent studies showed that 10 h were sufficient to achieve full polymer-



Composites, Multifunctional, Figure 6
Schematic of a propagating crack in a polymer with micro-capsules filled with a healing agent

ization (full healing or full strength), and that the fatigue life can be increased with over 200% if the structure is allowed to rest sufficiently for the healing agent to polymerize [13,14]. Most engineering structures are allowed to "rest" between operations. For example, cars are normally used for commuting to work and get sufficient time to "rest," both day and night, whereas airplanes are scheduled for regular maintenance that keeps them grounded for many hours that may be sufficient for the polymerization to take place. Thus, this system is a promising approach towards extending the lifetime of polymer matrix composites.

The micro-sphere approach has the clear advantage of being possible to be incorporated into a range of materials, and that no particular treatment is needed to activate the healing processes. There are, however, some drawbacks. These include that the shell of the micro-capsules have to be designed so that it breaks when a crack has developed in the bulk material, and that the healing agent comes across the catalyst. Moreover, the up to 200 μm diameter spheres can possibly interfere with the reinforcement of the polymer, including introducing an unwanted waviness of the fiber reinforcement. The latter drawback can be addressed by replacing the micro-spheres with hollow micro-cylinders [11,36,68,82,83]. The current state-of-the-art for hollow micro-cylinders focuses on using commercial hollow glass fibers embedded in composite materials [11,82,83]. In a similar manner as to the case of micro-spheres, the hollow cylinders are filled with a "healing agent" that is activated once the fiber breaks. A two-phase epoxy system is used, where the epoxy resin is stored in one set of cylinders and the hardening agent is stored in a second set of cylinders. In a layered composite material, the hollow glass fibers are aligned with the reinforcement fibers, for example the fibers with the epoxy resin are aligned with the 0°-ply and the fibers with the hardening agent with the 90°-ply. When cracks develop and propagate, the glass tubes break, allowing the epoxy and the hardening-agent to fill the damaged zone. The materials are selected so that the epoxy cures at ambient conditions. The major challenge with this approach relates to the difficulty of finding suitable glass tubes. Ideally, the properties of the hollow glass tubes should match that of the original reinforcement, so they can replace or enhance the composite structure. To address this, Pang and Bond [83] purchased commercial borosilicate glass tubing and using in-house facilities drew the fibers to external diameter of 60 μm and inner diameter of approximately 42 μm. The fibers were filled with a commercial epoxy repair agent (MY750 Ciba–Geigy) and the corresponding hardening agent respectively [83]. In this case, about 90% of the strength of the original strength is retained after repair, but the strength degrades with time.

With the exception of the reversible cross linking polymers, the repair schemes discussed so far for polymer composites are all based on one-time repairs; once a micro-capsule or micro-fiber breaks the healing agent is consumed, and no further healing will occur if another crack should develop again at the same point. In contrast, self-healing in biological systems can occur multiple times for repeated injuries, assuming a reasonable frequency of injuries. In animals, this is possible by the continuous flow of an intelligent mixture of biochemicals in the vascular network, which is related to the circulatory system. Some attempts are made to mimic vascular network for self-healing [104,107], where a constant supply of healing agent could potentially be provided. There are several manufacturing issues involved here, and opens up many potential research avenues.

Multifunctional Coatings

Applying coating on a structure is many time a cost effective way of obtaining a multifunctional composite material. There are many examples that illustrate this, for example environmental barrier coatings, coatings for increased wear resistance, and thermal barrier coatings. Most coatings combine several functions by having multiple layers where each layer contributes a particular function.

Coatings for corrosion resistance (sometimes referred to as environmental coatings) are probably one of the most common classes of coatings, for example covering steel with zinc to obtain a galvanic protection, (the zinc is sacrificed to protect the underlying steel). Even though functional, these cannot be categorized as multifunctional and will not be discussed here. More advanced coatings are now being developed to protect steel and other metals. Some of these coatings have multifunctional capacities. Some particular interesting coating materials are electropolymerized polymer composites including polyaniline (PANi) [51,78,93,102] and polypyrrole (PPy) [51,102]. Polyaniline (PANi) is formed by polymerizing aniline (phenylamine, aminobenzene), $C_6H_5NH_2$ and polypyrrole (PPy) is synthesized pyrrole, C_4H_4NH. The polymers are typically deposited through an electrochemical synthesis in which the thickness can be controlled. The corrosion resistance depends on the deposition parameters including applied potential and the feeding rate of the monomers. By producing a composite of PPy and PANi, the corrosion rate can be reduced with more than two order of magnitudes compared to unprotected materials [51]. To achieve this improved rate, it is crucial to ensure a proper bonding of the structure of the polymer composites deposited on the metal, which must be controlled through the processing parameters [102]. This class of coatings protects in sulfuric acid (H_2SO_4), not so well in hydrochloric acid (HCl), and not at all in a Sodium chloride (NaCl) solution [93]. Thus, care must be taken when using this type of coating for corrosion protection, but evidently, it can be quite useful for a range of applications.

A second class of important coatings is coatings used to ensure low friction and increased wear resistance of the underlying structure, tribological coatings. These coatings are critical for a range of applications, including moving contacts (e. g., bearings), materials processing (e. g., drilling), and applications where addition of lubricants or materials debris from wearing is unacceptable (e. g., food processing, medical implants). Also, by reducing friction in moving parts in vehicles, the fuel efficiency of the vehicle can be significantly increased. When optimizing a coating for wear resistance, the goal is to reach as high hardness as possible [110]. When combining wear resistance with low friction, many other aspects much be considered. There are now several systems used as solid lubricants which allows for both low friction and wear resistance. These include diamond and diamond-like carbon, graphite, molybdenum disulfide, hexagonal boron nitride, boric acid as well as soft metals [37]. An interesting example of a low friction wear-resistant coating consists of a composite coating made from a titanium nitride matrix, TiN, with molybdenum sulphides, MoS_x, dispersed as a second phase. Up to 8% (by weight) addition of MoS_x does not effect the hardness of the coating (thus promoting wear resistance), but decreased the coefficient of friction with more than a factor of two, and consequently increasing the life up to 500 times compared to the TiN coating alone [29].

Of high interest is to combine the corrosion resistance coating with the tribological coatings. This multifunctional coating would then resist both corrosion, wear and provide a low coefficient of friction [113,117]. This would increase the lifetime of many engineering applications, and for example, increase the fuel efficiency of vehicles since it reduces energy losses due to friction. Tribological coatings under stress and at the same time in aggressive environments degrade at a significantly faster rate compared to if they were subjected to wear alone or to the aggressive environments alone, since the two conditions aid each other to aggravate the deterioration of the coatings, as illustrated in Fig. 7. In a recent review by Wood [117] it is clear that this is a research area that requires significant attention in the future.

The last class of coatings we will discuss is coatings used for high temperature protection: thermal barrier coatings (TBCs), used to protect the underlying metallic substrate. TBCs are commonly used for protecting superalloys in gas turbines (both stationary for energy production and mobile for propulsion of airplanes). These systems are a material system with multiple layers, in which each layer is optimized for a particular function. It is made up of a *bond coat* being deposited on a metallic base, after which a ceramic *top coat* is deposited, see Fig. 8. In gas turbine engines, a thermal gradient over the top coat of up to 150°C is achieved from active cooling of the superalloy and by selecting top coat materials with relatively low thermal conductivities [38,66,79,99,100,118]. The metal-

lic bond coat provides oxidation protection to the superalloy by sacrificing itself by supplying aluminum to form an alpha-alumina scale (α-Al_2O_3) between the bond coat and the top coat (Fig. 8). As the alumina scale grows, the aluminum content decreases in the bond coat, ultimately changing the bond coat properties [32,96]. Thus, it is important to control the chemical content of the materials since even small amounts of critical trace elements can enhance or reduce the interfacial fracture toughness of the structure. Even though TBCs have been used for more than a decade, improvements of these multifunctional materials are still critical. By improving their reliability and durability, gas turbine powerplants and aircraft engines can become significantly more efficient, reducing their fuel consumption and reducing the pollution associated with energy production and propulsion.

Other Multifunctional Composites

Polyaniline (PANi) as discussed earlier has also been used as nanoparticles (rather than the matrix) to achieve multifunctional composites. For example Dispenza et al. [34] used PANi particles in a hydrogel matrix obtaining a biocompatible nanocomposite with properties suitable for the development of optoelectronic devices. The composite was obtained by a multistep process, starting with water dispersion polymerization of aniline, followed by γ-irradiation. The γ-irradiation cross links the PANi to the steric stabilizers (either poly-vinyl-pyrrolidone, PVP or poly-vinyl-alcohol, PVA). Depending on the processing conditions, various properties can be obtained, but the PANi particles remain spherical [34]. The composites can undergo two optical transitions and the fluorescence signals can vary in wave-length as a function of pH-value.

Composites with 3-dimensional reinforcements have been developed in order to eliminate a number of shortcomings like low shear and transverse stiffness and strength exhibited by laminated composites, with application in areas such as the aerospace industry. 3-dimensional braided reinforcements give reinforcing support in all the three directions thereby suppressing delamination in the composite and giving a higher damage tolerance [80,81,119].

Another group of composites that are multifunctional are the hybrid composite materials. A hybrid composite is made by combing two or more types of fibers in a single matrix material or in two or more types of matrix materials. This gives a greater possibility of achieving multi-functions by changing the combinations of fibers and/or matrix materials [111]. However, the interactions of the constituent components of a hybrid composite and large number of design variables involved make the design of such a composite complex. Examples are carbon-aramid reinforced epoxy, glass-carbon reinforced epoxy, and carbon-Kevlar reinforced epoxy. Lee [58] classified hybrid composites as (1) interply or tow-by-tow, in which tows of the two or more constituent types of fiber are mixed in a regular or random manner; (2) sandwich hybrids, also known as core-shell, in which one material is sandwiched between two layers of another; (3) interply or laminated, where alternate layers of two (or more) materials are stacked in a regular manner; (4) intimately mixed hybrids, where the constituent fibers are made to mix as randomly as possible so that no over-concentration of any one type is present in the material; (5) other kinds, such as those reinforced with ribs, pultruded wires, thin veils of fiber or combinations of the above [58].

Future Directions

Biomimetics is seeking to mimic nature to design and produce materials comparable or better than the ones nature has produced. The goal is to be able to synthesize organs for replacement in the body. Such organs should be able to perform and grow just like the natural one being replaced. This will eliminate looking for or waiting for donors wanting to donate such a needed organ which, in some cases, the body of the patient may reject in the end.

For non-biological applications, mimicking multifunctional biocomposites should be directed at designing synthetic composite materials that can simultaneously perform more than one function. Self-healing is another aspect being targeted to be achieved in material design. The future goal is not only to achieve multifunctionality in composite materials but also such materials should be self-healing. One great lesson from nature is that nature does not waste materials in building its structures yet with incredible relevant properties. This is because nature builds from bottom up, from molecular level to macro level. Ability to control the design and structure of the material on the molecular level will allow production and fabrication of components, devices and structures with incredible properties and functionalities without excessive use of material or energy inputs. This is a great advantage in conservation of material and energy.

Computational Chemistry, Introduction to Complexity in

DANAIL BONCHEV
Department of Mathematics and Applied Mathematics
and Center for the Study of Biological Complexity,
Virginia Commonwealth University, Richmond, USA

Defining complexity one remembers the words of St. Augustine: "I know very well what time is, until I have to explain it to somebody else." Intuitively so clear, complexity is so difficult to define rigorously. Complexity is sometimes mistaken with size, large systems are presumably complex. Are they always? Is a big piece of rock more complex than a tiny living cell? What makes a system complex is not the number of its components, but the number and kind of their interactions. As a result of these interactions the system formed has properties and behavior different from those of its components. The dynamics of a complex system's interactions is described by more sophisticated mathematical models (nonlinear differential equations). But how much complexity is needed to observe such emergent properties and dynamics? Given the number of components how many interactions would produce a new behavior?

We may not be able to specify an ideal definition of complexity or a detailed reply to these questions. However, what we can and must do is to quantify complexity, to measure it, as we do with electric charge without knowing what exactly it is. In the realm of computational chemistry, this has been done during the last 30 years defining a variety of measures of *molecular complexity* – compositional, structural, and dynamic. While molecular compositional complexity is straightforward for calculation from the number of atoms of different elements, the structural complexity of molecules can be quantitatively assessed by a variety of descriptors (termed also topological indices), based on graph theory and information theory. Presenting molecular structure as a graph gives rise to a multitude of quantitative descriptors. However, only few of them satisfy the set of criteria formulated in this field. A major requirement for a complexity descriptor is to match in a series of molecules certain patterns of increasing complexity, based on the number of complexifying elements – branches, cycles, central organization, and others (see ▶ Topological Complexity of Molecules). New methods consider as effective complexity measures the overall subgraph count, the sum of vertex degrees of all subgraphs ("overall connectivity"), and the count of all random walks. Shannon's information theory has also been broadly used in quantifying complexity of chemical systems. Shannon's function was found to be very useful in characterizing different distributions of atoms in molecules. It reflects the increase in complexity with the increase in the diversity of atoms and bonds in molecules, the diversity being caused not only by the elemental composition of atoms, but also by the vertex degrees and vertex total distances distributions in molecular graphs. Moreover, Shannon's information indices calculated from electron distributions in atoms and nucleon distributions in atomic nuclei were shown to be an important tool for predicting the properties of superheavy chemical elements, and their isotopes (see ▶ Information Theoretic Complexity Measures). The universality of the graph theoretical and information theoretical methods developed in the field of computational chemistry makes them also of interest in network complexity analysis in biology, social sciences, computer sciences, and other branches of science and technology.

A higher-level theoretical framework of molecular similarity and complexity is the quantum mechanical, density-functional formalism (DFT). This quantitative approach enables comparing and ordering of molecular structures, which finds application in a quantum version of the linear and nonlinear QSPR (see ▶ Quantum Similarity and Quantum Quantitative Structure-Properties Relationships (QQSPR)). Tuning the relative reaction rates of the different steps of a complex chemical reaction would enable the optimal design of many industrially important reactions. The DFT technique was recently used to address such a fine tuning procedure (see ▶ Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis). Such an approach promises to provide in the near future tools for effective screening of potential new materials with tailored catalytic properties.

Drug discovery is a major field of interest for applied computational chemistry. The lengthy process of design of a new drug starts with a search for the best computational model that relates molecular structure, composition, and properties to certain biological activity that has the desired therapeutic effect. This vast area of research, which spans over the last 50 years and is known as QSAR (Quantitative Structure-Activity Relationships) modeling, reduces strongly the potential drug candidates selected for synthesis and testing. While composition and properties are experimentally determined quantities, the translation of molecular structure into numbers is not unique, and includes a multitude of structural parameters termed molecular descriptors (see ▶ Drug Design, Molecular Descriptors in). Different classes of descriptors capture different aspects of molecular structure. The manner in which atoms are connected to each other is characterized by graph theory-based structural invariants called topological or two-dimensional (2D) indices. Three-dimensional (3D) descriptors are used to account for the metric and geometry of molecules, while conformational (or 4D) parameters complete the picture by accounting for the presence of a variety of 3D structures in molecules having free rotating atomic groups. Distinct classes include quantum chemical descriptors, such as atomic charges, bond orders, superdelocalizabilities and dipole moments, as well as physicochemical properties like solubility and binding constants. No theory exists to predict which of these descriptor classes would work the best for a given class of biologically active compounds, thus making all of them useful tools in drug design.

The search for new promising drug candidates experienced a quantum leap, when the intelligent guesses based on analogies with naturally occurring compounds were replaced by automated searches in huge databases of chemical compounds. The use of such combinatorial libraries has led to an explosive increase in the number of identified therapeutic targets, and enabled producing tailor-made drug molecules. All this increased considerably the complexity of the *in silico* methods used in drug discovery. The QSAR modeling reached a stage of maturity, with rigorously defined criteria for selection of molecular descriptors, as well as selection of methods for model validation and determining the applicability domains of the models derived (see ▶ QSAR Modeling and QSAR Based Virtual Screening, Complexity and Challenges of Modern). It was realized that no particular QSAR modeling method has an advantage over the others, as well as that each specific technique and each specific class of descriptors have their unique contribution to the relationship with the examined biological activity. This resulted in the creation of combinatorial QSAR methodology, which produces a multitude of models, satisfying a set of acceptability criteria.

In parallel with the optimization of traditional QSAR methods and their adaptation to the complex datasets available, the field of drug design benefited tremendously by using the methods of artificial intelligence. Most of these methods have been inspired by the manner in which the living things function and evolve (see ▶ Drug Design with Artificial Intelligence Methods). Genetic and evolutionary algorithms are stochastic methods that solve optimization problems by evolving solutions based on concepts of DNA genetics and Darwinian evolution. The ant colony optimization (ACO) algorithms mimic the behavior of some ant species when searching for the shortest path to a food source. The particle swarm optimization (PSO) algorithm mirrors the social behavior of large groups of individuals, such as bird flocking, fish schooling, and animal herding. Swarm intelligence algorithms are used in drug design for diverse application, including selection of structural descriptors for QSAR models, enzyme-inhibitor docking, and gene expression. Another class of algorithms, termed Artificial Immune Systems (AIS), makes use of learning and memory principles used in the human immune system. AIS models found application in diverse biological and medical problems, such as prediction of protein structure, cancer diagnosis, classification of gene expression data, and recognition of ECG arrhythmia. Machine learning (decision trees, support vector machines, k-nearest neighbors, etc.) is an important field of artificial intelligence methods. It extracts information from experimental data by computational and probabilistic methods, and by using a set of rules it predicts the properties of objects not included in the learning set (see ▶ Drug Design with Machine Learning). Machine-learning techniques, such as artificial neural networks (ANNs), have been widely applied to QSAR data (see ▶ Drug Design with Artificial Neural Networks). Its success story began with the creation of algorithms for the training of multilayer feed-forward (MLF) artificial neural networks. MLF was widely used to model biological and toxicological properties of chemical compounds. Other networks used in drug design are self-organizing maps, counter-propagation networks, and probabilistic neural networks.

Biochemistry became for biology what physics has been for chemistry – the fundament to build on and explain. The essence of life, and even its origin, is nowadays in a process of redefining, proceeding from the self-organization of biomolecules (DNA, RNA, proteins, metabolites) in biochemical networks. All aspects of biological development, such as cell differentiation, tissue multilayering, segmentation and left-right asymmetry, can be related to the physicochemical processes of self-organizing. The complex dynamics of self-organizing is characterized by oscillations, pattern formation, and the emergence of multiple steady states. Origin of life is the domain where chemical self-organization and biological evolution meet (see ▶ Biological Development and Evolution, Complexity and Self-organization in). Networks of different kinds and sizes appear at different stages of molecular evolution. (see ▶ Molecular Evolution, Networks in). The evolution of networks is not yet studied in detail, yet it is already established that gene mutations cause addition and deletion of nodes in protein–protein interaction networks, transcriptional regulatory networks, and metabolic networks, whereas rewiring of nodes is an evolutionary mechanism observed only in the first two networks.

Complexity of biological systems is multifaceted. Traditionally, the genome sequence complexity is viewed as a universal method for comparing species complexity, despite the controversy with some of the complexity measures examined. The Kolmogorov's information, Shannon's information, and Jensen–Shannon divergence are among the most frequently used measures (see ▶ Biological Complexity and Biochemical Information). Other types of biocomplexity, based on the structure and functionality of biological systems, have also been analyzed. Recently, the advance in the study of biological networks has offered new options for the assessment of biological complexity, including modeling the evolution of complexity in artificial life systems. Essential for each specific quantitative measure of network complexity is its divergence from the random network having the same size and the same average connectivity. Modular and motif (subgraph) information content of biological networks were shown to reflect well the complex network organization. Complexity of the dynamics of biochemical reactions is closely related to the cell fractal structure, and has important consequences for the dynamic behavior of cells. The processes of organizing the intracellular macromolecular systems obey chaotic dynamics. Non-linear interactions in and between spatial and temporal domains and over wide ranges of scales underlie the emergent properties of complex biological systems (see ▶ Biochemistry, Chaotic Dynamics, Noise, and Fractal Space in). With their nonlinearity, fractal dimensions, and attractors-controlled dynamics, the processes of the self-organizing chaos are of major importance for complexity theory. The high complexity of biological systems is a challenge for the traditional modeling of dynamics based on continuous models and ordinary differential equations (ODE). The cellular automata method (see ▶ Cellular Automata Modeling of Complex Biochemical Systems) appears as a viable alternative for modeling of processes within biological systems, including their metabolic, protein, and gene regulatory networks, as well as for identifying dynamic patterns, and devising of strategies for pathway control.

Chemistry and chemical engineering have entered into the 21st century with a broad spectrum of new classes of sophisticated and even "smart" materials of high complexity. Nanotechnology offers structures of unusual properties based on atomic clusters, nanotubes, and DNA. Composite materials and special polymers extend essentially the areas of application of classical materials. Many of the new materials are created with the technology of molecular self-assembly, adopted from the living nature. The high complexity of nanoscale materials (see ▶ Nanoscale Atomic Clusters, Complexity of) stems from the wealth of possible structures, and the very strong size-dependence of their properties. Clusters have great potential as a means of optimization of existing technologies, developing principally new technological processes, materials, and devices.

DNA provides basic building blocks for constructing nanostructures with specific functional features like molecular recognition, self-assembly, and predictable structure (see ▶ DNA-Templated Self-Assembly of Protein Arrays and Highly Conductive Nanowires). Periodic protein arrays can be constructed by templated self-assembly onto DNA nanogrids. This enables producing target materials with predictable 3D structure like highly conductive nanowires. The principles of biomolecular self-assembly can be extended to the modern materials synthesis, leading to a broad range of new materials and processes with significant technological impact (see ▶ Self--assembled Materials). The complex nature of self-assembling processes makes their modeling a nontrivial task. The methods used cover from atomic scale (molecular dynamics and Monte Carlo simulations) to mesoscale (kinetic Monte Carlo and phase field modeling) to lattice methods, to Random Sequential Adsorption (RSA) and cellular automata techniques. The development of complex, multi-scale modeling approaches is under way and shows great promise.

The mass-production of industrial polymers was dominated for a long time by polymers with linear macromolecular structure like polyethylene and polypropylene,. The appearance of nonlinear polymers with a variety of branched-tree topologies offered new classes of materials with properties unseen in linear polymers (see ▶ Polymers, Non-linearity in). The entanglement of branches in the star- and comb-shaped, and hyper-branched (known also as dendrimers) polymers, results in complicated conformational statistics and dynamics. The latter is modeled surprisingly well using graph theory, providing reliable prediction of the materials' properties in melt and solid states. Even more unusual properties are offered by composites. Composite materials combine the best features of different materials and are ideally suited to achieve multifunctionality and to form materials that have a broad spectrum of desired properties (see ▶ Composites, Multifunctional). Carbon fiber and carbon nanotube-based composites can be formed with materials as diverse as polymers, cement, and ceramics. Perhaps the most unusual property demonstrated by some complex composites is the self-healing. Inspired from the technological secrets of the living things, such dream materials not requiring continuous support will become one of the most exciting novelties of 21st century.

Computational and Theoretical Nanoscience, Introduction to

Nanoscience and nanotechnology change the nature of almost every human-made object in this century. Advances in the field of nanoscience empower us with new tools for proving electronic devices with ever-decreasing scale. Many people have projected that nanometer-scale devices will continue this trend, bringing control of matter to unprecedented scales. This includes scale reduction not only in microelectronics, but also in fields such as quantum-switch-based computing in the shorter term. These advances have the potential to change the way we engineer our environment, construct and control systems, and interact in society.

Computational science, which has emerged as a third way of doing research, one that complements theory and experiment, plays a key role in developing our understanding of materials at the nanometer scale and in the development "by-design" of new nanoscale materials and devices. Hence, modeling and simulation are now integral components of scientific research.

It is essential to have a detailed understanding of quantum effects in electronic transport to design devices effectively at the nanoscale, sustain the miniaturization trends of integrated circuits, and create new engineered nanostructures [see ▶ Quantum Phenomena in Semiconductor Nanostructures]. The resonance phenomena has a special attention in the electronic transport of non-interacting electrons through the infinite rectilinear quantum wires with impurities and one-dimensional rings with impurities connected to current leads [see ▶ Resonances in Electronic Transport Through Quantum Wires and Rings]. The Fano resonance, which is a manifestation of the interference between a localized state and the continuum states, is investigated in an Aharonov–Bohm ring and in an open three-terminal interferometer with a quantum dot [see ▶ Quantum Dots: Fano Resonances in an Aharonov–Bohm Ring]. It is also important to understand quantum transport and Kondo physics in coupled quantum dots with Anderson impurity [see ▶ Quantum Impurity Physics in Coupled Quantum Dots]. The complex quantum dots, treated as artificial molecules, are an excellent model system for studying dynamical symmetries and Kondo effect. The simplest of such complex objects is the double quantum dot which consists of two islands with confined electrons [see ▶ Tunneling Through Quantum Dots with Discrete Symmetries]. Since the quantum interference of the system depends not only on the dynamical phase but also on the geometric phase, the investigation of the geometric phase and its effect on nanostructures in a dynamical process of the environment is of particular interest [see ▶ Geometric Phase and Related Phenomena in Quantum Nanosystems]. In studying complex systems we have to deal with coupled phenomena and processes at a multitude of different spatial and temporal scales. Understanding interactions in the low dimensional semiconductor nanostructures and its response at multiple scales is a fundamental quest of modern science. [See ▶ Nanoscale Processes, Modeling Coupled and Transport Phenomena in Nanotechnology].

The spin phenomena in mesoscopic transport have moved only recently into the focus of attention, as one branch of the field of spintronics. The interplay between quantum coherence with confinement- or interaction-effects gives rise to a variety of unexpected spin phenomena in mesoscopic conductors and allows moreover to control and engineer the spin of the charge carriers. The spin interference is often the basis for spin-valves, spin-filters and detectors, and spin-switches. Their underlying mechanisms may gain relevance on the way to future semiconductor-based spin electronics. A quantitative and theoretical understanding of spin-dependent mesoscopic transport calls for developing efficient and flexible numerical algorithms.

The electronic and transport properties of quantum dot spin transistors are studied with emphasis on single-electron tunneling and shell structure using comprehensive modeling approach. For example, self-consistent calculation of the Poisson and Schrödinger equations within the spin-density-functional theory and the exact diagonalization of the many-body Schrödinger equation can be employed to describe spin transport properties of quantum dots [see ▶ Quantum Dot Spin Transistors, Self–consistent Simulation of]. With rising interest in spin-dependent transport, the interplay of the electron spin and charge degree of freedom has been exploited in a variety of spin interference devices. Charge and spin transport through phase-coherent conductors of mesoscopic scales carry imprints of wave interference as predominant and characteristic features [see ► Spin-Polarized Quantum Transport in Mesoscopic Conductors: Computational Concepts and Physical Phenomena]. Novel physical phenomena that may lead to improved memory devices and advances in quantum information processing are closely related to spin-orbit interactions. Hence, it is important to investigate a semiclassical wave-packet description of spin transport in the presence of electric fields by explaining how the microscopic motion of carriers gives rise to a spin current [see ► Semiclassical Spin Transport in Spin-Orbit Coupled Systems].

In the meantime, the theory of exchange-correlation energy is of great interest in modern density-functional many-body approaches. Hence, the spin dependent exchange-correlation energy in an interacting system such as the two-dimensional electron layers is of critical importance in the proper design of modern nano-structure devices and quantum-well lasers from a technological point of view [see ► Spin Dependent Exchange and Correlation in Two-Dimensional Electron Layers]. In addition, the time revolution of correlation functions in disordered spin systems is also worth to investigate [see ► Spin Dynamics in Disordered Solids].

Carbon nanotubes are referred to as the fabric of nanotechnology, and will play a central role in the future development of this technology. Understanding the properties of nanotubes, via computational simulation studies, has been one of the most intensive areas of research in physical sciences. Carbon nanotubes form the fourth allotrope of crystalline carbon after graphite, diamond, and a variety of caged-like fullerene molecules. Their mechanical properties make them stronger than steel, and their thermal conductivity is faster than copper. They have very exotic electronic-conduction properties by changing their geometry or by introducing topological defects into their structure and therefore, their electronic conductance can change from metals to semi-conductors. In general, carbon nanotubes show very different mechanical, thermal, electronic and optical properties.

The investigation into nanotube properties has prompted an intensive experimental and theoretical/computational research. One of the most active areas has involved the use of predictive computational modeling of their mechanical, thermal and mass transport properties [see ► Carbon Nanotubes, Thermo-mechanical and Transport Properties of]. One of the computational methods includes atomistic simulations using tight-binding molecular dynamics to study the nucleation and formation of carbon fullerenes and single-walled carbon nanotubes [see ► Tight-Binding Molecular Dynamics for Carbon and Applications to Nanostructure Formation]. Furthermore, the non-equilibrium Green's Function approach can be employed to study nanowire field effect transistors (FETs) such as a silicon nanowire FETs and carbon nanotube FETs [see ► Quantum Simulations of Ballistic Nanowire Field Effect Transistors]. Therefore, carbon nanotubes are viewed as highly relevant nanostructures with extensive potential applications.

The physical implementation of the quantum bit (or qubit) has been, and still is, the starting point of any proposal for quantum information processing device. The research of quantum computing focuses on qubits and quantum entanglement based on both a large spectrum of systems and solid-state devices. Hence, it is interesting to consider the practical realizability of quantum computers based on solid-state flying qubits and a simple quantum-gate network [see ► Charge-Based Solid-State Flying Qubits].

For device sizes in the range of tens of nanometers, the atomistic granularity of constituent materials cannot be neglected. Effects of atomistic strain, surface roughness, unintentional doping, the underlying crystal symmetries, or distortions of the crystal lattice can have a dramatic impact on the device operation and performance. In an atomistic simulation, one takes into account both the atomistic/granular and quantum properties of the underlying nanostructure. The variety of geometries, materials, and doping configurations in semiconductor devices at the nanoscale suggests that a general Nanoelectronic Modeling tool (NEMO 3-D) is needed [see ► Multimillion Atom Simulations with Nemo3D].

There is a persistent need of miniaturization of machines and energy conversion devices for various engineering applications. In the field of robotics, there is a need to develop nano-scale actuators, motors and other machine components [see ► Viral Protein Nano-Actuators, Computational Studies of Bio-nanomachines]. These nano-scale robots, machines, and sensors can be used to deliver drugs to specific locations in the body, or detect individual cancer cells, or be used as molecular filters to separate minute particles from the environment. On the other hand, the field computation, which is a model of computation that information is represented primarily in fields, is to provide a mathematical language for describing information processing in the brain and in other natural and artificial systems [see ► Field Computation in Natural and Artificial Intelligence]. This field computation can be expected to provide an increasingly important analytical and intuitive framework for understanding massively parallel analog computation in natural and artificial intelligence.

In conclusion, there is no doubt that computational and theoretical nanoscience research such as quantum electronic and spintronic nanodevices will yield new applications in the near future for sensing, information processing, and quantum computation.

Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis

Article Outline

Glossary

Surface site is a position on the surface. High-symmetry positions are usually named as top, bridge, and hollow sites and designate positions over a surface atom, over two neighboring surface atoms, and over the void in between neighboring surface atoms, respectively.

Surface reaction center is a group of atoms on the surface where an elementary reaction occurs. The term reaction site will be used occasionally.

Adsorption is a process where molecules from the gas-phase or from liquid-solution bind to a solid or liquid surface. In this article, adsorption from the gas-phase to a solid surface is considered exclusively.

Chemisorption is a type of adsorption where a molecule binds to the surface through a direct chemical bond, whereas in physisorption the binding is due to van der Waals interaction.

Catalyst's activity is related to the rate of catalytic reaction, and can be expressed as amount of product made per unit time per active site (i.e. turnover frequency).

Catalyst's selectivity is a ratio between the amount of desired product obtained per amount of consumed reactants.

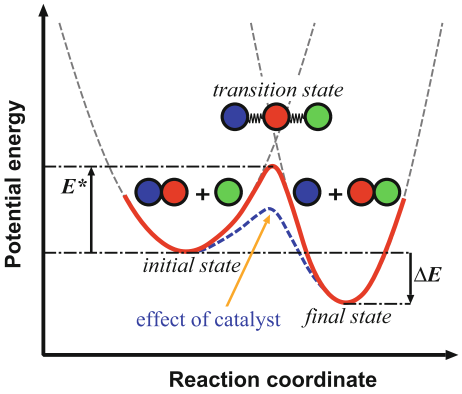
Definition of the Subject

First-principles (in Latin *ab initio*) quantum-mechanical-based computer simulations can deliver an atomic-level insight into elementary constituents of phenomena such as chemical reactions. The knowledge and understanding thus obtained may be used to propose new reaction-centers with on-demand tailored catalytic properties. The purpose of this article is to demonstrate with several examples how to gain such an insight and on this basis how to help design new *heterogeneous* reaction centers. In particular, surfaces of transition metals are considered, which are traditionally known as good heterogeneous catalysts. However, *ab initio* calculations of the properties of individual reaction centers present only the first part of the endeavor, because dynamical properties (e. g. overall reaction rates) are, in general, determined by the interplay between many elementary atomic-scale processes. The recipe for calculating the properties of such a dynamical system may therefore be accomplished by a hierarchy approach, where different computational methods are utilized for different time and lengths scales. For example, the information provided by the atomic-scale quantum-mechanical calculations can be utilized by statistical mechanics methods like kinetic Monte Carlo to follow the time evolution of the system. Such (statistical) methods are beyond the subject of this article and are just shortly outlined.

Introduction

A chemical reaction is a process of conversion of substances into other substances. Consider for example a simple chemical reaction, where molecules A and B react so as to form molecules C and D. The molecules A and B that enter into reaction are called reactants, and the molecules C and D are the reaction products. To understand the mechanism of reaction we need to envisage the atomic structure of the involved molecules and the trajectory during their inter-conversion. In general, during chemical reaction some bonds are broken and new bonds are formed. Perhaps the simplest picture of a chemical bond—a bond linking two atoms together—is that of a mechanical spring governed by Hook's law. This means that atoms "feel" a harmonic potential around equilibrium positions. Imagine for example that during chemical reaction an *a*–*b* bond breaks and *b*–*c* bond forms. This means that the *a*–*b* bond will be stretched first (the potential energy will increase) and eventually broken (point of maximum potential energy), and then a new *b*–*c* bond will start to form (the potential energy will decrease). This process is schematically shown in Fig. 1. Already this simple picture shows that chemical reaction is an activated process, that is, the system has to cross an energy barrier when passing from reactants to products. In reality the majority of chemical reactions are activated. Moreover, in many cases, the energy barrier of the reaction is so large that the reaction does not take place: more precisely the rate of reaction is too slow to be observed. Namely, the rate of chemical reaction depends exponentially on the energy barrier: the larger the barrier, the smaller is the rate. To accelerate a chemical reaction, a "third" substance, called a catalyst, is used. A catalyst is a substance that accelerates the rate of a chemical reaction, but is itself not consumed by the reaction. In terms of the above discussion of activated process, this means that the catalyst reduces the height of the activation barrier (see Fig. 1), for example, by means of providing a new reaction mechanism.



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 1
Reaction energy profile of a simple reaction (*red curve*): *ab* + *c* → *a* + *bc*. Around equilibrium positions (local minima) atoms feel harmonic potential (indicated by *two dashed gray parabolas*). As a consequence chemical reaction (bond-breaking and bond-making) will involve overcoming an energy barrier, *E. The effect of a catalyst on the chemical reaction is to reduce the *E** (*blue curve*) and correspondingly to enhance the rate of reaction**

A catalyst can be either homogeneous or heterogeneous. A homogeneous catalyst is in the same phase (solid, liquid, and gas), whereas heterogeneous catalyst is in a different phase with respect to reactants. A typical example of heterogeneous catalysis is where a solid catalyst is used to accelerate the gas-phase reaction. At present, about 90% of all chemicals are produced as heterogeneously catalyzed processes [62], where catalysts are solids, and provide a range of products such as fuels, fertilizers and plastics. Moreover heterogeneous catalysis is used to clean poisonous emissions from power plants, cars, and industrial production. Because of the technological and economical importance of catalysis, it makes it worthwhile to improve the catalysts even if the gain is as minor as only a few percentage points or less in performance. The efficiency of the production process strongly depends on the specific properties of the catalyst. A deeper knowledge of the interactions between the reactants and the catalyst and the understanding of the reaction mechanism would allow for the optimization of the production of many chemicals.

To understand the reaction mechanism of a given chemical reaction in detail, it is clear that the above-mentioned spring-picture of the chemical bonds holding the atoms within the molecule together will not suffice. Moreover, when a catalyst is used to accelerate the rate of reaction, the complexity of the system rises, because the number of degrees of freedom increases substantially. The progress attained in the last few decades in the field of computer simulations of matter at the atomic scale have opened new perspectives toward an atomic-scale understanding of the catalysts. In particular, electronic structure calculations, which for the description of solids are mainly based on Density Functional Theory (DFT), can provide information that are otherwise hard to obtain from experiment, such as the details of the reaction mechanisms and identification of the nature of the transition states. Therefore they help elucidate the factors that determine the activity and selectivity of catalysts, and consequently provide a way for their improvement.

Ab Initio Electronic Structure Calculations

The dynamics of a chemical reaction could, in principle, be treated by solving the time-dependent Schrödinger equation. In practice, this is not feasible (except maybe for a few trivial cases), and therefore several approximations are made. For example, one could proceed with a time-independent Schrödinger equation that is simplified with Born–Oppenheimer approximation. The time-independence stems from the fact, that, for example, the Hamiltonian (the energy operator) of an isolated molecule or crystal (in the absence of any external time-varying "*influence*") does not depend on time, whereas the Born–Oppenheimer approximation allows one to decouple the electronic motion from the motion of nuclei. This is made possible, because the mass of the nucleus is about three orders of magnitude heavier than the mass of the electrons and therefore the time scale of ionic dynamics is much larger than the electronic one. This means that one picks a given fixed configuration of nuclei (kinetic energy of nuclei is thus neglected) and then solves the electronic problem (hence the name *electronic structure theory*). Formally, this can be written as:

$$\widehat{H}_{\{\mathbf{R}\}}\Psi_{\{\mathbf{R}\}} = E(\{\mathbf{R}\})\Psi_{\{\mathbf{R}\}}\,, \tag{1}$$

where $\widehat{H}_{\{\mathbf{R}\}}$ and $\Psi_{\{\mathbf{R}\}}$ are the Hamiltonian and wave-function of n interacting electrons moving in the field of N fixed nuclei with coordinates $\{\mathbf{R}\}$. $E(\{\mathbf{R}\})$ is the energy of the Hamiltonian $\widehat{H}_{\{\mathbf{R}\}}$, and can be seen as the potential energy that the nuclei "feel" at configuration $\{\mathbf{R}\}$. As for the analysis of chemical reactions, it is often only the ground-state $E(\{\mathbf{R}\})$ that is of interest. The $E(\{\mathbf{R}\})$ is therefore a function of the coordinates of nuclei. Solving Eq. (1) for many different configurations of the nuclei, would allow for the construction of the potential-energy-surface (PES), that can be used to analyze the motion of nuclei. Once the PES is constructed the forces acting on atoms can be calculated as $\mathbf{F}_I = -\frac{\partial E(\{\mathbf{R}\})}{\partial \mathbf{R}_I}$ (I designates a given atom), and the dynamics (e. g. motion of atoms) can be studied, for example, by integrating the classical equation of motions—a method known as *ab initio* molecular dynamics (MD). However, the construction of PES is only feasible for very simple systems, for others *ab initio* MD consists of solving Eq. (1) at each snapshot during the *discretized* time evolution (t, $t+\delta t$, $t+2\delta t, \ldots$) of the system. At each snapshot the forces are calculated by Hellman–Feynman theorem as $\mathbf{F}_I = -\frac{\partial E(\{\mathbf{R}\})}{\partial \mathbf{R}_I} = -\langle\Psi_{\{\mathbf{R}\}}|\frac{\partial H_{\{\mathbf{R}\}}}{\partial \mathbf{R}_I}|\Psi_{\{\mathbf{R}\}}\rangle$, and the system is propagated by δt accordingly. Note that in such MD treatment the quantum effects of nuclei (e. g. tunneling) are neglected.

For practical purposes, even solving Eq. (1) is too complicated (analytical solution does not exist, except for a few trivial cases), and the n-electron equation is further simplified into a set of one-electron equations with the following form:

$$\left[-\tfrac{1}{2}\nabla^2 + \upsilon_{\text{eff}}(\mathbf{r})\right]\phi_i = \varepsilon_i\phi_i\,, \quad i = 1, n\,, \tag{2}$$

where $\upsilon_{\text{eff}}(\mathbf{r})$ is an effective one-electron potential (for notational simplicity, nonmagnetic insulator is considered). One possible scheme is the Hartree–Fock (HF) method, where the many-electron wave-function Ψ is approximated by an anti-symmetrized product (*Slater determinant*) of one-electron orbitals, ϕ_i, thus satisfying the Pauli exclusion principle according to which the wave-function has to be anti-symmetric with respect to exchange of two electrons. In HF method the effective potential $\upsilon_{\text{eff}}(\mathbf{r})$ is given by:

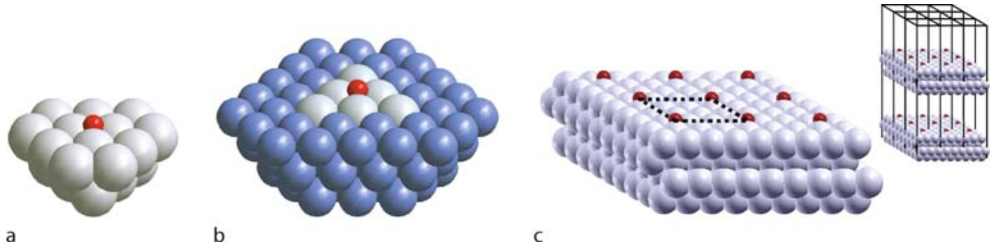
$$\widehat{\upsilon}^{\text{HF}}_{\text{eff}}(\mathbf{r}) = \upsilon(\mathbf{r}) + \int_{\mathbf{r}'} \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}' - \widehat{K}(\mathbf{r})\,. \tag{3}$$

The $\upsilon(\mathbf{r})$ is the *external* potential due to nuclei charges, $\rho(\mathbf{r}')$ is the electron density (the integral accounts for the electron-electron Coulomb interaction), and $\widehat{K}(\mathbf{r})$ is the exchange operator that arises due to "anti-symmetry" of the wave-function. The HF method, although computationally appealing, gives too poor results due to neglect of the correlation effects. The procedure for treating correlations is well established, but the corresponding wave-function-based methods are computationally very demanding [104].

Another computationally appealing method is provided by Density Functional Theory, where the electronic structure problem is simplified by realizing that the ground-state energy is a functional of the electron ground-state density [35]. The practical DFT approach also consists of solving a set of one-electron equations (*Kohn–Sham* equations [46]), similar to those of HF, but the DFT formalism—although formally exact—allows one to treat the correlation effects, in practice, in an approximate way. In DFT the effective potential $\upsilon_{\text{eff}}(\mathbf{r})$ is given by:

$$\upsilon^{\text{KS}}_{\text{eff}}(\mathbf{r}) = \upsilon(\mathbf{r}) + \int_{\mathbf{r}'} \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}' + \upsilon_{\text{xc}}(\mathbf{r})\,, \tag{4}$$

where the $\upsilon_{\text{xc}}(\mathbf{r})$ is the exchange-correlation potential, which is given in terms of exchange-correlation (XC) energy functional $E_{\text{xc}}[\rho]$ as $\upsilon_{\text{xc}}(\mathbf{r}) = \delta E_{\text{xc}}[\rho]/\delta\rho(\mathbf{r})$. There are two types of approximations in DFT, depending on how



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 2
Three types of surface models: a cluster, b embedded cluster, and c slab model (surface unit cell is indicated by *dashed line*). The multi-slab flavor of the slab model is shown in the *inset* of c

the $E_{xc}[\rho]$ is approximated [79]. In the local-density-approximation (LDA) the XC functional depends solely on electron density (i. e. the space is partitioned into infinitesimally small cubes, which are treated as uniform electron gas), whereas the generalized-gradient-approximation (GGA) incorporates also the density gradient terms into the XC functional. The LDA usually gives poor estimates of activation energies (poorly describes the bond-breaking and bond-making), because it favors homogeneous systems. Because a more bonded system is more homogeneous, the LDA overestimates the binding energies, and correspondingly severely underestimates the activation energy (E^*) of bond-making processes (and vice versa for bond-breaking reactions). On the other hand, the GGA gives more accurate binding and activation energies. There are many flavors of GGA functionals, for the description of solids the most popular are those of Perdew [80,81].

Modeling the Surface

In order to describe a surface (or a catalyst) with a computer, one needs to construct an appropriate model. Such models consists of a limited number of atoms, because it is not possible to treat a macroscopic number of (inequivalent) atoms. Three types of surface models are used (see Fig. 2):

Cluster model: surface is represented by a cluster of atoms that is obtained by a "finite cut" from an ideal lattice. This model builds on the assumption that adsorption is a phenomenon of strong local character. The cluster models of metallic surfaces are prone to cluster-size effects [34,86,109], in particular, the adsorption energy is known to undergo large variations as a function of the cluster size and shape [34,86].

Embedding scheme: embedding schemes divide the adsorbate/substrate system into at least two zones: (i) the cluster region and (ii) an outer region. The essence of embedding is to correctly connect the cluster to the outer part of the model so as to diminish the size effects of the cluster model. The most sophisticated embedding schemes are based on Green function formalism [6,24].

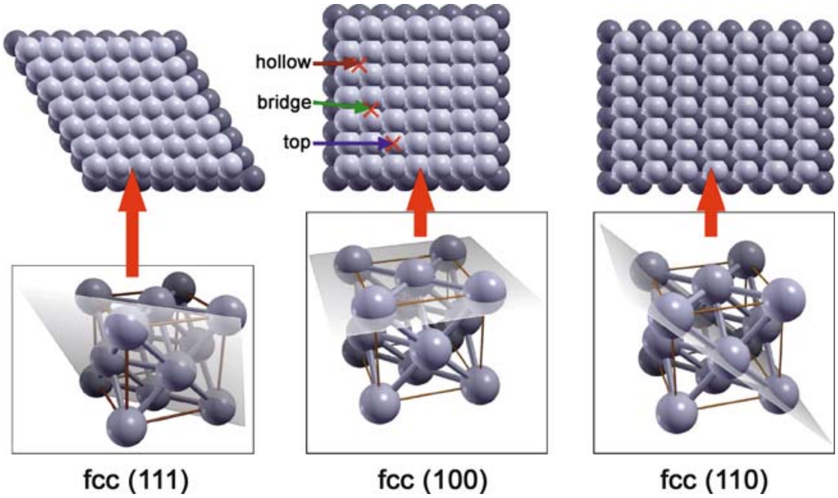
Periodic slab model: describes the surface by an infinite periodic slab in the *xy*-direction with finite thickness in the *z*-direction. The structure (and description) of such a slab is entirely given by a surface unit cell. There are two flavors: a single slab and a multi-slab model. The latter is actually an infinite 3D model, where individual slabs are separated by vacuum layers that are thick enough to prevent adjacent slab–slab interaction.

A given surface can be cut from the bulk crystal with many possible orientations. Miller indices are used to designate the surface plane by three integers as (*hkl*). These indices denote a plane that intercepts the three lattice vectors at $1/h$, $1/k$, and $1/l$, respectively. Figure 3 shows the three low-Miller index surfaces of an fcc (face-centered-cubic) crystal, which are (100), (110), and (111).

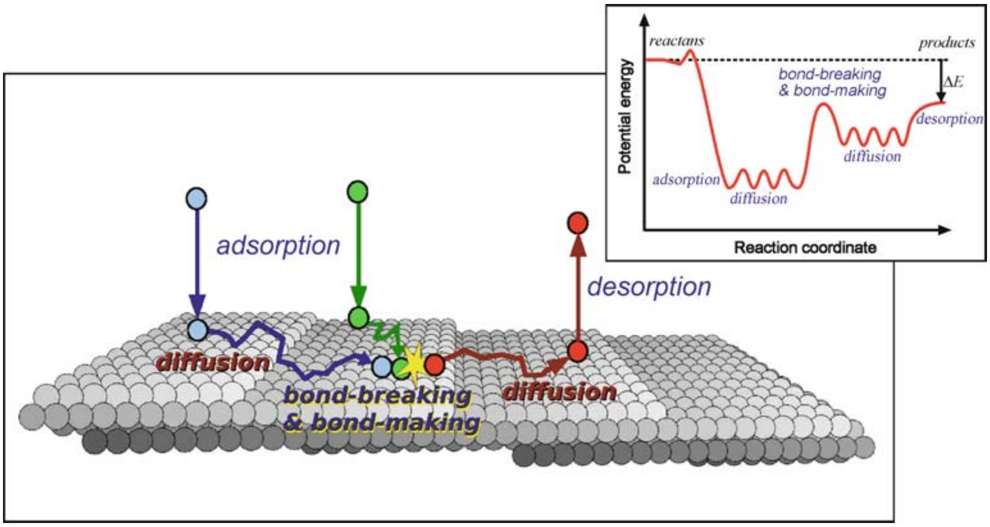
Description of Activated Processes

As mentioned in the Introduction, a chemical reaction is an activated process, and reactants have to overcome an energy barrier (E^*) during their conversion to products. The transition over the energy barrier occurs on average once per $t_{\text{slow}} \approx t_{\text{fast}} e^{E^*/kT}$, where t_{fast} is the time-scale characteristic to microscopic dynamics, and kT is the thermal energy. Usually $E^* \gg kT$ and the two time-scales differ by many orders of magnitude (the transition itself is very fast but it occurs rarely). Hence activated processes cannot be studied directly by molecular-dynamics (MD) simulations, as this would require an unfeasible number of MD integration steps before a single transition would occur (the time step used in MD must be smaller than the t_{fast}).

In general, there are several energy barriers involved in a chemical reaction. In this case the description of the overall chemical reaction is decomposed into several elementary steps, where each elementary step is associated



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 3
Three low Miller index surfaces of an fcc (face-centered-cubic) crystal: (111), (100), and (110). In the *bottom row* of plots the direction of the plane used to cut the corresponding surfaces is indicated. The positions of high-symmetry surface sites (*hollow*, *bridge*, and *top*) are also shown on the (100) surface



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 4
Chemical reactions consist of several elementary steps. The Figure shows a typical mechanism of surface catalyzed reaction (i. e. Langmuir–Hinshelwood mechanism), which consists of the following reaction steps: adsorption of reactants, their diffusion on the surface, one or more elementary steps where some bonds are broken and new ones are formed so as to form the product molecules, which eventually desorb from the surface. The *inset* shows the associated reaction energy profile

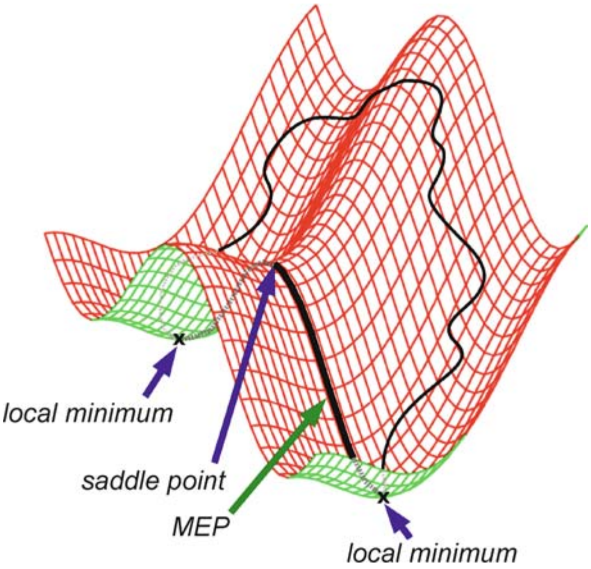
with (at most) one energy barrier. Figure 4 shows elementary steps involved in a typical surface-catalyzed reaction. Therefore, one needs to consider each elementary step in order to understand the overall chemical reaction. The hierarchical approach to the problem would consist of first analyzing each elementary step individually by electronic structure calculations, and then to assemble them into an overall picture by other methods, such as, for example, kinetic Monte Carlo (Sect. "Putting It All Together").

Let us consider an activated elementary step, such as depicted in Fig. 1. A stable molecular configuration on the left side of the barrier is called initial-state (IS) and that on the right side the final-state (FS) of an elementary step, whereas the point of the highest energy along the path from IS to FS is called a "transition state" (TS), and its energy difference with respect to IS, is the activation energy, E^*:

$$E^* = E_{\mathrm{TS}} - E_{\mathrm{IS}} \,. \tag{5}$$

But for an isolated diatomic molecule, the potential-energy-surface is multidimensional, hence there is an infinite number of trajectories going from IS to FS, and among there is also the minimum-energy-path (MEP), which is characterized by vanishing force components orthogonal to the path. The MEP's tangent is therefore parallel to the force vector and the configuration of the highest energy along the MEP is the TS—a first-order stationary point (see Fig. 5).

The calculation of PES is, due to its multidimensional nature, computationally too demanding to be sampled accurately but for a few simple cases. However, in many instances it turns out that the knowledge of the stationary points on the PES and its shape around them is sufficient to calculate reaction rates. Accurate estimates of transition rates, can be obtained, for example, by using a statistical approach known as *transition-state theory* (TST) [16,18]. According to TST the (forward) rate constant depends exponentially on the activation energy, E^*, and is given by a van't Hoff–Arrhenius type expression:



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 5

Two-dimensional potential-energy-surface (PES). Two trajectories are shown linking the two local minima: one of them is the minimum-energy-path (MEP) that is characterized by the vanishing force components orthogonal to the path and passes through the saddle point. In an elementary chemical reaction, reactant (initial-state, IS) and product (final-state, FS) are associated with local minima on the PES, and the reactant is transformed into the product by proceeding along a given trajectory on the PES that links the two minima. Statistically, the most probable trajectory displays the smallest barrier, hence it passes through the saddle point (first-order stationary point). The configuration at the saddle point is called the transition state (TS)

$$k_{\mathrm{f}} = \nu \mathrm{e}^{-E^*/kT} \,, \tag{6}$$

where k is a Boltzmann constant (please note that k and k_{f} label two distinct quantities), T is temperature, and ν is a prefactor, which depends on the shape of the PES around the stationary points. The letter "f" in the k_{f} indicates that this is the rate-constant for the forward direction of the elementary step, i. e. from IS to FS. There will also be backward jumps from FS to IS, and the net rate, r, of the elementary step will be given by the difference between the forward and backward rates, $r = r_{\mathrm{f}} - r_{\mathrm{b}}$. The TST also provides an insight into the physical origin of prefactor ν. In the harmonic TST approximation, where the PES around the IS and TS is expanded in normal modes, the prefactor ν can be described in terms of the vibration frequencies ν_i of IS and TS, and Eq. (6) can be written as:

$$k_{\mathrm{f}} = \frac{\prod_i^{3N} \nu_i^{\mathrm{IS}}}{\prod_i^{3N-1} \nu_i^{\mathrm{TS}}} \mathrm{e}^{-E^*/kT} \,. \tag{7}$$

Note that the product in the denominator is only over $3N - 1$ frequencies (N being the number of atoms), because the TS's normal mode tangent to reaction coordinate cancels out in the derivation of TST. On the basis of (harmonic) TST it is therefore clear why the knowledge of the stationary points on the PES and its shape around them suffices (in many cases) to calculate reaction rate. In the one-dimensional case, Eq. (7) would reduce to $k_{\mathrm{f}} = \nu^{\mathrm{IS}} \mathrm{e}^{-E^*/kT}$, where ν^{IS} is the oscillator frequency around the IS. Bond-stretching frequencies are on the order of 10^{12} to $10^{13}\mathrm{s}^{-1}$, and this gives an idea about the typical value of the prefactor in Eq. (6).

Identification of Transition-States

The dependence of the rate constant on the E^* is exponential and only linear on the prefactor ν, Eq. (6). It is precisely for this reason why the identification of the transition state is so crucial: knowing its structure and understanding its chemistry would allow for the design of a reaction site that would lower the energy of TS and consequently increase the rate of the elementary step. The premise behind this is that by "chemically" acting on the reaction-center, the prefactor would not change substantially, and the exponential dependence on E^* would prevail in determining the rate. Moreover, it is much more intuitive to act on the energetic stability of the TS than on the "shape" of the PES around the IS and TS. As for the overall reaction rate, one would consequently need to lower the energy barrier for all elementary steps to increase the overall rate, but it turns out that in catalytic reactions, some barriers are anti-correlated, that is, lowering a barrier for one elementary step increases the barrier for some other elementary step.

At this point one could ask: why bother with computer atomistic simulations to identify transition states involved in given chemical reactions? The reason is that transition states are very hard to identify experimentally, because of their too short lifetimes. Moreover, the identification of transition states is quite demanding even by computer simulations: usually at least one order of magnitude heavier than the identification of equilibrium configurations (local minima on PES). The reason is that the methods based solely on the first derivatives of PES—the forces —do not converge to saddle points. Among the most popular methods for the identification of saddle points is the nudged-elastic-band method (NEB) [32,33], where instead of searching solely for TS, one considers a path connecting the IS and FS. This path is then discretized into several structures called images. The images are connected by "springs" to prevent them from sliding down the PES into the nearest local minimum during the optimization procedure (the spring forces are allowed to act parallel to the path and the true forces orthogonal to it). The NEB method therefore converges the path to the MEP. The highest point along a stable MEP—which by definition is a saddle point (a first-order stationary point)—is then found by allowing one of the images to "climb up" until the forces vanish. Actually the NEB will converge to MEP's whenever these are stable (i. e. when the curvature of the PES on hyperplanes orthogonal to the MEP itself is everywhere positive). When the MEP's are not stable different techniques based on the use of collective variables should be preferred [110].

Brønsted–Evans–Polanyi Relationship

Because the PES is such an illusive object, chemists have long attempted to develop some concepts that would surpass the explicit knowledge of the PES and even of the transition states. Although these are mainly empirical, they are useful and can be used as guides or in explanatory purposes when searching for improved reaction sites. Various relationships have been proposed, and they are derived from some assumptions of the shape of the potential-energy-surface. Perhaps the most widely used, at least in the field of heterogeneous catalysis, is the *Brønsted–Evans–Polanyi* (BEP) relationship [7,17,62], according to which the activation energy for a set of related elementary reactions correlates linearly with the reaction energy, ΔE (ΔE is defined graphically in Figs. 1 and 7):

$$E^* = a + b\Delta E \, . \tag{8}$$

This relation tells us that the smaller ΔE is, the smaller will be the activation energy. Small here means negative, that is, exothermic or thermodynamically favored. In Eq. (8) there are two parameters, a and b, which give the slope and the intercept of the BEP line. These two parameters were given various names, e. g. the slope is called the reaction coefficient, whereas the intercept is the intrinsic barrier of reaction [62]. It has been shown that the BEP relation holds well for dissociation reactions at surfaces [3,71], because the transition state is *late*, product-like, and variations in the stability of dissociated products are likely to reflect the stability of the transition state. Analogously, for an *early*, reactant-like, transition state the variation in the stability of the reactant will correspondingly affect the stability of the transition state, but the barrier will be little affected. This is schematically shown in Fig. 6. For this reason the BEP slope is large for reactions with *late* transition state, and small for *early* transition state.

Description of the Overall Reaction

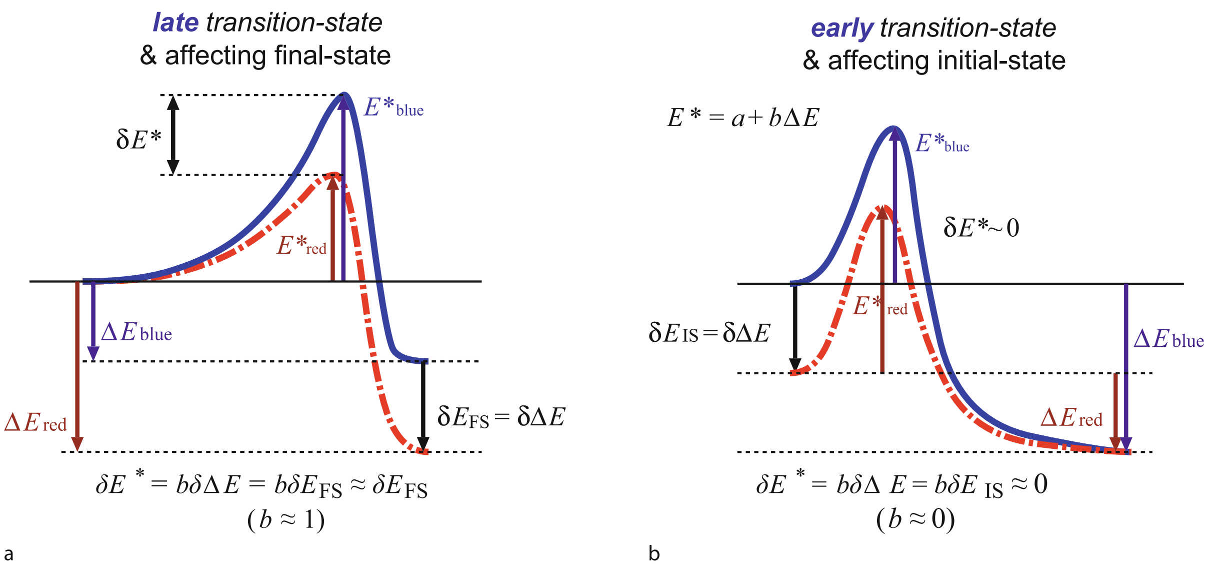
Decomposition into Elementary Steps

A heterogeneous catalytic reaction involves several elementary steps, such as the adsorption of the gas-phase reactants on the solid surface, their diffusion on the surface, one or more elementary steps involving breaking some of the reactant chemical bonds and making new ones so as to form the product molecules, which eventually desorb from the surface (see Fig. 4). Consider, for example, ammonia (NH_3) synthesis, which is among the largest industrial catalytic processes (Haber–Bosch process) and one of the most studied [94]. The overall reaction is:

$$N_2 + 3H_2 \rightarrow 2NH_3 \, , \tag{9}$$

and it consists of the following elementary steps [94] (omitting diffusion of adsorbed species):

$$\begin{array}{lr} 1. & N_{2(g)} \rightarrow N_{2(ad)} \\ 2. & N_{2(ad)} \rightarrow 2N_{(ad)} \\ 3. & H_{2(g)} \rightarrow 2H_{(ad)} \\ 4. & N_{(ad)} + H_{(ad)} \rightarrow NH_{(ad)} \\ 5. & NH_{(ad)} + H_{(ad)} \rightarrow NH_{2(ad)} \\ 6. & NH_{2(ad)} + H_{(ad)} \rightarrow NH_{3(ad)} \\ 7. & NH_{3(ad)} \rightarrow NH_{3(g)} \, , \end{array} \tag{10}$$



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 6
Effect on the variation of relative stability of final (FS) and initial state (IS) on the activation energy for *late*- and *early*-type transition state (TS), respectively, according to the BEP relation. a For *late* TS the stabilization of FS stabilizes the TS leading to a reduction of the activation energy, *E. b For *early* TS the stabilization of IS stabilizes the TS, but this affects the *E** very little**

where labels (g) and (ad) designate the gas-phase and adsorbed species, respectively. This set of elementary steps can be classified into three groups:

(i) dissociative adsorption of nitrogen (N_2) and hydrogen (H_2), Eqs. (10.1)–(10.3);
(ii) reactions of the dissociated N and H species to form the product NH_3 species: in this step, the adsorbed N is successively hydrogenated, Eqs. (10.4)–(10.6);
(iii) desorption of the product ammonia molecules, Eq. (10.7).

Sabatier Principle

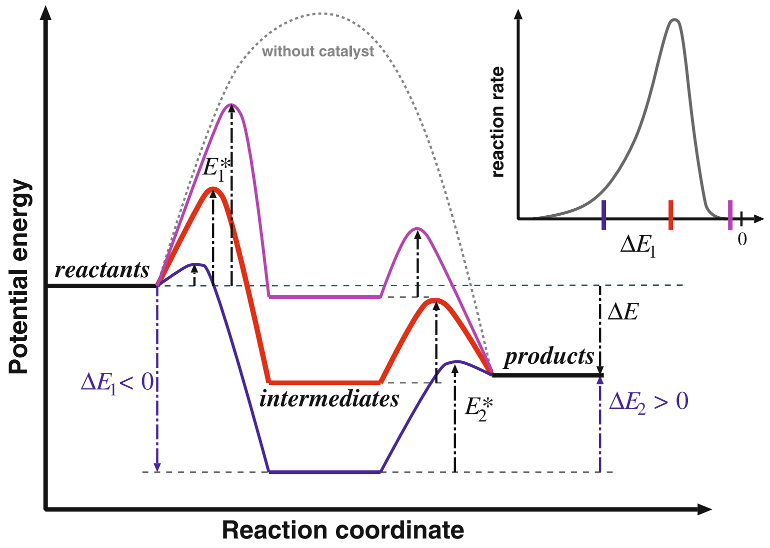
As for the above NH_3 synthesis, a good catalyst must facilitate both the dissociation of reactant N_2 and H_2 molecules, as well as the formation of the product molecules. Because the reactants are the molecules in the gas phase, the reaction energy of dissociation steps is given by the dissociative chemisorption energies. According to the BEP relation, Eq. (8), the more negative (exothermic) is the chemisorption energy the smaller will be the activation energy, and the easier (faster) the formation of intermediates. This indicates that a very reactive surface should be used that forms strong bonds with the dissociated species. However, there is an opposite trend for the formation of product molecules, see Fig. 7 (it is worth mentioning that the BEP slope for association reactions tends to be much smaller than for dissociation reactions [71]). In addition, if the surface is too reactive intermediates will fully cover it thus inhibiting the reaction. Therefore, weakly chemisorbed intermediates would be required to form the product molecules. The best catalyst will be therefore a compromise with an intermediate chemisorption energy. This is the *principle of Sabatier*, which results in the so-called volcano activity plots (see inset of Fig. 7).

Considerations presented above demonstrate why the surface acts as a catalyst: the main effect is to stabilize the intermediates, which reduces the activation energies accordingly. But the stabilization should not be overdone, because then the reaction rate would decrease again.

Putting It All Together

From the preceding section it is rather obvious that the dynamics of the overall reaction may develop pattern(s), that may not be guesses merely by considering elementary steps individually. Namely, macroscopic dynamical properties are, in general, determined by the interplay between many elementary atomic-scale processes. For this reason, after the individual elementary steps have been quantified, they need to be put into a broader context that will link them together so as to construct a coherent picture of the overall reaction.

Mean-Field Description: Rate Equations One could setup rate equations for all elementary steps. The procedure for doing that is well established [15,61,102]. Consider for example, an elementary step where adsorbed



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 7
Surface acts as the catalyst, because it stabilizes the intermediates, and therefore decreases the activation energy. The more they are stabilized (the more negative ΔE_1) the smaller is the activation energy for their formation (*left barrier*, E_1^*), but the barrier for their conversion into products will display the opposite trend (*right barrier*, E_2^*). The optimum is therefore a compromise between the two anti-correlated effects, hence the catalyst should bind intermediates moderately (*Sabatier principle*). *Inset*: the rate of reaction displays a *volcano* dependence on the intermediate chemisorption energy (ΔE_1)

species A and B react so as to form adsorbed species AB:

$$A_{(ad)} + B_{(ad)} \rightleftharpoons AB_{(ad)} \, . \tag{11}$$

Naively speaking, the forward rate, r_f, of this step will be given by the "*probability of* A *and* B *to meet at the same site*" times the "*probability to overcome the barrier*" per unit time. If we define the coverage of species x as $\theta_x = N_x/N$, where N_x is the number of adsorbed x molecules and N is the number of all surface sites, then the first probability is given by the product of the two coverages, $\theta_A\theta_B$, whereas the second probability is given by the forward rate constant, k_f. In this case the rate is normalized to the number of "jumps" per site per unit time. The reverse rate, r_b, will be analogously given by $\theta_{AB} \times k_b$, where k_b is the rate constant for the backward direction (activation energy in the backward direction is $E^*_{bck} = E^* - \Delta E$, e. g. see Fig. 1). The net rate is therefore given by:

$$\begin{aligned} r = r_f - r_b &= \theta_A\theta_B k_f - \theta_{AB} k_b \\ &= \theta_A\theta_B\left[\nu_f e^{-E^*/kT}\right] - \theta_{AB}\left[\nu_b e^{-(E^*-\Delta E)/kT}\right] , \end{aligned} \tag{12}$$

where ν_f and ν_b designate prefactors for the forward and backward direction, respectively. Note, however, that if the *probability* is expressed as $\theta_A\theta_B$ then A and B are treated as independent. Therefore, in this scheme the lateral interactions between the adsorbed species can be treated only by mean-field description through dependence of the activation energies and prefactors on the coverage. After rate equations are constructed for all elementary steps the so-obtained set of equations needs to be solved. The resulting equations may be highly nonlinear and very interesting patterns such as kinetic oscillations and chaos may develop [116]. In order to simplify the treatment several approximations may be applied, such as steady-state (SSA) and quasi-equilibrium approximation (QEA) [61].

Kinetic Monte Carlo A more detailed description of the overall reaction could be obtained with a *kinetic Monte Carlo* (kMC) simulation [19,115], but it requires larger computational effort. In kMC the surface is usually mapped onto a two-dimensional lattice and the adsorbate positions are associated with lattice sites (adsorption for example is simulated by random "arrivals" of molecules to the lattice sites). At each simulation step the rates of all considered elementary processes are evaluated. A given process is then executed by a random selection with appropriately weighted probability (i. e. the rate of jumps is proportional to the associated barriers). In kMC the time evolution is coarse-grained to time scale appropriate for the rare activated events. At each step a detailed atomic configuration is known, and the activation energies can be calculated taking into account proper local environment.

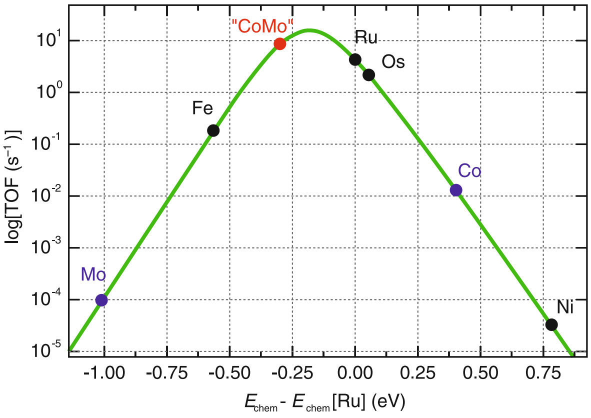
In kMC the number of particles as well as the number of steps is very large, and to calculate all the interactions and activation energies on the fly with ab-initio methods is far from feasible. Therefore, a model Hamiltonian (e.g. *lattice gas* Hamiltonian) is constructed that allows for fast on the fly calculation of required energies. A model Hamiltonian may be built by expanding it into various interaction terms that are determined from a number of *ab initio* pre-calculated structures [85].

Rate-Limiting Step An analysis of the rates of the involved elementary steps reveals that not all the elementary steps are equally significant in determining the rate of the overall chemical reaction. The step that most significantly determines the rate of the overall chemical reaction is called the rate-determining step. This may imply that the rate-determining step is the "slowest" among all elementary steps, however under steady state conditions, by definition, the rates of all the steps will be equal. For example, in the ammonia synthesis mentioned above, the dissociation of N_2 is rate-determining. There may be more than one kinetically relevant steps in a given chemical reaction. From Eq. (12), we see that the rate depends exponentially on activation energy and temperature, whereas the dependence on the other parameters is weaker. Therefore, if a given elementary step has much larger E^* than the others, it is likely to be rate-determining. Note also that under different experimental conditions (T, P) different steps may be rate-determining. For example, under large enough T the E^*/kT ratio will become small enough, and other factors, such as, the availability of sites and partial pressures of reactants may prevail.

Optimum Chemisorption Energy For a class of heterogeneous reactions, where dissociative adsorption is the rate-determining step, like the ammonia synthesis considered above, an analysis of the reaction rates gives a universal result that the optimum chemisorption energy should be, broadly speaking, in the range from -1.0 to -2.0 eV per molecule [3,76]. This universality is a consequence of the BEP dependence of the activation energy on the chemisorption energy. This implies that the stronger the bond in the diatomic molecule, the more reactive will be the "optimum" catalyst. For example, the bond of N_2 is stronger than that of oxygen, O_2, therefore a good catalyst for reactions involving dissociation of N_2 is more reactive than the catalyst for reactions involving the O_2 dissociation. The catalysts for ammonia synthesis are metals such as ruthenium (Ru) and iron (Fe), whereas oxidation reactions typically involve less reactive silver (Ag), palladium (Pd) and platinum (Pt) catalysts.

The general result presented in the paragraph above calls for an in-depth understanding of the factors that govern the dissociative chemisorption energies and these factors will be underlined in Sect. "Theory and Trends of Chemisorption and Reactivity on Transition Metals". Theory and computer simulations have played an important role here. They helped to provide an understanding of chemisorption phenomenon and moreover computer simulations based on DFT have provided systematic databases of dissociative chemisorption energies.

Although the range of optimum chemisorption energies suggested above is relatively broad, it turns out that for a given diatomic molecule this range typically involves only a few elemental metals, and none of them may even lie close to the volcano curve maximum [76]. Hence a fine-tuning of the chemisorption energy would be required so as to move toward the volcano maximum. A simple rational approach would be to form a bimetallic alloy by simple interpolation [39], i. e., by mixing a given metal that lies on the left side of the volcano peak (too strong chemisorption energy, E_{chem}) with the one on the right (too weak E_{chem}). As for the ammonia synthesis discussed above, mixing Mo—which binds N too strongly—with Co —which binds N too weakly—results in a catalyst that is closer to the volcano maximum and therefore more active than the best elemental metals Fe, Ru, and Os [39] (see Fig. 8). This is precisely what was found experimentally [38,47]. Note that both Mo and Co display lower activity than Fe, Ru, and



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 8

Calculated volcano plot [39]: catalyst's activity (i. e. turnover frequency, TOF) for ammonia synthesis as a function of chemisorption energy of nitrogen with respect to Ru, $E_{\text{chem}} - E_{\text{chem}}$[Ru] (eV per N_2 molecule). Curve is calculated by microkinetic model assuming linear BEP relation between nitrogen chemisorption energy and the activation energy for N_2 dissociation. On the basis of results from [39]

Os, and without the knowledge of the principal factor that governs the activity, this would only be guessed by error-and-trial.

For the mixed catalyst to have the interpolated properties, several requirements have to be fulfilled. In particular the constituent metals should not segregate. More issues about alloys will be discussed in Sect. "Theory and Trends of Chemisorption and Reactivity on Transition Metals".

Selectivity Issues

Tuning solely the reactivity of a catalyst—for example according to the above-mentioned Sabatier volcano plot principle—in order to optimize its activity is in many cases not sufficient. Chemical reactions are accompanied with the formation of (unwanted) byproducts. In some cases the selectivity issues may be crucial (selectivity can be defined as a ratio between the amount of desired product obtained per amount of consumed reactants), because some of the reaction byproducts may even poison the catalyst, such as, for example, coke formation during the syngas production (e. g. see Sect. "Improvement of Steam-Reforming Catalyst"). Therefore, it is clear that improving the catalyst's selectivity is of great importance.

DFT simulations can help improve the catalyst's selectivity by disentangling the mechanisms that govern the reactivity of catalysts toward competitive reaction pathways. Consider the formation of two competitive species from a given adsorbed intermediate:

$$\begin{aligned} &A_{(\mathrm{ad})} \to \mathrm{B} \\ &A_{(\mathrm{ad})} \to \mathrm{C}\,. \end{aligned} \tag{13}$$

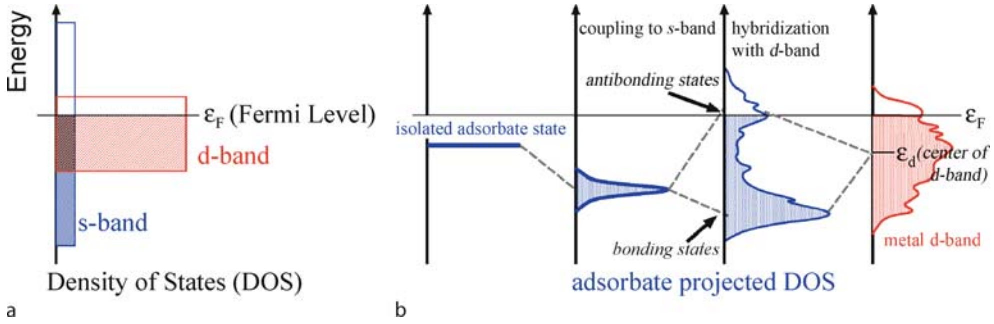
If B and C are adsorbed species, then the BEP relation suggests that in order to favor the formation of, for example, B species the reaction center should be designed such as to relatively enhance the magnitude of adsorption energy of B with respect to C. However, if the species B and C are gas-phase molecules, or if the reactions do not obey the BEP relation, the design of the proper reaction center that will favor the formation of wanted species will be more difficult. A possible strategy is to act on stabilities of involved transition states by designing such a reaction center that will stabilize the TS of the desired reaction channel with respect to those of undesired pathways. To do so the transition states have to be identified: knowing their structure and understanding their chemistry would allow one to act on their stability. In this respect, the understanding of the factors that determine the adsorbate–substrate bonding should be most helpful. For this reason a simple chemisorption model and its applicability under different circumstances will be presented below. Then it will be demonstrated with a few examples how quantum mechanical computer simulations can be used to help in designing novel reaction-centers with tailored properties.

Theory and Trends of Chemisorption and Reactivity on Transition Metals

Ab initio electronic structure methods, such as DFT, allow one to calculate the properties needed for the quantitative description of chemical reactions, such as equilibrium and transition state structures, their energies, and vibrational properties. On the other hand, one needs a simple model, which would describe in terms of a few parameters the trends of these properties, and therefore provide understanding of the most important factors that govern them.

Below a short description of the Hammer–Nørskov chemisorption model [28,30] is given, which is based on the Newns–Anderson chemisorption theory [75]. This model provides a simple description of the chemisorption trends on transition metal (TM) surfaces. Consider, for example, that a single one-electron state of an adsorbed atom interacts with a TM surface. This state will interact with all the valence electron states of the surface metal atoms, which can be described with *s*- and *d*-band (i. e. valence electrons of a given (isolated) TM atom are described by discrete *s*- and *d*-states, but in a solid these states form *s*- and *d*-band). The former is very broad and approximately half filled for all TM (containing one electron/TM-atom). The *d*-band is instead much narrower, as shown in Fig. 9a. The delocalized *s*-states interact weakly with the adsorbate state, resulting in its broadening, whereas the localized *d*-states (which can be approximately considered as molecular state) interact strongly forming the adsorbate–surface bonding- and antibonding-states. This is schematically shown in Fig. 9b. Because the *s*-band and its interaction with the adsorbate is similar for all TM, the variation in the adsorbate–surface bonding is described merely by considering the *d*-band in the Hammer–Nørskov model. The variation of the adsorbate–surface bonding is determined mainly by two effects: (i) the amount of empty anti-bonding adsorbate–surface states; note that anti-bonding interaction is repulsive, so the more these states are empty the stronger is the adsorbate–surface interaction, and (ii) Pauli type repulsion arising from the orthogonalization of the overlapping adsorbate and metal states. This term is proportional to the square of coupling matrix elements between adsorbate state and metal *d*-states.

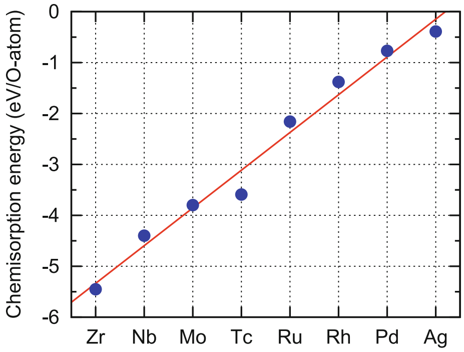
As for the effect (i), the amount of the empty antibonding states is related to the position of the *d*-band with respect to the Fermi level, ε_F (Fermi level is the energy of the highest occupied state in the metal). In the Hammer–



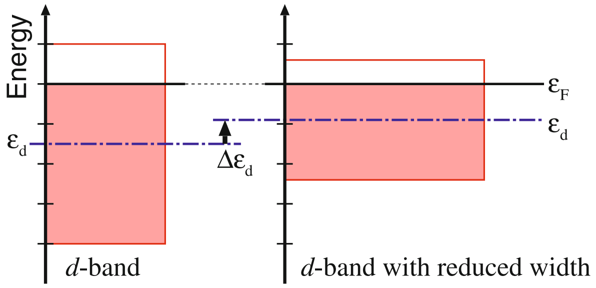
Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 9
a Electronic structure of transition metal (TM); b schematic illustration of adsorbate interaction with TM surface

Nørskov model this position is described by the center of the *d*-band, ε_d. The higher is the ε_d with respect to ε_F the more empty are the antibonding states and the stronger is the adsorbate–surface bond. This explains why the reactivity of TM decreases from left to right in the Periodic Table: the more the *d*-band is occupied the more below the Fermi level it is (lower ε_d). Figure 10 shows the trend of the DFT calculated chemisorption energies of oxygen on close packed surfaces of 4*d* transition metals. It is due to this trend and the Sabatier principle that mainly *late* transition metals (i. e. those with more than a half filled *d*-band) are catalytically interesting, because *early* transition metals (i. e. those with less than a half filled *d*-band) bind adsorbates too strongly. The reactivity also reduces when going down from the 3*d* to 5*d* row in the Periodic Table, because the latter states are more extended and therefore the effect (ii) is more repulsive.

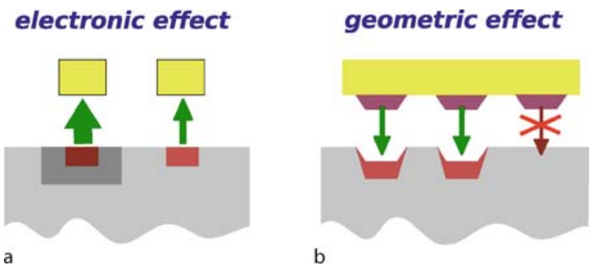
For a given adsorbate, its interaction to the surface can be affected not only by changing the metal (as shown in Fig. 10), but also by other means that are more subtle, and can be used to fine-tune the adsorbate–surface interaction. Consider what happens to the reactivity of a given *late* transition metal if the width of the *d*-band is reduced by some means. DFT calculations reveal that in such cases no charging or decharging of *d*-states occurs [30], and in order to keep the number of *d*-electrons fixed the *d*-band has to move up causing an up-shift of its center thus increasing the adsorbate–surface interaction. This is schematically presented in Fig. 11. In general, the less *effectively* a given TM atom is bonded the smaller is the width of its local *d*-band (the density-of-states projected to *d*-states of the considered metal atom), resulting in increased reactivity for late TM. The variation of the width of the *d*-band can be achieved, for example, by varying the coordination of surface atoms or by strain. Consider for example (111) and (100) low Miller index surfaces of an fcc metal (these two surfaces are shown in Fig. 3): the former has nine-fold coordinated surface atoms, whereas the latter has eight-



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 10
DFT calculated dissociative chemisorption energies of oxygen with respect to gas-phase O_2 molecule (in eV per O-atom) on closed-packed surfaces of 4*d* transition metals. On the basis of results from Refs. [13,54]. The *line* is drawn to guide the eye



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 11
Effect of the reduced band width on the center of the *d*-band for *late* (more than a half filled *d*-band) transition metal: in order to keep the number of electrons fixed (number of electrons is given by the colored area below ε_F), the *d*-band has to shift up, resulting in the $\Delta\varepsilon_d$ shift of the center of the *d*-band, ε_d. The effect would be the opposite for *early* (less than a half filled *d*-band) transition metal: the ε_d would be down-shifted



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 12
Schematic representation of electronic and geometric effects. a The adsorbate–surface interaction can be tuned by changing the electronic properties of the binding site by acting on its environment (electronic effect). b The adsorbate–surface interaction is hindered if the ensemble of the active binding site on the surface does not match the "geometric" requirements of the adsorbate (geometric effect)

fold coordinated surface atoms. Surface atoms of the (111) facet are therefore effectively more bonded than those of the (100) facet, and therefore we may anticipate that the former binds simple adsorbates less than the latter.

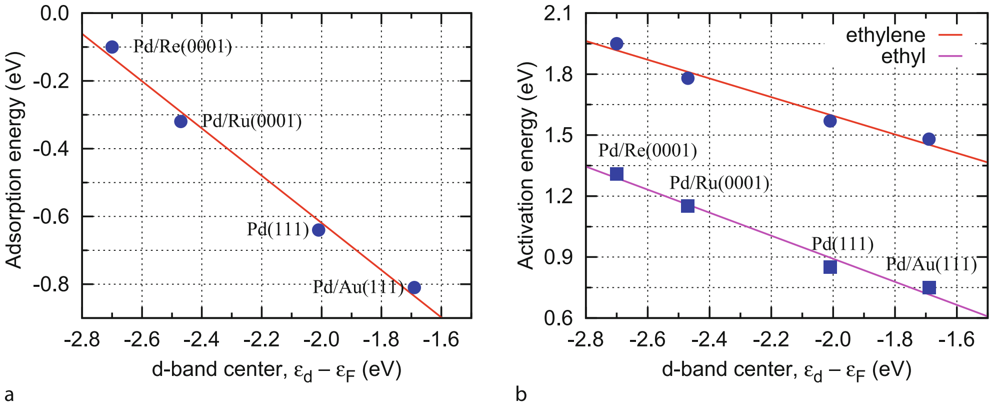
Considerations presented above were made for an atom (with a single state) interacting with the TM surface, but the arguments can be generalized to molecules by considering several adsorbate states interacting with the surface. The above *electronic* effects are still valid (e. g. see Fig. 13 for the correlation between the *d*-band center and molecular adsorption and activation energies), but in addition to that there is another effect, which is related to the geometry of the molecule and surface. Indeed, the two types of effects are termed *electronic* (or ligand) and *geometric* (or ensemble) effects, and provide a basic framework for tuning the reactivity of surface reaction centers. The way the two effects work is presented schematically in Fig. 12, and they may be described as:

- Electronic (ligand) effect is due to modifications of catalytic properties due to the interaction of a surface atom that the molecule binds to with its neighbors (e. g. shift of the d-band center).
- Geometric (ensemble) effect is related to the number of active surface atoms required for a given molecule to bind.

Above we implicitly assume that the larger the adsorbate–surface bond strength the larger the reactivity of the surface (i. e. the two terms were used casually; here surface reactivity toward dissociation reactions is meant). This can by justified by the BEP relation and also by the fact that the interaction of TS with the surface can be treated like a molecule–surface interaction, hence the stronger is this interaction the lower is the energy barrier.

Special Active Sites at Surfaces

What we have not mentioned explicitly so far is that not all sites on any real surface are alike. For example, lattice imperfections are always present on surfaces. This is particularly the case for industrial catalysts which consist of small dispersed particles on a ceramic support and display a large variety and concentration of defects [99]. It may be anticipated on the basis of the *d*-band model that such structural variations should influence the reactivity. Indeed, nowadays a large amount of experimental evidence indicates that the binding of adsorbates at surfaces is strengthened by the presence of low-coordinated



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 13
a DFT calculated ethylene adsorption energy as a function of the *d*-band center (ε_d) of the Pd(111) surface and commensurate Pd overlayer over close packed Re(0001), Ru(0001), and Au(111) surfaces. b DFT calculated C–H bond activation energies for ethylene (C_2H_4, ●) and ethyl (C_2H_5, ■) dehydrogenation versus Pd *d*-band center for the same systems as in a. On the basis of results from [77]

defects [83,93,98,112]. Below we shortly survey how the reactivity can be tuned by strain, defects and alloying.

Strain With computer simulations the effect of strain can be very easily modeled by merely increasing/decreasing the lattice spacings. Although such calculations are fictitious, they are useful to discern the effects of strain on the reactivity, and show that surface reactivity increases with tensile strain and vice-versa [65]. As anticipated on the basis of the *d*-band model, this is due to the fact that a reduced overlap between the *d*-states at neighboring atoms reduces the width of the *d*-band. Experimentally the strained sites can be made, for example, by growing atomically thin commensurate overlayers on support with different lattice spacings [9,87,95]. This way both compressive and tensile strained overlayers can be achieved (depending on the relative lattice spacings of support with respect to metal constituting the overlayers). An example is shown in Fig. 13, which shows the adsorption energy of ethylene (C_2H_4) and activation energies for dehydrogenation of ethylene and ethyl (C_2H_5) on palladium overlayers over rhenium (Re), ruthenium (Ru), and gold (Au) [77]. Correlation between these energies and the *d*-band center is rather good. The Pd overlayer on Au is more reactive than pure Pd, because lattice spacings of Au are larger than that of Pd and vice-versa for Ru. So Pd overlayer experiences tensile and compressive strain on Au and Ru, respectively. Rhenium is an exception, because of very similar lattice spacings to that of Pd, yet the reactivity trend is captured by the *d*-band center, which is apparently affected by the electronic interaction between Pd and Re.

Surface Defects The importance of surface defects in determining the reactivity of heterogeneous catalysts can hardly be overestimated [30]. Not only do defects usually bind adsorbates more strongly than perfect facets do, but in certain cases the reactivity of the step defects is so much larger than that of the terraces as to dominate the dissociation reaction rate at concentrations as low as 1% of step atoms [14]. This can be attributed both to electronic and geometric effects. As for the former, the width of the *d*-band of atoms at defects is reduced due to their decreased coordination (up-shift of ε_d), as shown in Fig. 14. The reactivity is then further increased by geometric effect, because of the availability of new sites. The extent of the two effects is apparent from Fig. 15, which displays the TS for NO dissociation under three different circumstances [26]: (a) shows the TS structure over the perfect facet of Ru(0001), and in (b) the same TS structure (no geometric effect) is shown near the step-edge defect. The reduction of E^* by 0.5 eV as going from (a) to (b) is therefore due to increased reactivity of step atoms (*electronic effect*). The barrier then further decreases by 0.7 eV, by taking advantage of the geometry of the step (*geometric effect*), because the TS structure shown in (c) benefits from being highly coordinated. Note that the TS's for the dis-

sociation of diatomic molecules such as N_2, NO, O_2, and CO are late [71,76], atomic-like, and isolated atoms are "unhappy" (reactive) and they want to be as highly coordinated as possible. So on one hand, the coordination of metal atoms at the step-edge defect is reduced, but on the other hand the step-edge defects provide the surface sites with high coordination. Therefore, at step-edges the electronic and geometric effects are cooperative resulting in their large reactivity toward dissociation reactions.

Indeed, the surface defects are so much more reactive than flat terraces, that even gold—the noblest among metals [29]—under certain circumstances becomes reactive enough to display very interesting catalytic properties [37]. For example, gold is inert toward the oxidation of carbon monoxide ($CO+\frac{1}{2}O_2 \rightarrow CO_2$), because of its inability to dissociate oxygen molecules. However, small gold nanoparticles supported on oxides (see Fig. 16) have been found to be active [31,107]. This behavior may be attributed to several effects: (i) the abundance of low coordinated reactive sites, which increases with decreasing the particle size (these sites appear at the intersections of low Miller-index planes and include edge, kink and even adatom defects) [66,84]; (ii) strain induced due to oxide-support and small particle size [66], and (iii) the appearance of new special sites at the perimeter of the oxide–metal interface (e. g. due to oxide-induced charge transfer to adsorbate) [60,72,73,74].

Alloying Alloying presents a very interesting way of changing the reactivity of the surface. On one hand addition of another metal (impurity) into a given host metal changes its electronic structure, but on the other hand it opens a way to tailor a selectivity by a geometric effect. The electronic effect on the reactivity of alloys is well captured by the shift of the *d*-band center, and these shifts have been calculated by DFT and tabulated for many catalytically interesting bimetallic alloys [88], thus providing a guideline for an on-demand tuning of the electronic structure of the surface. An interesting and counterintuitive example of alloying is that in some cases the addition of an inert IB metal enhances the adsorption ener-

gies on more reactive VIII group metals [28,77]. This is mainly due to strain [88], i. e., if a "small" metal atom is added into a "larger" host, it will experience a tensile strain and vice-versa (and the *d*-band center will shift accordingly).

As for the geometric effect, it has long been known from experiments that the addition of a group-IB metal (Cu, Ag, Au) to group-VIII metals (Fe, Co, Ni; Ru, Rh, Pd; Os, Ir, Pt) can lead to an increased selectivity of the catalyst [97]. In particular, it is known that such catalysts hinder hydrogenolysis reactions which involve C–C bond breaking, but do not significantly affect dehydrogenation reactions which involve C–H bond breaking [97]. For example, the hydrogenolysis reaction require sites with a larger ensemble of active atoms than dehydrogenation reactions. Already the addition of a small amount of IB metal will substantially decrease the number of sites composed of a large ensemble of active metal atoms, thus disfavoring reactions that require large ensembles of active atoms (as shown schematically by Fig. 12b) and making the dehydrogenation reactions—which require a small ensemble of active atoms—more selective [97].

Tuning the surface composition of an alloy represents an exciting way of designing new reaction centers with tailored catalytic properties. However, the actual composition cannot be varied at random. Some combinations of metals may lead to segregation, while for others the composition at the surface differs from that in the bulk (the amount of a given metal at the surface is either enriched or depleted). An extensive database of surface segregation energies have been compiled by DFT calculations [89], and the segregation tendency may be explained by surface energy and crystal structure differences between the host and impurity. Even if the two metals do not form a bulk alloy (i. e. they are immiscible), they may form an alloy on the surface. Such alloys have been shown to have interesting catalytic properties [2,22,23,44,97]. An example of a AuNi surface alloy used to catalyze steam reforming will be presented in Sect. "Improvement of Steam-Reforming Catalyst".

An exiting novel class of near surface alloys have been considered recently where the impurity metal atoms are located primarily in the subsurface layer [22,44] (see Fig. 17). The DFT calculations indicate that such alloys yield superior catalytic behavior for hydrogen related reaction, because they bind atomic hydrogen weakly, yet they are able to dissociate the H_2 molecule efficiently [22]. As for the water–gas shift reaction ($CO + H_2O \rightarrow CO_2 + H_2$), such a type of subsurface alloy was also suggested to be promising due to the ability to bind CO weakly and to dissociate water easily [44].

Examples

As described above the reactivity of special sites on the surface can be tuned in several ways, which are relatively easy to achieve with computer DFT simulations, because there we are assembling a given structure "atom by atom", and hence we have total control over it. Computer simulations allow one to consider and investigate structures under various circumstances that are otherwise unfeasible in reality with the aim to gain new understanding. One could envisage many different surface reaction centers and some of them may have very appealing catalytic properties. Below a few examples are presented with the aim to demonstrate how new reaction centers may be proposed on the basis of insight gained by careful analysis of results of quantum mechanical computer simulations.

Tuning the Relative Rates of Methane Dehydrogenation

One of the problems in the conversion of methane (CH_4)—the principal component of natural gas—to more useful liquid-phase chemicals, such as methanol, is that, although many catalysts are able to cleave the C–H bonds, they do so in a nonselective manner. The efficiency of catalysts is thus limited by the tendency of dehydrogenation to proceed until graphite is eventually formed on the surface, thus poisoning the catalyst [20]. Although a symbolic reaction equation may look as simple as $CH_4 + ? \rightarrow CH_3OH + \cdots$ it appears in reality so difficult that—despite its importance —a direct conversion of methane to methanol (or other liquid chemicals) is not yet feasible. For this reason let us ask a simpler question: is it possible to design a reactive center that will cleave the C–H bonds of methane selectively?

By careful analysis of the results of DFT computer simulations, it has been shown how to design such a reaction center that effectively activates the first dehydrogenation step while hindering the second one [48,49,114]:

$$\begin{aligned} &1.\quad CH_4 \rightleftharpoons CH_3 + H\,, \\ &2.\quad CH_3 \rightleftharpoons CH_2 + H\,, \end{aligned} \tag{14}$$

The activation energies can be used as a measure of reaction rate constants (e. g. Eq. (6), $k_f = \nu e^{-E^*/kT}$), therefore a target reaction center has to reverse the natural order of the two barriers' heights. This means that the barrier for the first step has to be lower than that for the second.

Local Geometry of the Reaction Site Kokalj et al. [48] have investigated the effect of local geometry of the reaction center on the two energy barriers. These authors considered the Rh(111) surface because Rh is known for its reactivity toward the C–H bond cleavage of CH_4 [103]. The local geometry of the reaction center was varied by "creating" progressively less coordinated defective sites on the surface, passing from perfect (111) facet with nine-fold coordinated surface atoms (coordination number, $N_C = 9$), to step-edge ($N_C = 7$), added row ($N_C = 5$), and finally to an ad-atom defect ($N_C = 3$). These surface structures are shown in Fig. 18, and the corresponding *d*-band projected density of states is shown in Fig. 14. For each one of them, the DFT calculated optimal adsorption energies of the involved CH_4, methyl (CH_3), ethylene (CH_2), and hydrogen (H) species are reported in Fig. 19a. The adsorption of CH_4, CH_3, and CH_2 is rather sensitive to the coordination of the metal atoms at the binding site, whereas the adsorption of hydrogen is not so much so.

As for CH_3 and CH_2, we may see that they are stabilized at low coordinated defects, as expected on the basis of the Hammer–Nørskov *d*-band model, except for the ad-atom defect, where the trend is reversed. Moreover, the ad-atom behaves rather unexpectedly also with respect to C–H activation energies, as shown in Fig. 19b: although the barrier for the first dehydrogenation step decreases as expected with the coordination of the reaction center, the dehydrogenation of methyl ($CH_3 \rightarrow CH_2 + H$) is hindered at an ad-atom defect, where the first dehydrogenation step is instead most favored. Therefore, the behavior of the ad-atom is so peculiar that neither can the adsorption of CH_3 and CH_2 be explained solely by the Hammer–Nørskov *d*-band model (*electronic* effect) nor can the dehydrogenation barriers be explained by the BEP relation. As will be shown below this is related to structural features of the ad-atom (*geometric* effect). We proceed by analyzing the involved structures, in particular, adsorbed CH_3, CH_2,

and the corresponding TS structures for the two dehydrogenation steps.

Analysis of CH_3 Adsorption Methyl is a radical whose unsaturated C atom strongly binds to the metal surface. But in addition to this C–metal bond, methyl also displays a peculiar three-center C–H–metal bond, which is in part responsible for the peculiar behavior mentioned above. The three-center C–H–metal bond is usually referred to as *agostic bond* in organometallic chemistry [12,25,111]. The *agostic* bond results essentially from the hybridization of $1e$ C–H bonding orbitals with the d states of the metal surface [68,78]. *Agostic* bonds occur when the adsorption geometry allows for a small H–metal distance. Consider for example a methyl radical adsorbed at an fcc hollow site with H atoms pointing toward either the nearest hollow sites (no agostic bonds, Fig. 20a) or toward the nearest metal atoms (thus giving rise to agostic bonds, Fig. 20b). The difference between the two adsorption energies is rather large (≈ 0.4 eV); also note that in the latter case, the C–H distance is slightly larger than in the former. This effect is enhanced when going from the (111) facet to the step edge and ad-row: the C–H distance increases, Fig. 20, and more charge is delocalized from the C–H bond toward the Rh atom, Fig. 21. On the other hand, at an ad-atom defect the H–metal distance is quite large, indicating a smaller *agostic* interaction, and consequently explaining the reversed trend of methyl adsorption energy at the ad-atom.

Agostic bonding also stretches and correspondingly weakens the C–H bond [69], thus helping break it, and this may partially explain why the ad-atom reaction center is not so efficient for methyl dehydrogenation.

Analysis of CH_2 Adsorption To explain the reversed trend of methylene adsorption energy at the ad-atom, note that to couple the two unpaired electrons of the methylene diradical, CH_2 has to form (at least) two bonds with the substrate. The local structure of an ad-atom defect, however, is such that this requirement is not easily fulfilled. As passing from a (111) facet to a step edge and an added row, CH_2 binds to progressively less coordinated atoms, however at an ad-atom defect it bridges the ad-atom ($N_C = 3$) to a surface atom underneath ($N_C = 10$). The average coordination number of the two bridged atoms is thus $N_C = 6.5$, close to the value $N_C = 7$ of the step edge. As a result, the adsorption energy of methylene at an ad-atom and at a step edge are very similar: -4.26 and -4.25 eV, respectively (see Fig. 19a).

Structural Analysis of Transition States An analysis of a large number of identified TS structures, not only those on currently considered reaction centers, but also on Ru(0001) [11], Ni(111) [52,70,108], Pd(100) [113], and Pt(110)(1×2) [82] reveals that the TS's display some universal features [49,114], which are evident from Fig. 22, and can be described as:

(i) For both reactions the TS is *late*, i. e., its structure is close to that of the final state: the C–H distance for the detaching H atom at the TS is in the range 1.6–1.7 Å, to be compared with an equilibrium bond length of 1.1 Å.
(ii) The TS of the first dehydrogenation step involves only one metal atom: the CH_3 fragment is located at the top site.
(iii) On the other hand, the TS for the second dehydrogenation step involves two metal atoms: the CH_2 (methylene) fragment is located at the bridge site, while the dissociating H atom is at the top site.

We further notice that although the adsorption energy of H is rather insensitive to the coordination of the metal reaction center (see Fig. 19), this is so only for the best adsorption sites corresponding to each reaction center (hollow or bridge). However, at the TS of the $CH_3 \rightarrow CH_2 + H$, the H atom is located instead close to a top site (see Fig. 22b). The hydrogen adsorption energies on top of a metal atom are also rather similar for the (111) facet, at step edge, and at ad-row (≈ -2.45 eV). However, on top of the ad-atom the adsorption is about 0.2 eV less stable, and this further contributes to the large value of the E^* at an ad-atom defect.

Requirements for Reaction Center The insight obtained on the basis of the analysis presented above, may be used to design new reaction centers, which would enhance the first reaction while hindering the second, by not only acting on the local geometry, but also on the local chemical composition. On the basis of the above analysis the following three requirements should be met [49]:

(i) One of the CH_2–metal bonds should be substantially weakened;
(ii) The strength of the H–metal bond at the top site should be reduced, and
(iii) *Agostic* C–H–metal bonding of CH_3 should be prevented.

Note that *agostic* interactions are small, hence the effect of *agostic* bonding on the reaction barrier can only be small. On the other hand, the CH_2–surface and H–surface bonds are strong, and a large reduction of these bond strengths can affect the reaction barrier substantially. It turns out

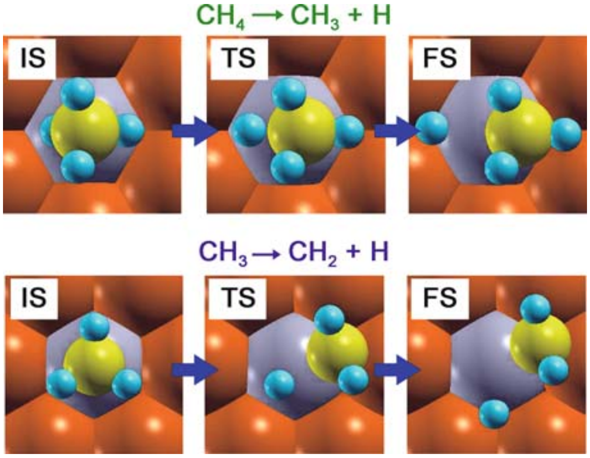
that the above requirements can be fulfilled more or less simultaneously.

Local Chemical Composition of Reaction Site The requirements just outlined, suggest that a proper reaction center should be composed of solely one reactive atom, embedded, for example, in an inert environment (shown schematically in Fig. 22c). Consider, for example, an isolated reactive Rh atom substitutionally embedded into a more inert Cu(111) surface, such as shown in Fig. 23a [49]. This can be seen as a model for a Cu-rich phase of a RhCu alloy. Bulk RhCu alloy shows two phases: a Rh-rich phase (with Cu concentration, $X_{\mathrm{Cu}} \lesssim 0.1$) and a Cu-rich phase (with $X_{\mathrm{Cu}} \gtrsim 0.8$) [63]. However, on the surface the amount of Cu is enriched, e. g., already at a small amount of Cu ($X_{\mathrm{Cu}} > 0.05$) the Cu-rich phase will form on the surface [10].

At this reaction center (Fig. 23a), the CH_2 forms one strong bond with the substitutional Rh atom, while the other bond with a Cu atom is much weaker. In addition, agostic bonding is also prevented. Therefore, it performs much better than the Rh(111): the calculated E^* for the first dehydrogenation step is 0.70 eV, whereas that for the second is as large as 0.84 eV (to be compared with 0.69 and 0.42 eV at the Rh(111), respectively) [49]. Snapshots of the two reactions are shown in Fig. 24. Given that the two reaction barriers on clean Cu(111) are predicted to be 1.7 and 1.5 eV [49], dehydrogenation would selectively occur near the Rh atom.

Tuning the chemical composition of the reaction center therefore substantially increases the barrier for the second dehydrogenation step, but hardly affects the barrier for the first step in the current case. However, by combining the structural effects with the chemical effects just outlined, it is possible to selectively increase the barrier of the second dehydrogenation step, while reducing that of the first. Consider for example a Rh ad-atom adsorbed onto a Cu(111) surface, as shown in Fig. 23b [49]. In this case, the reaction barrier for the first reaction is very small, $E^* = 0.35$ eV, while the barrier for the second reaction is quite large, $E^* = 0.89$ eV [49]. In order to illustrate the effects of the local atomic structure and local chemical composition on the two dehydrogenation steps, the reaction energy profiles at the considered reaction centers are shown in Fig. 25.

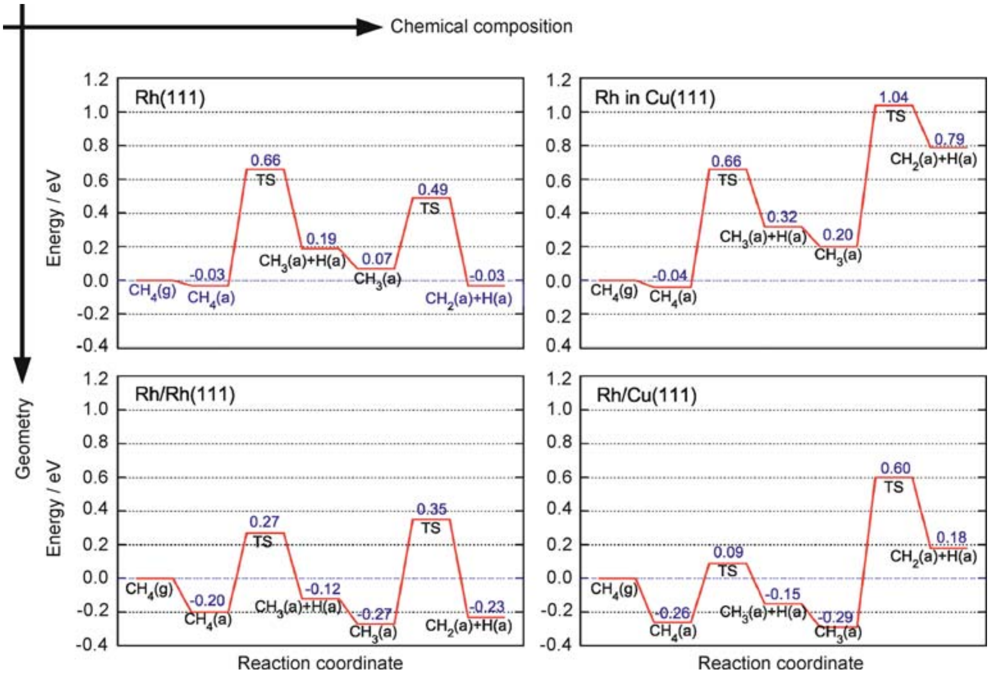


Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 24
Initial- (IS), transition- (TS), and final-state (FS) structures for the first two steps of methane dehydrogenation over the Rh atom substitutionally embedded into Cu(111). Reprinted with permission from [49]

The reaction center based on metal ad-atoms, such as just considered (Fig. 23b), is merely an academic model system, because the naked metal ad-atoms would either cluster or diffuse into the bulk. Nevertheless, the kind of arguments and analysis presented and utilized above are instrumental to the understanding of the mechanisms responsible for the reactivity of reaction centers on real catalysts and to the design and realization of new materials with tailored catalytic properties. As for the ad-atoms, the problem is of course open on how to stabilize them. For example, Zhang and Hu [114] considered isolated Pt ad-atoms on an oxide $MoO_3(010)$ surface, and calculated that the barrier for methane dehydrogenation is significantly lower than that on a Pt(111), while the further dehydrogenation of methyl is blocked.

Improvement of Steam-Reforming Catalyst

Today, the conversion of methane to liquid chemicals is utilized via an in-direct route: in a first step the methane is transformed into a syngas (a mixture of H_2 and CO). Then in the second step the liquid chemicals such as, for exam-



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 25

Reaction profiles for the two dehydrogenation reactions. *Arrows* indicate the improved parameter of the reaction center. The zero level is the energy of the gas phase methane. Difference between the labels "CH$_3$(a)+H(a)" and "CH$_3$(a)" is that for the latter the H(a) diffused to an equivalent site far from CH$_3$(a). Labels Rh in Cu(111), Rh/Rh(111), and Rh/Cu(111) stand for Rh atom substitutionally embedded into Cu(111) (Fig. 23a), Rh ad-atom on Rh(111), and Rh ad-atom on Cu(111) (Fig. 23b), respectively. Reprinted with permission from [49]

ple, methanol are synthesized from syngas. Note, however, that a direct route to methanol synthesis would surpass a very expensive syngas production.

The syngas may be produced via several processes, one of them being the steam reforming:

$$CH_4 + H_2O \rightleftharpoons CO + 3H_2 \quad (\Delta H^0_{298K} = 2.14\,\text{eV}) . \quad (15)$$

The elementary reaction steps can be classified into two groups, and can be written as (omitting adsorption, diffusion, and desorption steps):

(i) dissociation of reactants:

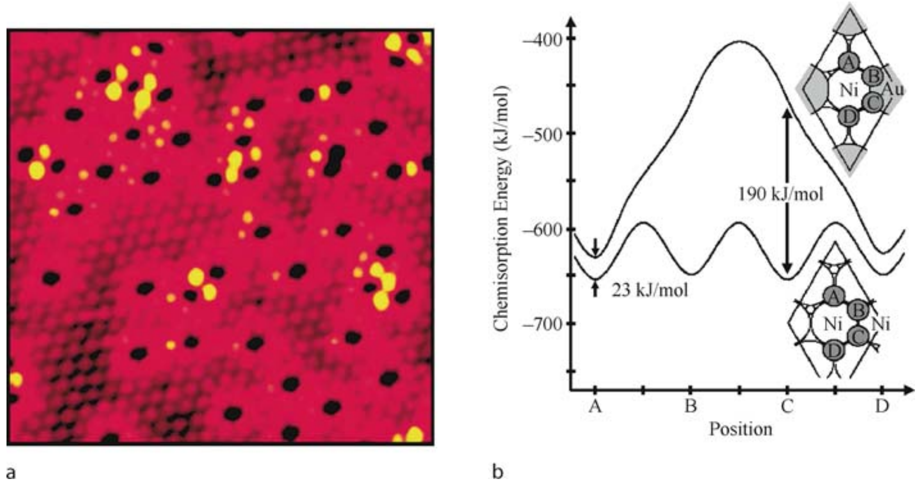
$$\begin{aligned} &1. \quad CH_4 \rightarrow CH_{3(ad)} + H_{(ad)} \\ &2. \quad CH_{3(ad)} \rightarrow CH_{2(ad)} + H_{(ad)} \\ &3. \quad CH_{2(ad)} \rightarrow CH_{(ad)} + H_{(ad)} \\ &4. \quad CH_{(ad)} \rightarrow C_{(ad)} + H_{(ad)} \\ &5. \quad H_2O \rightarrow OH_{(ad)} + H_{(ad)} \\ &6. \quad OH_{(ad)} \rightarrow O_{(ad)} + H_{(ad)} \end{aligned} \qquad (16)$$

(ii) formation of products:

$$\begin{aligned} &1. \quad H_{(ad)} + H_{(ad)} \rightarrow H_2 \\ &2. \quad O_{(ad)} + C_{(ad)} \rightarrow CO \end{aligned} \qquad (17)$$

On the basis of detailed investigation of elementary processes by means of atomistic DFT computer-simulations and surface-science experiments, Besenbacher et al. [2] designed an improved high surface area alloy catalyst for steam-reforming process. The process is obviously limited by the ability of a catalyst to activate hydrocarbon molecules, and its tendency to form an undesired graphite, $C_{(ad)} \rightarrow C_{(s)}$, which poisons the catalysts. As already stated, catalysts are able to break C–H bonds, but in a nonselective manner, which is precisely what is done in steam-reforming, where methane is stripped off all the H atoms, Eqs. (16.1)–(16.4). At this point, two issues are crucial: (i) the surface should prevent naked $C_{(ad)}$ atoms from clustering so as to avoid the graphite growth, and (ii) the $C_{(ad)}$ should not bind too strongly to the surface: recall that the less the $C_{(ad)}$ binds to the surface the easier it will react with chemisorbed $O_{(ad)}$.

A traditional catalyst in steam-reforming is based on Ni as the active element [45]. Kratzer and Besenbacher et al. [2,52] considered adding a small amount of Au into the Ni. The idea is to prevent the $C_{(ad)}$ atoms from clustering. Although the two metals do not form a bulk alloy—they are immiscible in the bulk—they do form an alloy in the



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 26

outermost surface layer, as shown by an STM image in Fig. 26a.

As already discussed in Sect. "Tuning the Relative Rates of Methane Dehydrogenation", the transition states for dehydrogenations are similar on various transition metals, so in the current case they will be similar to those displayed in Fig. 22 for the first two dehydrogenation steps. DFT calculations by Kratzer et al. [52] predicted that the addition of Au into Ni(111) decreases the reactivity toward the C–H bond breaking, in accord with experimental observation [36]. The activation barrier for the first dehydrogenation step increases by 0.17 eV at the reaction center involving one Au atom, and more than twice that for the center with two Au atoms. This is at variance with what was predicted on RhCu alloy [49] (Sect. "Tuning the Relative Rates of Methane Dehydrogenation"), where the barrier for CH_4 dehydrogenation was almost not affected by the presence of Cu. This can be explained by the fact that Ni and Au atoms differ substantially in size, whereas Cu and Rh do not. Addition of "larger" Au impurity onto the Ni layer therefore down-shifts the *d*-band center of Ni thus decreasing its reactivity [52]. Nevertheless, the effect of addition of Au on dehydrogenation is relatively modest compared to the effect it has on naked $C_{(ad)}$ atoms and on formation of graphite. In particular, a Au atom makes all the nearest neighboring hollow sites completely unstable for adsorption of carbon atoms (by almost 2 eV), and also destabilizes by 0.24 eV the second nearest neighbor sites, as shown in Fig. 26b. This has a tremendous consequence: a single Au atom excludes six surface Ni metal atoms from binding with $C_{(ad)}$ (corresponding to six nearest neighbor hollow sites), and additionally makes the next neighboring sites less stable and therefore somewhat more susceptible to CO formation. Therefore, even a small amount of Au prevents the $C_{(ad)}$ atoms from clustering and therefore from graphite being formed.

That actually all works as suggested by DFT calculations, the authors have performed several experiments: (i) they first synthesized a Au/Ni catalyst in a high surface area form on a $MgAl_2O_4$ support, then (ii) they performed a surface structure characterization by means of EXAFS to confirm the Ni and Au actually formed surface alloy, and finally (iii) they measured the steam-reforming activity of a catalyst. They showed that, while the Ni catalyst deactivates rapidly, the activity of the Au/Ni was almost constant under the measured time interval (see Fig. 27) [2].

It is instructive to compare the RhCu model catalyst discussed in Sect. "Tuning the Relative Rates of Methane Dehydrogenation", designed to suppress the dehydrogenation of methyl, to the current NiAu catalyst: the AuNi catalyst consists of individual inert atoms in a reactive substrate, whereas the RhCu model catalyst consists of isolated reactive atoms embedded in an inert (or less reactive) substrate. This is entirely due to the geometric (ensemble) effect: The C atom requires sites composed of a large ensemble of active surface atoms, whereas for the dehydro-

genation of methyl already two reactive neighboring atoms are sufficient.

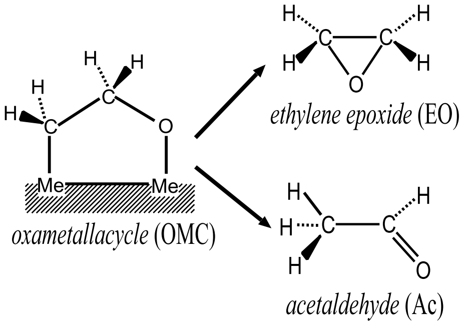
Ethylene Epoxidation

To further illustrate how quantum mechanical simulations help disentangle the mechanisms responsible for the reactivity and selectivity of a catalyst, we consider one more example, the epoxidation of ethylene, which is one of the most important selective oxidation processes based on heterogeneous metallic catalysis [1,53,92,96]. Ethylene epoxide (oxirane) is an important intermediate in the fabrication of glycols and polyols, and silver is a remarkably good catalyst for this reaction with a selectivity at high temperature and high pressure up to 80% in the presence of promoters such as Cl and Cs [53,92,96]. Although a symbolic reaction equation may look as simple as:

$$C_2H_4 + \tfrac{1}{2}O_2 \rightarrow C_2H_4O\,, \tag{18}$$

the elucidation of the reaction mechanism has been a subject of long debate. Its understanding has emerged only recently and was made possible by the synergy between the surface-science experiments and DFT computer simulations. Early studies have mainly focused on the identity of active oxygen species in the reaction and tried to resolve the longstanding question whether molecular or atomic species are the active oxidant [8,21,91]. It has been established only recently that the reaction proceeds via the surface oxametallacycle (OMC) intermediate, which then transforms either to ethylene epoxide (EO) or to acetaldehyde (Ac) [5,42,43,55,56,57,59,67,100,101], the latter reaction leading to undesired total combustion. The overall reaction can be described by the following minimal-sequence of steps:

$$\begin{array}{lr} 1. & O_{2(g)} \rightarrow O_{2(ad)} \\ 2. & O_{2(ad)} \rightarrow 2O_{(ad)} \\ 3. & C_2H_{4(g)} \rightarrow C_2H_{4(ad)} \\ 4. & C_2H_{4(ad)} + O_{(ad)} \rightarrow OMC_{(ad)} \\ 5a. & OMC_{(ad)} \rightarrow EO \\ 5b. & OMC_{(ad)} \rightarrow Ac\,. \end{array} \tag{19}$$



For a more elaborate list of elementary steps see, for example, the work of Stegelmann [101]. For ethylene epoxidation to occur, the catalyst must be reactive enough to dissociate the oxygen molecule [53], but it should be also mild enough so as to form and to stabilize an OMC intermediate, rather than to break C–H bonds, either in the ethylene or in the OMC intermediate [51]. Silver fulfills all these requirements quite well: it is among the most appropriate metals for reactions involving dissociation of oxygen (Sect. "Optimum Chemisorption Energy"), does not activate the C–H bonds [51,92,96] and also binds the OMC weakly to the surface [50,56,64] so that its transformation to EO is facile (as will be shown below). As for dissociation of oxygen, for example, palladium would be also acceptable (Sect. "Optimum Chemisorption Energy"), but at variance with Ag is able to break the C–H bonds [90] (see also Fig. 13b).

Provided that the C–H bond activation is not an issue, the main reaction byproduct involves the formation of Ac [51,56,57]. The Ac molecule is thermodynamically more stable than the EO by about 1 eV. The reason that the EO can be synthesized is because a proper catalyst makes the barrier for its formation smaller or at least comparable to the barrier for Ac formation. The epoxidation of ethylene is therefore an example of a kinetically favored reaction. Linic et al. [56,57] showed that the selectivity of a catalyst is determined by the branching reaction of OMC to form EO rather than the competitive Ac. In particular, at given temperature it would mainly depend on the difference between the Ac and EO activation energies, $\Delta E^* = E^*_{\mathrm{Ac}} - E^*_{\mathrm{EO}}$ (assuming the two corresponding prefactors are similar). The selectivity, S, can be approximately expressed as:

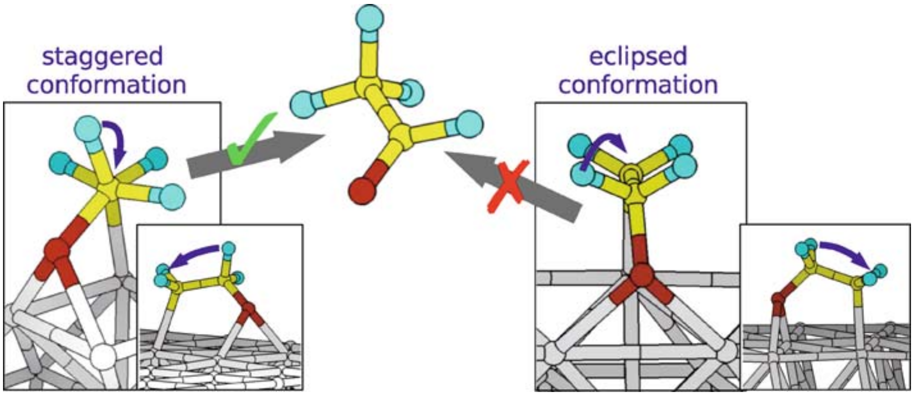
$$S = \frac{r_{\mathrm{EO}}}{r_{\mathrm{EO}} + r_{\mathrm{Ac}}} \approx \frac{\mathrm{e}^{-E^*_{\mathrm{EO}}/kT}}{\mathrm{e}^{-E^*_{\mathrm{EO}}/kT} + \mathrm{e}^{-E^*\mathrm{Ac}/kT}} = \frac{1}{1 + \mathrm{e}^{-\Delta E^*/kT}}, \qquad (20)$$

where r_{EO} and r_{Ac} are the rates of EO and Ac formation, respectively. Therefore, the larger is the ΔE^* the larger is the selectivity. The ability to stabilize the transition state for EO formation with respect to that for Ac formation would therefore lead to increased selectivity.

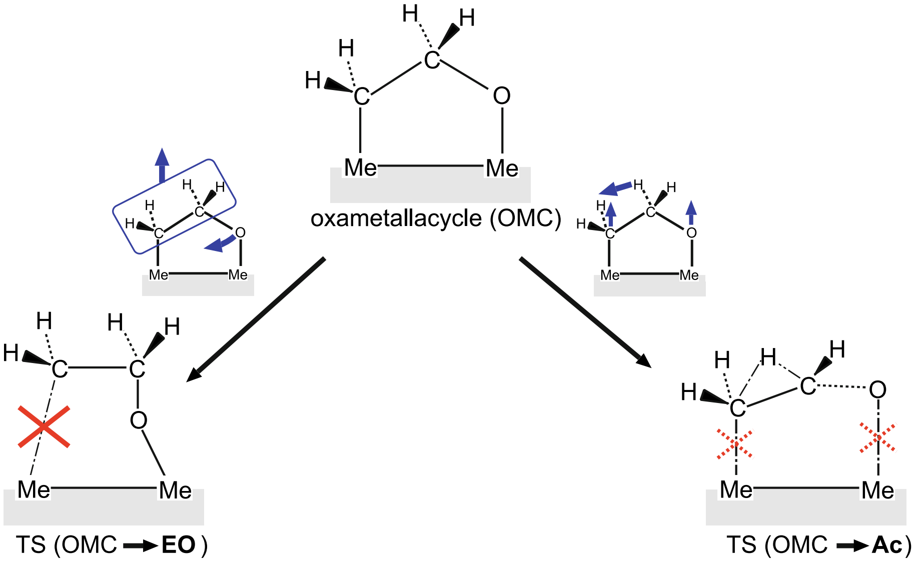
Bocquet et al. [4] realized on the basis of DFT calculations that the selectivity is linked to the conformational arrangement of the OMC intermediate. By considering the trajectories of atoms during the EO and Ac formation and the structure of the two transition states, they suggested that staggered OMC conformation favors the formation of Ac, whereas eclipsed OMC conformation favors the EO formation. This is due to the fact that the Ac formation involves the shift of the H-atom from the first C atom to the second C atom, which is assisted if the two CH_2 groups of the OMC intermediate are in staggered conformation. This is schematically shown in Fig. 28. Hence, if on a given surface both staggered and eclipsed forms exist, the difference between the two activation energies would be related to the relative energy stability of the two conformational OMC forms.

Kokalj et al. [51] provided on the basis of DFT calculations an alternative explanation as to what determines the selectivity. These authors applied the BEP relationship for the EO and Ac formation on a number of different circumstances, including (111) and (100) surfaces of Rh, Cu, Ag, and Au. This analysis revealed that the formation of Ac follows remarkably well the BEP relation, whereas the formation of EO does so to a lesser extent. By knowing that the EO and Ac bind weakly to the surface [51,64], the main message from this BEP analysis was that the stronger is the OMC–surface interaction the larger are the two barriers [51], which demonstrates that for a facile OMC to EO and Ac transformation a less reactive catalyst is required, such as, for example, silver.

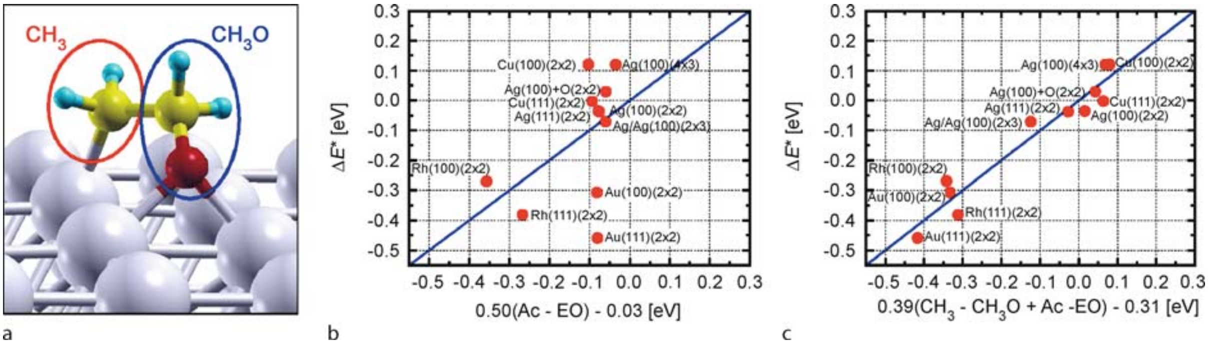
Although an approximate magnitude of the activation barriers for the EO and Ac formation can be determined from the BEP principle, the BEP principle alone is not accurate enough to estimate the selectivity of a catalyst toward the EO formation (see Fig. 30b). The identification of other important factors that determine the catalyst's selectivity toward the formation of EO with respect to Ac formation was made possible by the structural analysis of the TS's for both reactions. Figure 29 schematically depicts the TS's for the EO and Ac formation from OMC on Ag(100). The main difference between the two is that, in TS for EO formation the C–surface bond is fully broken, whereas in TS for Ac formation both C– and O–surface bonds are only partially broken [51]. This may suggest that the two bonds contribute differently to the two activation energies. In particular the stronger is the OMC's O–surface bond with respect to the C–surface bond, the more selective the substrate will be toward EO formation. This argument was quantified by decomposing the OMC–surface interaction into C– and O–surface contributions, which were approximated by the interaction of methyl ($CH_3\cdot$) and methoxy



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 28
The formation of acetaldehyde (Ac) proceeds through the staggered conformation of the two CH_2 groups in oxametallacycle (OMC). Bocquet et al. [4] realized on the basis of DFT calculations that the selectivity in the OMC branching reaction toward either EO or Ac is related to the relative stabilities of eclipsed and staggered conformations of the OMC



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 29
Schematic presentation of an OMC intermediate and transition states for EO (*left*) and Ac (*right*) formation. In the TS leading to EO the C–surface bond is broken, whereas in the TS leading to Ac both C– and O–surface bonds are elongated. During the EO formation the O–atom moves beneath the ethylene fragment, which is concomitantly shifted upward (indicated by *blue arrows*) and as a consequence the C–metal bond is ruptured, whereas in the formation of Ac the whole molecule is upshifted during the 1,2 hydrogen shift, and consequently the C– and O–surface bonds are partially broken. Based on [51]



Computer-Aided Design of the Reaction Site in Heterogeneous Catalysis, Figure 30
a The OMC–surface interaction can be decomposed into C– and O–surface terms, which can be approximated by the CH_3– and CH_3O–surface interaction, respectively. This leads to an indicator embodied in Eq. (21) that predicts the $\Delta E^* = E^*_{Ac} - E^*_{EO}$ remarkably better than the standard BEP relation. b Standard BEP and c indicator of Eq. (21) in predicting the ΔE^*. The rms and the maximum errors are 0.19 and 0.38 eV, respectively. Reprinted from [51]

($CH_3O\cdot$) radicals with the surface, respectively, as shown in Fig. 30a. By combining this observation with the BEP relation and after some trivial algebra, an equation for the ΔE^* was derived. This equation was than fitted to calculated data, and that resulted in the following expression [51]:

$$\Delta E^* \simeq 0.39\left[E^{CH_3}_{ads} - E^{CH_3O}_{ads} + E^{Ac}_{ads} - E^{EO}_{ads}\right] - 0.31\,, \quad (21)$$

where E_{ads} stands for adsorption energy of corresponding species. The quality of the fit given by Eq. (21) is compared to that obtained from the simple BEP relation in Figs. 30b and 30c. The indicator as embodied in Eq. (21) is able to estimate ΔE^* with an accuracy better than 0.1 eV (the rms and maximum errors are 0.05 and 0.07 eV, respectively), and it suggests that ΔE^* is mainly determined by two contributions: (i) *differential bonding affinity* of the catalyst toward the O- and C-atoms of the OMC, and (ii) the difference between the adsorption energies of the two final states, Ac and EO.

Recently, Linic et al. [58] showed on the basis of DFT computational screening, that Cu/Ag alloy should display a greater selectivity toward EO compared to pure

Ag, which was later confirmed by surface science experiments [40,41]. However, no explanation was given of why this is so. This finding can be straightforwardly explained by the model presented above [51]. The reasons are that Cu shows larger bonding affinity toward the O-atom with respect to the C-atom than silver (this also explains why Cu is intrinsically more selective than Ag for OMC transformation into EO [105,106]). Because Cu is also more reactive than Ag, this implies that on diluted $Ag_{1-x}Cu_x$ alloys ($x \ll 1$, assuming no Cu-Cu nearest neighbors), the most stable OMC binds its O-atom to Cu and its C-atom to Ag (for instance, such OMC orientation is preferred by 0.16 eV on Cu/Ag(100)), enhancing the O–metal bond strength and making the C–metal bond "relatively" weaker. According to the *differential bonding affinity* term of Eq. (21), this makes the formation of EO more selective. In particular, on Cu/Ag(100) alloy ΔE^* is larger than on Ag by 0.17 eV, where 0.04 eV is due to BEP contribution, and 0.10 eV is due to *differential bonding affinity* [51].

Future Directions

Electronic structure calculations, such as DFT, have reached the point, where they can provide understanding of the atomic-scale details of the elementary steps and the mechanisms underlying the reactivity of a catalyst toward specific chemical reactions. This knowledge can then be exploited in the search for better catalysts, and surpasses the *traditional* error-and-trial procedure. In particular, applications are emerging, where new materials are screened computationally. Ever increasing computer power will make it possible to screen large numbers of new materials in the future, and this has great potential in the search for new materials with tailored catalytic properties.

Article Outline

Glossary

Computer generated imagery (CGI) The use of computer generated images for special effects purposes in film production.

Intelligent agent A hardware or (more usually) software-based computer system that enjoys the properties autonomy, social ability, reactivity and pro-activeness.

Non-player character (NPC) A computer controlled character in a computer game – as opposed to a player controlled character.

Virtual character A computer generated character that populates a virtual world.

Virtual world A computer generated world in which places, objects and people are represented as graphical (typically three dimensional) models.

Definition of the Subject

As the graphics technology used to create virtual worlds has improved in recent years, more and more importance has been placed on the behavior of virtual characters in applications such as games, movies and simulations set in these virtual worlds simulations. The behavior of these virtual characters should be believable in order to create the illusion that virtual worlds are populated with living characters. This has led to the application of agent-based modeling to the control of virtual characters. There are a number of advantages of using agent-based modeling techniques which include the fact that they remove the requirement for hand controlling all agents in a virtual environment, and allow agents in games to respond to unexpected actions by players or users.

Introduction

Advances in computer graphics technology in recent years have allowed the creation of realistic and believable virtual worlds. However, as such virtual worlds have been developed for applications spanning games, education and movies it has become apparent that in order to achieve real believability, virtual worlds must be populated with life-like virtual characters. This is where the application of agent-based modeling has found a niche in the areas of computer graphics and, in a huge way, computer games. Agent-based modeling is a perfect solution to the problem of controlling the behaviors of the virtual characters that populate a virtual world. In fact, because virtual characters are embodied and autonomous these applications require an even stronger notion of agency than many other areas in which agent-based modeling is employed.

Before proceeding any further, and because there are so many competing alternatives, it is worth explicitly stating the definition of an intelligent agent that will inform the remainder of this article. Taken from [83] an intelligent agent is defined as "… *a hardware or (more usually) software-based computer system that enjoys the following properties:*

- ***autonomy:*** *agents operate without the direct intervention of humans or others, and have some kind of control over their actions and internal state;*
- ***social ability:*** *agents interact with other agents (and possibly humans) via some kind of agent-communication language;*
- ***reactivity:*** *agents perceive their environment, (which may be the physical world, a user via a graphical user interface, a collection of other agents, the INTERNET, or*

perhaps all of these combined), and respond in a timely fashion to changes that occur in it;

- ***pro-activeness:*** *agents do not simply act in response to their environment, they are able to exhibit goal-directed behavior by taking the initiative."*

Virtual characters implemented using agent-based modeling techniques satisfy all of these properties. The characters that populate virtual worlds should be fully autonomous and drive their own behaviors (albeit sometimes following the orders of a director or player). Virtual characters should be able to interact believably with other characters and human participants. This property is particularly strong in the case of virtual characters used in games which by their nature are particularly interactive. It is also imperative that virtual characters appear to perceive their environments and react to events that occur in that environment, especially the actions of other characters or human participants. Finally virtual characters should be pro-active in their behaviors and not always require prompting from a human participant in order to take action.

The remainder of this article will proceed as follows. Firstly, a broad overview of the use of agent-based modeling in computer graphics will be given, focusing in particular on the genesis of the field. Following on from this, the focus will switch to the use of agent-based modeling techniques in two particular application areas: computer generated imagery (CGI) for movies, and computer games. CGI has been used to astounding effect in movies for decades, and in recent times has become heavily reliant on agent-based modeling techniques in order to generate CGI scenes containing large numbers of computer generated extras. Computer games developers have also been using agent-based modeling techniques effectively for some time now for the control of non-player characters (NPCs) in games. There is a particularly fine match between the requirements of computer games and agent-based modeling due to the high levels of interactivity required.

Finally, the article will conclude with some suggestions for the future directions in which agent-based modeling technology in computer graphics and games is expected to move.

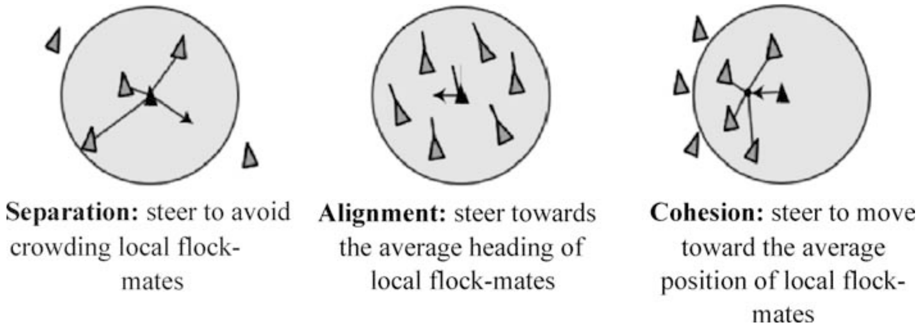
Agent-Based Modelling in Computer Graphics

The serious use of agent-based modeling in computer graphics first arose in the creation of autonomous groups and crowds – for example, crowds of people in a town square or hotel foyer, or flocks of birds in an outdoor scene. While initially this work was driven by visually unappealing simulation applications such as fire safety testing for buildings [75], focus soon turned to the creation of visually realistic and believable crowds for applications such as movies, games and architectural walkthroughs. Computer graphics researchers realized that creating scenes featuring large virtual crowds by hand (a task that was becoming important for the applications already mentioned) was laborious and time-consuming and that agent-based modeling techniques could remove some of the animator's burden. Rather than requiring that animators hand-craft all of the movements of a crowd, agent-based systems could be created in which each character in a crowd (or flock, or swarm) could drive its own behavior. In this way the behavior of a crowd would emerge from the individual actions of the members of that crowd.

Two of the earliest, and seminal, examples of such systems are Craig Reynolds' Boids system [64] and Tu & Terzopoulos' animations of virtual fish [76]. The Boids system simulates the flocking behaviors exhibited in nature by schools of fish, or flocks of birds. The system was first presented at the prestigious SIGGRAPH conference (www.siggraph.org) in 1987 and was accompanied by the short movie "Stanley and Stella in: Breaking the Ice". Taking influence from the area of artificial life (or aLife) [52], Reynolds postulated that the individual members of a flock would not be capable of complex reasoning, and so flocking behavior must emerge from simple decisions made by individual flock members. This notion of emergent behavior is one of the key characteristics of aLife systems.

In the original Boids system, each virtual agent (represented as a simple particle and known as a *boid*) used just three rules to control its movement. These were separation, alignment and cohesion and are illustrated in Fig. 1. Based on just these three simple rules extremely realistic flocking behaviors emerged. This freed animators from the laborious task of hand-scripting the behavior of each creature within the flock and perfectly demonstrates the advantage offered by agent-based modeling techniques for this kind of application.

The system created by Tu and Terzopoulos took a more complex approach in that they created complex models of biological fish. Their models took into account fish physiology, with a complex model of fish muscular structure, along with a perceptual model of fish vision. Using these they created sophisticated simulations in which properties such as schooling and predator avoidance were displayed. The advantage of this approach was that it was possible to create unique, unscripted, realistic simulations without the intervention of human animators. Terzopoulos has since gone on to apply similar techniques to the control of virtual humans [68].



Separation: steer to avoid crowding local flock-mates

Alignment: steer towards the average heading of local flock-mates

Cohesion: steer to move toward the average position of local flock-mates

Computer Graphics and Games, Agent Based Modeling in, Figure 1
The three rules used by Reynolds' original Boids system to simulate flocking behaviors

Moving from animals to crowds of virtual humans, the Virtual Reality Lab at the Ecole Polytechnique Fédérale de Lausanne in Switzerland (vrlab.epfl.ch) led by Daniel Thalmann has been at the forefront of this work for many years. They group currently has a highly evolved system, VICrowd, for the animation of virtual crowds [62] which they model as a hierarchy which moves from individuals to groups to crowds. This hierarchy is used to avoid some of the complications which arise from trying to model large crowds in real time – one of the key gaols of ViCrowd.

Each of the levels in the ViCrowd hierarchy can be modeled as an agent and this is done based on *beliefs*, *desires* and *intentions*. The beliefs of an agent represent the information that the agent possesses about the world, including information about places, objects and other agents. An agent's desires represent the motivations of the agent regarding objectives it would like to achieve. Finally, the intentions of an agent represent the actions that an agent has chosen to pursue. The belief-desire-intention (BDI) model of agency was proposed by Rao and Georgeff [61] and has been used in many other application areas of agent-based modeling.

ViCrowd has been used in ambitious applications including the simulation of a virtual city comprised of, amongst other things, a train station a park and a theater [22]. In all of these environments the system was capable of driving the believable behaviors of large groups of characters in real-time.

It should be apparent to readers from the examples given thus far that the use of agent-based modeling techniques to control virtual characters gives rise to a range of unique requirements when compared to the use of agent based modeling in other application areas. The key to understanding these is to realize that the goal in designing agents for the control of virtual characters is typically not to design the most efficient or effective agent, but rather to design the most interesting or believable character. Outside of very practical applications such as evacuation simulations, when creating virtual characters, designers are concerned with maintaining what Disney, experts in this field, refer to as the *illusion of life* [36].

This refers to the fact that the user of a system must believe that virtual characters are living, breathing creatures with goals, beliefs, desires, and, essentially, lives of their own. Thus, it is not so important for a virtual human to always choose the most efficient or cost effective option available to it, but rather to always choose reasonable actions and respond realistically to the success or failure of these actions. With this in mind, and following a similar discussion given in [32], some of the foremost researchers in virtual character research have the following to say about the requirements of agents as virtual characters.

Loyall writes [46] that "*Believable agents are personality-rich autonomous agents with the powerful properties of characters from the arts.*" Coming from a dramatic background it is not surprising that Loyall's requirements reflect this. Agents should have strong personality and be capable of showing emotion and engaging in meaningful social relationships.

According to Blumberg [11], "*… an autonomous animated creature is an animated object capable of goal-directed and time-varying behavior*". The work of Blumberg and his group is very much concerned with virtual creatures, rather than humans in particular, and his requirements reflect this. Creatures must appear to make choices which improve their situation and display sophisticated and individualistic movements.

Hayes–Roth and Doyle focus on the differences between "*animate characters*" and traditional agents [27]. With this in mind they indicate that agents' behaviors must be "*variable rather than reliable*", "*idiosyncratic instead of predictable*", "*appropriate rather than correct*", "*effective instead of complete*", "*interesting rather than effi-*

cient", and "*distinctively individual as opposed to optimal*".

Perlin and Goldberg [59] concern themselves with building believable characters "*that respond to users and to each other in real-time, with consistent personalities, properly changing moods and without mechanical repetition, while always maintaining an author's goals and intentions*".

Finally, in characterizing believable agents, Bates [7] is quite forgiving requiring "*only that they not be clearly stupid or unreal*". Such broad, shallow agents must "*exhibit some signs of internal goals, reactivity, emotion, natural language ability, and knowledge of agents … as well as of the … micro-world*".

Considering these definitions, Isbister and Doyle [32] identify the fact that the consistent themes which run through all of the requirements given above match the general goals of agency – virtual humans must display autonomy, reactivity, goal driven behavior and social ability – and again support the use of agent-based modeling to drive the behavior of virtual characters.

The Spectrum of Agents

The differences between the systems mentioned in the previous discussion are captured particularly well on the *spectrum of agents* presented by Aylett and Luck [5]. This positions agent systems on a spectrum based on their capabilities, and serves as a useful tool in differentiating between the various systems available. One end of this spectrum focuses on *physical agents* which are mainly concerned with simulation of believable physical behavior, (including sophisticated physiological models of muscle and skeleton systems), and of sensory systems. Interesting work at this end of the spectrum includes Terzopoulos' highly realistic simulation of fish [76] and his virtual stuntman project [21] which creates virtual actors capable of realistically synthesizing a broad repertoire of lifelike motor skills.

Cognitive agents inhabit the other end of the agent spectrum and are mainly concerned with issues such as reasoning, decision making, planning and learning. Systems at this end of the spectrum include Funge's cognitive modeling approach [26] which uses the situation calculus to control the behavior of virtual characters, and Nareyek's work on planning agents for simulation [55], both of which will be described later in this article.

While the systems mentioned so far sit comfortably at either end of the agent spectrum, many of the most effective inhabit the middle ground. Amongst these are *c*4 [13], used to great effect to simulate a virtual sheep dog with the ability to learn new behaviors, *Improv* [59] which augments sophisticated physical human animation with scripted behaviors and the *ViCrowd* system [62] which sits on top of a realistic virtual human animation system and uses planning to control agents' behavior.

Virtual Fidelity

The fact that so many different agent-based modeling systems, for the control of virtual humans exist gives rise to the question why? The answer to this lies in the notion of *virtual fidelity*, as described by Badler [6]. Virtual fidelity refers to the fact that virtual reality systems need only remain true to actual reality in so much as this is required by, and improves, the system.

In [47] the point is illustrated extremely effectively. The article explains that when game designers are architecting the environments in which games are set, the scale to which these environments are created is not kept true to reality. Rather, to ease players' movement in these worlds, areas are designed to a much larger scale, compared to character sizes, than in the real world. However, game players do not notice this digression from reality, and in fact have a negative response to environments that are designed to be more true to life finding them cramped. This is a perfect example of how, although designers stay true to reality for many aspects of environment design, the particular blend of virtual fidelity required by an application can dictate certain real world restrictions can be ignored in virtual worlds.

With regard to virtual characters, virtual fidelity dictates that the set of capabilities which these characters should display is determined by the application which they are to inhabit. So, the requirements of an agent-based modeling system for CGI in movies would be very different to those of a agent-based modeling system for controlling the behaviors of game characters.

Agent-Based Modelling in CGI for Movies

With the success of agent-based modeling techniques in graphics firmly established there was something of a search for application areas to which they could be applied. Fortunately, the success of agent-based modeling techniques in computer graphics was paralleled with an increase in the use of CGI in the movie industry, which offered the perfect opportunity. In many cases CGI techniques were being used to replace traditional methods for creating expensive, or difficult to film scenes. In particular, scenes involving large numbers of people or animals were deemed no longer financially viable when set in the real world. Creating these scenes using CGI involved painstaking hand animation of each character within a scene, which again was not financially viable.

The solution that agent-based modeling offers is to make each character within a scene an intelligent agent that drives its own behavior. In this way, as long as the initial situation is set up correctly scenes will play out without the intervention of animators. The facts that animating for movies does not need to be performed in real-time, and is in no way interactive (there are no human users involved in the scene), make the use of agent-based modeling a particularly fine match for this application area.

Craig Reynolds' Boids system [64] which simulates the flocking behaviors exhibited in nature by schools of fish, or flocks of birds and was discussed previously is one of the seminal examples of agent-based modeling techniques being used in movie CGI. Reynold's approach was first used for CGI in the 1999 film "Batman Returns" [14] to simulate colonies of bats. Reynold's technologies have been used in "The Lion King" [4] and "From Dusk 'Till Dawn" [65] amongst other films. Reynolds' approach was so successful, in fact, that he was awarded an Academy Award for his work in 1998.

Similar techniques to those utilized in the Boids system have been used in many other films to animate such diverse characters as ants, people and stampeding wildebeest. Two productions which were released in the same year, "Antz" [17] by Dreamworks and "A Bug's Life" [44] by Pixar took great steps in using CGI effects to animate large crowds for. For "Antz" systems were developed which allowed animators easily create scenes containing large numbers of virtual characters modeling each as an intelligent agent capable of obstacle avoidance, flocking and other behaviors. Similarly, the creators of "A Bug's Life" created tools which allowed animators easily combine pre-defined motions (known as alibis) to create behaviors which could easily be applied to individual agents in scenes composed of hundreds of virtual characters.

However, the largest jump in the use of agent-based modeling in movie CGI was made in the recent Lord of the Rings trilogy [33,34,35]. In these films the bar was raised markedly in terms of the sophistication of the virtual characters displayed and the sheer number of characters populating each scene. To achieve the special effects shots required by the makers of these films, the Massive software system was developed by Massive Software (www.massivesoftware.com). This system [2,39] uses agent-based modeling techniques, again inspired by aLife, to create virtual extras that control their own behaviors. This system was put to particularly good use in the large scale battle sequences that feature in all three of the Lord of the Rings films. Some of the sequences in the final film of the trilogy, the Return of the King, contain over 200,000 digital characters.

In order to create a large battle scene using the Massive software, each virtual extra is represented as an intelligent agent, making its own decisions about which actions it will perform based on its perceptions of the world around it. Agent control is achieved through the use of fuzzy logic based controllers in which the state of an agent's brain is represented as a series of motivations, and knowledge it has about the world – such as the state of the terrain it finds itself on, what kinds of other agents are around it and what these other agents are doing. This knowledge about the world is perceived through simple simulated visual, auditory and tactile senses. Based on the information they perceive agents decide on a best course of action. Designing the brains of these agents is made easier that it might seem at first by the fact that agents are developed for short sequences, and so a small range of possible tasks. So for example, separate agent models would be used for a fighting scene and a celebration scene.

In order to create a large crowd scene using Massive animators initially set up an environment populating it with an appropriate cast of virtual characters where the brains of each character are slight variations (based on physical and personality attributes) of a small number of archetypes. The scene will then play itself out with each character making it's own decisions. Therefore there is no need for any hand animation of virtual characters. However, directors can view the created scenes and by tweaking the parameters of the brains of the virtual characters have a scene play out in the exact way that they require.

Since being used to such impressive effect in the Lord of the Rings trilogy (the developers of the Massive system were awarded an academy award for their work), the Massive software system has been used in numerous other films such as "I, Robot" [60], "The Chronicles of Narnia: The Lion, the Witch and the Wardrobe" [1] and "Ratatouille" [10] along with numerous television commercials and music videos.

While the achievements of using agent-based modeling for movie CGI are extremely impressive, it is worth noting that none of these systems run in real-time. Rather, scenes are rendered by banks of high powered computers, a process that can take hours for relatively simple scenes. For example, the famous Prologue battle sequence in the "Lord of the Rings: The Fellowship of the Ring" took a week to render. When agent-based modeling is applied to the real-time world of computer games, things are very different.

Agent-Based Modelling in Games

Even more so than in movies, agent-based modeling techniques have been used to drive the behaviors of virtual characters in computer games. As games have become graphically more realistic (and in recent years they have become extremely so) game-players have come to expect that games are set in hugely realistic and believable virtual worlds. This is particularly evident in the widespread use of realistic physics modeling which is now commonplace in games [67]. In games that make strong use of physics modeling, objects in the game world topple over when pushed, float realistically when dropped in water and generally respond as one would expect them to. Players expect the same to be true of the virtual characters that populate virtual game worlds. This can be best achieved by modeling virtual characters as embodied virtual agents. However, there are a number of constraints which have a major influence on the use of agent-based modeling techniques in games.

The first of these constraints stems from the fact that modern games are so highly interactive. Players expect to be able to interact with all of the characters they encounter within a game world. These interactions can be as simple as having something to shoot at or having someone to race against; or involve much more sophisticated interactions in which a player is expected to converse with a virtual character to find out specific information or to cooperate with a virtual character in order to accomplish some task that is key to the plot of a game. Interactivity raises a massive challenge for practitioners as there is very little restriction in terms of what the player might do. Virtual characters should respond in a believable way at all times regardless of how bizarre and unexpected the actions of the player might be.

The second challenge comes from the fact that the vast majority of video games should run in real time. This means that the computational complexity must be kept to a reasonable level as there are only a finite number of processor cycles available for AI processing. This problem is magnified by the fact that an enormous amount of CPU power it usually dedicated to graphics processing. When compared to the techniques that can be used for controlling virtual characters in films some of the techniques used in games are rudimentary due to this real-time constraint.

Finally, modern games resemble films in the fact that creators go to great lengths to include intricate storylines and control the building of tension in much the way that film script writers do. This means that games are tested heavily in order to ensure that the game proceeds smoothly and that the level of difficulty is finely tuned so as to always hold the interest of a player. In fact, this testing of games has become something of a science in itself [77]. Using autonomous agents gives game characters the ability to do things that are unexpected by the game designers and so upset their well laid plans. This can often be a barrier to the use of sophisticated techniques such as learning.

Unfortunately there is also a barrier to the discussion of agent-based modeling techniques used in commercial games. Because of the very competitive nature of the games industry, game development houses often consider the details of how their games work as valuable trade secrets to be kept well guarded. This can make it difficult to uncover the details of how particularly interesting features of a game are implemented. While this situation is improving – more commercial game developers are speaking at games conferences about how their games are developed and the release of game systems development kits for the development of game modifications (or *mods*) allows researchers to plumb the depths of game code – it is still often impossible to find out the implementation details of very new games.

Game Genres

Before discussing the use of agent-based modeling in games any further, it is worth making a short clarification on the kinds of computer games that this article refers to. When discussing modern computer games, or video games, this article does not refer to computer implementations of traditional games such as chess, backgammon or card games such as solitaire. Although these games are of considerable research interest (chess in particular has been the subject of extremely successful research [23]) they are typically not approached using agent-based modeling techniques. Typically, artificial intelligence approaches to games such as these rely largely on sophisticated searching techniques which allow the computer player to search through a multitude of possible future situations dictated by the moves it will make and the moves it expects its opponent to make in response. Based on this search, and some clever heuristics that indicate what constitutes a good game position for the computer player, the best sequence of moves can be chosen. This searching technique relies on the fact that there are usually a relatively small number of moves that a player can make at any one time in a game. However, the fact that the ancient Chinese game of Go-Moku has not, to date, been mastered by computer players [80] illustrates the restrictions of such techniques.

The common thread linking together the kinds of games that this article focuses on is that they all contain computer controlled virtual characters that possess

Computer Graphics and Games, Agent Based Modeling in, Figure 2
A screenshot of the upcoming action game Rogue Warrior from Bethesda Softworks (image courtesy of Bethesda Softworks)

a strong notion of agency. Efforts are often made to separate the many different kinds of modern video games that are the focus of this article into a small set of descriptive genres. Unfortunately, much like in music, film and literature, no categorization can hope to perfectly capture the nuances of all of the available titles. However, a brief mention of some of the more important game genres is worth while (a more detailed description of game genres, and artificial intelligence requirements of each is given in [41]).

The most popular game genre is without doubt the *action game* in which the player must defeat waves of demented foes, typically (for increasingly bizarre motivations) bent upon global destruction. Illustrative examples of the genre include *Half-Life 2* (www.half-life2.com) and the *Halo* series (www.halo3.com). A screenshot of the upcoming action game *Rogue Warrior* (www.bethsoft.com) is shown in Fig. 2.

Strategy games allow players to control large armies in battle with other people, or computer controlled opponents. Players do not have direct control over their armies, but rather issue orders which are carried out by agent-based artificial soldiers. Well regarded examples of the genre include the *Age of Empires* (www.ageofempires.com) and *Command & Conquer* (www.commandandconquer.com) series.

Role playing games (such as the *Elder Scrolls* (www.elderscrolls.com) series) place game players in expansive virtual worlds across which they must embark on fantastical quests which typically involve a mixture of solving puzzles, fighting opponents and interacting with non-player characters in order to gain information. Figure 3 shows a screenshot of the aforementioned role-playing game *The Elder Scrolls IV: Oblivion*.

Almost every sport imaginable has at this stage been turned into a computer based *sports game*. The challenges in developing these games are creating computer controlled opponents and team mates that play the games at a level suitable to the human player. Interesting examples include *FIFA Soccer 08* (www.fifa08.ea.com) and *Forza Motorsport 2* (www.forzamotorsport.net).

Finally, many people expected that the rise of massively multi-player online games (MMOGs), in which hundreds of human players can play together in an online world, would sound the death knell for the use of virtual non-player characters in games. Examples of MMOGs include *World of Warcraft* (www.worldofwarcraft.com) and *Battlefield 2142* (www.battlefield.ea.com). However, this has not turned out to be the case as there are still large numbers of single player games being produced and even MMOGs need computer controlled characters for roles that players do not wish to play.

Of course there are many games that simply do not fit into any of these categorizations, but that are still relevant for a discussion of the use of agent-based techniques – for example *The Sims* (www.thesims.ea.com) and the *Microsoft Flight Simulator* series (www.microsoft.com/games/flightsimulatorx). However the categorization still serves to introduce those unfamiliar with the subject to the kinds of games up for discussion.

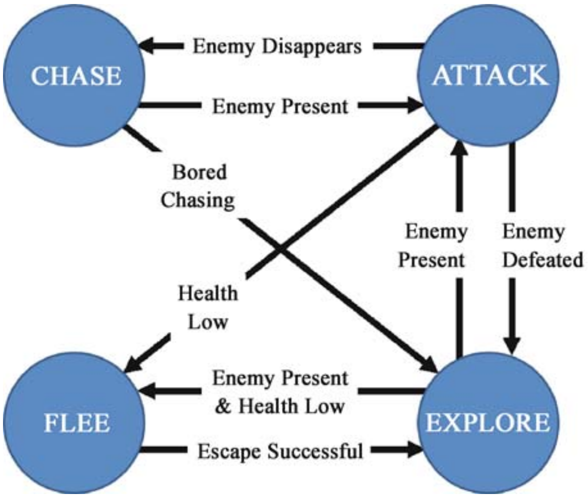
Implementing Agent-Based Modelling Techniques in Games

One of the earliest examples of using agent-based modeling techniques in video games was its application to path planning. The ability of non-player characters (NPCs) to manoeuvre around a game world is one of the most basic competencies required in games. While in very early games it was sufficient to have NPCs move along prescripted paths, this soon become unacceptable. Games programmers soon began to turn to AI techniques which might be applied to solve some of the problems that were arising. The A* path planning algorithm [74] was the first example of such a technique to find wide-spread use in the games industry. Using the A* algorithm NPCs can be given the ability to find their own way around an environment. This was put to particularly fine effect early on in real-time strategy games where the units controlled by players are semi-autonomous and are given orders rather than directly controlled. In order to use the A* algorithm a game world must be divided into a series of cells each of which is given a rating in terms of the effort that must be expended to cross it. The A* algorithm then performs a search across these cells in order to find the shortest path that will take a game agent from a start position to a goal.

Since becoming widely understood amongst the game development community many interesting additions have been made to the basic A* algorithm. It was not long before three dimensional versions of the algorithm became commonly used [71]. The basic notion of storing the energy required to cross a cell within a game world has also been extended to augment cells with a wide range of other useful information (such as the level of danger in crossing a cell) that can be used in the search process [63].

The next advance in the kind of techniques being used to achieve agent-based modeling in games was the finite state machine (FSM) [30]. An FSM is a simple system in which a finite number of *states* are connected in a directed graph by *transitions* between these states. When used for the control of NPCs, the nodes of an FSM indicate the possible actions within a game world that an agent can perform. Transitions indicate how changes in the state of the game world or the character's own attributes (such as health, tiredness etc) can move the agent from one state to another.

Figure 4 shows a sample FSM for the control of an NPC in a typical action game. In this example the behaviors of the character are determined by just four states – CHASE, ATTACK, FLEE and EXPLORE. Each of these states provides an action that the agent should take. For exam-



Computer Graphics and Games, Agent Based Modeling in, Figure 4

A simple finite state machine for a soldier NPC in an action game

ple, when in the EXPLORE state the character should wander randomly around the world, or while in the FLEE state the character should determine a direction to move in that will take it away from its current enemy and move in that direction. The links between the states show how the behaviors of the character should move between the various available states. So, for example, if while in the ATTACK state the agent's health measure becomes low, they will move to the FLEE state and run away from their enemy.

FSMs are widely used because they are so simple, well understood and extremely efficient both in terms of processing cycles required and memory usage. There have also been a number of highly successful augmentations to the basic state machine model to make them more effective, such as the introduction of layers of parallel state machines [3], the use of fuzzy logic in finite state machines [19] and the implementation of cooperative group behaviors through state machines [72].

The action game *Halo 2* is recognized as having a particularly good implementation of state machine based NPC control [79]. At any time an agent could be in any one of the four states *Idle*, *Guard/Patrol*, *Attack/Defend*, and *Retreat*. Within each of these states a set of rules was used in order to select from a small set of appropriate actions for that state – for example a number of different ways to attack the player. The decisions made by NPCs were influenced by a number of character attributes including strength, speed and cowardliness. Transition between states was triggered by perceptions made by characters simulated senses of vision and hearing and by internal attributes such as health. The system implemented also allowed for group behaviors allowing NPCs to hold conversations and cooperate to drive vehicles.

However, FSMs are not without their drawbacks. When designing FSMs developers must envisage every possible situation that might confront an NPC over the course of a game. While this is quite possible for many games, if NPCs are required to move between many different situations this task can become overwhelming. Similarly, as more and more states are added to an FSM designing the links between these states can become a mammoth undertaking.

From [31] the definition of rule based systems states that they are "*… comprised of a database of associated rules. Rules are conditional program statements with consequent actions that are performed if the specified conditions are satisfied*". Rule based systems have been applied extensively to control NPCs in games [16], in particular for the control of NPCs in role-playing games. NPCs behaviors are scripted using a set of rules which typically indicate how an NPC should respond to particular events within the game world. Borrowed from [82], the listing below shows a snippet of the rules used to control a warrior character in the RPG *Baldur's Gate* (www.bioware.com).

```
IF
  // If my nearest enemy is not within 3
  !Range(NearestEnemyOf(Myself),3)
  // and is within 8
  Range(NearestEnemyOf(Myself),8)
THEN
  // 1/3 of the time
  RESPONSE #40
    // Equip my best melee weapon

The implementation of an NPC using a rule-based system would consist of a large set of such rules, a small set of which would fire based on the conditions in the world at any given time. Rule based systems are favored by game developers as they are relatively simple to use and can be exhaustively tested. Rule based systems also have the advantage that rule sets can be written using simple proprietary scripting systems [9], rather than full programming languages, making them easy to implement. Development companies have also gone so far as to make these scripting languages available to the general public, enabling them to author there own rule sets.

Rule based systems, however, are not without their drawbacks. Authoring extensive rule sets is not a trivial task, and they are usually restricted to simple situations. Also, rule based systems can be restrictive in that they don't allow sophisticated interplay between NPCs motivations, and require that rule set authors foresee every situation that the NPC might find itself in.

Some of the disadvantages of simple rule based systems can be alleviated by using more sophisticated inference engines. One example uses Dempster Schafer theory [43] which allows rules to be evaluated by combining multiple sources of (often incomplete) evidence to determine actions. This goes some way towards supporting the use of rule based systems in situations where complete knowledge is not available.

ALife techniques have also been applied extensively in the control of game NPCs, as much as a philosophy as any particular techniques. The outstanding example of this is *The Sims* (thesims.ea.com) a surprise hit of 2000 which has gone on to become the best selling PC game of all time. Created by games guru Will Wright the Sims puts the player in control of the lives of a virtual family in their virtual home. Inspired by aLife, the characters in the game have a set of motivations, such as hunger, fatigue and boredom and seek out items within the game world that can satisfy these desires. Virtual characters also develop sophisticated social relationships with each other based on common interest, attraction and the amount of time spent together. The original system in the Sims has gone on to be improved in the sequel *The Sims 2* and a series of expansion packs.

Some of the more interesting work in developing techniques for the control of game characters (particularly in action games) has been focused on developing interesting sensing and memory models for game characters. Players expect when playing action games that computer controlled opponents should suffer from the same problems that players do when perceiving the world. So, for example, computer controlled characters should not be able to see through walls or from one floor to the next. Similarly, though, players expect computer controlled characters to be capable of perceiving events that occur in a world and so NPCs should respond appropriately to sound events or on seeing the player.

One particularly fine example of a sensing model was in the game *Thief: The Dark Project* where players are required to sneak around an environment without alerting guards to their presence [45]. The developers produced a relatively sophisticated sensing model that was used by non-player characters which modeled visual effects such as not being able to see the player if they were in shadows, and moving some way towards modeling acoustics so that non-player characters could respond reasonably to sound events.

2004's *Fable* (fable.lionhead.com) took the idea of adding memory to a game to new heights. In this adventure game the player took on the role of a hero from boyhood to manhood. However, every action the player took had an impact on the way in which the game world's population would react to him or her as they would remember every action the next time they met the player. This notion of long-term consequences added an extra layer of believability to the game-playing experience.

Serious Games & Academia

It will probably have become apparent to most readers of the previous section that much of the work done in implementing agent-based techniques for the control of NPCs in commercial games is relatively simplistic when compared to the application of these techniques in other areas of more academic focus, such as robotics [54]. The reasons for this have been discussed already and briefly relate to the lack of available processing resources and the requirements of commercial quality control. However, a large amount of very interesting work is taking place in the application of agent-based technologies in academic research, and in particular the field of serious games. This section will begin by introducing the area of serious games and then go on to discuss interesting academic projects looking at agent-based technologies in games.

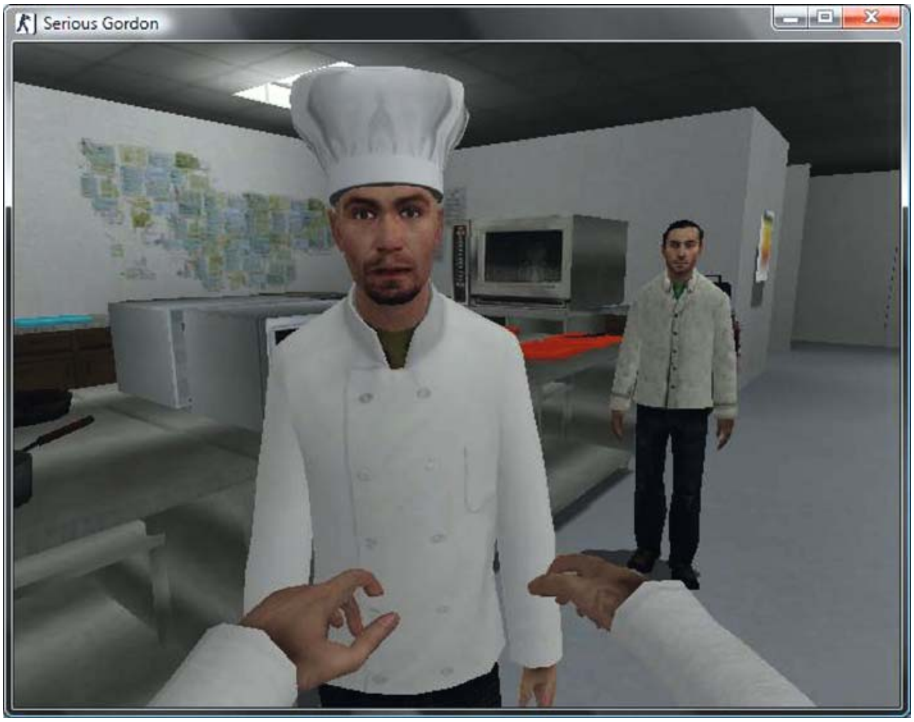
The term serious games [53] refers to games designed to do more than just entertain. Rather, serious games, while having many features in common with conventional games, have ulterior motives such as teaching, training, and marketing. Although games have been used for ends apart from entertainment, in particular education, for a long time, the modern serious games movement is set apart from these by the level of sophistication of the games it creates. The current generation of serious games is comparable with main-stream games in terms of the quality of production and sophistication of their design. Serious games offer particularly interesting opportunities for the use of agent-based modeling techniques due to the facts that they often do not have to live up to the rigorous testing of commercial games, can have the requirement of specialized hardware rather than being restricted to commercial games hardware and often, by the nature of their application domains, require more in-depth interactions between players and NPCs.

The modern serious games movement can be said to have begun with the release of *America's Army* (www.americasarmy.com) in 2002 [57]. Inspired by the realism of commercial games such as the *Rainbow 6* series (www.rainbow6.com), the United States military developed America's Army and released it free of charge in order to give potential recruits a flavor of army life. The game was hugely successful and is still being used today as both a recruitment tool and as an internal army training tool.

Spurred on by the success of America's Army the serious games movement began to grow, particularly within academia. A number of conferences sprung up and notably the Serious Games Summit became a part of the influential Game Developer's Conference (www.gdconf.com) in 2004.

Some other notable offerings in the serious games field include *Food Force* (www.food-force.com) [18], a game developed by the United Nations World Food Programme in order to promote awareness of the issues surrounding emergency food aid; *Hazmat Hotzone* [15], a game developed by the Entertainment Technology Centre at Carnegie Mellon University to train fire-fighters to deal with chemical and hazardous materials emergencies; *Yourself!Fitness* (www.yourselffitness.com) [53] an interactive virtual personal trainer developed for modern games consoles; and *Serious Gordon* (www.seriousgames.ie) [50] a game developed to aid in teaching food safety in kitchens. A screen shot of Serious Gordon is shown in Fig. 5.

Over the past decade, interest in academic research that is directly focused on artificial intelligence, and in particular agent-based modelling techniques and their application to games (as opposed to the general virtual character/computer graphics work discussed previously) has grown dramatically. One of the first major academic research projects into the area of Game-AI was led by John Laird at the University of Michigan, in the United States. The SOAR architecture was developed in the early nineteen eighties in an attempt to *"develop and apply a unified theory of human and artificial intelligence"* [66]. SOAR is essentially a rule based inference system which takes the current state of a problem and matches this to production rules which lead to actions.



Computer Graphics and Games, Agent Based Modeling in, Figure 5
A screenshot of Serious Gordon, a serious game developed to aid in the teaching of food safety in kitchens

After initial applications into the kind of simple puzzle worlds which characterized early AI research [42], the SOAR architecture was applied to the task of controlling computer generated forces [37]. This work lead to an obvious transfer to the new research area of game-AI [40].

Initially the work of Laird's group focused on applying the SOAR architecture to the task of controlling NPC opponents in the action game *Quake* (www.idsoftware.com) [40]. This proved quite successful leading to opponents which could successfully play against human players, and even begin to plan based on anticipation of what the player was about to do. More recently Laird's group have focused on the development of a game which requires more involved interactions between the player and the NPCs. Named *Haunt 2*, this game casts the player in the role of a ghost that must attempt to influence the actions of a group of computer controlled characters inhabiting the ghost's haunted house [51]. The main issue that arises with the use the SOAR architecture is that it is enormously resource hungry, with the NPC controllers running on a separate machine to the actual game.

At Trinity College in Dublin in Ireland, the author of this article worked on an intelligent agent architecture, the Proactive Persistent Agent (PPA) architecture, for the control of background characters (or support characters) in character-centric games (games that focus on character interactions rather than action, e. g. role-playing games) [48,49]. The key contributions of this work were that it made possible the creation of NPCs that were capable of behaving believably in a wide range of situations and allowed for the creation of game environments which it appeared had an existence beyond their interactions with players. Agent behaviors in this work were based on models of personality, emotion, relationships to other characters and behavioral models that changed according to the current role of an agent. This system was used to develop a stand alone game and as part of a simulation of areas within Trinity College. A screenshot of this second application is shown in Fig. 6.

At Northwestern University in Chicago the Interactive Entertainment group has also applied approaches from more traditional research areas to the problems facing game-AI. Ian Horswill has led a team that are attempting to use architectures traditionally associated with robotics for the control of NPCs. In [29] Horswill and Zubek consider how perfectly matched the behavior based architectures often used in robotics are with the requirements of NPC control architectures. The group have demonstrated some of their ideas in a test-bed environment built on top

Computer Graphics and Games, Agent Based Modeling in, Figure 6
Screenshots of the PPA system simulating parts of a college

of the game Half-Life [38]. The group also looks at issues around character interaction [85] and the many psychological issues associated with creating virtual characters asking how we can create virtual game agents that display all of the foibles that make us relate to characters in human stories [28].

Within the same research group a team led by Ken Forbus have extended research previously undertaken in conjunction with the military [24] and applied it to the problem of terrain analysis in computer strategy games [25]. Their goal is to create strategic opponents which are capable of performing sophisticated reasoning about the terrain in a game world and using this knowledge to identify complex features such as ambush points. This kind of high level reasoning would allow AI opponents play a much more realistic game, and even surprise human players from time to time, something that is sorely missing from current strategy games.

As well as this work which has spring-boarded from existing applications, a number of projects began expressly to tackle problems in game-AI. Two which particularly stand out are the Excalibur Project, led by Alexander Nareyek [55] and work by John Funge [26]. Both of these projects have attempted to applying sophisticated planning techniques to the control of game characters.

Nareyek uses constraint based planning to allow game agents reason about their world. By using techniques such as local search Nareyek has attempted to allow these sophisticated agents perform resource intensive planning within the constraints of a typical computer game environment. Following on from this work, the term *anytime agent* was coined to describe the process by which agents actively refine original plans based on changing world conditions. In [56] Narayek describes the directions in which he intends to take this work in future.

Funge uses the situational calculus to allow agents reason about their world. Similarly to Nareyek he has addressed the problems of a dynamic, ever changing world, plan refining and incomplete information. Funge's work uses an extension to the situational calculus which allows the expression of uncertainty. Since completing this work Funge has gone on to be one of the founders of AiLive (www.ailive.net), a middleware company specializing in AI for games.

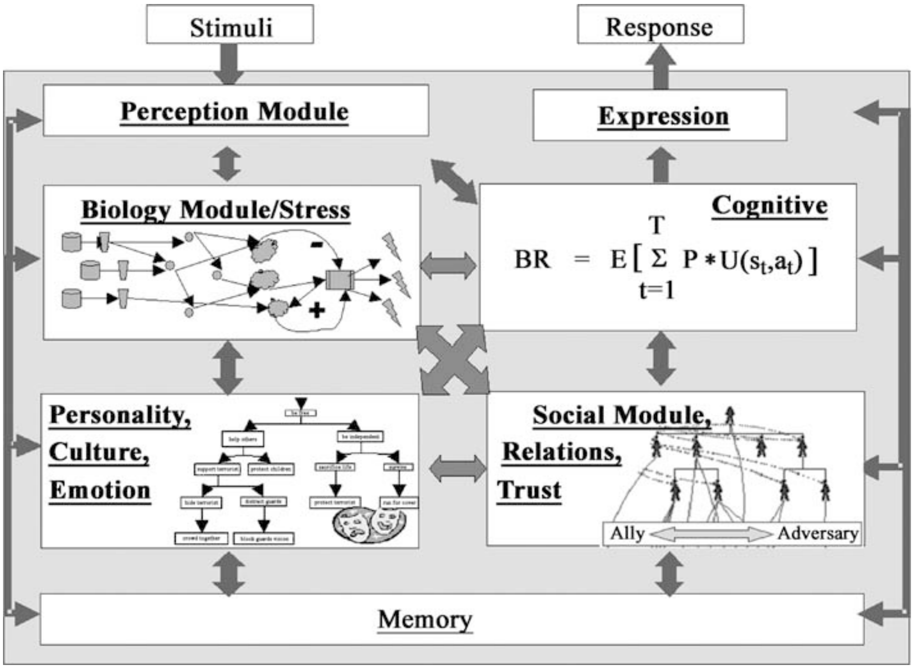
While the approaches of both of these projects have shown promise within the constrained environments to which they have been applied during research, (and work continues on them) it remains to be seen whether such techniques can be successfully applied to a commercial game environment and all of the resource constraints that such an environment entails.

One of the most interesting recent examples of agent-based work in the field of serious games is that undertaken by Barry Silverman and his group at the University of Pennsylvania in the United States [69,70]. Silverman models the protagonists in military simulations for use in training programmes and has taken a very interesting approach in that his agent models are based on established cognitive science and behavioral science research. While Silverman admits that many of the models described in the cognitive science and behavioral science literature are not well quantified enough to be directly implemented, he has adapted a number of well respected models for his purposes. Silverman's work is an excellent example of the capabilities that can be explored in a serious games setting rather than a commercial game setting, and as such merits an in depth discussion. A high-level schematic diagram of Silverman's approach is shown in Fig. 7 and shows the agent architecture used by Silverman's system, PMFserv.

The first important component of the PMFserv system is the biology module which controls biological needs using a metaphor based on the flow of water through a system. Biological concepts such as hunger and fatigue are simulated using a series of reservoirs, tanks and valves which model the way in which resources are consumed by the system. This biological model is used in part to model stress which has an important impact on the way in which agents make decisions. To model the way in which agent performance changes under pressure Silverman uses *performance moderator functions* (PMFs). An example of one of the earliest PMFs used is the Yerkes–Dodson "inverted-u" curve [84] which illustrates that as mental arousal is increased performance initially improves, peaks and then trails off again. In PMFserv a range of PMFs are used to model the way in which behavior should change depending on stress levels and biological conditions.

The second important module of PMFserv attempts to model how personality, culture and emotion affect the behavior of an agent. In keeping with the rest of their system PMFserv uses models inspired by cognitive science to model emotions. In this case the well known OCC model [58], which has been used in agent-based applications before [8], is used. The OCC model provides for 11 pairs of opposite emotions such as pride and shame, and hope and fear. The emotional state of an agent with regard to past, current and future actions heavily influences the decisions that the agent makes.

The second portion of the Personality, Culture, Emotion module uses a value tree in order to capture the values of an agent. These values are divided into a Preference Tree which captures long term desired states for the world, a Standards Tree which relates to the actions that an agent



Computer Graphics and Games, Agent Based Modeling in, Figure 7
A schematic diagram of the main components of the PMFserv system (with kind permission of Barry Silverman)

believes it can or cannot follow in order to achieve these desired states and a Goal Tree which captures short term goals.

PMFserv also models the relationships between agents (Social Model, Relations, Trust in Fig. 7). The relationship of one agent to another is modeled in terms of three axes. The first is the degree to which the other agent is thought of as a human rather than an inanimate object – locals tend to view American soldiers as objects rather than people. The second axis is the cognitive grouping (ally, foe etc) to which the other agent belongs and whether this is also a group to which the first agent has an affinity. Finally, the valence, or strength, of the relationship is stored. Relationships continually change based on actions that occur within the game world. Like the other modules of the system this model is also based on psychological research [58].

The final important module of the PMFserv architecture is the Cognitive module which is used to decide on particular actions that agents will undertake. This module uses inputs from all of the other modules to make these decisions and so the behavior of PMFserv agents is driven by their stress levels, relationships to other agents and objects within the game world, personality, culture and emotions. The details of the PMFserv cognitive process are beyond the scope of this article, so it will suffice to say that action selection is based on a calculation of the utility of a particular action to an agent, with this calculation modified by the factors listed above.

The most highly developed example using the PMFserv model is a simulation of the 1993 event in Mogadishu, Somalia in which a United States military Black Hawk helicopter crashed, as made famous by the book and film "Black Hawk Down" [12]. In this example, which was developed as a military training aid as part of a larger project looking at agent implementations within such systems [78,81] the player took on the role of a US army ranger on a mission to secure the helicopter wreck in a modification (or "mod") of the game *Unreal Tournament* (www.unreal.com). A screenshot of this simulation is shown in Fig. 8.

The PMFserv system was used to control the behaviors of characters within the game world such as Somali militia, and Somali civilians. These characters were imbued with physical attributes, a value system and relationships with other characters and objects within the game environment. The sophistication of PMFserv was apparent in many of the behaviors of the simulations NPCs. One particularly good example was the fact that Somali women would offer themselves as human shields for militia fighters. This behavior was never directly programmed into the agents make-up, but rather emerged as a result of their values and assessment of their situation. PMFserv remains one of the most sophisticated current agent implementa-

tions and shows the possibilities when the shackles of commercial game constraints are thrown off.

Future Directions

There is no doubt that with the increase in the amount of work being focused on the use of agent-based modeling in computer graphics and games there will be major developments in the near future. This final section will attempt to predict what some of these might be.

The main development that might be expected in all of the areas that have been discussed in this article is an increase in the depth of simulation. The primary driver of this increase in depth will be the development of more sophisticated agent models which can be used to drive ever more sophisticated agent behavior. The PMFserv system described earlier is one example of the kinds of deeper systems that are currently being developed. In general computer graphics applications this will allow for the creation of more interesting simulations including previously prohibitive features such as automatic realistic facial expressions and other physical expressions of agents' internal states. This would be particularly use in CGI for movies in which, although agent based modeling techniques are commonly used for crowd scenes and background characters, main characters are still animated almost entirely by hand.

In the area of computer games it can be expected that many of the techniques being used in movie CGI will filter over to real-time game applications as the processing power of game hardware increases – this is a pattern that has been evident for the past number of years. In terms of depth that might be added to the control of game characters one feature that has mainly been conspicuous by its absence in modern games is genuine learning by game agents. 2000's *Black & White* and its sequel *Black & White 2* (www.lionhead.com) featured some learning by one of the game's main characters that the player could teach in a reinforcement manner [20]. While this was particularly successful in the game, such techniques have not been more widely applied. One interesting academic project in this area is the NERO project (www.nerogame.org) which allows a player to train an evolving army of soldiers and have them battle the armies of other players [73]. It is expected that these kinds of capabilities will become more and more common in commercial games.

One new feature of the field of virtual character control in games is the emergence of specialized middleware. Middleware has had a massive impact in other areas of game development including character modeling (for example Maya available from www.autodesk.com) and physics modeling (for example Havok available from www.havok.com). AI focused middleware for games is now becoming more common with notable offerings including AI-Implant (www.ai-implant.com) and Kynogon (www.kynogon.com) which perform path finding and state machine based control of characters. It is expected that more sophisticated techniques will over time find their way into such software.

To conclude the great hope for the future is that more and more sophisticated agent-based modeling techniques from other application areas and other branches of AI will find their way into the control of virtual characters.

Article Outline

Glossary

Some of the terms used in our article are the same as in the article of Adamatzky in this volume, and they are explained in the glossary of ► Reaction-Diffusion Computing.

Activator A substance that increases the rate of reaction.

Excitability Here we call a dynamical system excitable if it has a single stable state (the rest state) with the following properties: if the rest state is slightly perturbed then the perturbation uniformly decreases as the system evolves towards it. However, if the perturbation is sufficiently strong it may grow by orders of magnitude before the system approaches the rest state. The increase in variables characterizing the system (usually rapid if compared with the time necessary to reach the rest state) is called an excitation. A forest is a classical example of excitable medium and a wildfire that burns it is an excitation. A dynamical system is non-excitable if applied perturbations do not grow up and finally decay.

Excitability level The measure of how strong a perturbation has to be applied to excite the system. For example, for the Ru-catalyzed Belousov–Zhabotinsky reaction, increasing illumination makes the medium less excitable. The decrease in the excitability level can be observed in reduced amplitudes of spikes and in decreased velocities of autowaves.

Firing number The ratio between the number of generated excitations to the number of applied external stimulations. In most of the cases we define the firing number as the ratio between the number of output spikes to the number of arriving pulses.

Inhibitor A substance that decreases the rate of reaction or even prevents it.

Medium In the article we consider a chemical medium, fully characterized by local concentrations of reagents and external conditions like temperature or illumination level. The time evolution of concentrations is governed by a set of reaction-diffusion equations, where the reaction term is an algebraic function of variables characterizing the system and the non-local coupling is described by the diffusion operator. We are mainly concerned with a two dimensional medium (i. e., a membrane with a solution of reagents used in experiments), but the presented ideas can be also applied to one-dimensional or three-dimensional media.

Refractory period A period of time during which an excitable system is incapable of repeating its response to an applied, strong perturbation. After the refractory period the excitable medium is ready to produce an excitation as an answer to the stimulus.

Spike, autowave In a spatially distributed excitable medium, a local excitation can spread around as a pulse of excitation. Usually a propagating pulse of excitation converges to a stationary shape characteristic for the medium, which is not dependent on initialization and propagates with a constant velocity – thus it is called an autowave.

Subexcitability A system is called subexcitable if the amplitude and size of the initiated pulse of excitation decreases in time. However, if the decay time is comparable with the characteristic time for the system, defined as the ratio between system size and pulse velocity, then pulses in a subexcitable system travel for a sufficiently long distance to carry information. Subexcitable media can be used to control the amplitude of excitations. Subexcitability is usually related to system dynamics, but it may also appear as the result of geometrical constraints. For example, a narrow excitable channel surrounded by a non-excitable medium may behave as a subexcitable system because a propagating pulse dies out due to the diffusion of the activator in the neighborhood.

Definition of the Subject

It has been shown in the article of Adamatzky ▶ Reaction-Diffusion Computing that an excitable system can be used as an information processing medium. In such a medium, information is coded in pulses of excitation; the presence of a single excitation or of a group of excitations forms a message. Information processing discussed by Adamatzky is based on a homogeneous excitable medium and the interaction between pulses in such medium. Here we focus our attention on a quite specific type of excitable medium that has an intentionally introduced structure of regions characterized by different excitability levels. As the simplest case we consider a medium composed of excitable regions where autowaves can propagate and non-excitable ones where excitations rapidly die. Using such two types of medium one can, for example, construct signal channels: stripes of excitable medium where pulses can propagate surrounded by non-excitable areas thick enough to cancel potential interactions with pulses propagating in neighboring channels. Therefore, the propagation of a pulse along a selected line in an excitable system can be realized in two ways. In a homogeneous excitable medium, it can be done by a continuous control of pulse propagation and the local feedback with activating and inhibiting factors (▶ Reaction-Diffusion Computing). In a structured excitable medium, the same result can be achieved by creating a proper pattern of excitable and non-excitable regions. The first method gives more flexibility, the second is just simpler and does not require a permanent watch. As we show in this article, a number of devices that perform simple information processing operations, including the basic logic functions, can be easily constructed with structured excitable medium. Combining these devices as building blocks we can perform complex signal processing operations. Such an approach seems similar to the development of electronic computing where early computers were built of simple integrated circuits.

The research on information processing with structured excitable media has been motivated by a few important problems. First, we would like to investigate how the properties of a medium can be efficiently used to construct devices performing given functions, and what tasks are the most suitable for chemical computing. There is also a question of generic designs valid for any excitable medium and specific ones that use unique features of a particular system (for example, a one-dimensional generator of excitation pulses that can be built with an excitable surface reaction [23]). In information processing with a structured excitable medium, the geometry of the medium is as important as its dynamics, and it seems interesting to know what type of structures are related to specific functions. In the article we present a number of such structures characteristic for particular information processing operations.

Another important motivation for research comes from biology. Even the simplest biological organisms can process information and make decisions important for their life without CPU-s, clocks or sequences of commands as it is in the standard von Neumann computer architecture [15]. In biological organisms, even at a very basic cellular level, excitable chemical reactions are responsible for information processing. The cell body considered as an information processing medium is highly structured. We believe that analogs of geometrical structures used for certain types of information processing operations in structured excitable media will be recognized in biological systems, so we will better understand their role in living organisms. At a higher level, the analogies between information processing with chemical media and signal processing in the brain seems to be even closer because the excitable dynamics of calcium in neural tissue is responsible for signal propagation in nerve system [30]. Excitable chemical channels that transmit signals between processing elements look similar to dendrites and axons. As we show in the article, the biological neuron has its chemical analog, and this allows for the construction of artificial neural networks using chemical processes. Having in mind that neural networks are less vulnerable to random errors than classical algorithms one can go back from biology to man-made computing and adopt the concepts in a fast excitable medium, for example especially prepared semiconductors (▶ Unconventional Computing, Novel Hardware for).

The article is organized in the following way. In the next section we discuss the basic properties of a structured chemical medium that seem useful for information processing. Next we consider the binary information coded in propagating pulses of concentration and demonstrate how logic gates can be built. In the following chapter we show that a structured excitable medium can acquire information about distances and directions of incoming stimuli. Next we present a simple realization of read-write memory cell, discuss its applications in chemical counting devices, and show its importance for programming with pulses of excitation. In the following section we present a chemical realization of artificial neurons that perform multiargument operation on sets of input pulses. Finally we discuss the perspectives of the field, in particular more efficient methods of information coding and some ideas of self-organization that can produce structured media capable of information processing.

Introduction

Excitability is the wide spread behavior of far-from-equilibrium systems [35,39] observed, for example, in chemical reactions (Bielousov–Zhabotynsky BZ-reaction [45], CO oxidation on Pt [37], combustion of gases [26]) as well as in many other physical (laser action) and biochemical (signaling in neural systems, contraction of cardiovascular tissues) processes [51]. All types of excitable systems share a common property that they have a stable stationary state (the rest state) they reside in when they are not perturbed. A small perturbation of the rest state results only in a small-amplitude linear response of the system that uniformly decays in time. However, if a perturbation is sufficiently large then the system can evolve far away from the rest state before finally returning to it. This response is strongly nonlinear and it is accompanied by a large excursion of the variables through phase space, which corresponds to an excitation peak (a spike). The system is refractory after a spike, which means that it takes a certain recovery time before another excitation can take place. The excitability is closely related with relaxation oscillations and the phenomena differ by one bifurcation only [56].

Properties of excitable systems have an important impact on their ability to process information. If an excitable medium is spatially distributed then an excitation at one point of the medium (usually seen as an area with a high concentration of a certain reagent), may introduce a sufficiently large perturbation to excite the neighboring points as the result of diffusion or energy transport. Therefore, an excitation can propagate in space in the form of a pulse. Unlike mechanical waves that dissipate the initial energy and finally decay, traveling spikes use the energy of the medium to propagate and dissipate it. In a typical excitable medium, after a sufficiently long time, an excitation pulse converges to the stationary shape, independent of the initial condition what justifies to call it an autowave. Undamped propagation of signals is especially important if the distances between the emitting and receiving devices are large. The medium's energy comes from the nonequilibrium conditions at which the system is kept. In the case of a batch reactor, the energy of initial composition of reagents allows for the propagation of pulses even for days [41], but a typical time of an experiment in such conditions is less than an hour. In a continuously fed reactor pulses can run as long as the reactants are delivered [44].

If the refractory period of the medium is sufficiently long then the region behind a pulse cannot be excited again for a long time. As a consequence, colliding pulses annihilate. This type of behavior is quite common in excitable systems. Another important feature is the dispersion relation for a train of excitations. Typically, the first pulse is the fastest, and the subsequent ones are slower, which is related to the fact that the medium behind the first pulse has not relaxed completely [63]. For example, this phenomenon is responsible for stabilization of positions in a train of pulses rotating on a ring-shaped excitable area. However, in some systems [43] the anomalous dispersion relation is observed and there are selected stable distances between subsequent spikes. The excitable systems characterized by the anomalous dispersion can play an important role in information processing, because packages of pulses are stable and thus the information coded in such packages can propagate without dispersion.

The mathematical description of excitable chemical media is based on differential equations of reaction-diffusion type, sometimes supplemented by additional equations that describe the evolution of the other important properties of the medium, for example the orientation of the surface in the case of CO oxidation on a Pt surface [12,37]. Numerical simulations of pulse propagation in an excitable medium which are presented in many papers [48,49] use the FitzHugh–Nagumo model describing the time evolution of electrical potentials in nerve channels [17,18,54]. The models for systems with the Belousov–Zhabotinsky (BZ) reaction, for example the Rovinsky and Zhabotinsky model [61,62] for the ferroin catalyzed BZ reaction with the immobilized catalyst, can be derived from "realistic" reaction schemes [16] via different techniques of variable reduction. Experiments with the Ru-catalyzed, photosensitive BZ reaction have become standard in experiments with structured excitable media because the level of excitation can be easily controlled by illumination; see for example [7,27,33]. Light catalyzes the production of bromine that inhibits the reaction, so non illuminated regions are excitable and those strongly illuminated are not. The pattern of excitable (dark) and non-excitable (transparent) fields is just projected on a membrane filled with the reagents. For example, the labyrinth shown in Fig. 1 has been obtained by illuminating a membrane through a proper mask. The presence of a membrane is important because it stops convection in the solution and reduces the speed and size of spikes, so studied systems can be smaller. The other methods of forming excitable channels based on immobilizing a catalyst by imprinting it on a membrane [68] or attaching it by lithography [21,71,72] have been also used, but they seem to be more difficult.

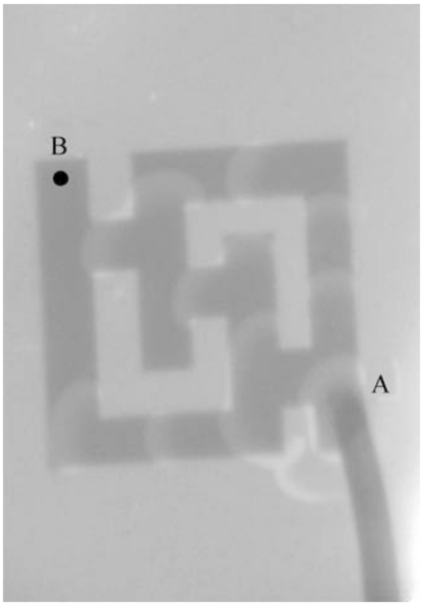
Numerical simulations of the Ru-catalyzed BZ reaction can be performed with different variants of the Oregonator model [9,19,20,38]. For example, the three-variable model uses the following equations:

$$\varepsilon_1 \frac{\partial u}{\partial t} = u(1-u) - w(u-q) + D_u \nabla^2 u \qquad (1)$$

$$\frac{\partial v}{\partial t} = u - v \qquad (2)$$

$$\varepsilon_2 \frac{\partial w}{\partial t} = \phi + f v - w(u+q) + D_w \nabla^2 w \qquad (3)$$

where u, v and w denote dimensionless concentrations of the following reagents: $HBrO_2$, Ru(4,4′-dm-bpy)$_3^{3+}$, and Br^-, respectively. In the considered system of equations, u is an activator and v is an inhibitor. The set of Oregonator equations given above reduces to the two-variable model cited in the article of Adamatzky ▶ Reaction-Diffusion Computing if the processes responsible for bromide production are very fast if compared to the other reactions ($\varepsilon_2 \ll \varepsilon_1 \ll 1$). In such cases, the local value of w can be calculated assuming that it corresponds to the stationary solution of the third equation. If such a w is substituted into the first equation, one obtains the two-variable Oregonator model. In the equations given above, the units of space and time are dimensionless and they have been chosen to scale the reaction rates. Here we also neglected the diffusion of ruthenium catalytic complex because usually it is much smaller than those of the other reagents. The reaction-diffusion equations describing the time evolution of the system can be solved with the standard numerical techniques [57].



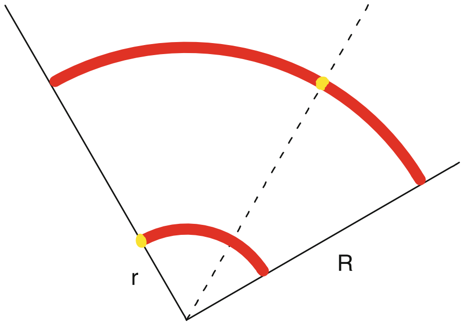
Computing in Geometrical Constrained Excitable Chemical Systems, Figure 1
Pulses of excitation propagating in a labyrinth observed in an experiment with a Ru-catalyzed BZ-reaction. The excitable areas are *dark*, the non-excitable *light*. The source of a train of pulses (a tip of a silver wire) is placed at the point A

The parameter ϕ represents the rate of bromide production caused by illumination and it is proportional to the applied light intensity. Therefore, by adjusting the local illumination (or choosing the proper ϕ as a function of space variables in simulations) we create regions with the required level of excitability, like for example excitable stripes insulated by a non-excitable neighborhood. Of course, the reagents can freely diffuse between the regions characterized by different illuminations.

The structure of the equations describing the system's evolution in time and space gives the name "reaction diffusion computing" [4] to information processing with an excitable medium. Simulations play an important role in tests of potential information processing devices, because, unlike in experiment, the conditions and parameters of studied systems can be easily adjusted with the required precision and kept forever. Most of the information processing devices discussed below were first tested in simulations and next verified experimentally. One of the problems is related to the short time of a typical experiment in a batch condition (a membrane filled with reagents) that does not exceed one hour. In such systems the period in which the conditions can be regarded as stable is usually shorter than 30 minutes and within this time an experimentalist should prepare the medium, introduce the required illumination and perform observations. The problem can be solved when one uses a continuously fed reactor [44], but experimental setups are more complex. On the other hand, simulations often indicate that the range of parameters in which a given phenomenon appears is very narrow. Fortunately experiments seem to be more robust than simulations and the expected effects can be observed despite of inevitable randomness in reagent preparation. Having in mind the relatively short time of experiments in batch conditions and the low stability of the medium, we believe that applications of a liquid chemical excitable medium like the Ru-catalyzed BZ reaction as information processors (wetware) are rather academic and they are mainly oriented on the verification of ideas. Practical applications of reaction-diffusion computers will probably be based on an other type of medium, like structured semiconductors (▶ Unconventional Computing, Novel Hardware for).

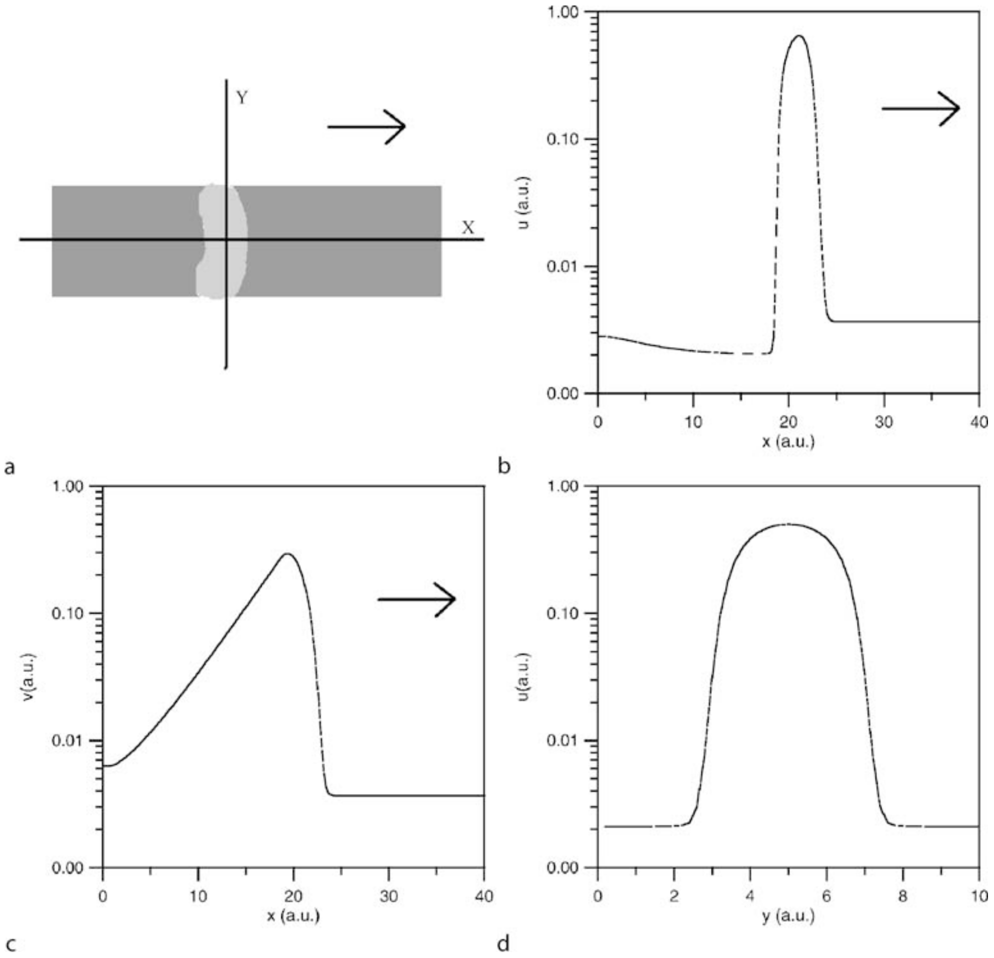
In an excitable reaction-diffusion medium, spikes propagate along the minimum time path. Historically, one of the first applications of a structured chemical medium used in information processing was the solution of the problem of finding the shortest path in a labyrinth [67]. The idea is illustrated in Fig. 1. The labyrinth is build of excitable channels (dark) separated by non-excitable medium (light) that does not allow for interactions between pulses propagating in different channels. Let us assume that we are interested in the distance between the right bottom corner (point A) and the left upper corner (point B) of the labyrinth shown. The algorithm that scans all the possible paths between these points and selects the shortest one is automatically executed if the paths in labyrinth are build of an excitable chemical medium. To see how it works, let us excite the medium at the point A. The excitation spreads out through the labyrinth, separates at the junctions and spikes enter all possible paths. During the time evolution, pulses of excitation can collide and annihilate, but the one that propagates along the shortest path has always unexcited medium in front. Knowing the time difference between the moment when the pulse is initiated at the point A and the moment when it arrives at the point B and assuming that the speed of a pulse is constant, we can estimate the length of shortest path linking both points. The algorithm described above is called the "prairie fire" algorithm and it is automatically executed by an excitable medium. It finds the shortest path in a highly parallel manner scanning all possible routes at the same time. It is quite remarkable that the time required for finding the shortest path does not depend on the the complexity of labyrinth structure, but only on the distance between the considered points.

Although the estimation of the minimum distance separating two points in a labyrinth is relatively easy (within the assumption that corners do not significantly change pulse speed) it is more difficult to tell what is the shortest path. To do it one can trace the pulse that arrived first and plot a line tangential to its velocity. This idea was discussed in [6] in the context of finding the length of the shortest path in a nonhomogeneous chemical medium with obstacles. The method, although relatively easy, requires the presence of an external observer who follows the propagation of pulses. An alternative technique of extracting the shortest path based on the image processing was demonstrated in [59]. One can also locate the shortest path connecting two points in a labyrinth in a purely chemical way using the coincidence of excitations generated at the endpoints of the path. Such a method, described in [29], allows one to find the midpoint of a trajectory, and thus locate the shortest path point by point.



Computing in Geometrical Constrained Excitable Chemical Systems, Figure 2

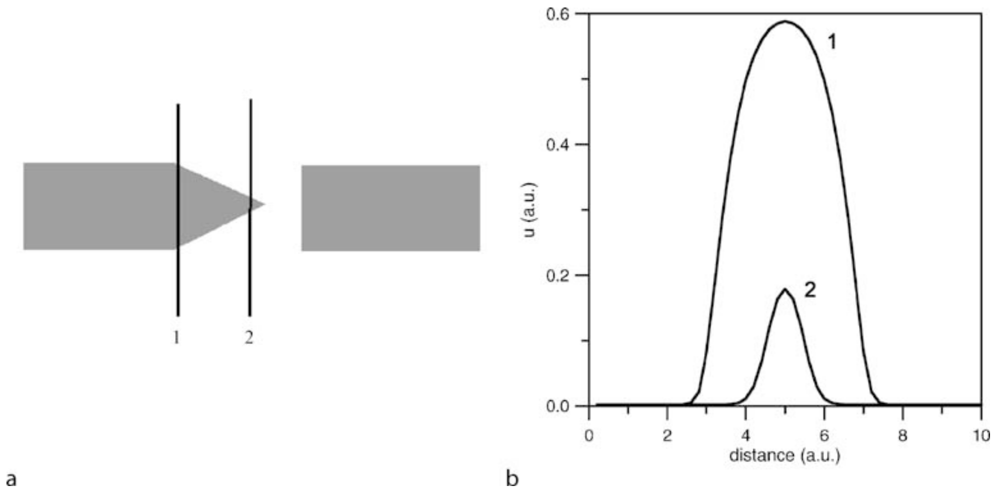
The idea of angle trisection. Angle arms are linked with *red* arc shaped excitable channels with the radius ratio $r : R = 1 : 3$. The channels have been excited at the same time at the right arm of the angle. At the moment when the excitation pulse (*a yellow dot*) on a smaller arch reaches the second arm the excitation on the other arch shows a point on a line trisecting the angle (*the dashed line*)



Computing in Geometrical Constrained Excitable Chemical Systems, Figure 3
The shape of the excitation pulse in a stripe of excitable medium. The *arrow* indicates the direction of propagation. Calculations were done for the Oregonator model (Eqs. (1)–(3)) and the following values of parameters were applied: $f = 1.12, q = 0.002, \varepsilon_1 = 0.08, \varepsilon_2 = 0.00097, \phi_{\text{excitable}} = 0.007, \phi_{\text{non-excitable}} = 0.075$. a The position of a spike on the stripe, b, c concentration of activator and inhibitor along the *x*-axis, d concentration of activator along the *y*-axis

The approximately constant speed of excitation pulses in a reaction-diffusion medium allows one to solve some geometrically oriented problems. For example one can "measure" the number π by comparing the time of pulse propagation around a non-excitable circle of the radius d with the time of propagation around a square with the same side [69]. Similarly, a constant speed of propagating pulses can be used to obtain a given fraction of an angle. For example, a trisection of an angle can be done if the angle arms are linked with two arc-shaped excitable channels as shown in Fig. 2. The ratio of channel radii should be equal to 3. Both channels are excited at the same time at points on the same arm. The position of excitation at the larger arch at the moment when the excitation propagating on the shorter arch reaches the other arm belongs to a line that trisects the angle.

The examples given above are based on two properties of structured excitable medium: the fact that the non-excitability of the neighborhood can restrict the motion of an excitation pulse to a channel, and that the speed of propagation depends on the excitability level of the medium but not on channel shape. This is true when channels are wide and the curvature is small. There are also other properties of an excitable medium useful for information processing. A typical shape of a pulse propagating in a stripe of excitable medium is illustrated in Fig. 3. The pulse moves from the left to the right as the arrow indicates. The profiles on Fig. 3b,c show cross sections of the concentrations



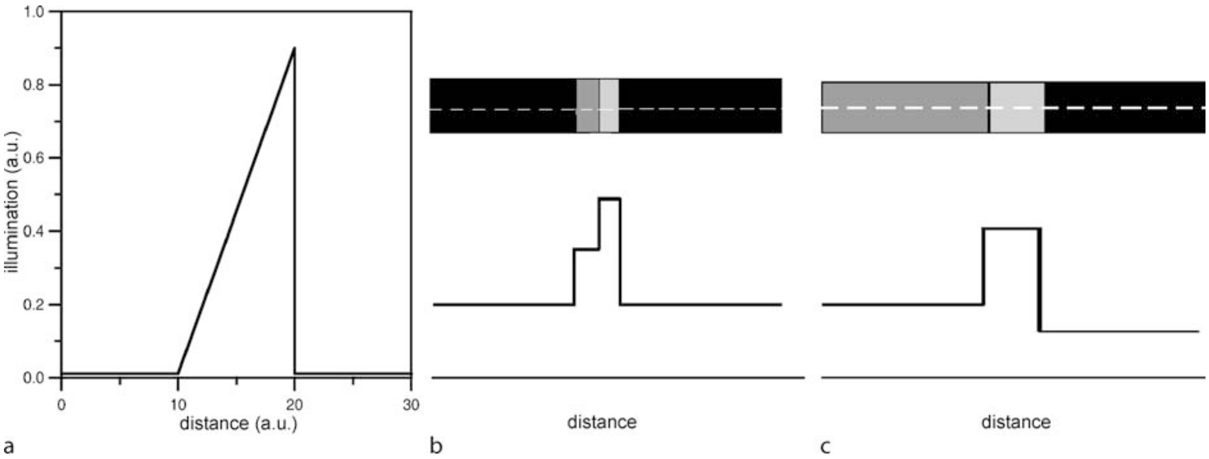
Computing in Geometrical Constrained Excitable Chemical Systems, Figure 4
The shape of activator concentration in an excitable medium of a triangular shape. a The structure of excitable (*dark*) and non-excitable (*light*) regions, b concentration of activator along the lines marked in a. The profiles correspond to times when the activator reaches its maximum at a given line

of the activator $u(x, y)$ and inhibitor $v(x, y)$ along the horizontal axis of the stripe at a selected moment of time. The peak of the inhibitor follows activator maximum and is responsible for the refractory character of the region behind the pulse. Figure 3d illustrates the profile of an activator along the line perpendicular to the stripe axis. The concentration of the activator reaches its maximum in the stripe center and rapidly decreases at the boundary between the excitable and non-excitable areas. Therefore, the width of the excitable channel can be used as a parameter that controls the maximum concentration of an activator in a propagating pulse.

Figure 4 shows profiles of a concentration in an excitable channel with a triangular shape. The two curves on Fig. 4b illustrate the profile of u along the lines 1 and 2, respectively measured at the time when the concentration of u on a given line reaches its maximum. It can be seen that the maximum concentration of the activator decreases when a pulse propagates towards the tip of the triangle. This effect can be used to build a chemical signal diode. Let us consider two pieces of excitable medium, one of triangular shape and another rectangular, separated by a non-excitable gap as shown on Fig. 4a. It is expected that a perturbation of the rectangular area by a pulse propagating towards the tip of the triangular one is much smaller than the perturbation of the triangular area by a pulse propagating towards the end of rectangular channel. Using this effect, a chemical signal diode that transmits pulses only in one direction can be constructed just by selecting the right width of non-excitable medium separating two pieces of excitable medium: a triangular one and a rectangular one [5,40].

The idea of a chemical signal diode presented in Fig. 4a was, in some sense, generalized by Davydov et al. [46], who considered pulses of excitation propagating on a 2-dimensional surface in 3-dimensional space. It has been shown that the propagation of spikes on surfaces with rapidly changing curvature can be unidirectional. For example, such an effect occurs when an excitation propagates on the surface of a tube with a variable diameter. In such a case, a spike moving from a segment characterized by a small diameter towards a larger one is stopped.

For both of the chemical signal diodes mentioned above, the excitability of the medium is a non trivial function of some space variables. However, a signal diode can be also constructed when the excitability of the medium changes in one direction only, so in a properly selected coordinate system it is a function of a single space variable. For example, the diode behavior in a system where the excitability level is a triangular function of a single space variable has been confirmed in numerical simulations based on the Oregonator model of a photosensitive, Ru-catalyzed BZ reaction (Eqs. (1)–(3)) [76]. If the catalyst is immobilized, then pulses that enter the region of inhomogeneous illumination from the strongly illuminated site are not transmitted, whereas the pulses propagating in the other direction can pass through (see Fig. 5a). A similar diode-like behavior resulting from a triangular profile of medium excitability can be expected for oxidation of CO on a Pt surface. Calculations demonstrate that a triangular

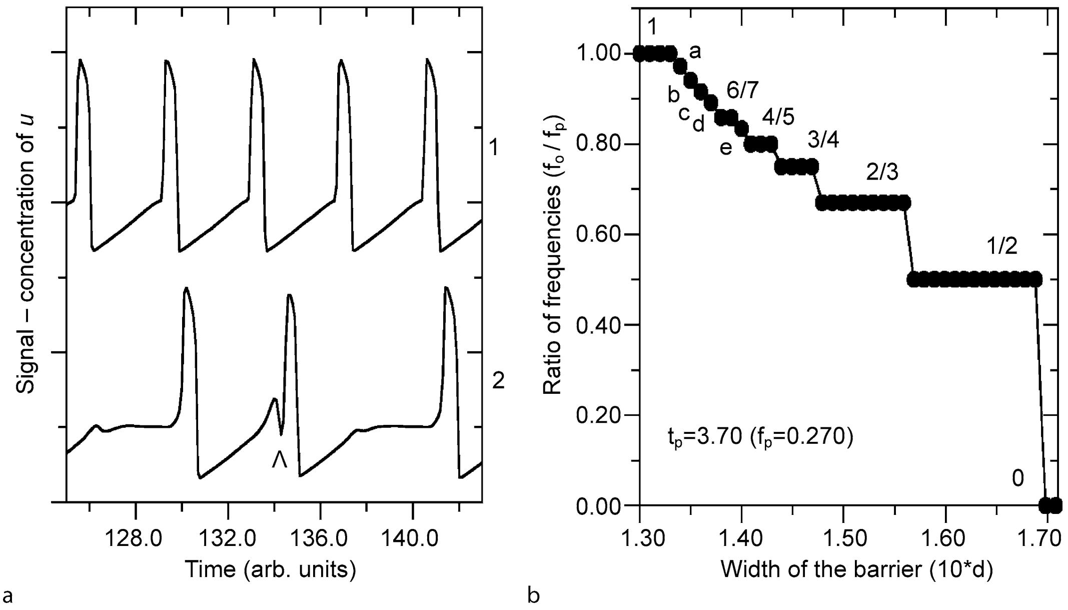


Computing in Geometrical Constrained Excitable Chemical Systems, Figure 5
The excitability as a function of a space variable in different one-dimensional realizations of a signal diode with BZ- reaction inhibited by light: a a triangular profile of illumination, b the illumination profile in a diode composed of two non-excitable barriers, c the illumination profile in a single barrier diode with nonsymmetrical excitable inputs. The *upper graphs* in b and c illustrate illumination on a membrane used in experiments [25]

profile of temperature (in this case, reduced with respect to that which characterizes the excitable medium) allows for the unidirectional transmission of spikes characterized by a high surface oxygen concentration [23]. However, a realization of the chemical signal diode can be simplified. If the properties of excitable channels on both sites of a diode are the same, then the diode can be constructed with just two stripes of non-excitable medium characterized by different excitabilities as illustrated in Fig. 5b. If the symmetry is broken at the level of input channels then the construction of a signal diode can be yet simpler, and it reduces to a single narrow non-excitable gap with a much lower excitability than that of the neighboring channels (cf. Fig. 5c). In both cases the numerical simulations based on the Oregonator model have shown that a diode works. The predictions of simulations have been qualitatively confirmed by experimental results [25]. Different realizations of a signal diode show that even for very simple signal processing devices the corresponding geometrical structure of excitable and non-excitable regions is not unique. Alternative constructions of chemical information processing devices seem important because they tell us on the minimum conditions necessary to build a device that performs a given function. In this respect a diode built with a single non-excitable region looks interesting, because such situation may occur at a cellular level, where the conditions inside the cell are different from those around. The diode behavior in the geometry shown on Fig. 5c indicates that the unidirectional propagation of spikes can be forced by a channel in a membrane, transparent to molecules or ions responsible for signal transmission.

Wave-number-dependent transmission through a non-excitable barrier is another feature of a chemical excitable medium important for information processing [48]. Let us consider two excitable areas separated by a stripe of non-excitable medium and a pulse of excitation propagating in one of those areas. The perturbation of the area behind the stripe introduced by an arriving pulse depends on the direction of its propagation. If the pulse wavevector is parallel to the stripe then the perturbation is smaller than in the case when it arrives perpendicularly [48]. Therefore, the width of the stripe can be selected such that pulses propagating perpendicularly to the stripe can cross it, whereas a pulse propagating along the stripe do not excite the area on the other side. This feature is frequently used to arrange the geometry of excitable channels such that pulses arriving from one channel do not excite the other.

Non-excitable barriers in a structured medium can play a more complex role than that described above. The problem of barrier crossing by a periodic train of pulses can be seen as an excitation via a periodic perturbation of the medium. It has been studied in detail in [13]. The answer of the medium is quite characteristic in the form of a devil-staircase-like firing number as a function of perturbation strength. In the case of barrier crossing, the strength of the excitation behind a barrier generated by an arriving pulse depends on the character of the non-excitable medium, the barrier width, and the frequency of the incoming signal (usually, due to an uncompleted relaxation of the medium, the amplitude of spikes decreases with frequency). A typical complex frequency transformation



Computing in Geometrical Constrained Excitable Chemical Systems, Figure 6

Frequency transformation on a barrier – the results for the FitzHugh–Nagumo model [64]. a The comparison of an arriving train of pulses (1) and the transmitted signal (2). b A typical dependence of the firing number as a function of barrier width. The plateaus are labeled with corresponding values of firing number (1, 6/7, 4/5, 3/4, 2/3, 1/2 and 0). At points labeled a–e the following values have been observed: a – 35/36; b – 14/15; c – 10/11; d – 8/9 and e – 5/6

The firing number as a function of the barrier width *d* and the interval of time between consecutive pulses (t_p). Labels in the *white* areas give the firing number, and the *gray* color marks values of parameters where more complicated transformations of frequency occur. a Results calculated for the FitzHugh–Nagumo model, b the Rovinsky–Zhabotinsky model. Both space and time are in dimensionless units

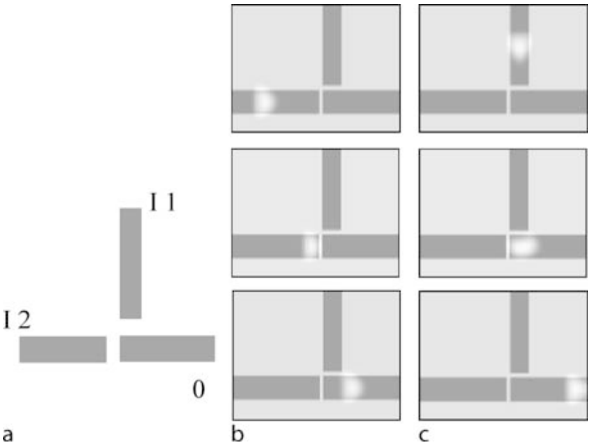
after barrier crossing is illustrated in Fig. 6. Experimental and numerical studies on firing number of a transmitted signal have been published [10,64,72,74]. It is interesting that the shape of regions characterized by the same firing number in the space of two parameters, barrier width and signal frequency, is not generic and depends on the type of the excitable medium. Figure 7 compares the firing numbers obtained for FitzHugh–Nagumo and Rovinsky–

Zhabotinsky models. In the first case, trains of pulses with small periods can cross wider barriers than trains characterized by low frequency; for the second model the dependence is reversed.

Logic Gates, Coincidence Detectors and Signal Filters

The simplest application of excitable media in information processing is based on the assumption that the logical FALSE and TRUE variables are represented by the rest state and by the presence of an excitation pulse at a given point of the system respectively. Within such interpretation a pulse represents a bit of information propagating in space. When the system remains in its rest state, no information is recorded or processed, which looks plausible for biological interpretation. Information coded in excitation pulses is processed in regions of space where pulses interact (via collision and subsequent annihilation or via transient local change in the properties of the medium). In this section we demonstrate that the geometry of excitable channels and non-excitable gaps can be tortured (the authors are grateful to prof. S. Stepney for this expression) to the level at which the system starts to perform the simplest logic operations on pulses. The binary chemical logic gates can be used as building blocks for devices performing more complex signal processing operations. Information processing with structured excitable media is "unconventional" because it is performed without a clock that sequences the operations, as it is in the standard von Neumann type computer architecture. On the other hand, in the signal processing devices described below, the proper timing of signals is important and this is achieved by selecting the right length and geometry of channels. In some cases, for example for the operations on trains of pulses, the presence of a reference signal, which plays a role similar to a clock, would significantly help to process information [70]. Historically, the logical gates were the first devices that have been realized with a structured chemical medium [1,2,14,65,73,75].

The setup of channels that execute the logic sum (OR) operation is illustrated in Fig. 8 [48]. The gate is composed of three excitable stripes (marked gray) surrounded by a non-excitable medium. The gaps separating the stripes have been selected such that a pulse that arrives perpendicularly to the gap can excite the area on the other side and a pulse that propagates parallel to the gap does not generate sufficient perturbation to excite the medium behind the gap. If there is no input pulse, the OR gate remains in the rest state and does not produce any output. A pulse in any of the input channels I1 and I2 can cross the gap separating these channels from the output O and an output spike appears. The excitation of the output channel generated by a pulse from one of the input channels propagates parallel to the gap separating the other input channel so it does not interfere with the other input as seen in Fig. 8b and c. The frequency at which the described OR gate operates is limited by the refractory period of the output medium. If the signals from both input channels arrive, but the time difference between pulses is smaller than the refractory time, then only the first pulse will produce the output spike.



Computing in Geometrical Constrained Excitable Chemical Systems, Figure 8
The distribution of excitable channels (*dark*) that form the OR gate. b and c illustrate the time evolution of a single pulse arriving from inputs I1 and I2, respectively

The gate that returns the logic product (AND) of input signals is illustrated in Fig. 9. The width of the gap separating the output channel O from the input one (I1,I2) is selected such that a single excitation propagating in the input channel does not excite the output (Fig. 9b). However, if two counterpropagating pulses meet, then the resulting perturbation is sufficiently strong to generate an excitation in the output channel (Fig. 9c). Therefore, the output signal appears only when both sites of the input channel have been excited and pulses of excitation collided in front of the output channel. The width of the output channel defines the time difference between input pulses treated as simultaneous. Therefore, the structure shown in Fig. 9 can also be used as a detector of time coincidence between pulses.

The design of the negation gate is shown in Fig. 10. The gaps separating the input channels, the source channel and the output channel can be crossed by a pulse that propagates perpendicularly, but they are non-penetrable for pulses propagating parallel to the gaps. The NOT gate

should deliver an output signal if the input is in the rest state. Therefore, it should contain a source of excitation pulses (marked S). If the input is in the rest state then pulses from the source propagate unperturbed and enter the output channel. If there is an excitation pulse in the input channel then it enters the channel linking the source with the output and annihilates with one of pulses generated by the source. As a result no output pulse appears. At the first look, the described NOT gate works fine, but if we assume that a single pulse is used in information coding than the input pulse should arrive at the right time to block the source. Therefore, additional synchronization of the source is required. If information is coded in trains of pulses then the frequency of the source should match with the one used for coding.

The structure of excitable channels for the exclusive OR (XOR) gate is illustrated in Fig. 11c [34]. Two input channels bring signals to the central area C. The output channels are linked together via diodes (Fig. 4) that stop possible backward propagation. As in the previous cases only pulses perpendicular to the gaps can pass through non-excitable gaps between the central area and both input and output channels. The shape of the central area has been designed such that an excitation generated by a single input pulse propagates parallel to one of the outputs and is perpendicular to another. As the result one of the output channels is excited (see Fig. 11a). However, if pulses from both input channels arrive at the same time then the wavevector of the excitation in the central part is always parallel to the boundaries (Fig. 11b). Therefore, no output signal appears. Of course, there is no output signal if none of the inputs are excited. It is worth noticing that for some geometries of the XOR gate the diodes in output channels are not necessary because the backward propagation does not produce a pulse with a wavevector perpendicular to a gap as seen in the fourth frame of Fig. 11a.

Another interesting example of behavior resulting from the interaction of pulses has been observed in a cross-shaped structure built of excitable regions, separated by gaps penetrable for perpendicular pulses [65,66] shown in Fig. 12. The answer of cross-shaped junction to a pair pulses arriving from two perpendicular directions has been studied as a function of the time difference between pulses. Of course, if the time difference is large, pulses propagate independently along their channels. If the time difference is small the cross-junction acts like the AND gate and the output excitation appears in one of the corner areas. However, for a certain time difference the first arriving pulse is able to redirect the other and force it to follow. The effect is related to uncompleted relaxation of the central area of the junction at the moment when the second pulse arrives. Pulse redirection seems to be an interesting effect from the point of programming with excitation pulses, but in practice it requires a high precision in selecting the right time difference.

The logic gates described above can also be applied to transform signals composed of many spikes. For example, two trains of pulses can be added together if they pass through an OR gate. The AND gate creates a signal composed of coinciding pulses from both trains. It is also easy to use a structured excitable medium and generate a signal that does not contain coinciding pulses [50]. The structure of the corresponding device is illustrated in Fig. 13. All non-excitable gaps are penetrable for perpendicular pulses. If a pulse of excitation arrives from one of the input channels then it excites the segment A and propagates towards the other end of it. If there is no spike in the other input channel then this excitation propagates unperturbed and activates the output channel. However, if a pulse from the other channel arrives it annihilates with the original

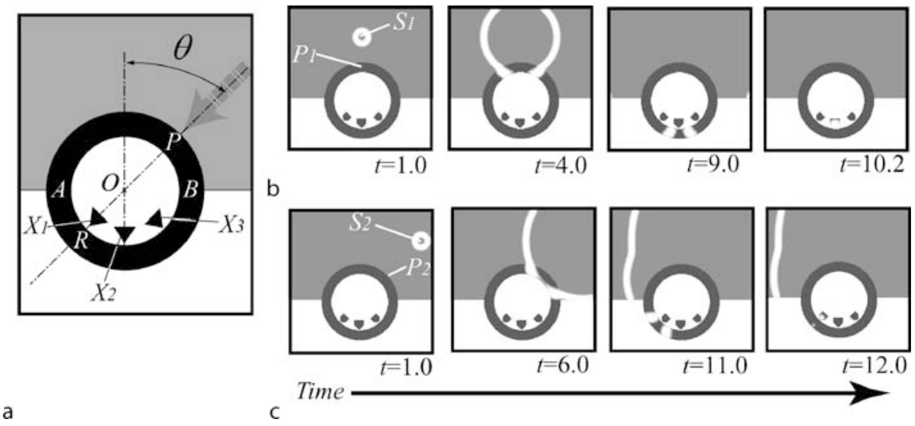
The *black dots* mark periods for which the signal is not transmitted, the *empty* ones indicate full transmission, the *empty diamonds* mark the periods of the arriving signal for which every second spike is transmitted

pulse and no output signal is generated. The structure illustrated on Fig. 13a can be easily transformed into a device that compares two trains of pulses such that the resulting signal is composed of spikes of the first signal that do not coincide with the pulses of the second train. Such a device can be constructed just by neglecting one of the output channels. Figure 13b illustrates the geometry of the device that produces the output signal composed of pulses in arriving at the input I1 that have no corresponding spikes in the signal arriving from I2.

The coincidence detector can be used as a frequency filter that transmits periodic signals within a certain frequency interval [22,50]. The idea of such a filter is shown in Fig. 14. The device tests if the time between subsequent spikes of the train remains in the assumed range. As illustrated the signal arriving from the input I separates and enters the segment E through diodes D1 and D2. The segments E and F form a coincidence detector (or an AND gate, c. f. Fig. 9). The excitation of the output appears when an excitation coming to E via the segment C and D2 is in the coincidence with the subsequent spike of the train that arrived directly via D1. The time shift for which coincidences are tested is decided by the difference in lengths of both paths. The time resolution depends on the width of the F channel (here $l_2 - l_1$). For periodic signals the presented structure works as a frequency filter and transmits signals within the frequency range $f_{\pm} = v/(\Delta r \pm (\Delta w)/2)$, where Δr is the difference of distances traveled by spikes calculated to the point in E placed above the center of F channels ($\sim 2 * l_e$), Δw is the width of the output channel, and v is the velocity of a spike in the medium. Typical characteristics of the filter are illustrated on Fig. 14b. The points represent results of numerical simulations and the line shows the filter characteristics calculated from the equation given above. It can be noticed that at the ends of the transmitted frequency band a change in output signal frequency is observed. This unwelcome effect can be easily avoided if a sequence of two identical filters is used. A filter tuned to a certain frequency will also pass any of its harmonics because the output signal can be generated by the coincidence of every second, third, etc. pulses in the train.

Chemical Sensors Built with Structured Excitable Media

Even the simplest organisms without specialized nerve systems or brains are able to search for the optimum living conditions and resources of food. We should not be astonished by this fact because even chemical systems can receive and process information arriving from their neighborhood. In this section we describe how simple struc-



Computing in Geometrical Constrained Excitable Chemical Systems, Figure 15

The excited output channel depends on the direction of the source (copied from [53] with the permission of the authors)

tures built of excitable media can be used for direction and distance sensing. In order to simplify the conversion between an external stimulus and information processed by a sensor, we assume that the environment is represented by the same excitable medium as the sensor itself, so a stimulus can directly enter the sensor and be processed.

One possible strategy of sensing is based on a one-to-one relationship between the measured variable and the activated sensor channel [53]. An example of a sensor of that type is illustrated on Fig. 15. It is constructed with a highly excitable, black ring surrounded by a number of coincidence detectors, denoted as X_1, X_2 and X_3. The excitation of a detector appears if a pair of pulses collide on the ring in front of it. Let us consider a homogeneous excitable environment and a spherical pulse of excitation with the source at the point S_1. High excitability of the ring means that excitations on the ring propagate faster than those in the surrounding environment. At a certain moment the pulse arrives at the point P_1, which lies on a line connecting the S_1 and the center of the ring (see Fig. 15b). The arriving pulse creates an excitation on the ring originating from the point P_1. This excitation splits into a pair of pulses rotating in opposite directions and after propagating around the ring, they collide at the point, which is symmetric to P with respect to the center of the ring O. The point of collision can be located by an array of coincidence detectors and thus we have information on the wave vector of the arriving pulse. In this method the resolution depends on the number of detectors used because each of them corresponds to a certain range of the measured wave vectors. The fact that a pulse has appeared in a given output channel implies that no other channel of the sensor gets excited. It is interesting that the output information is reversed in space if compared with the input one; the left sensor channels are excited when an excitation arrives from the right and vice versa.

The geometry of the direction sensor that sends information as an excitation pulse in one of its detector channels can be yet simplified. Two such realizations are illustrated in Fig. 16. The excitable areas that form the sensor are marked black, the excitable surrounding medium where stimuli propagate is gray, and the non-excitable areas are white. Let us consider an excitation generated in the medium M by a source S. It is obvious that if the source is located just above the sensor then pulses of excitation are generated at the ends of the sensor channel D at the same time and they finally annihilate above the central coincidence channel and generate an output pulse in it. If the source is located at a certain angle with respect to the vertical line then the annihilation point is shifted off the center of D. We have performed a series of numerical simulations to find the relation between the position of the source and the position of annihilation point in D. In Fig. 16c and 16d the position of the annihilation point is plotted as a function of the angle between the source position and the vertical line. Although the constructions of sensors seem to be very similar, the working range of angles is larger for the sensor shown on Fig. 16b whereas the sensor shown in Fig. 16a offers slightly better resolution. Using information from two detectors of direction, the position of the source of excitation can be easily located because it is placed on the intersection of the lines representing the detected directions [77].

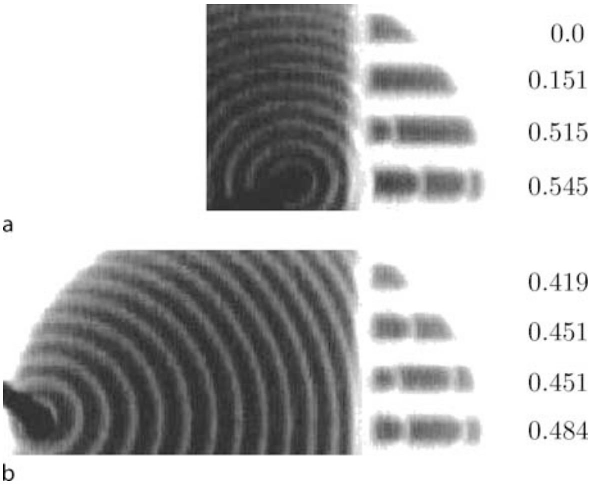
The distance sensor based on frequency transformation. a The distribution of excitable channels, b the firing numbers in different channels as a function of distance; *black, green, blue red and violet curves* correspond to signals in channels 1–5, respectively

Another strategy of sensing is based on the observation that frequencies of pulses excited in a set of sensor channels by an external periodic perturbation contain information on the location of a stimulus. Within this strategy there is no direct relationship between the number of sensor channels and sensor resolution, and, as we show below, a sensor with a relatively small number of channels can quite precisely estimate the distance separating it from the excitation source. As we have mentioned in the Introduction, the frequency of a chemical signal can change after propagating through a barrier made of non-excitable medium. For a given frequency of arriving spikes the frequency of excitations behind the barrier depends on the barrier width and on the angle between the normal angle to the barrier and the wave vector of arriving pulses. This effect can be used for sensing. The geometrical arrangement of excitable and non-excitable areas in a distance sensor is shown in Fig. 17. The excitable signal channels (in Fig. 17a they are numbered 1–5) are wide enough to ensure stable propagation of spikes. They are separated from one another by parallel non-excitable gaps that do not allow for interference between pulses propagating in the neighboring channels. The sensor channels are separated from the excitable medium M by the non-excitable sensor gap G. The width of this gap is very important. If the gap is too wide then no excitation of the medium M can generate a pulse in the sensor channels. If the gap is narrow then any excitation in front of the sensor can pass G and create a spike in each sensor channel so the signals sent out by the sensor channels are identical. However, there is a range of gap widths such that the firing number depends on the wave vector characterizing a pulse at the gap in front of the channel. If the source S is close to the array of sensor channels, then the wave vectors characterizing excitations in front of various channels are significantly different. Thus the frequencies of excitations in various channels should differ too. On the other hand, if the source of excitations is far away from the gap G then the wave vectors in front of different channels should be almost identical and the frequencies of excitations should be the same. Therefore, the system illustrated in Fig. 17a can sense the distance separating it from the source of excitations. If this distance is small then the firing numbers in neighboring sensor channels are different and these differences decrease when the source of excitations moves away. A typical distance dependence of firing numbers observed in different channels is illustrated in Fig. 17b. This result has been obtained in numerical simulations based on the Oregonator model.

The range of sensed distances depends on the number of sensor channels. A similar sensor, but with 4 sensor channels, was studied in [28]. Comparing the results, we observe that the presence of 5th channel significantly improves the range of distances for which the sensor operates. On the other hand, the additional channel has almost no effect on sensor resolution at short distances. The sensor accuracy seems to be a complex function related to the width of the sensor gap and the properties of channels. The firing number of a single channel as a function of the distance between the sensor and the source has a devil-staircase-like form with long intervals where the function is constant corresponding to simple fractions as illustrated in Fig. 5b. In some range of distances the steps in firing numbers of different channels can coincide, so the resolution in this range of distances is poor. For the other regions, the firing numbers change rapidly and even small changes in distance can be easily detected.

The signal transformation on a barrier depends on the frequency of incoming pulses (c. f. Fig. 6) so the distance sensor that works well for one frequency may not work for another. In order to function properly for different stimuli the sensor has to be adapted to the conditions it operates. In practice such adaptation can be realized by the comparison of frequencies of signals in detector channels with the frequency in a control channel. For example the control channel can be separated from the medium M by a barrier so narrow that every excitation of the medium generates a spike. The comparison between the frequency of exci-



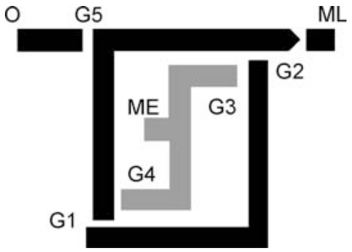
Computing in Geometrical Constrained Excitable Chemical Systems, Figure 18
Two snapshots from the experimental realization of the distance sensor with four channels. In the *upper* figure the source (1 mm thick silver wire) is placed 2 mm away from the sensor; in the *bottom* one the source is 12 mm away. The firing numbers are given next to the corresponding channels

tations in the control channel and in the sensor channels can be used to adjust the sensor gap G. If the frequency of excitations in the sensor channels is the same as in the control channels then the width of the gap should be increased or its excitability level decreased. On the other hand if the frequency in the sensor channel is much smaller than in the control channel (or null) then the gap should be more narrow or more excitable. Such an adaptation mechanism allows one to adjust the distance detector to any frequency of arriving excitations.

The fact that the distance detector described above actually works has been confirmed in experiments with a photosensitive Ru-catalyzed BZ reaction. Typical snapshots from two experiments performed for the source placed 2 and 12 mm away from the sensors are shown in Fig. 18. The firing numbers observed in different sensor channels confirm qualitatively the predictions of numerical simulations. If the source of excitations is close to the sensor gap, then the differences between firing numbers observed in neighboring channels are large. On the other hand, when the source of excitations is far away from the sensor, the frequencies in different channels become similar. The range of distances at which the sensor works is measured in centimeters so it is of the same order as the sensor size.

The Ring Memory and Its Applications

The devices discussed in the previous section can be classified as instant machines [58] capable of performing just the task they have been designed for. A memory where information coded in excitation pulses can be written-in, kept, read-out and, if necessary, erased, significantly increases the information processing potential of structured excitable media. Moreover, due to the fact that the state of memory can be changed by a spike, the memory allows for programming with excitation pulses. One possible realization of a chemical memory is based on the observation that a pulse of excitation can rotate on a ring-shaped excitable area as long as the reactants are supplied and the products removed [41,52,55]. Therefore, a ring with a number of spikes rotating on it can be regarded as a loaded memory cell. Such memory can be erased by counterpropagating pulses. The idea of memory with loading pulses rotating in one direction and erasing pulses in another has been discussed in [49]. If the ring is big then it can be used to memorize a large amount of information because it has many states corresponding to different numbers of rotating pulses. However, in such cases, loading the memory with subsequent pulses may not be reliable because the input can be blocked by the refractory tail left by one of already rotating pulses. The same effect can block the erasing pulses. Therefore, the memory capable of storing just a single bit seems to be more reliable and we consider it in this section. Such memory has two states: if there is a rotating pulse the ring is in the logical TRUE state (we call it loaded); if there is no pulse the state of memory corresponds to the logical FALSE and we call such memory erased.



Computing in Geometrical Constrained Excitable Chemical Systems, Figure 19
The distribution of excitable channels (*dark*) that form a memory cell. The cell is composed of the loading channel ML, the memory ring, the erasing channel ME (marked *gray*) and the output channel O

Let us consider the memory illustrated in Fig. 19. The black areas define the memory ring, the output channel O, and the loading channel ML. The memory ring is formed by two L-shaped excitable areas. The areas are separated by gaps and, as we show below, with a special choice of the gaps the symmetry of the ring is broken and unidirectional rotation ensured. The Z-shaped excitable area composed of gray segments inside the ring forms the erasing channel. The widths of all non-excitable gaps separating excitable areas are selected such that a pulse of excitation propagating perpendicularly to the gap excites the active area on the other site of the gap, but the gap is impenetrable for pulses propagating parallel to the gap. The memory cell can be loaded by a spike arriving from the ML channel. Such a spike crosses the gap and generates an excitation on the ring rotating counterclockwise. The information about loaded memory is periodically sent out as a series of spikes through the output channel O. The rotating pulse does not affect the erasing channel because it always propagates parallel to it. The erasing excitation is generated in the center of the Z-shaped area and it splits into two erasing pulses. These pulses can cross the gaps separating the erasing channel from the memory ring and create a pair of pulses rotating clockwise. A spike that propagates clockwise on the memory ring is not stable because it is not able to cross any of the gaps and dies. It also does not produce any output signal. Therefore, if the memory has not been loaded then an erasing excitation does not load it. On the other hand, if the memory is loaded then clockwise rotating pulses resulting from the excitation of the erasing channel annihilate with the loading pulse and the memory is erased. The idea of using two places where erasing pulses can enter the memory ring is used to ensure that at least one of those places is fully relaxed and so one of erasing pulses can always enter the ring.

In order to verify that such memory works, we have performed a number of simulations using the Rovinsky–Zhabotinsky model of a BZ reaction and have done the experiments. We considered a loaded memory and at a random time the excitation was generated in the middle of the erasing channel. In all cases, such an excitation erased the memory ring. A typical experimental result is illustrated in Fig. 20. Here the channels are 1.5 mm thick and the gaps are 0.1 mm wide. Figure 20a shows the loaded memory and initiated pair of pulses in the erasing channel. In Fig. 20b one of the pulses from the erasing channel enters the memory ring. The memory ring in front of the left part of erasing channel is still in the refractory state so the left erasing pulse has not produced an excitation on the ring. Finally in Fig. 20c we observe the annihilation of the loading pulse with one of erasing pulses. Therefore, the state of memory changed from loaded to unloaded. The experiment was repeated a few times and the results were in a qualitative agreement with the simulations: the loaded memory cell kept its information for a few minutes and it was erased after every excitation of the erasing channel.

Figure 21 illustrates two simple, yet interesting, applications of a memory cell. Figure 21a shows a switchable unidirectional channel that can be opened or closed depending on the state of memory [29]. The channel is constructed with three excitable segments A, B and C separated by signals diodes D1 and D2 (c. f. Fig. 4). The mid segment B is also linked with the output of the memory ring M. Here the erasing channels of M are placed outside the memory ring, but their function is exactly the same as in the memory illustrated in Fig. 19. The idea of switchable channel is similar to the construction of the NOT gate (Fig. 10). If the memory is not loaded then the spike propagation from input I to output O is unperturbed. However, if the memory is loaded then pulses of excitation periodically enter the segment B and annihilate with the transmitted signal. As a result, the channel is either open or blocked depending on the state of the memory. The excitations generated by the memory ring do not spread outside the B segment. On one end their propagation is stopped by the diode D1, on the other by the geometry of the junction between the B channel and the memory output. The state of memory is controlled by the excitation pulses coming from loading and erasing channels, so switchable channels can be used in devices that are programmable with excitation pulses. Figure 21b illustrates a self-erasing memory cell that changes its state from loaded to erased after a certain time. In such a memory cell, the output channel is connected with the erasing one. When the memory is loaded the output signal appears. After some time decided by the length of connecting channels an output pulse returns as an erasing pulse and switches the memory to

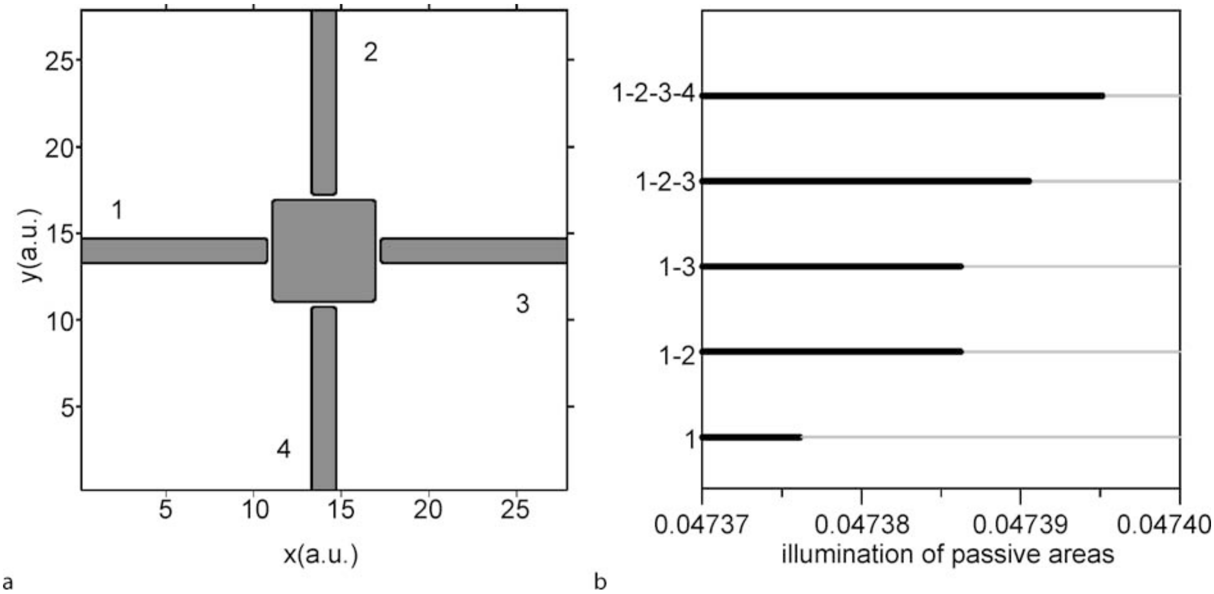
unloaded state. This behavior is an example of a simple feedback process common in self regulating information processing systems.

Using memory cells, signal diodes, and coincidence detectors, one can construct devices which perform more complex signal processing operations. As an example, we present a simple chemical realization of a device that counts arriving spikes and returns their number in any chosen positional representation [27]. Such a counter can be assembled from single digit counters. The construction of a single digit counter depends on the representation used. Here, as an example, we consider the positional representation with the base 3. The geometry of a single digit counter is schematically shown in Fig. 22. Its main elements are two memory cells M_1 and M_2 and two coincidence detectors C_1 and C_2. At the beginning let us assume that none of the memory cells are loaded. When the first pulse arrives through the input channel I_0, it splits at all junctions and excitations enter segments B_0, B_1 and B_2. The pulse that has propagated through B_0 loads the memory cell M_1. The pulses that have propagated through B_1 and B_2 die at the bottom diodes of segments C_1 and C_2 respectively. Thus, the first input pulse loads the memory M_1 and does not change the state of M_2. When M_1 is loaded, pulses of excitation are periodically sent to segments B_0 and C_1 via the bottom channel. Now let us consider what happen when the second pulse arrives. It does not pass through B_0 because it annihilates with the pulses arriving from the memory M_1. The excitations generated by the second pulse can enter B_1 and B_2. The excitation that propagated through B_2 dies at the bottom diode of the segment C_2. The pulse that has propagated through B_1 enters C_1, annihilates with a pulse from memory M_1 and activates the coincidence detector. The output pulse from the coincidence detector loads the memory M_2. Therefore, after the second input pulse both memories M_1 and M_2 are loaded. If the third pulse arrives the segments B_0 and B_1 are blocked by spikes sent from the memory rings. The generated excitation can enter channel B_2 and its collision with a pulse coming from the memory cell M_2 activates the output channel of C_2. The output signal is directed to the counter of responsible for the digit at next position (I1) and it is also used to erase all memory cells. Thus after the third pulse both memory cells M1 and M2 are erased. The counter shown in Fig. 22 returns a digit in a representation with the base 3: here 0 is represented by the $(M_1, M_2) = (0, 0)$, 1 by $(1, 0)$, 2 by $(1, 1)$ and the next pulse changes the state of memory cell into $(M_1, M_2) = (0, 0)$. Of course, using $n - 1$ memory cells in a single digit counter we can represent digits of the system with base n. A cascade of single digit counters (see Fig. 22b) gives a positional representation of the number of arriving pulses.

Artificial Chemical Neurons with Excitable Medium

In this section we discuss a simple realization of an artificial neuron with structured excitable medium and show how neuron networks can be used in programmable devices. We consider a chemical analogy of the McCulloch–Pitts neuron, i. e., a device that produces the output signal if the combined activation exceeds a critical value [32]. The geometry of a chemical neuron is inspired by a the structure of biological neuron [30]. One of its realizations with an excitable medium is illustrated on Fig. 23. Another geometry of a neuron has been discussed in [24]. In an artificial chemical neuron, like in real neurons, dendrites (input channels 1–4) transmit weak signals which are added together through the processes of spatial and temporal integration inside the cell body (part C). If the aggregate excitation is larger than the threshold value the cell body gets excited. This excitation is transmitted as an output signal down the axon (the output channel) and the amplitude of the output signal does not depend on the value of integrated inputs but only on the properties of the medium that makes the output channel. In Fig. 23a the axon is not shown and we assume that it is formed by an excitable channel located perpendicularly above the cell body. In the construction discussed in [24] both dendrites and the axon were on a single plane. We have studied the neuron using numerical simulations based on the Oregonator model and the reaction-diffusion equations have been solved on a square grid. The square shape of the neuron body and the input channels shown on Fig. 23a allows for precise definition of the boundary between the excitable and non-excitable parts. The idea behind the chemical neuron is similar to that of the AND gate: perturbations introduced by multiple inputs combine and generate a stronger excitation of the cell body than this resulting from a single input pulse. Therefore, it is intuitively clear that if we are able to adjust the amplitudes of excitations coming from individual input channels, then the output channel becomes excited only when the required number of excitations arrive from the inputs.

In the studied neuron, the amplitudes of spikes in input channels have been adjusted by sub-excitability of



Computing in Geometrical Constrained Excitable Chemical Systems, Figure 23
Artificial chemical neuron. a The geometry of excitable and non-excitable areas; b The response of the neuron to different types of excitations as a function of the illumination of non-excitable regions. The numbers given on the *left list* the excited channels. The values of ϕ_p for which the neuron body gets excited are marked by a *thick line*

these channels which can be controlled by the channel width or by the illumination of surrounding non-excitable medium. In our simulations we considered different values of ϕ_p for non-excitable areas, whereas $\phi_a = 0.007$ characterizing excitable regions has been fixed for dendrites and the neuron body. Simulation results shown on Fig. 23b indicate that the properties of chemical neurons are very sensitive with respect to changes in ϕ_p. The thick line marks the values of ϕ_p for which the output signal appears. For the parameters used when ϕ_p is slightly below 0.047377 any single excitation produces an output signal. On the other hand if $\phi_p > 0.047397$ then even the combined excitation of all inputs is not sufficient to excite the neuron. In between those two limiting values we observe all other thresholds; i. e., an output excitation as the result of two or three combined inputs. Therefore, by applying the proper illumination level the structure shown in Fig. 23a can work as a four input McCulloch–Pitts neuron with the required threshold. A similar high sensitivity of the neuron properties on ϕ_a is also observed. It means that neuron properties can be controlled with tiny changes in system parameters.

The chemical neuron illustrated in Fig. 23a can be used to program signal processing with pulses of excitation. If we set the illuminations such that any two input pulses produce the output and use one of the inputs to control the device, then if the control pulse is present the device performs the OR operation on the other inputs. If there is no control pulse, it calculates an alternative on conjunctions of all pairs of channels.

The geometry of a network constructed with neurons can be easily controlled if the switchable channels illustrated on Fig. 21b are used to establish or cut connections between processing elements. The state of the memory that controls the channel may depend on the state of the network through a feedback mechanism what allows for network training. In the chemical programming described above pulses of concentration of the same reagent are used to store and process information, and to program the medium. Therefore, the output signal may be directly used to change the network geometry. External programming factors like illumination or a temperature field [3] are difficult for applications in three dimensional structures. The pulse based programming seems to be easier if the proper geometry of switchable channels and of the feedbacks is introduced.

At the first look it seems that a practical realization of a network built of chemical neurons may be difficult. However, the geometry of a considered neuron looks quite similar to structures of phases formed in a multicomponent system. For example, the diamond structure in an oil-water-surfactant system, which spontaneously appears at certain thermodynamic conditions [11], has a form of centers linked with the four nearest neighbors. If the reactants corresponding for excitability are soluble in water, but not in oil then the water rich phase forms the structure of excitable channels and processing elements just as the result of thermodynamic conditions. Within a certain range of parameters, such a structure is thermodynamically stable. This means that the network has an auto-repair ability and robustness against unexpected destruction. The subexcitability of a channel is related to its diameter, so the required value can be obtained by selecting the right composition of the mixture and the conditions at which the phase transition occurs. Moreover, the structure is three dimensional, which allows for a higher density of processing elements than that obtained with the classical two-dimensional techniques, for example lithography.

Perspectives and Conclusions

Perspectives

In this article we have described a number of simple devices constructed with structured excitable chemical media which process information coded in excitation pulses. All the considered systems process information in an unconventional (non-von Neumann) way; i. e., without an external clock or synchronizing signal that controls the sequence of operations. On the other hand, in many cases the right timing of performed operation is hidden in the geometrical distribution and sizes of excitable regions. The described devices can be used as building blocks for more complex systems that process signals formed of excitation pulses. Some of the discussed devices can be controlled with spikes. Therefore, there is room for programming and learning. However, the further development of applications of structured excitable medium for information processing along this line seem to follow the evolution of classical electronic computing. In our opinion it would be more interesting to step away from this path and learn more about the potential offered by excitable media.

It would be interesting to study new types of excitable media suitable for information processing. Electrical analogs of reaction-diffusion systems (▶ Unconventional Computing, Novel Hardware for) seem promising, because they are more robust than the wetware based on liquid BZ media. In such media, spikes propagate much faster and the spatial scale can be much reduced if compared with typical chemical systems. They seem to be promising candidates for the hardware in geometrically oriented problems and direct image processing [4]. However, two interesting properties of chemical reaction-diffusion systems are lost in their electrical analogs. First, chemical information processing systems, unlike the electronic ones, integrate two functions: the chemical reactivity and the ability to process information. Having in mind the excitable oxidation of CO on a Pt surface and the potential application of this medium for information processing [23], we can think of catalysts that are able to monitor their activity and report it. Second, the media described in ▶ Unconventional Computing, Novel Hardware for are two-dimensional. Most of the systems discussed in this article can be realized in three dimensions. The use of two dimensional media in chemical experiments is mainly related with significant difficulties in observations of three dimensional chemical excitations [42]. Potential application of phase transitions for channel structure generation described in the previous section should increase the interest in information processing with three dimensional medium.

Studies on more effective methods of information coding are important for the further development of reaction-diffusion computing. The most simple translation of chemistry into the language of information science based on the equivalence between the presence of a spike and the TRUE logic value is certainly not the most efficient. It can be expected that information interpreted within multi-valued logic systems is more suitable for transformations with the use of structured media [47]. As an example, let us consider three-valued logic encoded by excitation pulses in the following way: the lack of a pulse represents a logical FALSE (F), two pulses separated by time δt correspond at the logical TRUE (T), and one pulse is interpreted as a "nonsense" (★). Let us assume that two signals coded as described above are directed to the inputs of the AND gate illustrated on Fig. 9 and that they are fully synchronized at the input. The gap between the input and output channels is adjusted such that an activator diffusing from a single traveling pulse is not sufficient to generate a new pulse in the output channel, but the excitation resulting from the collision of facing pulses at the junction point exceeds the threshold and the output pulse is generated. Moreover, let us assume that the system is described by the dynamics for which signals are transformed as illustrated in Fig. 7a (for example FitzHugh–Nagumo dynamics) and that the time difference between spikes δt is selected such that the second spike can pass the gap. The output signal appears when spikes from both input channels are in coincidence or when the second spike from the same input arrives. As a result the device performs the following function within 3-valued logic [47]:

$\boxdot_{\mathcal{F}_1}$	T	F	$\star$
T	T	$\star$	$\star$
F	$\star$	F	F
$\star$	$\star$	F	$\star$

The same operation, if performed on a classical computer would require a procedure that measures time between spikes. The structured excitable medium performs it naturally provided that the time δt is adjusted with the properties of the medium and the geometry of the gap. Of course, similar devices that process variables of n-valued logic can be also constructed with structured excitable media.

Conclusions

In the article we have presented a number of examples that should convince the reader that structured excitable media can be used for information processing. The future research will verify if this branch of computer science is fruitful. It would be important to find new algorithms that can be efficiently executed using a structured excitable medium. However, the ultimate test for the usefulness of ideas should come from biology. It is commonly accepted that excitable behavior is responsible for information processing and coding in living organisms [8,31,36,60]. We believe that studies on chemical information processing will help us to better understand these problems. And, although at the moment computing with a homogeneous excitable medium seems to offer more applications than that with the structured one, we believe the proportions will be reversed in the future. After all, our brains are not made of a single piece of a homogeneous excitable medium.

Acknowledgments

The research on information processing with structured excitable medium has been supported by the Polish State Committee for Scientific Research project 1 P03B 035 27.

Article Outline

Glossary

Integrable This term is generally used in more than one way and in different contexts. For the purposes of this article, a partial differential equation or system of partial differential equations is *integrable* if it can be solved explicitly to yield *solitons* (qv).

Manakov system A system of two cubic Schrödinger equations where the self- and cross-phase modulation terms have equal weight.

Nonlinear Schrödinger equation A partial differential equation that has the same form as the Schrödinger equation of quantum mechanics, with a term nonlinear in the dependent variable, and for the purposes of this article, interpreted classically.

Self- and cross-phase modulation Any terms in a nonlinear Schrödinger equation that involve nonlinear functions of the dependent variable of the equation, or nonlinear functions of a dependent variable of another (coupled) equation, respectively.

Solitary wave A solitary wave is a wave characterized by undistorted propagation. Solitary waves do not in general maintain their shape under perturbations or collisions.

Soliton A soliton is a solitary wave which is also robust under perturbations and collisions.

Turing equivalent Capable of simulating any Turing Machine, and hence by Turing's Thesis capable of performing any computation that can be carried out by a sequence of effective instructions on a finite amount of data. A machine that is Turing equivalent is therefore as powerful as any digital computer. Sometimes a device that is Turing equivalent is called "universal."

Definition of the Subject

Solitons are localized, shape-preserving waves characterized by robust collisions. First observed as water waves by John Scott Russell [29] in the Union Canal near Edinburgh and subsequently recreated in the laboratory, solitons arise in a variety of physical systems, as both temporal pulses which counteract dispersion and spatial beams which counteract diffraction.

Solitons with two components, vector solitons, are computationally universal due to their remarkable collision properties. In this article, we describe in detail the characteristics of Manakov solitons, a specific type of vector soliton, and their applications in computing.

Introduction

In this section, we review the basic principles of soliton theory and spotlight relevant experimental results. Interestingly, the phenomena of soliton propagation and collision occur in many physical systems despite the diversity of mechanisms that bring about their existence. For this reason, the discussion in this article will treat temporal and spatial solitons interchangeably, unless otherwise noted.

Scalar Solitons

A pulse in optical fiber undergoes dispersion, or temporal spreading, during propagation. This effect arises because the refractive index of the silica glass is not constant, but is rather a function of frequency. The pulse can be decomposed into a frequency range—the shorter the pulse, the broader its spectral width. The frequency dependence of the refractive index will cause the different frequencies of the pulse to propagate at different velocities, giving rise to dispersion. As a result, the pulse develops a chirp, meaning that the individual frequency components are not evenly distributed throughout the pulse. There are two types of dispersion: normal and anomalous. If the longer wavelengths travel faster, the medium is said to have *normal*dispersion. If the opposite is true, the medium has *anomalous* dispersion.

The response of a dielectric such as optical fiber is nonlinear. Most of the nonlinear effects in fiber originate from nonlinear refraction, where the refractive index n depends on the intensity of the propagating field according to the relation

$$n = n_0 + n_2|E|^2 , \tag{1}$$

where n_0 is the linear part of the refractive index, $|E^2|$ is the optical intensity, and n_2 is the coefficient of nonlinear contribution to the refractive index. Because the material responds almost instantaneously, on the order of femtoseconds, and because the phase shift $\Delta\phi$ is proportional to n, each component of an intense optical pulse sees a phase shift proportional to its intensity. Since the frequency shift $\delta\omega = -(\partial\Delta\phi)/(\partial t)$, the leading edge of the pulse is red-shifted ($\delta\omega < 0$), while the trailing edge is blue-shifted ($\delta\omega > 0$), an effect known as self-phase modulation (SPM). As a result, if the medium exhibits normal dispersion, the pulse is broadened; for anomalous dispersion, the pulse is compressed. Under the proper conditions, this pulse compression can exactly cancel the linear, dispersion-induced broadening, resulting in distortionless soliton propagation. For more details, see the book by Agrawal [3].

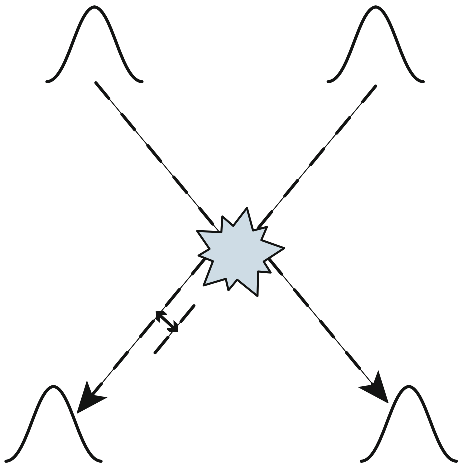
The idealized mathematical model for this pulse propagation is the nonlinear Schrödinger equation (NLSE):

$$i\frac{\partial u}{\partial z} \pm \frac{1}{2}\frac{\partial^2 u}{\partial x^2} + |u|^2 u = 0, \tag{2}$$

where $u(z,x)$ is the complex-valued field envelope, z is a normalized propagation distance and x is normalized time propagating with the group velocity of the pulse. The second and third terms describe dispersion and the intensity-dependent Kerr nonlinearity, respectively. The coefficient of the dispersion term is positive for anomalous dispersion and negative for normal dispersion. Equation (2), known as the *scalar* NLSE, is integrable—that is, it can be solved analytically, and collisions between solitons are 'elastic,' in that no change in amplitude or velocity occurs as a result of a collision. Zakharov and Shabat [38] first solved this equation analytically using the inverse scattering method. It describes, for example, the propagation of picosecond or longer pulses propagating in lossless optical fiber.

Two solitons at different wavelengths will collide in an optical fiber due to dispersion-induced velocity differences. A schematic of such a collision is depicted in Fig. 1. The scalar soliton collision is characterized by two phenomena— a position and phase shift—both of which can be understood in the same intuitive way. During collision, there will be a local increase in intensity, causing a local increase in the fiber's refractive index, according to Eq. (1). As a result, both the soliton velocity and phase will be affected during the collision.

From an all-optical signal processing perspective, the phase and position shifts in a soliton collision are not useful. This is because these effects are independent of any soliton properties that are changed by collision; that is, the result of one collision will not affect the result of subsequent collisions. Scalar solitons are therefore not useful for complex logic or computing, which depend on multiple, cascaded interactions.



Computing with Solitons, Figure 1
Schematic of a scalar soliton collision, in which amplitude and velocities are unchanged. The two soliton collision effects are a position shift (depicted through the translational shift in the soliton path) and phase shift (not pictured)

Despite this setback, it was discovered later that a system similar to the scalar NLSE, the Manakov system [19], possesses very rich collisional properties [26] and is integrable as well. Manakov solitons are a specific instance of two-component vector solitons, and it has been shown that collisions of Manakov solitons are capable of transferring information via changes in a complex-valued polarization state [16].

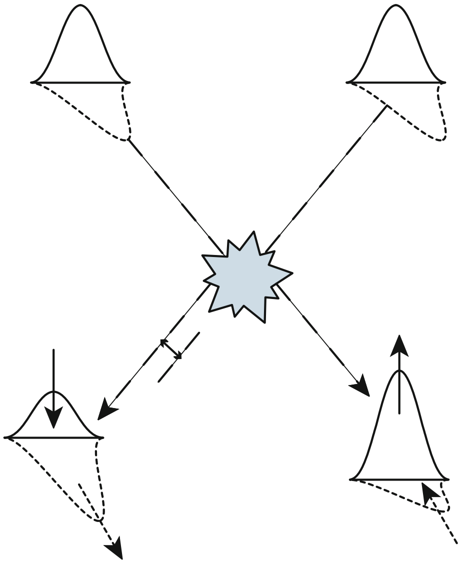
Vector Solitons

When several field components, distinguished by polarization and/or frequency, propagate in a nonlinear medium, the nonlinear interaction between them must be considered as well. This interaction between field components results in intensity-dependent nonlinear coupling terms analogous to the self-phase modulation term in the scalar case. Such a situation gives rise to a set of coupled nonlinear Schrödinger equations, and may allow for propagation of *vector* solitons. For the case of two components propagating in an ideal sl medium with no higher-order effects and only intensity-dependent nonlinear coupling, the equations become:

$$\begin{aligned} i\frac{\partial u_1}{\partial z} + \frac{\partial^2 u_1}{\partial x^2} + 2\mu(|u_1|^2 + \alpha|u_2|^2)u_1 = 0\,, \\ i\frac{\partial u_2}{\partial z} + \frac{\partial^2 u_2}{\partial x^2} + 2\mu(|u_2|^2 + \alpha|u_1|^2)u_2 = 0\,, \end{aligned} \tag{3}$$

where $u_1(z,x)$ and $u_2(z,x)$ are the complex-valued pulse envelopes for each component, μ is a nonlinearity parameter, and α describes the ratio between self- and cross-phase modulation contributions to the overall nonlinearity. Only for the special case of $\alpha = 1$ are Eqs. (3) integrable. First solved using the method of inverse scattering by Manakov [19], Eqs. (3) admit solutions known as Manakov solitons. For nonintegrable cases ($\alpha \neq 1$), some analytical solitary-wave solutions are known for specific cases, although in general a numerical approach is required [36]. The specific case of $\alpha = 2/3$, for example, corresponds to linearly birefringent polarization maintaining fiber, and will be considered in more detail in Sect. "Experiments".

Due to their multicomponent structure, vector solitons have far richer collision dynamics than their scalar, one-component counterparts. Recall that scalar collisions are characterized by phase and position shifts only. Vector soliton collisions also exhibit these effects, with the added feature of possible intensity redistributions between the component fields [19,26]. This process is shown schematically in Fig. 2. In the collision, two conservation relations are satisfied: (i) the energy in each soliton is conserved and (ii) the energy in each component is conserved. It can be seen that when the amplitude of one component in a soliton increases as a result of the collision, the other component decreases, with the opposite exchange in the second soliton. The experimental observation of this effect will be discussed in Sect. "Experiments". In addition to fundamental interest in such solitons, collisions of vector solitons make possible unique applications, including collision-based logic and universal computation [16,27,34,35], as discussed in Sect. "Manakov Soliton Computing".



Computing with Solitons, Figure 2
Schematic of a vector soliton collision, which exhibits a position shift and phase shift (not pictured), similar to the scalar soliton collision (cf. Fig. 1). Vector soliton collisions also display an energy redistribution among the component fields, shown here as two orthogonal polarizations. Arrows indicate direction of energy redistribution

Manakov Solitons

As mentioned in Sect. "Introduction", computation is possible using vector solitons because of an energy redistribution that occurs in a collision. In this section, we provide the mathematic background of Manakov soliton theory, in order to understand soliton computing and a remarkable way to achieve bistability using soliton collisions as described in Sects. "Manakov Soliton Computing" and "Multistable Soliton Collision Cycles", respectively.

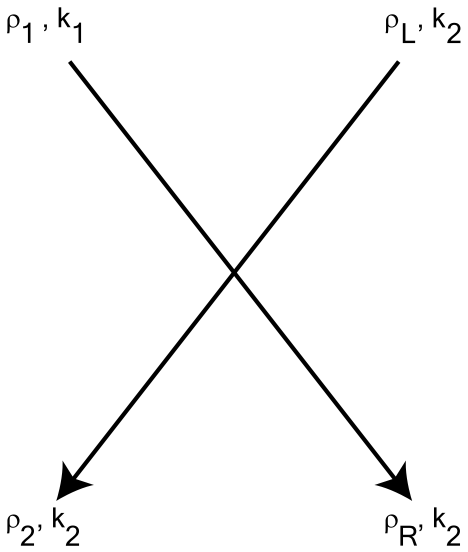
The Manakov system consists of two coupled NLSEs [19]:

$$\begin{aligned} i\frac{\partial q_1}{\partial z} + \frac{\partial^2 q_1}{\partial x^2} + 2\mu(|q_1|^2 + |q_2|^2)q_1 = 0\,, \\ i\frac{\partial q_2}{\partial z} + \frac{\partial^2 q_2}{\partial x^2} + 2\mu(|q_1|^2 + |q_2|^2)q_2 = 0\,, \end{aligned} \tag{4}$$

where $q_1(x,z)$ and $q_2(x,z)$ are two interacting optical components, μ is a positive parameter representing the strength of the nonlinearity, and x and z are normalized space and propagation distance, respectively. As mentioned in Sect. "Vector Solitons", the Manakov system is a special case of Eqs. (3) with $\alpha = 1$. The two components can be thought of as components in two polarizations, or, as in the case of a photorefractive crystal, two uncorrelated beams [11].

Manakov first solved Eqs. (4) by the method of inverse scattering [19]. The system admits single-soliton, two-component solutions that can be characterized by a complex number $k \equiv k_R + ik_I$, where k_R represents the energy of the soliton and k_I the velocity, all in normalized units. The additional soliton parameter is the complex-valued polarization state $\rho \equiv q_1/q_2$, defined as the (z- and x-independent) ratio between the q_1 and q_2 components.

Figure 3 shows the schematic for a general two-soliton collision, with initial parameters ρ_1, k_1 and ρ_L, k_2, corresponding to the right-moving and left-moving solitons, respectively. The values of k_1 and k_2 remain constant during collision, but in general the polarization state changes. Let ρ_1 and ρ_L denote the respective soliton states before impact, and suppose the collision transforms ρ_1 into ρ_R, and ρ_L into ρ_2. It turns out that the state change undergone



Computing with Solitons, Figure 3
Schematic of a general two-soliton collision. Each soliton is characterized by a complex-valued polarization state *ρ* and complex parameter *k*. Reprinted with permission from [34]. Copyright by the American Physical Society

by each colliding soliton takes on the very simple form of a linear fractional transformation (also called a bilinear or Möbius transformation). Explicitly, the state of the emerging left-moving soliton is given by [16]:

$$\rho_2 = \frac{[(1-g)/\rho_1^* + \rho_1]\rho_L + g\rho_1/\rho_1^*}{g\rho_L + (1-g)\rho_1 + 1/\rho_1^*} , \tag{5}$$

where

$$g \equiv \frac{k_1 + k_1^*}{k_2 + k_1^*} . \tag{6}$$

The state of the right-moving soliton is obtained similarly, and is

$$\rho_R = \frac{[(1-h^*)/\rho_L^* + \rho_L]\rho_1 + h^*\rho_L/\rho_L^*}{h^*\rho_1 + (1-h^*)\rho_L + 1/\rho_L^*} , \tag{7}$$

where

$$h \equiv \frac{k_2 + k_2^*}{k_1 + k_2^*} . \tag{8}$$

We assume here, without loss of generality, that k_{1R}, $k_{2R} > 0$.

Several properties of the linear fractional transformations in Eqs. (5) and (7) are derived in [16], including the characterization of inverse operators, fixed points, and implicit forms. In particular, when viewed as an operator every soliton has an *inverse*, which will undo the effect of the operator on the state. Note that this requires that the inverse operator have the same k parameter as the original, a condition that will hold in our application of computing in the next section.

These state transformations were first used by Jakubowski et al. [16] to describe logical operations such as NOT. Later, Steiglitz [34] established that arbitrary computation was possible through time gating of Manakov $(1+1)$-dimensional spatial solitons. We will describe this in Sect. "Manakov Soliton Computing".

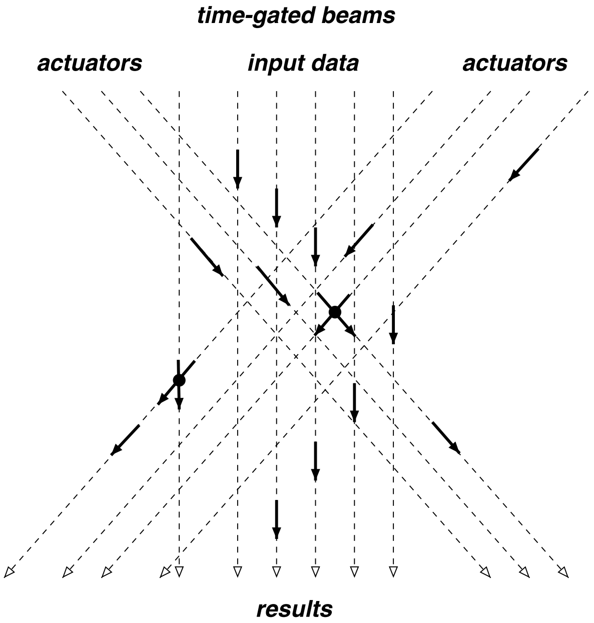
There exist several candidates for the physical realization of Manakov solitons, including photorefractive crystals [4,5,9,11,30], semiconductor waveguides [17], quadratic media [33], and optical fiber [23,28]. In Sect. "Experiments", we discuss in detail an experiment with vector solitons in linearly birefringent optical fiber.

Manakov Soliton Computing

We described in the previous section how collisions of Manakov solitons can be described by transformations of a complex-valued state which is the ratio between the two Manakov components. We show in this section that general computation is possible if we use (1+1)-dimensional spatial solitons that are governed by the Manakov equations and if we are allowed to time-gate the beams input to the medium. The result is a dynamic computer without spatially fixed gates or wires, which is unlike most present-day conceptions of a computer that involve integrated circuits, in which information travels between logical elements that are fixed spatially through fabrication on a silicon wafer. We can call such a scheme "nonlithographic," in the sense that there is no architecture imprinted on the medium.

The requirements for computation include cascadability, fanout, and Boolean completeness. The first, cascadability, requires that the output of one device can serve as input to another. Since any useful computation consists of many stages of logic, this condition is essential. The second, fanout, refers to the ability of a logic gate to drive at least two similar gates. Finally, Boolean completeness makes it possible to perform arbitrary computation.

We should emphasize that although the model we use is meant to reflect known physical phenomena, at least in the limit of ideal behavior, the result is a mathematical one. Practical considerations of size and speed are not considered here, nor are questions of error propagation. In this sense the program of this article is analogous to Fredkin and Toffoli [13] for ideal billiard balls, and Shor [31] for quantum mechanics. There are however several can-



Computing with Solitons, Figure 4

The general physical arrangement considered in this paper. didates for physical instantiation of the basic ideas in this paper, as noted in the previous section.

Although we are describing computation embedded in a homogeneous medium, and not interconnected *gates* in the usual sense of the word, we will nevertheless use the term *gates* to describe prearranged sequences of soliton collisions that effect logical operations. We will in fact adopt other computer terms to our purpose, such as *wiring* to represent the means of moving information from one place to another, and *memory* to store it in certain ways for future use.

We will proceed in the construction of what amounts to a complete computer in the following stages: First we will describe a basic gate that can be used for FANOUT. Then we will show how the same basic configuration can be used for NOT, and finally, NAND. Then we will describe ways to use time gating of the input beams to interconnect signals. The NAND gate, FANOUT, and interconnect are sufficient to implement any computer, and we conclude with a layout scheme for a general-purpose, and hence Turing-equivalent computer. The general picture of the physical arrangement is shown in Fig. 4.

Figure 5 shows the usual picture of colliding solitons, which can work interchangeably for the case of temporal or spatial solitons. It is convenient for visualization purposes to turn the picture and adjust the scale so the axes are horizontal and vertical, as in Fig. 6. We will use binary logic, with two distinguished, distinct complex numbers representing TRUE and FALSE, called 1 and 0, respectively. In fact, it turns out to be possible to use complex 1 and 0 for these two state values, and we will do that throughout this paper, but this is a convenience and not at all a necessity. We will thus use complex polarization states 1 and 0 and logical 1 and 0 interchangeably.

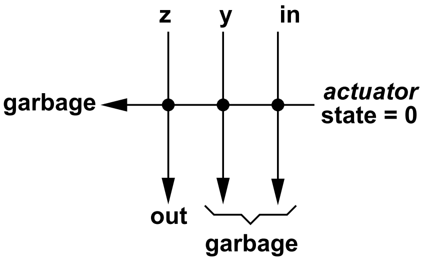
FANOUT

We construct the FANOUT gate by starting with a COPY gate, implemented with collisions between three down-moving, vertical solitons and one left-moving horizontal soliton. Figure 7 shows the arrangement. The soliton state labeled *in* will carry a logical value, and so be in one of the two states 0 or 1. The left-moving soliton labeled *actuator* will be in the fixed state 0, as will be the case throughout this paper. The plan is to adjust the (so far) arbitrary states z and y so that *out* = *in*, justifying the name COPY. It is reasonable to expect that this might be possible, be-



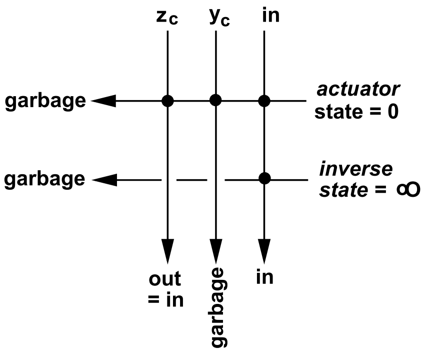
Computing with Solitons, Figure 7
COPY gate. Reprinted with permission from [34]. Copyright by the American Physical Society

cause there are four degrees of freedom in the two complex numbers z and y, and two complex equations to satisfy: that *out* be 1 and 0 when *in* is 1 and 0, respectively. Values that satisfy these four equations in four unknowns were obtained numerically. We will call them z_c and y_c. It is not always possible to solve these equations; Ablowitz et al. [1] showed that a unique solution is guaranteed to exist in certain parameter regimes. However, explicit solutions have been found for all the cases used in this section, and are given in Table 1.

To be more specific about the design problem, write Eq. (5) as the left-moving product $\rho_2 = L(\rho_1, \rho_L)$, and similarly write Eq. (7) as $\rho_R = R(\rho_1, \rho_L)$. The successive left-moving products in Fig. 7 are $L(in, 0)$ and $L(y, L(in, 0))$. The *out* state is then $R(z, L(y, L(in, 0)))$. The stipulation that 0 maps to 0 and 1 maps to 1 is expressed by the following two simultaneous complex equations in two complex unknowns

$$R(z, L(y, L(0, 0))) = 0 \,,$$
$$R(z, L(y, L(1, 0))) = 1 \,.$$

It is possible to solve for z as a function of y and then eliminate z from the equations, yielding one complex equation in the one complex unknown y. This is then solved numerically by grid search and successive refinement. There is no need for efficiency here, since we will require solutions in only a small number of cases.



Computing with Solitons, Figure 8
FANOUT gate. Reprinted with permission from [34]. Copyright by the American Physical Society

To make a FANOUT gate, we need to recover the input, which we can do using a collision with a soliton in the state which is the inverse of 0, namely ∞ [16]. Figure 8 shows the complete FANOUT gate. Notice that we indicate collisions with a dot at the intersection of paths, and require that the continuation of the inverse soliton not intersect the continuation of z that it meets. We indicate that by a broken line, and postpone the explanation of how this "wire crossing" is accomplished. It is immaterial whether the continuation of the inverse operator hits the continuation of y, because it is not used later. We call such solitons *garbage* solitons.

NOT and ONE Gates

In the same way we designed the complex pair of states (z_c, y_c) to produce a COPY and FANOUT gate, we can find a pair (z_n, y_n) to get a NOT gate, mapping 0 to 1 and 1 to 0; and a pair (z_1, y_1) to get a ONE gate, mapping both 0 and 1 to 1. These (z, y) values are given in Table 1.

We should point out that the ONE gate in itself, considered as a one-input, one-output gate, is not invertible, and could never be achieved by using the continuation of one particular soliton through one, or even many collisions. This is because such transformations are always nonsin-

Computing with Solitons, Table 1

gular linear fractional transformations, which are invertible [16]. The transformation of state from the input to the continuation of z is, however, much more complicated and provides the flexibility we need to get the ONE gate. It turns out that this ONE gate will give us a row in the truth table of a NAND, and is critical for realizing general logic.

Output/Input Converters, Two-Input Gates, and NAND

To perform logic of any generality we must of course be able to use the output of one operation as the input to another. To do this we need to convert logic (0/1) values to some predetermined z and y values, the choice depending on the type of gate we want. This results in a two-input, one-output gate.

As an important example, here's how a NAND gate can be constructed. We design a z-converter that converts 0/1 values to appropriate values of z, using the basic three-collision arrangement shown in Fig. 7. For a NAND gate, we map 0 to z_1, the z value for the ONE gate, and map 1 to z_n, the z value for the NOT gate. Similarly, we construct a y-converter that maps 0 to y_1 and 1 to y_n. These z- and y-converters are used on the fanout of one of the inputs, and the resulting two-input gate is shown in Fig. 9. Of course these z- and y-converters require z and y values themselves, which are again determined by numerical search (see Table 1).

The net effect is that when the left input is 0, the other input is mapped by a ONE gate, and when it is 1 the other input is mapped by a NOT gate. The only way the output can be 0 is if both inputs are 1, thus showing that this is a NAND gate. Another way of looking at this construction is that the 2×2 truth table of (left input)×(right input) has as its 0 row a ONE gate of the columns (1 1), and as its 1 row a NOT gate of the columns (1 0).

The importance of the NAND gate is that it is *universal* [20]. That is, it can be used with interconnects and fanouts to construct any other logical function. Thus we have shown that with the ability to "wire" we can implement any logic using the Manakov model.

We note that other choices of input converters result in direct realizations of other gates. Using input converters that convert 0 and 1 to (z_c, y_c) and (z_n, y_n), respectively, results in a truth table with first row (0 1) and second row (1 0), an XOR gate. Converting 0 and 1 to (z_c, y_c) and (z_1, y_1), respectively, results in an OR gate, and so on.

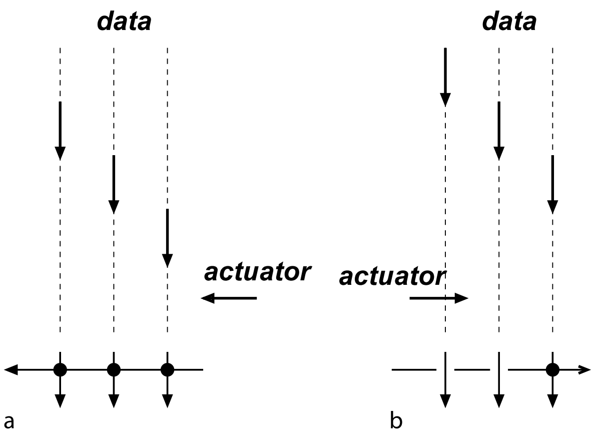
Time Gating

We next take up the question of interconnecting the gates described above, and begin by showing how the continuation of the input in the COPY gate can be restored without affecting the other signals. In other words, we show how a simple "wire crossing" can be accomplished in this case.

For spatial solitons, the key flexibility in the model is provided by assuming that input beams can be time-gated; that is, turned on and off. When a beam is thus gated, a finite segment of light is created that travels through the medium. We can think of these finite segments as finite light pulses, and we will call them simply *pulses* in the remainder of this article.

Figure 10a shows the basic three-collision gate implemented with pulses. Assuming that the actuator and data pulses are appropriately timed, the actuator pulse hits all three data pulses, as indicated in the projection below the space-space diagram. The problem is that if we want a later actuator pulse to hit the rightmost data pulse (to invert the state, for example, as in the FANOUT gate), it will also hit the remaining two data pulses because of the way they must be spaced for the earlier three collisions.

We can overcome this difficulty by sending the actuator pulse from the left instead of the right. Timing it appropriately early it can be made to miss the first two data



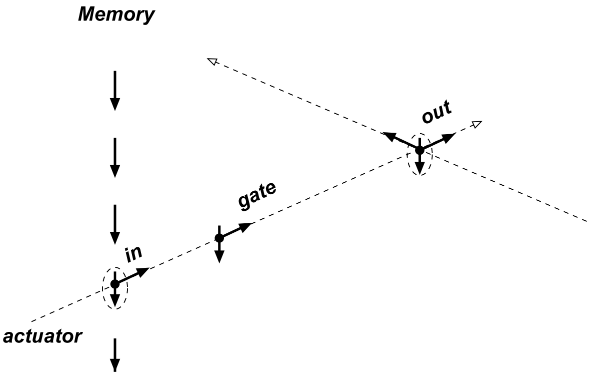
Computing with Solitons, Figure 10
a When entered from the right and properly timed, the actuator pulse hits all three data pulses, as indicated in the projection at the bottom; b When entered from the left and properly timed, the actuator pulse misses two data pulses and hits only the rightmost data pulse, as indicated in the projection at the bottom. Reprinted with permission from [34]. Copyright by the American Physical Society

pulses, and hit the third, as shown in Fig. 10b. It is easy to check that if the velocity of the right-moving actuator solitons is algebraically above that of the data solitons by the same amount that the velocity of the data solitons is algebraically above that of the left-moving actuator solitons, the same state transformations will result. For example, if we choose the velocities of the data and left-moving actuator solitons to be $+1$ and -1, we should choose the velocity of the right-moving actuator solitons to be $+3$. This is really a consequence of the fact that the g and h parameters of Eqs. (6) and (8) in the linear fractional transformation depend only on the difference in the velocities of the colliding solitons.

Wiring

Having shown that we can perform FANOUT and NAND, it remains only to show that we can "wire" gates so that any outputs can be fed to any inputs. The basic method for doing this is illustrated in Fig. 11. We think of data as stored in the down-moving pulses in a column, which we can think of as "memory". The observer moves with this frame, so the data appears stationary.

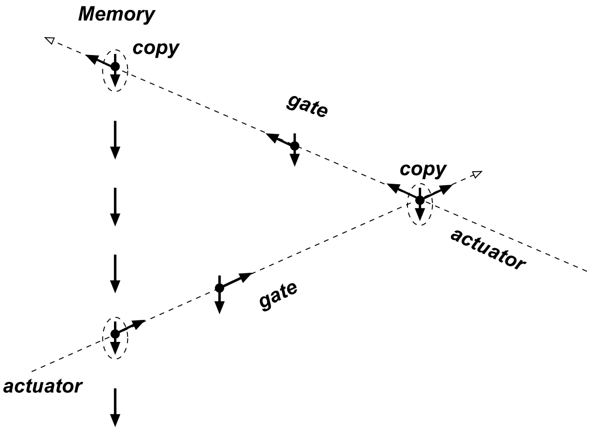
Pulses that are horizontal in the three-collision gates shown in previous figures will then appear to the observer to move upward at inclined angles. It is important to notice that these upward diagonally moving pulses are evanescent in our picture (and hence their paths are shown dashed in the figure). That is, once they are used, they do



Computing with Solitons, Figure 11
The frame of this figure is moving down with the data pulses on the left. A data pulse in memory is operated on with a three-collision gate actuated from the left, and the result deposited to the upper right. Reprinted with permission from [34]. Copyright by the American Physical Society

not remain in the picture with a moving frame and hence cannot interfere with later computations. However, all vertically moving pulses remain stationary in this picture.

Once a diagonal trajectory is used for a three-collision gate, reusing it will in general corrupt the states of all the stationary pulses along that diagonal. However, the original data pulse (gate input) can be restored with a pulse in the state inverse to the actuator, either along the same diagonal as the actuator, provided we allow enough time for the result (the gate output, a stationary z pulse) to be used, or along the other diagonal.



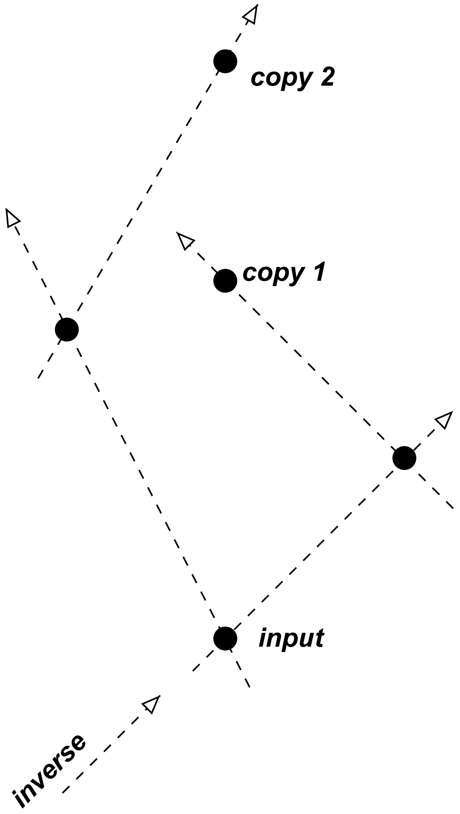
Computing with Solitons, Figure 12
A data pulse is copied to the upper right, this copy is copied to the upper left, and the result put at the top of memory. The original data pulse can then be restored with an inverse pulse and copied to the left in the same way. Reprinted with permission from [34]. Copyright by the American Physical Society

Suppose we want to start with a given data pulse in the memory column and create two copies above it in the memory column. Figure 12 shows a data pulse at the lower left being copied to the upper right with a three-collision COPY gate, initiated with an actuator pulse from the left. This copy is then copied again to the upper left, back to a waiting z pulse in the memory column. After the first copy is used, an inverse pulse can be used along the lower left to upper right diagonal to restore the original data pulse. The restored data pulse can then be copied to the left in the same way, to a height above the first copy, say, and thus two copies can be created and deposited in memory above the original.

A Second Speed and Final FANOUT and NAND

There is one problem still remaining with a true FANOUT: When an original data pulse in memory is used in a COPY operation for FANOUT, two diagonals are available, one from the lower left to the upper right, and the other from the lower right to the upper left. Thus, two copies can be made, as was just illustrated. However, when a data pulse is deposited in the memory column as a result of a logic operation, the logical operation itself uses at least one diagonal, which leaves at most one free. This makes a FANOUT of the *output* of a gate impossible with the current scheme.

A simple solution to this problem is to introduce another speed, using velocities ± 0.5, say, in addition to ± 1. This effectively provides four rather than two directions in which a pulse can be operated on, and allows true FANOUT and general interconnections. Figure 13 shows such a FANOUT; the data pulse at the lower left is copied to a position above it using one speed, and to another position, above that, using another.



Computing with Solitons, Figure 13
The introduction of a second speed makes true FANOUT possible. For simplicity, in this and the next figure, data and operator pulses are indicated by solid dots, and the y operator pulses are not shown. The paths of actuator pulses are indicated by dashed lines. Reprinted with permission from [34]. Copyright by the American Physical Society

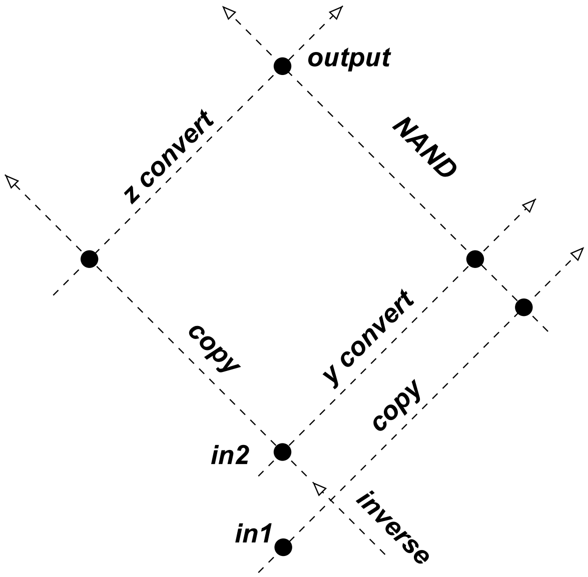
Finally, a complete NAND gate is shown in Fig. 14. The gate can be thought of as composed of the following steps:

- input 2 is copied to the upper left, and that copy transformed by a z-converter to the upper right, placing the z pulse for the NAND gate at the top of the figure;
- after the copy of input 2 is used, input 2 is restored with an inverse pulse to the upper left;
- input 2 is then transformed to the upper right by a y-converter;
- input 1 is copied to the upper right, to a position collinear with the z- and y-converted versions of the other input;
- a final actuator pulse converts the z pulse at the top to the output of the NAND gate.

Note that the output of the NAND has used two diagonals, which again shows why a second speed is needed if we are to use the NAND output as an input to subsequent logical operations. The y operator pulses, middle components in the three-collision COPY and converter gates, are not shown in the figure, but room can always be made for them to avoid accidental collisions by adding only a constant amount of space.

Universality

It should be clear now that any sequence of three-collision gates can be implemented in this way, copying data out of the memory column to the upper left or right, and performing NAND operations on any two at a time in the way shown in the previous section. The computation can proceed in a breadth-first manner, with the results of each successive stage being stored above the earlier results. Each additional gate can add only a constant amount of height



Computing with Solitons, Figure 14

Implementation of a NAND gate. A second speed will be necessary to use the output. Reprinted with permission from [34]. Copyright by the American Physical Society

and width to the medium, so the total area required is no more than proportional to the square of the number of gates.

The "program" consists of down-moving y and z operator pulses, entering at the top with the down-moving data, and actuator pulses that enter from the left or right at two different speeds. In the frame moving with the data, the data and operator pulses are stationary and new results are deposited at the top of the memory column. In the laboratory frame the data pulses leave the medium downward, and new results appear in the medium at positions above the old data, at the positions of newly entering z pulses.

Discussion

We have shown that in principle any computation can be performed by shining time-gated lasers into a completely homogeneous nonlinear optical medium. This result should be viewed as mathematical, and whether the physics of vector soliton collisions can lead to practical computational devices is a subject for future study. With regard to the economy of the model, the question of whether time gating is necessary, or even whether two speeds are necessary, is open.

We note that the result described here differs from the universality results for the ideal billiard ball model [13], the Game of Life [7], and Lattice Gasses [32], for example, in that no internal mirrors or structures of any kind are used inside the medium. To the author's knowledge, whether internal structure is necessary in these other cases is open.

Finally, we remark that the model used is reversible and dissipationless. The fact that some of the gate operations realized are not in themselves reversible is not a contradiction, since extra, "garbage" solitons [13] are produced that save enough state to run the computation backwards.

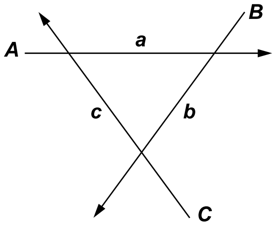
Multistable Soliton Collision Cycles

Bistable and multistable optical systems, besides being of some theoretical interest, are of practical importance in offering a natural "flip-flop" for noise immune storage and logic. We show in this section that simple cycles of collisions of solitons governed by the Manakov equations can have more than one distinct stable set of polarization states, and therefore these distinct equilibria can, in theory, be used to store and process information. The multistability occurs in the polarization states of the beams; the solitons themselves do not change shape and remain the usual sech-shaped solutions of the Manakov equations. This phenomenon is dependent only on simple soliton collisions in a completely homogeneous medium.

The basic configuration considered requires only that the beams form a closed cycle, and can thus be realized in any nonlinear optical medium that supports spatial Manakov solitons. The possibility of using multistable systems of beam collisions broadens the possibilities for practical application of the surprisingly strong interactions that Manakov solitons can exhibit, a phenomenon originally described in [26]. We show here by example that a cycle of three collisions can have two distinct foci surrounded by basins of attractions, and that a cycle of four collisions can have three.

The Basic Three-Cycle and Computational Experiments

Figure 15 shows the simplest example of the basic scheme, a cycle of three beams, entering in states A, B, and C, with intermediate beams a, b, and c. For convenience, we will refer to the beams themselves, as well as their states, as A, B, C, etc. Suppose we start with beam C initially turned off, so that $A = a$. Beam a then hits B, thereby transforming it to state b. If beam C is then turned on, it will hit A, closing the cycle. Beam a is then changed, changing b, etc., and the cycle of state changes propagates clockwise. The question we ask is whether this cycle converges, and if so, whether



Computing with Solitons, Figure 15
The basic cycle of three collisions. Reprinted with permission from [35]. Copyright by the American Physical Society

it will converge with any particular choice of complex parameters to exactly zero, one, two, or more foci. We answer the question with numerical simulations of this cycle.

A typical computational experiment was designed by fixing the input beams *A*, *B*, *C*, and the parameters k_1 and k_2, and then choosing points *a* randomly and independently with real and imaginary coordinates uniformly distributed in squares of a given size in the complex plane. The cycle described above was then carried out until convergence in the complex numbers *a*, *b*, and *c* was obtained to within 10^{-12} in norm. Distinct foci of convergence were stored and the initial starting points *a* were categorized by which focus they converged to, thus generating the usual picture of basins of attraction for the parameter *a*. Typically this was done for 50,000 random initial values of *a*, effectively filling in the square, for a variety of parameter choices *A*, *B*, and *C*. The following results were observed:

- In cases with one or two clear foci, convergence was obtained in every iteration, almost always within one or two hundred iterations.
- Each experiment yielded exactly one or two foci.
- The bistable cases (two foci) are somewhat less common than the cases with a unique focus, and are characterized by values of k_R between about 3 and 5 when the velocity difference Δ was fixed at 2.

Figure 16 shows a bistable example, with the two foci and their corresponding basins of attraction. The parameter *k* is fixed in this and all subsequent examples at 4 ± *i* for the right- and left-moving beams of any given collision, respectively. The second example, shown in Fig. 17, shows that the basins are not always simply connected; a sizable island that maps to the upper focus appears within the basin of the lower focus.

A Tristable Example Using a Four-Cycle

Collision cycles of length four seem to exhibit more complex behavior than those of length three, although it is dif-

ficult to draw any definite conclusions because the parameter spaces are too large to be explored exhaustively, and there is at present no theory to predict such highly nonlinear behavior. If one real degree of freedom is varied as a control parameter, we can move from bistable to tristable solutions, with a regime between in which one basin of attraction disintegrates into many small separated fragments. Clearly, this model is complex enough to exhibit many of the well-known features of nonlinear systems.

Fortunately, it is not difficult to find choices of parameters that result in very well behaved multistable solutions. For example, Fig. 18 shows such a tristable case. The smallest distance from a focus to a neighboring basin is on the order of 25% of the interfocus distance, indicating that these equilibria will be stable under reasonable noise perturbations.

Discussion

The general phenomenon discussed in this section raises many questions, both of a theoretical and practical nature. The fact that there are simple polarization-multistable cycles of collisions in a Manakov system suggests that similar situations occur in other vector systems, such as photorefractive crystals or birefringent fiber. Any vector system with the possibility of a closed cycle of soliton collisions becomes a candidate for multistability, and there is at this point really no compelling reason to restrict attention to the Manakov case, except for the fact that the explicit state-change relations make numerical study much easier.

The simplified picture we used of information traveling clockwise after we begin with a given beam *a* gives us stable polarization states when it converges, plus an idea of the size of their basins of attractions. It is remarkable that in all cases in our computational experience, except for borderline transitional cases in going from two to three foci in a four-cycle, this circular process converges consistently and quickly. But understanding the actual dynamics and convergence characteristics in a real material requires careful physical modeling. This modeling will depend on the nature of the medium used to approximate the Manakov system, and is left for future work. The implementation of a practical way to switch from one stable state to another is likewise critically dependent on the dynamics of soliton formation and perturbation in the particular material at hand, and must be studied with reference to a particular physical realization.

We remark also that no iron-clad conclusions can be drawn from computational experiments about the numbers of foci in any particular case, or the number possible for a given size cycle—despite the fact that we regularly used 50,000 random starting points. On the other hand, the clear cases that have been found, such as those used as examples, are very characteristic of universal behavior in other nonlinear iterated maps, and are sufficient to establish that bi- and tristability, and perhaps higher-mode multistability, is a genuine mathematical characteristic, and possibly also physically realizable. It strongly suggests experimental exploration.

We restricted discussion in this section to the simplest possible structure of a single closed cycle, with three or four collisions. The stable solutions of more complicated configurations are the subject of continuing study. A general theory that predicts this behavior is lacking, and it seems at this point unlikely to be forthcoming. This forces us to rely on numerical studies, from which, as we point out above, only certain kinds of conclusions can be drawn. We are fortunate, however, in being able to find cases that look familiar and which are potentially useful, like the bistable three-cycles with well separated foci and simply connected basins of attraction.

It is not clear however, just what algorithms might be used to find equilibria in collision topologies with more than one cycle. It is also intriguing to speculate about how collision configurations with particular characteristics can be designed, how they can be made to interact, and how they might be controlled by pulsed beams. There is promise that when the ramifications of complexes of vector soliton collisions are more fully understood they might be useful for real computation in certain situations.

Application to Noise-Immune Soliton Computing

Any physical instantiation of a computing technology must be designed to be immune from the effects of noise buildup from logic stage to logic stage. In the familiar computers of today, built with solid-state transistors, the noise-immunity is provided by physical state restoration, so that voltage levels representing logical "0" and "1" are restored by bistable circuit mechanisms at successive logic stages. This is state restoration at the physical level.

For another example, proposed schemes for quantum computing would be impractical without some means of protecting information stored in qubits from inevitable corruption by the rest of the world. The most common method proposed for accomplishing this is error correction at the software level, state restoration at the logical level.

In the collision-based scheme for computing with Manakov solitons described in Sect. "Manakov Soliton Computing", there is no protection against buildup of error from stage to stage, and some sort of logical state-restoration would be necessary in a practical realization. The bistable collision cycles of Manakov solitons described in this section, however, offer a natural computational building block for soliton computation with physical state restoration. This idea is explored in [27]. Figure 19 illustrates the approach with a schematic diagram of a NAND gate, implemented with bistable cycles to represent bits. The input bits are stored in the collision cycles (1) and (2), which have output beams that can be made to collide with input beam *A* of cycle (3), which represents the output bit of the gate. These inputs to the gate, shown as dashed lines, change the state of beam *A* of the ordinarily bistable cycle (3) so that it becomes *monostable*. The state of cycle (3) is then steered to a known state. When the input beams are turned off, cycle (3) returns to its normal bistable condition, but with a known input state. Its state then evolves to one of two bits, and the whole system of three collision cycles can be engineered so that the final state of cycle (3) is the NAND of the two bits represented by input cycles (1) and (2). (See [27] for details.)

A computer based on such bistable collision cycles is closer in spirit to present-day ordinary transistor-based computers, with a natural noise-immunity and state-restoration based on physical bistability. As mentioned in the previous subsection, however, the basic bistable cycle phenomenon awaits laboratory verification, and much remains to be learned about the dynamics, and eventual speed and reliability of such systems.

Experiments

The computation schemes described in the previous sections obviously rely on the correct mathematical modeling of the physics proposed for realization. We next describe experiments that verify some of the required soliton phenomenology in optical fibers. Specifically, we highlight the experimental observation of temporal vector soliton propagation and collision in a birefringent optical fiber [28]. This is both the first demonstration of temporal vector solitons with two mutually-incoherent component fields, and of vector soliton collisions in a Kerr nonlinear medium.

Temporal soliton pulses in optical fiber were first predicted by Hasegawa and Tappert [14], followed by the first experimental observation by Mollenauer et al. [24]. In subsequent work, Menyuk accounted for the birefringence in polarization maintaining fiber (PMF) and predicted that vector solitons, in which two orthogonally polarized components trap each other, are stable under the proper operating conditions [21,22]. For birefringent fibers, self-trapping of two orthogonally polarized pulses can occur when XPM-induced nonlinearity compensates the birefringence-induced group velocity difference, causing the pulse in the fiber's fast axis to slow down and the pulse in the slow axis to speed up. The first demonstration of temporal soliton trapping was performed in the sub picosecond regime [15], in which additional ultrashort pulse effects such as Raman scattering are present. In particular, this effect results in a red-shift that is linearly proportional to the propagation distance, as observed in a later temporal soliton trapping experiment [25]. Recently, soliton trapping in the picosecond regime was observed with equal amplitude pulses [18]. However, vector soliton propagation could not be shown, because the pulses propagated for less than 1.5 dispersion lengths. In other work, phase-locked vector solitons in a weakly birefringent fiber laser cavity with nonlinear coherent coupling between components were observed [12].

The theoretical model for linearly birefringent fiber is the following coupled nonlinear Schrödinger equation (CNLSE):

$$i\left(\frac{\partial A_x}{\partial z}+\beta_{1x}\frac{\partial A_x}{\partial t}\right)-\frac{\beta_2}{2}\frac{\partial^2 A_x}{\partial t^2}+\gamma\left(|A_x|^2+\frac{2}{3}|A_y|^2\right)A_x = 0\,,$$

$$i\left(\frac{\partial A_y}{\partial z}+\beta_{1y}\frac{\partial A_y}{\partial t}\right)-\frac{\beta_2}{2}\frac{\partial^2 A_y}{\partial t^2}+\gamma\left(|A_y|^2+\frac{2}{3}|A_x|^2\right)A_y = 0\,, \quad (9)$$

where t is the local time of the pulse, z is propagation distance along the fiber, and $A_{x,y}$ is the slowly varying pulse envelope for each polarization component. The parameter $\beta_{1x,y}$ is the group velocity associated with each fiber axis, and β_2 represents the group velocity dispersion, assumed equal for both polarizations. In addition, we neglect higher order dispersion and assume a loss less medium with an instantaneous electronic response, valid for picosecond pulses propagating in optical fiber.

The last two terms of Eqs. (9) account for the nonlinearity due to SPM and XPM, respectively. In linearly birefringent optical fiber, a ratio of 2/3 exists between these two terms. When this ratio equals unity, the CNLSE becomes the integrable Manakov system of Eqs. (4). On the other hand, solutions of Eqs. (9) are, strictly speaking, solitary waves, not solitons. However, it was found in [36] that the family of symmetric, single-humped (fundamental or first-order) solutions, to which the current investigation in this section belongs, are all stable. Higher-order solitons, characterized by multiple humps, are unstable. Furthermore, it was shown in [37] that collisions of solitary waves in Eqs. (9) can be described by application of perturbation theory to the integrable Manakov equations, indicating the similarities between the characteristics of these two systems.

Experimental Setup and Design

The experimental setup is shown in Fig. 20. We synchronized two actively mode-locked erbium-doped fiber lasers (EDFLs)—EDFL1 at 1.25 GHz repetition rate, and EDFL2 at 5 GHz. EDFL2 was modulated to match with the lower repetition rate of EDFL1. Each pulse train, consisting of 2 ps pulses, was amplified in an erbium-doped fiber amplifier (EDFA) and combined in a fiber coupler. To align polarizations, a polarization loop controller (PLC) was used in one arm, and a tunable delay line (TDL) was employed to temporally align the pulses for collision. Once combined, both pulse trains passed through a linear polarizer (LP) and a half-wave plate to control the input polarization to the PMF. Approximately 2 m of high birefringence (HB) PMF preceded the specially designed 500 m of low birefringence (LB) PMF used to propagate vector solitons. Although this short length of HB-PMF will introduce some pulse splitting (on the order of 2–3 ps), the birefringent axes of the HB- and LB-PMF were swapped in order to counteract this effect. At the output, each component of the vector soliton was then split at a polarization beam splitter, followed by an optical spectrum analyzer (OSA) for measurement.

The design of the LB-PMF required careful control over three characteristic length scales: the (polarization) beat length, dispersion length L_{d}, and nonlinear length L_{nl}. A beat length $L_{\mathrm{b}} = \lambda/\Delta n = 50$ cm was chosen at a wavelength of 1550 nm, where Δn is the fiber birefringence. According to the approximate stability criterion of [8], this choice allows stable propagation of picosecond vector solitons. By avoiding the sub picosecond regime, ultrashort pulse effects such as intrapulse Raman scattering will not be present. The dispersion $D = 2\pi c\beta_2/\lambda^2 =$ 16 ps/km nm and $L_{\mathrm{d}} = 2T_0^2/|\beta_2| \approx 70$ m, where $T_0 = T_{\mathrm{FWHM}}/1.763$ is a characteristic pulse width related to the full width at half maximum (FWHM) pulse width. Since $L_d \gg L_b$, degenerate four-wave mixing due to coherent coupling between the two polarization components can be neglected [23]. Furthermore, the total propagation distance is greater than 7 dispersion lengths.

Polarization instability, in which the fast axis component is unstable, occurs when $L_{nl} = (\gamma P)^{-1}$ is of the same order of magnitude or smaller than L_b, as observed in [6]. The nonlinearity parameter $\gamma = 2\pi n_2/\lambda A_{eff} = 1.3$ (km W)$^{-1}$, with Kerr nonlinearity coefficient $n_2 = 2.6 \times 10^{-20}$ m^2/W and measured effective mode area $A_{eff} = 83\,\mu m^2$. In the LB-PMF, the fundamental vector soliton power $P \approx 14$ W, thus $L_{nl} = 55$ m $\gg L_b$, mitigating the effect of polarization instability.

Vector Soliton Propagation

We first studied propagation of vector solitons using both lasers independently. The wavelength shift for each component is shown in Fig. 21a as a function of the input polarization angle ϕ, controlled through the half-wave plate. Due to the anomalous dispersion of the fiber at this wavelength, the component in the slow (fast) axis will shift to shorter (longer) wavelengths to compensate the birefringence. The total amount of wavelength shift between components $\Delta\lambda_{xy} = \Delta\beta_1/D = 0.64$ nm, where $\Delta\beta_1 = |\beta_{1x} - \beta_{1y}| = 10.3$ ps/km is the birefringence-induced group velocity difference and dispersion $D = 2\pi c\beta_2/\lambda^2 = 16$ ps/km nm.

As ϕ approaches 0° (90°), the vector soliton approaches the scalar soliton limit, and the fast (slow) axis does not shift in wavelength, as expected. At $\phi = 45°$, a symmetric shift results. For unequal amplitude solitons, the smaller component shifts more in wavelength than the larger component, because the former experiences more XPM. Numerical simulations of Eqs. (9), given by the dashed lines of Fig. 21a, agree very well with the experimental results. Also shown in Fig. 21 are two cases, $\phi = 45°$ and 37°, as well as the numerical prediction. The experimental spectra show some oscillatory features at 5 GHz, which are a modulation of the EDFL2 repetition rate on the optical spectrum. A sample input pulse spectrum from EDFL1 is shown in the inset of Fig. 21, which shows no modulation due to the limited resolution of the OSA. Vector solitons from both lasers produced similar results. In this and all subsequent plots in this section, the slow and fast axis components are depicted by solid and dashed lines, respectively.

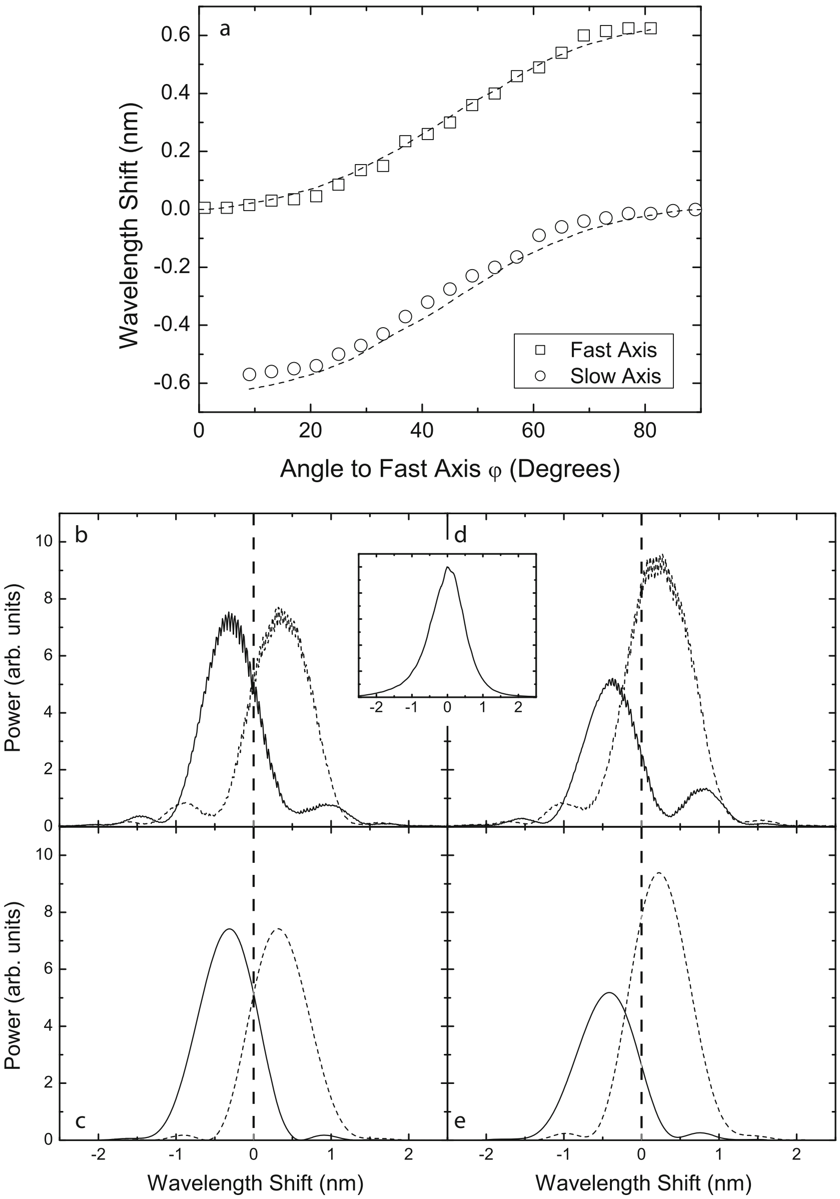
As the two component amplitudes become more unequal, satellite peaks become more pronounced in the smaller component. These features are also present in the simulations, but are not as dominant (cf. Fig. 21d and e). We attribute this to the input pulse, which is calibrated for the $\phi = 45°$ case, because the power threshold for vector soliton formation in this case is largest due to the 2/3 factor between SPM and XPM nonlinear terms in the CNLSE. As the input is rotated towards unequal components, there will be extra power in the input pulse, which will radiate in the form of dispersive waves as the vector soliton forms. Due to the nature of this system, these dispersive waves can be nonlinearly trapped, giving rise to the satellite features in the optical spectra. This effect is not as prevalent in the simulations because the threshold was numerically determined at each input angle ϕ.

Vector Soliton Collision

To prepare the experiment for a collision, we operated both lasers simultaneously, detuned in wavelength to allow for dispersion-induced walkoff, and adjusted the delay line in such a way that the collision occurred halfway down the fiber. We define a collision length $L_{coll} = 2T_{FWHM}/D\Delta\lambda$, where $\Delta\lambda$ is the wavelength separation between the two vector solitons. For our setup, $\Delta\lambda = 3$ nm, and $L_{coll} = 83.3$ m. An asymptotic theory of soliton collisions, in which a full collision takes place, requires at least 5 collision lengths. The total fiber length in this experiment is equal to 6 collision lengths, long enough to ensure sufficient separation of solitons before and after collision. In this way, results of our experiments can be compared to the asymptotic theory, even though full numerical simulations will be shown for comparison. To quantify our results, we introduce a quantity $R \equiv \tan^2\phi$, defined as the amplitude ratio between the slow and fast components.

Recall that in Sect. "Manakov Solitons", we introduced the Manakov equations (Eqs. (4)), and described collision-induced transformations of the polarization state of the soliton, which come about due to the asymptotic analysis of the soliton collision. The polarization state is the ratio between the two components $\rho \equiv A_x/A_y = \cot\phi \exp(i\Delta\theta)$, and is therefore a function of the polarization angle ϕ and the relative phase $\Delta\theta$ between the two components. In the context of the experiments described in this section, these state transformations (Eqs. (5) and (7)) predict that the resulting energy exchange will be a function of amplitude ratios $R_{1,2}$, wavelength separation $\Delta\lambda$, and the relative phase $\Delta\theta_{1,2}$ between the two components of each soliton, where soliton 1 (2) is the shorter (longer) wavelength soliton.

A word of caution is in order at this point. An interesting consequence of the 2/3 ratio between SPM and XPM, which sets the birefringent fiber model apart from



Computing with Solitons, Figure 21

Arbitrary-amplitude vector soliton propagation. a Wavelength shift vs. angle to fast axis ϕ, numerical curves given by dashed lines; b and d experimental results for $\phi = 45°$ and 37° with EDFL2, respectively. *Inset:* input spectrum for EDFL1; c and e corresponding numerical simulations of $\phi = 45°$ and 37°, respectively. the Manakov model, is the relative phase between the two components. For the Manakov soliton, each component 'feels' the same amount of total nonlinearity, because the strengths of both SPM and XPM are equal. Therefore, regardless of the polarization angle, the amount of total nonlinear phase shift for each component is the same (even though the contributions of SPM and XPM phase shifts are in general not equal). As a result, the relative phase between the two components stays constant during propagation, as does the polarization state. This is *not* the case for vector solitons in birefringent fiber. For the case of equal amplitudes, each component does experience the same amount of nonlinear phase shift, and therefore the polarization state is constant as a function of propagation

Computing with Solitons, Figure 22

Demonstration of phase-dependent energy-exchanging collisions. a–c Short HB-PMF; d–f long HB-PMF; a,d experiment, without collision; b, e experiment, with collision; c,f simulated collision result with c $\Delta\theta_2 = 90°$ and f $\Delta\theta_2 = 50°$. Copyright by the American Physical Society

distance. However, for arbitrary (unequal) amplitudes, the total phase shift for each component will be different. Consequently, the relative phase will change *linearly* as a function of propagation distance, and the polarization state will not be constant. As a result, the collision-induced change in polarization state, while being a function of the amplitude ratios $R_{1,2}$ and wavelength separation $\Delta\lambda$, will also depend upon the collision position due to the propagation dependence of the relative phase $\Delta\theta_{1,2}(z)$. To bypass this complication, we ensure that all collisions occur at the same spatial point in the fiber.

Because only one half-wave plate is used in our experiment (see Fig. 20), it was not possible to prepare each vector soliton individually with an arbitrary *R*. In addition, due to the wavelength dependence of the half-wave plate, it was not possible to adjust $\Delta\lambda$ without affecting *R*.

First, we investigated the phase dependence of the collision. This was done by changing the length of the HB-PMF entering the LB-PMF, while keeping *R* and $\Delta\lambda$ constant. As a result, we could change $\Delta\theta_{1,2}$ due to the birefringence of the HB-PMF. Approximately 0.5 m of HB-PMF was added to ensure that the total amount of temporal pulse splitting did not affect the vector soliton formation. The results are shown in Fig. 22, where Fig. 22a–c and d–f correspond to the short and long HB-PMFs, respectively. Figure 22a and d show the two vector solitons, which propagate independently when no collision occurs; as expected, the two results are similar because the OSA

Copyright by the American Physical Society

measurement does not depend on $\Delta\theta_{1,2}$. The result of the collision is depicted in Fig. 22b and e, along with the corresponding simulation results in Fig. 22c and f.

In both of these collisions, an energy exchange between components occurs, and two important relations are satisfied: the total energy in each soliton and in each component is conserved. It can be seen that when one component in a soliton increases as a result of the collision, the other component decreases, with the opposite exchange in the second soliton. The difference between these two collisions is dramatic, in that the energy redistributes in opposite directions. For the simulations, idealized sech pulses for each component were used as initial conditions, and propagation was modeled without accounting for losses. The experimental amplitude ratio was used, and (without loss of generality [16,19,26]) $\Delta\theta_2$ was varied while $\Delta\theta_1 = 0$. Best fits gave $\Delta\theta_2 = 90°$ (Fig. 22c) and 50° (Fig. 22f). Despite the model approximations, experimental and numerical results all agree to within 15%.

In the second set of results (Fig. 23), we changed R while keeping all other parameters constant. More specifically, we used the short HB-PMF, with initial phase difference $\Delta\theta_2 = 90°$, and changed the amplitude ratio. In agreement with theoretical predictions, the same direction of energy exchange is observed as in Fig. 22a–c.

Spatial Soliton Collisions

We mention here analogous experiments with spatial solitons in photorefractive media by Anastassiou et al. In [4], it is shown that energy is transferred in a collision of vector spatial solitons in a way consistent with the predictions for the Manakov system (although the medium is a saturable one, and only approximates the Kerr nonlinearity). The experiment in [5] goes one step farther, showing that one soliton can be used as an intermediary to transfer energy from a second soliton to a third. We thus are now at a point where the ability of both temporal and spatial vector solitons to process information for computation has been demonstrated.

Future Directions

This article discussed computing with solitons, and attempted to address the subject from basic physical principles to applications. Although the nonlinearity of fibers is very weak, the ultralow loss and tight modal confinement make them technologically attractive. By no means, however, are they the only potential material for soliton-based information processing. Others include photorefractive crystals, semiconductor waveguides, quadratic media, and Bose–Einstein condensates, while future materials research may provide new candidate systems.

From a computing perspective, scalar soliton collisions are insufficient. Although measurable phase and position shifts do occur, these phenomena cannot be cascaded to affect future soliton collisions and therefore cannot transfer information from one collision to the next. Meaningful computation using soliton collisions requires a new degree of freedom; that is, a new component. Collisions of vector solitons display interesting energy-exchanging effects between components, which can be exploited for arbitrary computation and bistability.

The vector soliton experiments of Sect. "Experiments" were proof-of-principle ones. The first follow-up experiments with temporal vector solitons in birefringent fiber can be directed towards a full characterization of the collision process. This can be done fairly simply using the experimental setup of Fig. 20 updated in such a way as to allow independent control of two vector soliton inputs. This would involve separate polarizers and half-waveplates, followed by a polarization preserving fiber coupler.

Cascaded collisions of temporal solitons also await experimental study. As demonstrated in photorefractive crystals with a saturable nonlinearity [5], one can show that information can be passed from one collision to the next. Beyond a first demonstration of two collisions is the prospect of setting up a multi-collision feedback cycle. Discussed in Sect. "Multistable Soliton Collision Cycles", these collision cycles can be bistable and lead to interesting applications in computation.

Furthermore, the recent work of Ablowitz et al. [2] shows theoretically that the useful energy-redistribution properties of vector soliton collisions extend perfectly to the semi-discrete case: that is, to the case where space is discretized, but time remains continuous. This models, for example, propagation in an array of coupled nonlinear waveguides [10]. The work suggests alternative physical implementations for soliton switching or computing, and also hints that the phenomenon of soliton information processing is a very general one.

Article Outline

Glossary

Backbone In a lattice percolation problem above the percolation threshold, that fraction of the infinite cluster with two disjoint connections to infinity.

Correlation length (ξ) Length scale in a randomly structured system over which the system cannot be regarded as homogeneous.

Critical exponent Exponent characterizing the dominant behavior of an observable quantity near a percolation threshold; e. g. $\xi \sim \text{constant} \times (p_c - p)^{-\nu}$ as $p \uparrow p_c$.

Effective medium approximation Approximate description of an inhomogeneous system obtained by matching averaged local fluctuations in properties in a self-consistent manner.

Flux Vector-valued function (in a continuum) or signed scalar (in a discrete system) quantifying transport or conduction rates.

Lattice Discrete structure (network/graph) of sites (nodes/vertices) connected by bonds (links/edges), including periodic lattices, random lattices, and tree-like or self-similar pseudolattices.

Percolation theory Idealized model of a random medium. In the classical discrete case, the bonds of a lattice are independently open with probability p (Bernoulli bond percolation) or the sites of a lattice are independently occupied with probability p (Bernoulli site percolation). There are various continuum analogues.

Percolation threshold (p_c) Dividing point in parameter space separating cases where long-range connectivity is precluded (infinite connected sets exist with probability 0) from those where long-range connectivity occurs (infinite connected sets exist with positive probability).

Percolative system Random two-phase continuous or discrete system in which one phase is deemed void or non-conducting; usually a percolation threshold exists in such systems.

Potential (V) Function distributed over space or over the sites of a network from which steady-state transport or conduction may be determined.

Pseudolattice A non-periodic discrete structure of sites (nodes/vertices) and bonds (links/edges), most commonly either topologically tree-like or geometrically self-similar.

Random walk Model of random motion, especially on lattices, consisting of a sequence of steps separated by constant or random time intervals.

Recurrent random walk Random walk process on a lattice for which the walker returns to the starting site with probability 1.

Renormalization Converting a system, either exactly or approximately, to a related system with a different characteristic length scale.

Transient random walk Random walk process on a lattice for which the walker has probability less than 1 of returning to the starting site.

Definition of the Subject

The problem of determining the macroscopic structural and transport properties of microscopically non-uniform materials has a long history and is of such central importance that it finds applications in an astonishingly wide range of areas of science and technology, from developmental biology to xerography [109,140,141]. Consider systems that consist of two phases, each of which is homogeneous in its properties, mixed in some way to create an inhomogeneous material. Let one phase occupy a fraction ϕ of the volume. If $\phi \ll 1$, so that the inhomogeneous structure is in some sense dilute, the possibility arises of determining the effective properties of the material as an expansion in powers of ϕ. Simple examples of this, when the dilute phase consists of identical spheres distributed in some reasonable manner, are the prediction variously associated with the names of Maxwell, Clausius, Mossotti, Lorenz, Lorentz and others that spheres of dielectric permittivity ϵ_1 embedded in a matrix of permittivity ϵ_0 produce an effective permittivity ϵ^* given by

$$\frac{\epsilon^* - \epsilon_0}{\epsilon^* + 2\epsilon_0} \approx \frac{\epsilon_1 - \epsilon_0}{\epsilon_1 + 2\epsilon_0}\phi \; ; \qquad (1)$$

and the prediction of Einstein [43,44] that the effective viscosity η^* of a random suspension of rigid, spheres occupying a volume fraction ϕ in a liquid of viscosity η is given by $\eta^* = \eta\left[1 + \frac{5}{2}\phi + o(\phi)\right]$ as $\phi \to 0$. Analogous calculations can be performed for many other "dilute" systems, leading to predictions at low volume fraction for effective electrical conductivity and other attributes. Simple examples demonstrate that as the volume fraction ϕ increases, quantitative information on exactly how the phases are distributed becomes essential for accurate prediction of, or even construction of decent bounds for, effective properties—knowing the volume fractions of the phases is not enough.

We address inhomogeneous systems and especially two-phase systems—both continua and lattices—that are randomly structured, with particular emphasis on systems in which only one phase (with relative abundance ϕ) sustains transport. The simplest such models arise by defining steady-state transport processes or random motions on the occupied phase in the lattice percolation model (▶ Percolation Phase Transition) of Broadbent and Hammersley [25,62,63,64] or its continuum analogues. (▶ Continuum Percolation). We call all such models *percolative models*. They exhibit threshold behavior at $\phi = \phi_c$, separating globally nonconducting states when the transport-sustaining phase is sufficiently rare $(0 \le \phi < \phi_c)$ from conducting states when the transport-sustaining phase is sufficiently abundant $(\phi_c < \phi \le 1)$. When the transport-sustaining phase only sparsely spans a large region, that is, just above the percolation threshold ϕ_c, asymptotic power-law dependence of the transport properties on $\phi - \phi_c$ is observed, but many results now deemed well-known still evade rigorous proof.

Introduction

We address problems of transport and conduction, both in continua and on lattices, where there are randomly distributed local transport properties, especially the cases where there are two phases present (for continua) or there are bonds or sites of two types present (for lattices). Although we later pay most attention to the lattice case, for the present and in Sect. "Continuum Models: Steady-State Phenomena" we discuss primarily continua in which two material phases with different properties are present. Frequently, one of these phases is empty space (void space). Within regions comprising only one phase, all properties of the system are uniform. The properties of regions containing both phases depend not only on the relative proportions of each phase present, but also on the way the phases are distributed. The fundamental question to be answered is this: if we pretend that the system is homogeneous, as it might indeed appear if we viewed a very large piece of it from a distance, what are the effective transport properties of the system?

A complete solution of the problem is not to be expected if the microstructure is elaborate or especially subtle, but sufficient progress has been made since the 1950s that for a number of conceptually simple models, some exact results and many approximate results of decent quality are available. The two cases amenable to treatment are periodic microstructure and random microstructure. The former case, which is not our present concern, presents few conceptual challenges and is increasingly amenable to numerical calculation, since the determination of the global properties of the system can usually be reduced to a study of a single finite region (the fundamental repeat unit) and this is usually computationally tractable.

Interest in modeling systems in which small (usually identical) pieces of one phase are randomly distributed in some way and the remaining phase occupies the rest of space goes back at least to James Clerk Maxwell (1831–1879), Ludvig Valentin Lorenz (1829–1891) and Hendrik Antoon Lorentz (1853–1928). The work of these authors in the latter half of the nineteenth century and some antecedents, culminating in results such as Eq. (1), is reviewed by Landauer [94], Markov [102] and Milton [109]. In the first two decades of the twentieth century the problem was addressed by Einstein [43,44] and others, but four major conceptual developments were needed to bring the subject beyond its infancy.

(a) In 1935 Bruggeman [27], building on ideas of earlier authors but arguing with much greater clarity, developed an *effective medium approximation*, in which an unknown overall property of the composite system, such as its effective conductivity σ_{eff}, is computed in an approximate but self-consistent manner that takes account of fluctuations in the corresponding local property. In the extreme case in which one phase is nonconducting, Bruggeman's approach predicts that for sufficiently small volume fraction ϕ of the conducting phase, there is no conductivity, but there is a critical volume fraction ϕ_c of the conducting phase above which there is conduction, with effective conductivity $\sigma_{\text{eff}} \sim \text{constant} \times (\phi - \phi_c)$ as $\phi \downarrow \phi_c$. Bruggeman's original treatment pays no attention to the manner in which the phases are randomly or periodically distributed.

(b) In 1965, Beran [11,12] established the foundations of a statistical study of effective properties of random media, in which the random placement of phases is statistically quantified. In particular, Beran brought out the importance of considering individual realizations of a random system equipped with a proper probability structure, and drew attention to the important issue of ergodicity, which in this context concerns the relation between volume averages (averages of properties over large volumes in a single realization) and ensemble averages (averages over many realizations).

(c) In 1957, Broadbent and Hammersley [25,62,63,64] considered a lattice model of random media, motivated by a problem of gas mask design for British coal miners. Although quantified transport was not part of their original model—they only addressed connectivity—this work is at the conceptual heart of modern discussions. In their model, now known as, the *percolation theory* lattice is randomly stripped so that either individual bonds remain with probability p (bond percolation) or individual sites remain with probability p (site percolation); the parameter p is the analogue of volume fraction ϕ in a two-phase random continuum, with what remains of the lattice viewed as a conducting phase in the original system. There is a well-defined relative abundance p of the conducting phase, called the *percolation threshold* p_c, above which there is long-distance connectivity and transport is possible. Although the percolation threshold plays for the lattice model a role analogous to the critical volume fraction predicted by Bruggeman's effective medium approximation (and indeed effective medium approximations can be set up for lattice systems), the existence of a precise percolation threshold p_c was rigorously established in 1957, and its value is known exactly for some lattices and approximately but to very high precision for other lattices. The probability that a given site belongs to an infinite connected cluster of the active phase when that phase has relative abundance p is the percolation probability $P_\infty(p)$, and it is accepted that $P_\infty(p) \sim \text{constant} \times (p - p_c)^\beta$ as $p \downarrow p_c$, with $\beta = 5/36$ in simple two-dimensional lattice systems and $\beta \leq 1$ more generally. A number of the techniques and concepts that have developed over 50 years for lattice-based percolation theory have now found their way into natural continuous-medium analogues [104]. Both the lattice and continuum percolation models have many applications [109,138,140,166].

(d) That percolation ideas would be significant in physics was realized almost immediately [5] following the 1957 paper of Broadbent and Hammersely. The final conceptual step needed was first articulated in 1968 by Ziman [174]: the stochastic geometry underlying percolation theory, though essential to the description of transport in random media, does not completely characterize the transport properties: there is also the specific contribution of the transport mechanism. The natural attempt to connect a transport coefficient such as effective conductivity $\sigma_{\text{eff}}(p)$ to the percolation probability $P_\infty(p)$ by writing $\sigma_{\text{eff}}(p) \propto P_\infty(p)$ [42] was refuted by experiments in 1971 of Last and Thouless [95] on the conductivity of a sheet of colloidal graphite with holes randomly punched in it in a manner appropriate to simulate site percolation on the square lattice. The experiments suggested that $\sigma_{\text{eff}}(p) \sim \text{constant} \times (p - p_c)^t$ as $p \downarrow p_c$, with $t > 1 \gg \beta$. The subtlety of the problem arises from the fact that just above the percolation threshold, the sample-spanning structure is tenuous and tortuous, with significant implications on observable quantities that characterize the transport process.

The developments stemming from the approximate work of Bruggeman and the rigorous work of Beran [(a) and (b) above] are well covered in the expansive texts of Milton [109] and Torquato [166]. The bulk of the present article is devoted to random medium problems—both continuous and discrete, though favoring the latter—with a percolative aspect [(c) and (d) above]. Steady-state continuum problems are discussed first in Sect. "Continuum Models: Steady-State Phenomena", with the physical contexts addressed in Sect. "Contexts". These contexts are also claimed by advocates of the analogous lattice models discussed in Sect. "Lattice Models: Steady-State Phenomena", to which we pay more attention. The model on which we primarily focus is the *random resistor network* (introduced in Sect. "The Random Resistor Problem"), which reveals most of the key features of random media, especially the existence of percolation thresholds and the subtlety of the active paths in the system close to the percolation threshold. Although many important and elegant results are now available for geometrical and topological aspects of the underlying percolation process, as discussed in the books by Bollobas and Riordan [21], Grimmett [59] and Hughes [75], and ▶ Percolation Phase Transition, considerable work is still needed to resolve major questions concerning the random resistor network and related systems.

We do not consider the mechanical properties (such as elastic modulii or fracture resistance) of random media, although many of the ideas and results presented here have been extended to mechanical properties in the literature. Less restricted surveys of the properties of random media can be found in the major texts of Milton [109], Sahimi [140,141] and Torquato [166]. Time-evolving problems in randomly structured media are of great interest, but our discussion in Sect. "Random Motion in a Random Environment" strongly emphasizes the model of random walk on a random lattice derived from a percolation process, poetically described as the *ant in the labyrinth* [24,33,75].

Continuum Models: Steady-State Phenomena

Despite the enormous efforts expended on discrete inhomogeneous and percolative systems, most scientific applications that motivate these studies arise in materials perhaps most naturally treated as continua. We briefly summarize several contexts in which percolative systems arise and review selected findings for continua that expose major concepts later discussed more extensively for the more tractable discrete analogues. Examples considered

(i) are scalar, so that we have scalar transport coefficients rather than tensors;

(ii) involve real potentials, so we consider only steady direct current electrical conduction, rather than frequency-dependent alternating current conduction;

(iii) have no explicit time dependence, and

(iv) have linear constitutive response.

The reader may refer to the expansive texts of Milton [109] and Sahimi [140,141] for discussions without the restrictions (i)–(iv).

Contexts

Problems Equivalent to Electrical Conduction In a variety of physical contexts the following mathematical problem arises. Let Ω be a domain (a connected spatial region), let $\sigma(\mathbf{r})$ (which we shall call a *transport coefficient*) be a prescribed function of position $\mathbf{r}$ in Ω, and let ∇ denote the usual gradient operator. We are to find a *potential* $V(\mathbf{r})$ that satisfies the equation

$$\nabla \cdot (\sigma \nabla V) = 0, \quad \mathbf{r} \in \Omega\,, \tag{2}$$

subject to prescribed conditions on the boundary $\partial\Omega$ of Ω, usually either the Dirichlet boundary condition [$V(\mathbf{r})$ prescribed], the Neumann [$\mathbf{n} \cdot \nabla V$ prescribed, where $\mathbf{n}$ is a unit vector normal to $\partial\Omega$ and, for consistency, the surface integral of $\mathbf{n} \cdot \nabla V$ over $\partial\Omega$ is zero], or Dirichlet and Neumann conditions applied to disjoint components of $\partial\Omega$. The potential V, which is uniquely defined for the Dirichlet boundary-value problem and is unique up to an additive constant for the pure Neumann boundary-value problem, is associated with a vector field

$$\mathbf{E} = -\nabla V\,, \tag{3}$$

and the field $\mathbf{E}$ and the transport coefficient σ determine a flux vector

$$\mathbf{J} = \sigma \mathbf{E}\,. \tag{4}$$

Equation (2) can be interpreted as a statement of a conservation law under steady-state conditions for a substance carried by the flux vector $\mathbf{J}$. Where the transport coefficient has surfaces of discontinuity (as is the case in two-phase media), one interprets the partial differential equations as holding in the distributional sense and the boundary conditions of continuity of V and of $\mathbf{n} \cdot \sigma \nabla V$ (where $\mathbf{n}$ is normal to the phase interface) follow.

The canonical example of the problem embodied in Eqs. (2)–(4) is steady state (direct current) electrical conduction, with V the electrostatic potential, $\mathbf{E}$ the electric field, $\mathbf{J}$ the electric current, and σ the electrical conductivity. Six different interpretations of the same mathematical

Conduction and Diffusion in Percolating Systems, Table 1
Mathematically equivalent potential theory problems

Transport coefficient	Flux law	Potential–field relation
Electrical conductivity σ	$\mathbf{J} = \sigma\mathbf{E}$	$\mathbf{E} = -\nabla V$ from Maxwell's $\nabla \times \mathbf{E} = \mathbf{0}$
Dielectric permittivity ϵ	$\mathbf{D} = \epsilon\mathbf{E}$	$\mathbf{E} = -\nabla V$ from Maxwell's $\nabla \times \mathbf{E} = \mathbf{0}$
Magnetic permeability μ	$\mathbf{B} = \mu\mathbf{H}$	$\mathbf{H} = -\nabla V$ from Maxwell's $\nabla \times \mathbf{H} = \mathbf{0}$

Transport coefficient	Flux–potential relation
Thermal conductivity κ	Fourier's Law (temperature T) $\mathbf{Q} = -\kappa\nabla T$
Diffusivity D	Fick's Law (pressure P, viscosity η) $\mathbf{q} = -(k/\eta)\nabla P$
Permeability k	Darcy's Law (concentration c) $\mathbf{J} = -D\nabla c$

problem are given in Table 1. For the first three interpretations, the potential V is the consequence of a fundamental physical equation of the form $\nabla \times \mathbf{E} = \mathbf{0}$. In the remaining examples in Table 1), the flux law $\mathbf{J} = \sigma\mathbf{E}$ and the potential–field relation $\mathbf{E} = -\nabla V$ do not have individual fundamental physical interpretations.

Caveats to the Electrical Interpretation In our discussion we shall use the terminology appropriate to electrical conductivity, however in interpreting the results in other contexts several caveats are needed. For time-dependent diffusive processes, we really wish to solve the equation

$$\frac{\partial c}{\partial t} = \nabla \cdot (D\nabla c)\,; \tag{5}$$

the electrical conduction analogue applies only to the steady state. Similar issues arise for heat conduction. For diffusion, problems in which the tracer is injected at an isolated point (a point source) are of great interest. In the extreme case in which one phase sustains diffusion and the other does not, the effect of placing the source at an arbitrary point in the phase that sustains diffusion depends critically on whether the source falls in a conducting region of finite extent or of infinite extent and these issues are not covered by a discussion confined to the electrical conduction analogue.

Although we have included porous medium permeability in Table 1, this exact equivalence to the electrical conduction problem only applies when we work at length scales large compared to pore sizes, so that the notion of permeability—whether constant or variable—is meaningful. A problem of great interest arises when one considers fluid flow through the void space of a medium consisting of an impermeable solid phase and a void phase [139]. In this case, there is no local partial differential equation at all for the solid phase, while in the void space the fluid is subject to the low Reynolds number limit of the Navier–Stokes equations.

The Idea of Homogenization

If the local conductivity σ is bounded, but fluctuates in some manner, one may seek a "homogenized" description of the medium, replacing the variable conductivity problem $\nabla \cdot (\sigma\nabla V) = 0$ by a uniform conductivity problem $\nabla \cdot (\sigma_{\text{eff}}\nabla V) = 0$ that matches it in some sense that needs to be made precise, with the constant *effective conductivity* σ_{eff} to be determined. A porous medium, viewed as a two-phase void/solid system as mentioned above, homogenizes in a different manner, since the equations for the desired uniform system, embodying Darcy's Law, are structurally different from the equations that govern the flow in the pore space [139]. We do not discuss this case here.

There are two basic rigorous approaches. One, on which we focus in the present article, is introduced in Sect. "Effective Conductivities". The other, which is generally described as *homogenization theory*, may be briefly summarized as follows. There are three length scales in the problem: a microscale, on which the structure fluctuates (perhaps strongly), a mesoscale over which unstructured continuum behavior emerges, and a macroscale over which parameters defined at the mesoscale may vary slowly. One may define volume averages $\langle\mathbf{E}\rangle$ and $\langle\mathbf{J}\rangle$ of the electric field over some representative domain large compared to the length scale on which microstructure fluctuates (that is, a mesoscale domain) and introduce a homogenized conductivity $\widehat{\sigma}$ defined by

$$\langle\mathbf{J}\rangle = \widehat{\sigma}\langle\mathbf{E}\rangle\,. \tag{6}$$

Homogenization is successful if, in an appropriate limit as the microscale dimension is sent to zero, a well-defined $\widehat{\sigma}$ emerges. The theory of homogenization has been well worked out for periodic microstructures [4,10], which are not our concern here, but is more challenging for the random microstructure case, although considerable progress has also been made there [56,79]; surveys of recent work will be found in the texts of Milton [109] and

Torquato [166]. The first strong results were derived for uniformly elliptic partial differential operators, which in the present context means that for some constants α and β we have $0 < \alpha \leq \sigma \leq \beta < \infty$, precluding the analysis of percolative systems, but extensions to percolative systems are discussed in the book of Jikov, Kozlov and Oleinik [79]. Percolative systems are subtle because the length scale on which the inhomogeneity is important—the correlation length—diverges at the percolation threshold; and the detailed geometrical arrangement of the conducting and non-conducting phases is very important except perhaps for very low or very high volume fractions of the conducting phase. It should be emphasized that in homogenizing random media, the determination of exact values of $\widehat{\sigma}$, either by formula or in terms of an algorithm for easy, highly precise computation, largely remains a distant goal. Establishing the existence of a well-defined $\widehat{\sigma}$ and determining any of its nontrivial qualitative properties is already a major achievement.

Effective Conductivities

As an alternative to the homogenization approach outlined above, one may simply define effective properties of an inhomogeneous system by a black box approach. In the electrical analogy, and considering three dimensions for definiteness, take a finite rectangular prism $-M < x < M$, $-M < y < M$, $0 \leq z \leq L$, occupied by the inhomogeneous conductor, with all boundaries save for $z = 0$ and $z = L$ being insulated ($\mathbf{n} \cdot \sigma \nabla V = 0$). If one specifies the potential to be $V = V_0$ at $z = 0$ and $V = 0$ at $z = L$, and the z-component of the current through the surface $x = 0$ is $J(x, y)$ per unit area, then a reasonable definition of the effective conductivity σ_{eff} is

$$\sigma_{\text{eff}} = \lim_{L\to\infty} \lim_{M\to\infty} \frac{1}{V_0/L} \int_{-M}^{M} \int_{-M}^{M} \frac{J(x, y)\mathrm{d}x\mathrm{d}y}{(2M)^2} , \qquad (7)$$

where L/M is held constant as L, $M \to \infty$. This is the most natural definition for physical experiments or computer simulation and the one we adopt below in our more detailed discussion of discrete models. Actually, for a randomly-structured two-phase system, unless one establishes that for the particular statistical model of the microstructure, the limit is well-defined and takes the same value for almost all realizations of the microstructure (that is, the limit exists and takes a unique value with probability 1), the integral has to be averaged over all realizations of the microstructure before the limit $L, M \to \infty$ is taken.

An alternative definition replaces the insulated boundary conditions on all faces other than $z = 0$ or $z = L$ by $V = V_0(L - z)/L$. One could alternatively set up a definition of effective conductivity by prescribing a uniform injection of current per unit area across the face $z = 0$ and studying the induced potential difference.

Golden and Papanicolaou [56] have examined the relation between the black box definition of effective conductivity for a finite region and the definition from homogenization, and shown their equivalence under the conditions of uniform ellipticity. Stronger results applicable to percolative systems will be found in Jikov et al. [79].

While results on the existence of a well-defined effective conductivity σ_{eff} are of course of significant interest, one really wants to determine its value.

Exact Results Few nontrivial exact results on the effective conductivity are available. Consider a one-dimensional conductor of length L, comprising N independent random conducting elements of length Δ, with the kth element having conductivity σ_k and sustaining a potential drop V_k. Then the current flowing is $J = \sigma_k V_k/\Delta$, the same in each element, and the field is

$$\frac{1}{L}\sum_{k=1}^{N} V_k = \frac{1}{N\Delta}\sum_{k=1}^{N} \frac{J\Delta}{\sigma_k} \to J\langle\sigma^{-1}\rangle , \qquad (8)$$

where we have taken the limit $N \to \infty$ and used the Strong Law of Large Numbers [47]. Hence we have the exact result that

$$\sigma_{\text{eff}} = \frac{1}{\langle\sigma^{-1}\rangle} . \qquad (9)$$

For two-dimensional systems there are a number of "phase interchange" or "duality" results, due to Keller [82] and others, discussed carefully by Milton [109]. In particular, an infinite chessboard, with the white squares having conductivity σ_{w} and the black squares having conductivity σ_{b} produces an exact effective conductivity

$$\sigma_{\text{eff}} = \sqrt{\sigma_{\text{w}}\sigma_{\text{b}}} . \qquad (10)$$

Bounds The electrical energy dissipation rate associated with a potential distribution V and corresponding electric field $\mathbf{E}$ and current $\mathbf{J}$ in the finite $2M \times 2M \times L$ rectangular prism of Sect. "Effective Conductivities" is

$$\begin{aligned}\mathcal{E}\{V\} &= \int_{-M}^{M}\int_{-M}^{M}\int_{0}^{L} \mathbf{J}\cdot\mathbf{E}\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z \\ &= \int_{-M}^{M}\int_{-M}^{M}\int_{0}^{L} \sigma|\nabla V|^2\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z .\end{aligned} \qquad (11)$$

Consider a potential V that satisfies the partial differential equation $\nabla \cdot (\sigma \nabla V) = 0$ in the interior and the boundary conditions $v = V_0$ on $z = 0$, $V = 0$ on $z = L$ and $\mathbf{n} \cdot \sigma \nabla V = 0$ on other surfaces: we call this an *admissible potential*. Let W, a *trial potential*, be any other function that satisfies the same boundary conditions but may not satisfy the partial differential equation. If we write $\eta = W - V$, expand $\mathcal{E}\{W\} = \mathcal{E}\{V + \eta\}$ and use the Divergence Theorem and the boundary conditions, we easily show that $\mathcal{E}\{W\} \geq \mathcal{E}\{V\}$, so that admissible potentials minimize energy dissipation. That is, we have a variational principle. It can be shown under reasonable conditions that

$$\sigma_{\text{eff}} \leq \frac{1}{(V_0/L)^2 (2M)^2 L} \int_{-M}^{M} \int_{-M}^{M} \int_{0}^{L} \sigma |\nabla W|^2 \mathrm{d}x\, \mathrm{d}y\, \mathrm{d}z\,, \tag{12}$$

so that trial potentials can be used to construct rigorous upper bounds on the effective conductivity. A complementary variational principle that leads to lower bounds on the effective conductivity can be derived by analyzing trial current distributions. The variational approach has its origin in work in 1955 of Brown [26] and has been developed in diverse contexts by many authors (Brown, Beran, Prager, Hashin and Shtrikman, Davies, ...) with varying degrees of rigor [109,166]. Bergman [15] introduced an alternative approach to variational methods for deriving bounds on effective conductivities, based on complex variable techniques. Bergman's work and many important consequences are reviewed by Milton [109].

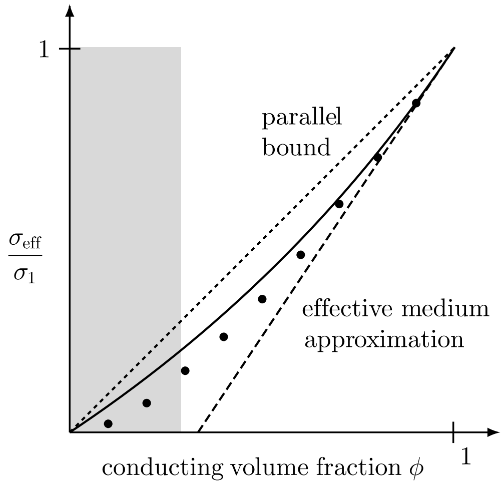
The most easily derived bounds hold without restriction on the distribution of phases in a multiphase system, and also apply for continuously varying local conductivities:

$$\frac{1}{\langle \sigma \rangle} \leq \sigma_{\text{eff}} \leq \langle \sigma \rangle\,, \tag{13}$$

where angle brackets denote the volume average. These bounds, first identified in 1912 by Wiener [168], are the best possible general bounds, since they become equalities in the case of slabs of homogeneous material parallel to the face $z = 0$ (conductors in series—$\sigma_{\text{eff}} = 1/\langle \sigma^{-1} \rangle$) or no variation in conductivity with z (conductors in parallel—$\sigma_{\text{eff}} = \langle \sigma \rangle$). If no additional assumptions are made except for statistical isotropy, the 1962 bounds of Hashin and Shtrikman [67] become the best possible. For high and low conductivity phases with volume fractions ϕ_{high} and ϕ_{low} and conductivities $\sigma_{\text{high}} \geq \sigma_{\text{low}}$, the Hashin–Shtrikman bounds in d dimensions ($d = 2$ or 3) are

$$\begin{aligned} \sigma_{\text{low}} + \frac{d\phi_{\text{high}}\sigma_{\text{low}}(\sigma_{\text{high}} - \sigma_{\text{low}})}{d\sigma_{\text{low}} + \phi_{\text{low}}(\sigma_{\text{high}} - \sigma_{\text{low}})} &\leq \sigma_{\text{eff}} \\ &\leq \sigma_{\text{high}} - \frac{d\phi_{\text{low}}\sigma_{\text{high}}(\sigma_{\text{high}} - \sigma_{\text{low}})}{d\sigma_{\text{high}} - \phi_{\text{high}}(\sigma_{\text{high}} - \sigma_{\text{low}})}\,. \end{aligned} \tag{14}$$

If we consider the case of a percolative system, where we have $\sigma_{\text{low}} = 0$, $\sigma_{\text{high}} = \sigma_1$ and for brevity we write $\phi_{\text{high}} = \phi$ (that is, ϕ is the volume fraction for the conducting phase) the lower bounds in (13) and (14) become trivial ($\sigma_{\text{eff}} \geq 0$) and neither upper bound is very strong, as shown by Fig. 1. For the case of spheres with independently located centers (technically, Poisson points) and either constant radii, or random radii with a reasonable distribution, it can be rigorously established [104] that for sufficiently small ϕ, the probability that there is an infinite connected region of the conducting phase is zero and consequently the effective conductivity will be zero below a percolation threshold ϕ_c. Numerical simulations with Poisson-centered conducting spheres of constant radius show that $\phi_c \approx 0.2895 \pm 0.0005$ [135]: the gray rectan-



Conduction and Diffusion in Percolating Systems, Figure 1

Bounds on the effective conductivity σ_{eff} for a conducting phase of conductivity σ_1 randomly and homogeneously distributed at volume fraction ϕ, with remaining space occupied by a nonconducting phase. The *gray* area lies below the percolation threshold estimate $\phi_c \approx 0.2895 \pm 0.0005$ of Rintoul and Torquato [135] for overlapping conducting spheres in a nonconducting matrix. The solid discs are numerical estimates of Kim and Torquato [87] for overlapping non-conducting spheres in a conducting matrix, where $\phi_c \approx 0.03$. *Upper broken line*: elementary ("parallel") bound $\sigma_{\text{eff}}/\sigma_1 \leq \phi$. Solid curve: Hashin–Shtrikman bound $\sigma_{\text{eff}}/\sigma_1 \leq 2\phi/(3 - \phi)$ [67]. Lower broken line: effective medium approximation $\sigma_{\text{eff}}/\sigma_1 \approx (3/2)(\phi - 1/3)$ for $\phi \geq 1/3$ from work of Bruggeman [27]

gle in Fig. 1 spans the interval $0 \leq \phi \leq \phi_c$ for this system, and parts of the upper bound curves (13) and (14) that intersect the Gray rectangle miss the threshold behavior entirely and are misleadingly uninformative for this specific system.

In Fig. 1 we also show as discs numerical estimates [87] of the conductivity in the case where the randomly placed spheres are non-conducting, the rest of space is conducting and the percolation threshold is much smaller ($\phi_c \approx 0.03$ [87]); physicists call this the *Swiss cheese model*. The Hashin–Shtrikman upper bound (14) works better because the percolation threshold is so low, but the Hashin–Shtrikman lower bound remains useless. Much better bounds than those shown are available for non-percolative problems, especially if additional information about correlations between phase locations is available [109,166].

Approximations Clarifying the work of earlier authors, in 1935 Bruggeman [27] derived an *effective medium approximation* for the effective conductivity. This approach represents an uncontrolled approximation—it does not give rigorous bounds and a priori estimation of its accuracy is not possible. One considers a spherical inclusion of unspecified constant conductivity within a uniform medium whose conductivity is taken to be the unknown effective conductivity σ_{eff}, which will be estimated "self-consistently". For a prescribed constant field **E** at infinity, the field within the inclusion is calculated. The requirement that, when averaging over material properties within the inclusion, the average field in the inclusion does not differ from the field at infinity yields an approximate equation for σ_{eff},

$$\left\langle \frac{3\sigma_{\text{eff}}}{\sigma + 2\sigma_{\text{eff}}} \right\rangle = 1\,. \tag{15}$$

In the case in which $\sigma = \sigma_1$ with probability ϕ, corresponding to a volume fraction ϕ of the conducting phase, this approximation predicts that for a percolative system

$$\sigma_{\text{eff}} = \frac{3}{2}\left(\phi - \frac{1}{3}\right)\sigma_1\,. \tag{16}$$

The physical requirement that $\sigma_{\text{eff}} \geq 0$ leads one to interpret this as predicting that $\sigma_{\text{eff}} = 0$ for $0 \leq \phi \leq 1/3$, so that there is a threshold for the conductivity at $\phi = 1/3$.

As shown in Fig. 1, this approximation closely conforms to the Hashin–Shtrikman upper bound near $\phi = 1$. Although it has the desirable feature of predicting a conductivity threshold, the actual predicted threshold (1/3) is not particularly close to numerical estimate for randomly placed spheres with independent centers (0.2895) and is very far from the estimated threshold for the Swiss cheese model (0.03).

Differences Between Continuum and Discrete Models

The considerable emphasis in the literature on discrete (lattice) models is partly motivated by the folklore of *universality*, under which, apart from some reasonable conditions that exclude direct, long-range connections and other oddities, qualitative features and associated critical exponents of analogous problems depend only on dimensionality. While this appears to be broadly true, there are some significant exceptions, two of which we mention here.

(a) A parameter value where properties of the infinite system which are elsewhere analytic lose analyticity is called a *critical point*. In the percolation model of Broadbent and Hammersley [25,62,63,64] on periodic lattices, there is only one critical point associated with global connectedness [106], namely the percolation threshold, and this coincides with the only critical point for the effective conductivity. Following on work of Kozlov [93], Jikov et al. [79] have discussed carefully a random chessboard, where the plane is divided into equal squares, colored independently. Squares are black (conductivity σ_b) with probability ϕ and white (conductivity σ_w) with probability $1 - \phi$. For $\phi = 1/2$, Eq. (10) holds, but more importantly, in the random chessboard model there are effectively two thresholds for a given color, one for long-distance connectivity using corner connections and one for long-distance connectivity through adjoining edges of the squares. If we let $p_c \approx 0.59$ denote the site percolation threshold of the square lattice (▶ Percolation Thresholds, Exact), then the following results hold as $\sigma_b \to 0$ with σ_w held fixed. For $0 \leq \phi \leq 1 - p_c$, the white phase has large components connected via edges of squares and

$$\lim_{\sigma_b \to 0} \sigma_{\text{eff}} = \sigma_w f(\phi) > 0\,.$$

For $1 - p_c < \phi < p_c$ neither color has large components connected via edges of squares, but both colors have large components connected via corners, and

$$c_1(\phi)\sqrt{\sigma_w \sigma_b} \leq \sigma_{\text{eff}} \leq c_2(\phi)\sqrt{\sigma_w \sigma_b}\,.$$

For $p_c < \phi < 1$, we have $\sigma_b \leq \sigma_{\text{eff}} \leq c_3(\phi)\sigma_b$. Berlyand and Golden [16] have established the stronger result that for $1 - p_c < \phi < p_c$, $\sigma_{\text{eff}} = \sqrt{\sigma_w \sigma_b} + O(\sigma_b)$ as $\sigma_b \to 0$ with σ_w held fixed. Torquato et al. [167] have reported numerical studies.

(b) The universality concept presupposes that all analogous systems in the same dimension have the same critical exponents for a given system property. Thus, for example, in a percolative continuous system where ϕ is the volume fraction of the conducting phase, we expect to see

$$\sigma_{\text{eff}} \sim \text{constant} \times (\phi - \phi_c)^t \quad \text{as } \phi \downarrow \phi_c\,. \tag{17}$$

where the conductivity exponent t (the general existence of which remains to be established, even for specific two and three dimensional systems) is independent of microstructure, and the same for lattices and continua in a given dimension. This expectation turns out to be wrong, with hopes being dashed by computational studies of Feng et al. [48] on the Swiss cheese model introduced in Sect. "Bounds": in two dimensions the lattice and Swiss cheese continuum model exponents are close together and possibly coincident; in three dimensions the exponent t for the Swiss cheese continuum is about 0.5 larger than the exponent t for the simple cubic lattice.

Lattice Models: Steady-State Phenomena

Notwithstanding the caveats exposed in Sect. "Differences Between Continuum and Discrete Models", we turn to a detailed discussion of discrete systems. We consider *lattices* (also known as networks or graphs) of *sites* (also known as nodes or vertices) connected by *bonds* (also called links or edges). The number of bonds attached to a site is its *coordination number* (also called degree or valence), and two sites that are attached to the same bond are called *nearest-neighbour sites*. The most commonly studied lattices are periodic in structure, the simplest example being the *hypercubic lattice* $\mathbb{Z}^d$ of sites with integer coordinates, connected by bonds of unit length, so that each site has coordination number $2d$. Other important infinite networks are sometimes called *pseudolattices* to distinguish them from periodic structures. The most important examples of pseudolattices are self-similar or fractal structures [100] (► Scaling Properties, Fractals, and the Renormalization Group Approach to Percolation) and tree-like structures, especially the *Cayley tree* or *Bethe lattice* [165] of coordination number z, in which there are no closed loops.

Key Results from Percolation Theory

In percolation theory for lattices sites, are declared *occupied* or *vacant* in some random way and bonds are declared *open* or *closed* in some random way. A site is deemed to belong to a cluster of size $n \geq 1$ (where n may be finite or infinite) if it is present and connected via open bonds to $n-1$ other sites; a vacant site is a cluster of size 0. In the (Bernoulli) *bond problem*, all sites are occupied, and bonds are independently declared open with probability p and closed with probability $1-p$. In the (Bernoulli) *site problem*, sites are occupied with probability p and vacant with probability $1-p$, and a bond is declared open if and only if the two sites it joins are both occupied. Every bond percolation problem is equivalent to a site percolation problem on a related lattice, so that it suffices to state general results for site percolation, although in many examples modeling transport and conduction, the language of bond percolation is more appropriate.

Viewed at sufficiently low resolution, a realization of bond or site percolation other than at the percolation threshold appears homogeneous. A measure of the length scale over which inhomogeneous structure is important is furnished by the *correlation length* $\xi(p)$. One way of defining this precisely on $\mathbb{Z}^d$ is to let τ_m denote the probability that the sites at $\mathbf{0}$ and $(m, 0, 0, \ldots, 0)$ belong to a common finite cluster. Then $\xi(p) = -\lim_{m\to\infty} m^{-1} \ln \tau_m$.

Rigorous General Results The following results are rigorously proven [21,59,75] for Bernoulli site percolation, provided that the lattice or pseudolattice is homogeneous in the sense that all sites are equivalent (as is the case for $\mathbb{Z}^d$ and the Bethe lattice), and the number of sites at most n bonds distant from a given site grows no faster than $c \exp(an^\kappa)$, where $a > 0$, $c > 0$ and $\kappa < 1$.

(i) There exists a percolation threshold $p_c > 0$ such that the probability $P_\infty(p)$ of a chosen site belonging to an infinite cluster is zero for $p < p_c$ and strictly greater than zero for $p > p_c$.

(ii) The probability $P_n(p)$ that a chosen site belongs to a cluster of size n decays exponentially rapidly with increasing n when $p < p_c$.

The exponential decay of $P_n(p)$ ensures the finiteness of the mean cluster size $\chi(p) = \sum_{n=0}^{\infty} nP_n(p)$ for $p < p_c$. The sum remains meaningful for $p > p_c$ if we exclude the infinite cluster $n = \infty$ and $\chi(p)/(1 - P_\infty(p))$ becomes the mean cluster size, conditioned on the cluster being finite. A result related to (ii) establishes that on $\mathbb{Z}^d$, the correlation length is well-defined and finite for $p < p_c$.

(iii) The mean cluster size $\chi(p)$ is finite for $p < p_c$ but $\chi(p) \geq pp_c(p_c - p)^{-1}$ when $p < p_c$, so that $\chi(p) \to \infty$ as $p \uparrow p_c$.

(iv) For a given value of p, there is a number k_0 (which may take no values other than 0, 1 or ∞) such that the number of distinct infinite clusters of occupied sites on the lattice takes the value k_0 with probability 1. When $P_\infty(p) = 0$, $k_0 = 0$.

For some pseudolattices, such as the Bethe lattice, if $P_\infty(p) > 0$ then $k_0 = \infty$; however, for a class of lattices which includes normal periodic lattices, if $0 < P_\infty(p) < 1$

then $k_0 = 1$. That is, when an infinite cluster exists it is unique.

(v) For $p > p_c$ a site is part of the backbone if it lies on the infinite cluster, and within that cluster there are two independent paths to infinity. If $B(p)$ is the probability that a given site belongs to the backbone then $B(p) \le p^{-1} P_\infty(p)^2$.

For a discussion of the determination of and actual values of site and percolation thresholds for particular lattices, see ► Percolation Thresholds, Exact.

Heuristics A heuristic scaling theory for percolation theory (► Scaling Properties, Fractals, and the Renormalization Group Approach to Percolation introduced in 1979 by Stauffer [153] and analogies between percolation and statistical mechanics first exhibited in 1972 by Fortuin and Kasteleyn [51,52] lead to the following folklore [75]. There are *critical exponents* that describe the non-analytic behavior of important attributes of the percolation model at the percolation threshold. If we use the proportionality symbol $\propto$ as a short notation, so that $f(p) \propto g(p)$ as $p \to p_c$ means that $f(p)/g(p) \to$ nonzero constant, then the critical exponents are defined as follows:

cluster size distribution at p_c

$$P_n(p_c) \propto n^{-1-1/\delta} \qquad \text{as } n \to \infty\,; \tag{18}$$

mean cluster size below p_c

$$\chi(p) \propto (p_c - p)^{-\gamma} \qquad \text{as } p \uparrow p_c\,; \tag{19}$$

mean cluster size above p_c

$$\chi(p) \propto (p_c - p)^{-\gamma'} \qquad \text{as } p \downarrow p_c\,; \tag{20}$$

correlation length below p_c

$$\xi(p) \propto (p_c - p)^{-\nu} \qquad \text{as } p \uparrow p_c\,; \tag{21}$$

correlation length above p_c

$$\xi(p) \propto (p_c - p)^{-\nu'} \qquad \text{as } p \downarrow p_c\,; \tag{22}$$

percolation probability

$$P_\infty(p) \propto (p - p_c)^{\beta} \qquad \text{as } p \downarrow p_c\,; \tag{23}$$

backbone probability

$$B(p) \propto (p - p_c)^{\beta_{\text{bb}}} \qquad \text{as } p \downarrow p_c\,. \tag{24}$$

For the Bethe lattice, it is established that $\delta = 2, \gamma = 1$, $\beta = 1$ and $\beta_{\text{bb}} = 2$ [75], but for standard lattices even the existence of critical exponents in the sense explained above is not rigorously established, although as noted below, a few weaker results consistent with this picture, such as $\lim_{p \downarrow p_c} \ln[P_\infty(p)]/\ln(p - p_c) = \frac{5}{36}$ for site percolation on the triangular lattice, are now proven.

Folklore asserts that exponents are the same for the all site and bond problems in a given dimension (universality), vary significantly with the dimension d in low dimensions, and are independent of dimension for $d \ge 6$, where they take the so-called *mean-field values* $\beta = \gamma = 1$ and $\nu = \frac{1}{2}$. (These values are rigorously established by work of Hara and Slade [66] for standard percolation for $d \ge 19$, and for a spread-out model of percolation for $d \ge 6$.) At $d = 6$, the prefactors in the dominant asymptotic forms that define the critical exponents may be modified by the inclusion of a power of $\ln|p - p_c|$. It is generally believed that $\gamma = \gamma'$ and $\nu = \nu'$. On modest hypotheses on lattice structure it is rigorously established [75] from work of various authors that, provided the exponents exist, $\beta \le 1$, $\gamma \ge 1, \gamma/d \le \nu \le \gamma$, and $\nu \ge 2/d$, but two much more informative scaling relations are accepted:

$$\gamma + 2\beta = \beta(\delta + 1) \tag{25}$$

in all cases, and for $d \le 6$,

$$d\nu = 2\beta + \gamma\,. \tag{26}$$

All credible numerical evidence supports the existence of critical exponents consistent with these scaling laws, they are rigorously established for site percolation on the triangular lattice [148], and natural probabilistic conditions equivalent to (26) for bond percolation on $\mathbb{Z}^d$ are known [22].

Rigorous Results for Two Dimensions For several two-dimensional lattices a number of exact results are known: in particular $p_c = 1/2$ for site percolation on the triangular lattice (coordination number 6) and bond percolation on the square lattice (coordination number 4). In these particular problems it has also been rigorously established that the percolation probability $P_\infty(p)$ is continuous for $0 \le p \le 1$, so that there is no infinite cluster present right at the percolation threshold. This result is believed to be true, but remains unproven, in three dimensions.

Major innovations in probability since 2000, primarily associated with the work of Lawler, Schramm, Smirnov and Werner, have led to the following results being rigorously established for the case of site percolation on the two-dimensional triangular lattice [148]:

$$P_\infty(p) = (p - \tfrac{1}{2})^{5/36 + o(1)} \qquad \text{as } p \downarrow \tfrac{1}{2}\,; \tag{27}$$

$$\chi(p) = |p - \tfrac{1}{2}|^{-43/18 + o(1)} \qquad \text{as } p \to \tfrac{1}{2}\,; \tag{28}$$

$$\xi(p) = |p - \tfrac{1}{2}|^{-4/3 + o(1)} \qquad \text{as } p \to \tfrac{1}{2}\,. \tag{29}$$

This is almost (but not quite) a proof of existence of critical exponents in the sense of physicists, and moreover shows that the scaling relations (25) and (26) hold in this one particular case and the accepted folklore for two dimensions that

$$\beta = \tfrac{5}{36}, \qquad \gamma = \gamma' = \tfrac{43}{18}, \qquad \nu = \nu' = \tfrac{4}{3}, \tag{30}$$

arrived at from scaling arguments, statistical mechanical arguments, heuristic arguments and numerical evidence, is indeed correct in this one particular case. The exact backbone exponent β_{bb} remains unknown, but it has been shown to be determined by the leading eigenvalue of a differential operator [96].

The Random Resistor Problem

The canonical discrete model of transport and conduction is the *random resistor network*, in which the bonds of a lattice or some less regular network are resistors of random resistance. A more extended discussion of this model, including proofs of many results stated here, will be found in Hughes [75]; for the Dirichlet, Thomson and Rayleigh Principles discussed below see also Doyle and Snell [40]. The first study of random resistor networks may fairly be ascribed to 1971 work of Kirkpatrick [88,89], although an equivalent system had already been studied as early as 1956 by Fatt [45] as a model for porous media, with hydraulic conductivities of bonds playing the role of resistance and pressure playing the role of voltage.

Problem Definition If we use Greek subscripts to index bonds of the lattice (each bond being assigned a nominal direction of orientation), then the (direct) current I and the potential difference V across a particular bond α are related by Ohm's Law $I = G_\alpha V$, where G_α is the conductance of bond α (the reciprocal of the resistance). Current is a signed quantity. If the potential at site $\mathbf{s}'$ is less than that at site $\mathbf{s}$ then the current flowing from $\mathbf{s}$ to $\mathbf{s}'$ is positive.

It is customary to assume that the conductances of different bonds are independent, identically distributed random variables. Note that one might consider more generally the case in which $I = \mathcal{G}_\alpha(V)$ where $\mathcal{G}_\alpha$ is a nonlinear function with several random parameters, but this problem is both subtle [29] and difficult [19,20,61,83,105,161] and will not be discussed here; see Sahimi [141].

If the bonds of a random resistor network have independent, identically distributed conductances governed by the probability density function

$$f(g) = (1-p)\delta_+(g) + p h(g), \quad 0 < p < 1, \tag{31}$$

where $h(g)$ is the conditional probability of the conductance, given that the conductance is nonzero, we call the network the *general percolation conduction problem*. We use the notation $\delta_+(g)$ to distinguish a delta function that acts on the right from the usual symmetric delta function $\delta(x)$. The specific case in which $h(g) = \delta(g - g_0)$, that is,

$$f(g) = (1-p)\delta_+(g) + p\delta(g - g_0)), \quad 0 < p < 1, \tag{32}$$

will be called the *standard* percolation conduction problem. The definitions (31) and (32) are directly associated with bond percolation. A standard percolation problem for site percolation arises on assigning each bond that links two occupied sites the conductance g_0, and making all other bonds non-conducting.

In general, we have a lattice with a potential (voltage) $V_{\mathbf{s}}$ at each site $\mathbf{s}$ and a current $i_{\mathbf{rs}}$ flowing from site $\mathbf{r}$ to site $\mathbf{s}$ along a bond of conductance $G_{\mathbf{rs}} = G_{\mathbf{sr}}$ (or, equivalently, resistance $R_{\mathbf{rs}} = 1/G_{\mathbf{rs}}$). From Ohm's Law

$$i_{\mathbf{rs}} = G_{\mathbf{rs}}(V_{\mathbf{r}} - V_{\mathbf{s}}) \tag{33}$$

and Kirchhoff's Law of conservation of current $\sum_{\mathbf{s}} i_{\mathbf{rs}} = I_{\mathbf{r}}$, we have

$$\sum_{\mathbf{s}} G_{\mathbf{rs}}(V_{\mathbf{r}} - V_{\mathbf{s}}) = I_{\mathbf{r}}, \tag{34}$$

where $I_{\mathbf{r}}$ is the current supply into site $\mathbf{r}$, positive if current is injected and negative if it is withdrawn. At most sites $\mathbf{r}$, we have $I_{\mathbf{r}} = 0$, but we impose the additional physical requirement that $\sum_{\mathbf{r}} I_{\mathbf{r}} = 0$, the sum being taken over all sites where current is injected or withdrawn. When appropriate boundary conditions are imposed on finite pieces of periodic lattice, or on finite networks more generally, the problem is completely specified and numerical determination of the potential distribution over the sites and the associated currents is possible; from this estimates of an effective conductivity σ_{eff} that we define in Sect. "Lattices of Dimension $d \geq 2$" below emerge.

Bounds for General Resistor Networks Before addressing the specific case of periodic lattices, we consider arbitrary finite networks. The *effective conductance* $C_{\mathbf{ab}}^{\text{eff}}$ *between two sites* $\mathbf{a}$ and $\mathbf{b}$ and its reciprocal, the *effective resistance* $R_{\mathbf{ab}}^{\text{eff}}$ *between the sites*, are defined by

$$C_{\mathbf{ab}}^{\text{eff}} = \frac{1}{R_{\mathbf{ab}}^{\text{eff}}} = \frac{I}{V_{\mathbf{a}} - V_{\mathbf{b}}}, \tag{35}$$

if a current I injected at site $\mathbf{a}$ and withdrawn at site $\mathbf{b}$ is associated with a potential difference $V_{\mathbf{a}} - V_{\mathbf{b}}$ between the sites. (Effective conductivities arise by scaling effective conductances with appropriate measures of network size.)

Variational principles enable bounds on the effective conductance to be deduced.

Dirichlet's Principle. Consider a finite resistor network with bond conductances $G_{\mathbf{rs}}$ ($0 \leq G_{\mathbf{rs}} < \infty$) and with a specified potential difference V between sites **a** and **b**. Let $\{W_{\mathbf{s}}\}$ be a *trial potential distribution* , that is, any set of real numbers subject to the requirement that $W_{\mathbf{a}} - W_{\mathbf{b}} = V$. Let $\{V_{\mathbf{s}}\}$ be an admissible potential distribution, that is, a set of real numbers satisfying the Kirchhoff–Ohm Law (34) for $\mathbf{s} \neq \mathbf{a}$ or **b**, as well as the constraint $V_{\mathbf{a}} - V_{\mathbf{b}} = V$. Then the effective conductance between sites **a** and **b** is given by

$$C^{\mathrm{eff}}_{\mathbf{ab}} = \frac{1}{2V^2} \sum_{\mathbf{r},\mathbf{s}} G_{\mathbf{rs}}(V_{\mathbf{r}} - V_{\mathbf{s}})^2 \leq \frac{1}{2V^2} \sum_{\mathbf{r},\mathbf{s}} G_{\mathbf{rs}}(W_{\mathbf{r}} - W_{\mathbf{s}})^2 . \tag{36}$$

Thomson's Principle. Consider a finite resistor network with bond resistances $R_{\mathbf{rs}}$ ($0 \leq R_{\mathbf{rs}} < \infty$) and a specified current $I_{\mathbf{a}}$ injected at site **a** and withdrawn at site **b**. Let $\{j_{\mathbf{sr}}\}$ be a *trial current distribution*, that is: $j_{\mathbf{rs}} = -j_{\mathbf{sr}}$; $\sum_{\mathbf{s}} j_{\mathbf{rs}} = 0$ if $\mathbf{r} \neq \mathbf{a}$ and $\mathbf{r} \neq \mathbf{b}$; and $\sum_{\mathbf{s}} j_{\mathbf{as}} = I_{\mathbf{a}} = -\sum_{\mathbf{s}} j_{\mathbf{bs}}$. Let $\{i_{\mathbf{sr}}\}$ be an *admissible current distribution*, that is, a trial current distribution for which Ohm's Law $V_{\mathbf{r}} - V_{\mathbf{s}} = i_{\mathbf{rs}} R_{\mathbf{rs}}$ holds. Then the effective resistance between sites **a** and **b** is given by

$$R^{\mathrm{eff}}_{\mathbf{ab}} = \frac{1}{2I^2_{\mathbf{a}}} \sum_{\mathbf{r},\mathbf{s}} i^2_{\mathbf{rs}} R_{\mathbf{rs}} \leq \frac{1}{2I^2_{\mathbf{a}}} \sum_{\mathbf{r},\mathbf{s}} j^2_{\mathbf{rs}} R_{\mathbf{rs}} . \tag{37}$$

The sums in the inequalities in Dirichlet's and Thomson's Principles may be interpreted as the rate of energy dissipation corresponding to the potential distribution or the current distribution respectively. These two principles assert that admissible potential and current distributions minimize the rate of energy dissipation. From these two principles a number of important results follow, including the following.

Rayleigh's Monotonicity Principle. For finite resistor networks, the resistance between two sites does not decrease if the resistances of some or all of the bonds are increased.

Exactly Solvable Models In one dimension, N random resistors in series yield an effective conductivity (here the overall conductance per unit length) $\sigma_{\mathrm{eff}} = \langle G^{-1} \rangle^{-1}$; the argument is the same as that used above for a random one-dimensional continuum. A slightly less trivial problem for which exact results are available is the standard percolation conduction problem on a Bethe lattice of coordination number z [70,75,156,157]. Pick an arbitrary site $\mathbf{s}_0$ of the lattice, set that site to have potential V_0 and prescribe that the potential is zero at the periphery of the tree (that is, the potential decays asymptotically to zero as we move outwards from $\mathbf{s}_0$ along any infinite path of open bonds that may be present). If a current I_0 flows from site $\mathbf{s}_0$ into the tree, then the tree conductance may be defined as $T = I_0/V_0$. Where the average is taken over all realizations of the system, it can be shown rigorously that $\langle T \rangle$ is zero for $p < p_{\mathrm{c}} = (z-1)^{-1}$ and

$$\langle T \rangle \sim \frac{2zg_0 c}{z-2}[p(z-1)-1]^2 \quad \text{as } p \downarrow p_{\mathrm{c}} , \tag{38}$$

where $c \approx 0.761$ is a constant. Since $p_{\mathrm{c}} = 1/(z-1)$ for the Bethe lattice, this result is consistent with the hypothesis that long-distance conduction is possible in the standard percolation conduction problem (32) if and only if $p > p_{\mathrm{c}}$. It is sometimes argued that the Bethe lattice correctly represents the critical behavior of periodic lattices of sufficiently high dimensionality and that would imply that effective conductivity σ_{eff} defined in Sect. "Lattices of Dimension $d \geq 2$" satisfies $\sigma_{\mathrm{eff}} \propto (p - p_{\mathrm{c}})^2$ as $p \downarrow p_{\mathrm{c}}$. Straley [159] has identified the flaw in this argument—in a Bethe lattice of finite size, a significant fraction of all sites are at the boundary—and has given a definition of the effective conductivity σ_{eff} of a Bethe lattice that gives bonds in all regions of the lattice comparable significance and leads to $\sigma_{\mathrm{eff}} \propto (p - p_{\mathrm{c}})^3$ as $p \downarrow p_{\mathrm{c}}$.

For some remarks concerning self-similar pseudolattices for which exact results are available, see Sect. "Conduction on Fractals".

Lattices of Dimension $d \geq 2$

For random resistor problems more appropriately related to transport and conduction problems in d-dimensional space, we consider periodic lattices. There have been numerical investigations of the standard percolation conduction on topologically random lattices created by the Voronoï algorithm [77,78], but we shall not pursue these extensions of the theory.

Defining the Conductivity Consider the specific case of a finite hypercube Λ_L cut from from the simple hypercubic lattice $\mathbb{Z}^d$, with $(L+1)^d$ sites at locations $\mathbf{s} = (s_1, s_2, \ldots, s_d)$ with integer coordinates subject to the inequalities $0 \leq s_j \leq L$. The faces $s_1 = 0$ and $s_1 = L$ are subjected to a potential difference V, so that there is a potential gradient V/L. In three dimensions, this corresponds to a cubic array of conducting elements sandwiched between two perfectly conducting plates. Boundary conditions on the other faces should be unimportant when L is large, but in numerical work periodic boundary conditions are often used (the faces $s_j = 0$ and $s_j = L$ are joined for $j = 2, \dots d$). If a total current I flows in response to the imposed potential difference, then the current per unit area (that is, per site) of the face $s_1 = 0$ is $I/(L+1)^{d-1}$. We therefore define the (specific) conductivity of the lattice as

$$\lim_{L\to\infty} \frac{I/(L+1)^{d-1}}{V/L} = \lim_{L\to\infty} \frac{L^{2-d} I}{V} . \tag{39}$$

For the random resistor network, one needs to discuss the existence of this limit for each realization ω of the lattice and one is especially interested in the mean value of the limit, which we take as defining the *effective conductivity* of the system:

$$\sigma_{\text{eff}} = \lim_{L\to\infty} \langle L^{2-d} I/V \rangle = \lim_{L\to\infty} \langle L^{2-d} C_L \rangle , \tag{40}$$

where $C_L = I/V$ is the conductance between the faces of the hypercube Λ_L.

For a considerable period the existence of a well-defined effective conductivity remained unproven, with the case of percolative problems providing an especially severe challenge, but this hurdle was eventually overcome [79]. In particular, for percolative problems it is now established there is a well-defined $\sigma_{\text{eff}}(p)$. The averages over realizations in Eq. (40) can be dropped, with the limit existing with probability 1, and being 0 for $p < p_c$ and strictly positive for $p > p_c$

Bounding the Conductivity The Dirichlet and Thompson Principles and Rayleigh's Monotonicity Law are stated for the case in which current is injected at one site and withdrawn at another, but by introducing appropriate links of zero resistance, the laws apply equally well to the case in which a potential difference V is maintained across two parallel faces of the hypercube Λ_L used in the definition of the effective conductivity, and a current I flows between the parallel faces.

THE SERIES AND PARALLEL BOUNDS. For a random resistor network on the simple hypercubic lattice $\mathbb{Z}^d$ with independent, identically distributed bond conductances, the conductance C_L between two parallel faces of the hypercube Λ_L satisfies the inequalities

$$L^{-1}(L+1)^{d-1}\langle G^{-1}\rangle^{-1} \le \langle C_L\rangle \le L^{-1}(L+1)^{d-1}\langle G\rangle, \tag{41}$$

where the random variable G corresponds to the conductance of any one bond of the lattice.

Hence $\langle L^{2-d} C_L\rangle$ is bounded above as $L \to \infty$ if the individual bond conductances G have finite mean, and is also bounded away from zero if the individual bond resistances $(1/G)$ have finite mean. Under these conditions, if σ_{eff} exists, then from Eq. (40), we have

$$\langle G^{-1}\rangle^{-1} \le \sigma_{\text{eff}} \le \langle G\rangle . \tag{42}$$

Hammersley [65] has used Dirichlet's Principle to derive some stronger results than the series and parallel bounds (42) for independent conductances. Chayes and Chayes [30] used variational principles to derive a not directly useful lower bound on the conductivity for the standard percolation conduction problem, and the following more encouraging upper bound.

UPPER BOUND OF CHAYES AND CHAYES. For the standard bond percolation conduction problem on the d-dimensional hypercubic lattice, with open bonds having conductance g_0, the effective conductivity $\sigma_{\text{eff}}(p)$ satisfies the inequality

$$\sigma_{\text{eff}}(p) \le g_0 \Pr\{\text{a given bond is part of the backbone}\} . \tag{43}$$

The *conductivity exponent* for the percolation conduction problem is defined by writing

$$\sigma_{\text{eff}}(p) \propto (p - p_c)^t \quad \text{as } p \downarrow p_c . \tag{44}$$

There is no rigorous proof, even in two dimensions, of the existence of the critical exponent, even in the weak sense that $t = \lim_{p\downarrow p_c} \ln[\sigma_{\text{eff}}(p)]/\ln(p - p_c)$. However, from the result (v) in Sect. "Rigorous General Results" and the upper bound of Chayes and Chayes we know that the conductivity is identically zero below the percolation threshold, as one's intuition demands, and if the accepted critical exponents do exist then we have the inequality

$$t \ge \beta_{\text{bb}} \ge 2\beta , \tag{45}$$

where β_{bb} is the backbone exponent and β is the exponent for the percolation probability $P_\infty(p)$. From numerical estimates $\beta_{\text{bb}} \approx 0.52$ in two dimensions, and we know that $2\beta = \frac{5}{18} \approx 0.28$, while $t > 1$ (see Sect. "Numerical Estimates of the Conductivity Critical Exponent t"), so neither equality is very sharp.

Scaling Theory for the Conductivity Straley [158] developed a heuristic scaling argument to describe the conductivity of a random resistor network for which the probability density function for the individual bond conductances is

$$f(g) = (1 - p)\delta(g - a) + p\delta(g - b) , \tag{46}$$

where $a \ll b$. The effective conductivity σ_{eff} changes in the obvious manner when the units of conductivity or length change. A prefactor μ in the conductivity can be regarded as accounting for this. Straley proposed that σ_{eff} is a homogeneous function near the percolation threshold:

$$\sigma_{\text{eff}}(p) \approx \mu S([p - p_c]\lambda^{-1}, a\mu^{-1}\lambda^{-A}, \mu b^{-1}\lambda^{-B}) , \quad (47)$$

with the approximation assumed valid when each argument of S is less than unity. The function S is singular when any of its arguments vanishes. The parameter λ embodies the interrelations via scaling of the parameters a, b and $p - p_c$. Setting $a = 0$, $\lambda = |p - p_c|$ and $\mu = \lambda^B b$ gives

$$\sigma_{\text{eff}}(p) \approx |p - p_c|^B bS(\operatorname{sgn}[p - p_c], 0, 1) . \quad (48)$$

This case describes the conductivity of the classical percolation conduction problem, so we are led to the conclusion that $S(-1, 0, 1) = 0$ and $S(1, 0, 1) > 0$, and we identify B with the conductivity exponent t. If instead we set $1/b = 0$, $\lambda = |p - p_c|$ and $\mu = \lambda^{-A} a$, we obtain

$$\sigma_{\text{eff}}(p) \approx |p - p_c|^{-A} aS(\operatorname{sgn}[p - p_c], 1, 0) . \quad (49)$$

This case describes the superconductivity problem in which a fraction $1 - p$ of the bonds are normal conductors, while the remaining bonds have infinite conductance, so we conclude that $S(-1, 1, 0) < \infty$ and $S(1, 1, 0) = \infty$ and we identify A with the Superconductivity exponent s. Thus

$$\sigma_{\text{eff}}(p) \approx \mu S([p - p_c]\lambda^{-1}, a\mu^{-1}\lambda^{-s}, \mu b^{-1}\lambda^{-t}) . \quad (50)$$

If we now take $p = p_c$ and $0 < a < b < \infty$, then setting $\lambda^{t+s} = a/b$ and $\mu = b\lambda^t$, we obtain

$$\sigma_{\text{eff}}(p_c) \approx a^u b^{1-u} S(0, 1, 1) , \quad (51)$$

where the exponent u is given by

$$u = t/(s + t) . \quad (52)$$

Special Results for two Dimensions Each two-dimensional lattice L with well-defined faces (polygons with the bonds as sides, not crossed by any bonds) is associated with a *dual lattice* L^D, obtained by placing a site of L^D in every face of L and joining sites of L^D by bonds if the original faces of L share a common bond in L. The square lattice is its own dual lattice; the triangular lattice and the hexagonal lattice form a dual pair. Duality is central to the exact determination of percolation thresholds in two dimensions ► Percolation Thresholds, Exact, but also has useful implications for the random resistor problem [17,101,160], which parallel the phase interchange relations for two-dimensional continua (Sect. "Effective Conductivities"). For the square lattice, if the probability density function for bond conductances is

$$f(g) = (1 - p)\delta(g - a) + p\delta(g - b) , \quad (53)$$

then the effective conductivity $\sigma_{\text{eff}}(p)$ satisfies the equation

$$\sigma_{\text{eff}}(p)\sigma_{\text{eff}}(1 - p) = ab , \quad (54)$$

and in particular $\sigma_{\text{eff}}(\frac{1}{2}) = \sqrt{ab}$. In the notation of Straley's scaling theory (Sect. "Scaling Theory for the Conductivity"), this implies that $u = \frac{1}{2}$ for the square lattice, and so $s = t$ for the square lattice. Although this does not prove rigorously that the conductivity exponent t and superconductivity exponent s coincide for the square lattice, it is taken as evidence for the claim that $s = t$ for all reasonable two-dimensional lattices. Numerical evidence is strongly against this result remaining true in higher dimensions.

It can also be shown from duality that for the square lattice, if

$$f(g) = \frac{1}{gD\sqrt{2\pi}} \exp\left[-\frac{(\log g - \log g_0)^2}{2D^2}\right] , \quad (55)$$

then $\sigma_{\text{eff}} = g_0$.

Effective Medium Approximations The effective medium ideas of Sect. "Approximations" were adapted to the estimation of the conductivity of random resistor networks on periodic lattices by Kirkpatrick [88,89]. A much fuller modern account than given here of the implementation of effective medium ideas for lattice systems and the application of the ideas to more subtle problems and in different contexts, will be found in Sahimi [140].

The random network is replaced by a network that is uniform with unknown bond conductance g_*, except for one special bond, which has conductance G. Let the lattice have coordination number z. It can be shown that the average fluctuation in current or potential difference across the special bond due to its differing in conductance from g_* vanishes provided that

$$\left\langle \frac{G - g_*}{g_* + (2/z)(G - g_*)} \right\rangle = 0 , \quad (56)$$

and this gives a self-consistent approximate determination of g_*. For the square and simple cubic lattices, g_* is an approximation for σ_{eff}. For other lattices, σ_{eff} is a constant multiple of g_*. In the case of a percolative conductance distribution, the approximation produces an estimate of the percolation threshold.

For the standard percolation conduction problem (32), where a fraction p of the bonds has nonzero conductance g_0, the effective medium approximation produces $g_*/g_0 \approx (p - 2/z)/(1 - 2/z)$ and as bond conductances must be non-negative this prediction is interpreted as meaning that

$$\frac{g_*}{g_0} \approx \begin{cases} 0, & p \le 2/z, \\ \dfrac{p - 2/z}{1 - 2/z}, & p > 2/z . \end{cases} \tag{57}$$

That is, the effective medium approximation predicts that the percolation threshold is $2/z$. This is fortuitously exact for the square lattice bond problem and reasonable for the triangular bond and honeycomb bond problems (▶ Percolation Thresholds, Exact), but works less well in three dimensions. The construction of effective medium approximations for site percolation problems is more delicate [75].

The major qualitative deficiency of the effective medium approximation is the conductivity exponent prediction: it asserts that $t = 1$ for all dimensions. This is already a poor approximation in two dimensions ($t \approx 1.3$—see Table 2) and is grossly misleading in three dimensions ($t \approx 2$—see Table 3). The effective medium approximation also predicts that the critical exponent is unchanged if the standard percolation conduction problem is replaced by the more general model (31), provided that the mean resistance of conducting bonds is finite, that is,

$$\int_0^\infty g^{-1} h(g) \mathrm{d}g < \infty . \tag{58}$$

When the conditional probability density function for the conductance of bonds of nonzero conductance has the asymptotic form $h(g) \propto g^{-\alpha}$ as $g \downarrow 0$ with $0 < \alpha < 1$, so that the condition (58) is violated, the effective medium approximation predicts that $t = 1/(1 - \alpha)$ [75,92].

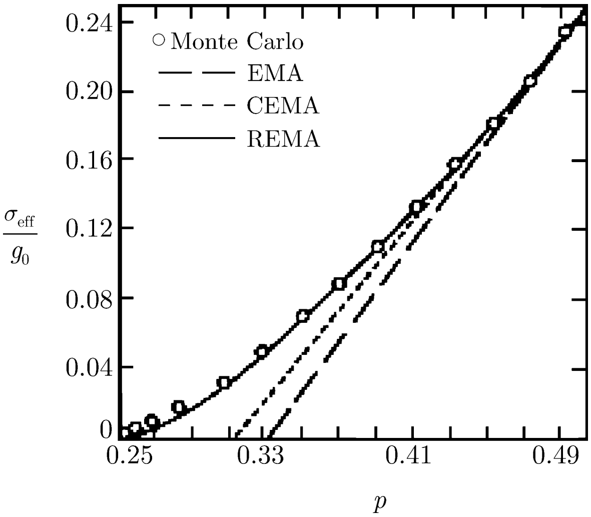
The effective medium approximation works well in non-percolative systems, and in percolative systems has some use when p is close to 1.

Renormalization By analogy with statistical mechanics applications, any process by which a lattice system is replaced by a similar lattice with bonds of different lengths is called (*real-space* or *position-space*) *renormalization*. Such a process can be performed exactly on some self-similar pseudolattices, but not on standard periodic lattices.

Numerical estimates of the effective conductivity based on simulation of finite lattice fragments often use an algorithm in which a finite subnetwork is replaced by a single effective bond for which the conductance may be calculated exactly [32,57,97]. This is especially effective near the percolation threshold, and is sometimes loosely described as an exact renormalization procedure [32]. The name is a little misleading, since the new random resistor network cannot generally be embedded in a natural way within the original underlying lattice structure.

There was considerable interest in real-space renormalization in the 1970s and 1980s, as it gave approximate predictions for critical exponents that differ from the so-called mean-field (high dimension) values of the geometrical exponents of percolation theory, and from the effective medium predictions of the conductivity exponent. Like the effective medium approximation, real-space renormalization is an uncontrolled approximation for which a priori estimates of the quality of the approximation are not available. For detailed accounts of real-space renormalization ideas applied to percolation and conduction, see Sahimi [140] and ▶ Scaling Properties, Fractals, and the Renormalization Group Approach to Percolation.

The effect of renormalization is to reduce the correlation length in the system, moving the system away from the percolation threshold. Sahimi et al. [144] have given an improved, though still uncontrolled approximation, in which approximate renormalization is used to map the system to parameter values where the effective medium approximation is more accurate. This renormalized effective medium approximation effectively increases the interval in which the effective medium approximation works, but like all effective medium treatments cannot accurately



Conduction and Diffusion in Percolating Systems, Figure 2
Effective conductivity of the simple cubic lattice bond problem for the standard percolation conduction model (32). Monte Carlo simulation data (*circles* [89] give clear evidence that the conductivity exponent *t* exceeds 1. The curves represent uncontrolled approximations: EMA, simple effective medium approximation [89]; CEMA, cluster effective medium approximation [1]; REMA, hybrid theory (renormalized effective medium approximation) [144]. Figure reproduced from [144]

portray the ultimate asymptotic behavior as $p \downarrow p_c$. An example of the resulting approximation is given in Fig. 2, together with the simple effective medium approximation [89], an alternative improved effective medium approximation [1] and simulation data [89]. The reader should note from the simulation data, which the approximate curve of Sahimi et al. matches well except very close to the threshold, the clear nonlinear behavior of the conductivity, in striking contrast to the global linear behavior predicted by the simple effective medium theory and the ultimate linear behavior also predicted by the improved approximations near their predicted approximate percolation thresholds.

Numerical Estimates of the Conductivity Exponent t
Although it is possible to estimate the conductivity exponent t from an approximate determination of $\sigma_{\text{eff}}(p)$ on an interval including p_c, greater computational efficiency comes from the extension of the finite scaling ideas of Fisher [49] to the percolation conduction problem [32,57,97,112,143].

We explain the argument for the hypercubic lattice $\mathbb{Z}^d$, but the argument should apply for all periodic lattices. As the percolation threshold is approached, the correlation length $\xi(p)$ in the infinite lattice diverges:

$$\xi(p) \propto |p - p_c|^{-\nu} \,. \tag{59}$$

Although in principle the critical exponents for the correlation length for $p > p_c$ (ν') and for $p < p_c$ (ν) could differ, they have been proved rigorously to coincide for site percolation on the triangular lattice and there is no evidence to support their being different for other lattices. The argument is therefore written out in terms of ν.

Consider the finite hypercube $\Lambda_L \subset \mathbb{Z}^d$ introduced in Sect. "Defining the Conductivity". The finite lattice Λ_L will represent the infinite lattice to a good approximation provided that $\xi(p) \ll L$. We assume that the conductivity $\sigma_L(p)$ of the finite lattice depends on $|p - p_c|$ only through the ratio $\xi(p)/L \propto (L|p - p_c|^{\nu})^{-1}$, and we write

$$\sigma_L(p) \approx L^{-\kappa} f(L|p - p_c|^{\nu}) \,. \tag{60}$$

Since the conductivity is nonzero at $p = p_c$ for some realizations of the finite lattice, $f(0) \neq 0$. We assume that $f(u) \propto u^{\lambda}$ as $u \to \infty$ so that $\sigma_L(p) \propto L^{-\kappa}[L|p - p_c|^{\nu}]^{\lambda}$. To recover the appropriate asymptotic law (44) for the conductivity of the infinite lattice, that is, $\sigma_{\text{eff}} \propto (p - p_c)^t$ as $p \to p_c^+$, we require $\lambda = \kappa$ (to cancel out the L-dependence), and to obtain the correct dependence on $p - p_c$, we need $t = \nu\lambda$. Hence

$$\sigma_L(p) \approx L^{-t/\nu} f(L|p - p_c|^{\nu}) \tag{61}$$

and in particular

$$\sigma_L(p_c) \approx L^{-t/\nu} f(0) \,. \tag{62}$$

The best available estimates of t come from the use of this asymptotic relation to determine t/ν and then using the exact value $\nu = \frac{4}{3}$ for $d = 2$ or independent numerical estimates of ν for $d \geq 3$.

In comparison with estimating the purely geometric or topological parameters of a percolation model, conductivity estimates are comparatively expensive in terms of computer time. There is a trade-off between having high precision in the values of the average conductivity of the finite lattice and having large enough L values to use the asymptotic relation (62). The most precise estimates of t/ν presently available come from Monte Carlo simulations, in which a random subset of the possible realizations of the lattice is generated for a sequence of values of L. Although the difference equations for the potential can be solved by standard techniques of numerical linear algebra, it is more efficient to perform a sequence of transformations that replace locally complicated small sections of the conducting backbone of the system by equivalent single bonds [32,57,97]; this is especially effective in two dimensions. An alternative technique for two-dimensional systems can be devised using transfer matrices, with the conductivity of one realization of an infinite strip of width L being estimated for a sequence of values of L [38,39], and a generalization of this method that works in higher dimensions is also available [28,72]. Other efficient methods of solving the relevant linear equations are also known [91].

Finite-size scaling arguments also apply to the superconductivity problem in which a fraction p of the bonds have infinite conductance, and one finds that

$$\sigma_L(p_c) \propto L^{s/\nu} \quad \text{as } L \to \infty \,. \tag{63}$$

A selection of the better estimates for t/ν and s/ν and corresponding predictions for t and s are given in Table 2 ($d = 2$) and Table 3 ($d = 3$), together with a few estimates not derived via finite-size scaling. A number of plausible conjectures on relations between various exponents, based on heuristic arguments or phenomenological relations observed from early numerical estimates, are now comprehensively refuted [57,75]. Grassberger [57] has carefully assessed the relative merits of different schemes for estimating t/ν in two dimensions, and notes major issues with the quality of random number generators used for some simulations, and problems arising from inappropriate assumptions concerning correction to scaling terms for the

square lattice bond problem. The square lattice site problem, and the bond problems on the triangular and honeycomb lattices, are better behaved [57,133]. Early estimates of t and s by finite-size scaling for lattices with unknown percolation thresholds are partly compromised by inaccuracy in numerical estimates of thresholds, but in some cases numerical estimates of thresholds are now available to extravagant precision (e. g., square lattice site problem, $p_c = 0.592\,746\,5 \pm 0.000\,000\,4$; simple cubic lattice site problem, $p_c = 0.311\,607\,7 \pm 0.000\,000\,4$ [37]).

A weak inequality relating the critical exponents t and ν can be deduced on the basis of finite-size scaling. For finite fragments of the square lattice, a duality argument shows that there is probability $\frac{1}{2}$ that the fragment is spanned by a conducting path at $p = \frac{1}{2}$. Each such realization of the system gives a conductance between the connected sides of the lattice which is no smaller than aL^{-2}, this worst case arising when there is a single path passing through all lattice sites. It follows that for the square lattice, $\sigma_L(p_c) \geq (a/2)ML^{-2}$ and so $t \leq 2\nu$ in two dimensions.

Conduction on Fractals Some progress has been made for percolation conduction problems on self-similar fractal structures [100], which have been proposed as possible models for the backbone of large clusters at the percolation threshold [53]. The plane Sierpinski lattice (triangular gasket) has percolation threshold $p_c = 1$, but unlike the linear chain which also has $p_c = 1$, the Sierpinski lattice has nontrivial finite-size scaling behavior, and the analogue of t/ν is $\log(5/3)/\log(2) \approx 0.73$ [53]. The analogue of s/ν has been evaluated numerically for this system as 0.27 ± 0.03 [162]. For a further discussion of fractal structures in the context of percolation see ▶ Scaling Properties, Fractals, and the Renormalization Group Approach to Percolation.

Structural Speculations

Despite recent spectacular advances in the understanding of two-dimensional percolation mentioned in Sect. "Rigorous Results for two Dimensions", an adequate theory for the conductivity exponent t and superconductivity exponent s remains elusive, even in two dimensions. A number of attempts have been made to model the structure of the backbone just above the percolation, and to model what physicists have called the "incipient infinite cluster" at the percolation threshold p_c, in the hope of predicting the values of t, s and related "dynamical" exponents of percolating systems.

The Backbone The backbone in a percolating system includes all sites with two independent connections to infinity. Only the backbone can carry current in the random resistor problem, although because of local symmetries, not all bonds of the backbone will carry nonzero current. On periodic lattices, the existence of a well-defined nonzero backbone probability $B(p)$ for $p > p_c$ ensures (as a consequence of ergodic theory [18]) a well-defined density of backbone sites, and so the number $B_L(p)$ of sites with two disjoint connections to the boundary in a hypercube of side L is asymptotically a multiple of $L^d B(p)$ as $L \to \infty$. Natural finite-size scaling analysis [155] (cf. Sect. "Numerical Estimates of the Conductivity Critical Exponent t" above) based on the functional form $B_L(p) = L^\kappa b(L|p-p_c|^\nu)$ with $b(z) \propto z^\lambda$ as $z \to \infty$ and the requirement that $B(p) \propto (p-p_c)^{\beta_{bb}}$ as $p \downarrow p_c$ leads to the conclusion that $d = \kappa + \lambda$ and $\beta_{bb} = \lambda\nu$. Thus, in particular, $B_L(p_c) \propto L^{d_{bb}}$, where $d_{bb} = d - \beta_{bb}/\nu$ is a formula believed to hold by physicists for $d \leq 6$, interpreted by them as the fractal dimension [100] of the backbone at the percolation threshold, and estimated by simulation. Grassberger [57] estimates that $d_{bb} = 1.6432 \pm 0.0008$ from a careful study of the square lattice site and bond percolation problems. The occurrence of this noninteger exponent suggests delicate structure of the backbone just above the percolation threshold.

The first attempts to model the backbone in detail and thereby make predictions about the conductivity exponent t date from 1975 and 1976 and are due to de Gennes [34] and Skal and Shklovskii [147]. In their view, the backbone consisted of a "superlattice" of nodes connected by macrobonds or links. If the node spacing is estimated as $\xi(p)$, the correlation length, and the conductivity of a macrobond is given by $g(p) \propto (p-p_c)^\zeta$ for some exponent ζ, then the effective conductivity is predicted to scale as

$$\sigma_{\text{eff}}(p) \approx \xi(p)^{2-d} g(p) \propto (p-p_c)^{(d-2)\nu+\zeta} , \qquad (64)$$

the factor of $\xi(p)^{2-d}$ being motivated by Eq. (39). This prediction implies that the conductivity exponent is $t = \nu(d-2) + \zeta$, and it was suggested [34] that $\zeta = 1$ in all dimensions. However, Chayes and Chayes [31] proved rigorously that $\zeta > \nu$ in all dimensions, implying that $t > \nu(d-1)$. For $d = 2$, this gives $t > \frac{4}{3}$, a result which is no longer credible given the precision recently attained in numerical estimates and the simple superlattice model is unviable.

Problems with the superlattice model were already noted by Kirkpatrick [90] in 1978. He proposed instead a self-similar fractal model, and this idea was further pursued by Gefen et al. [53]. An implication of the self-similar fractal model that $t \leq (d-1)\nu$ is consistent with numerical data in low dimensions, but fails for $d = 6$, where it is accepted that $\nu = \frac{1}{2}$ and $t = 3$.

The most plausible picture of the backbone structure just above the percolation threshold is inelegantly described as the "nodes–links–blobs" model [151,152], with approximately self-similar structures over smallest scales linked together in some way by tortuous, quasi-one-dimensional links but the structure is far from completely characterized.

The Incipient Infinite Cluster Since the percolation probability $P_\infty(p)$ is proven rigorously to be zero at the percolation threshold for several two-dimensional percolation problems, there is with probability 1 no infinite cluster present at the percolation threshold. The *incipient infinite cluster* at the percolation threshold in the sense originally used by physicists is therefore a dubious construct. Kesten has given a rigorous discussion of two mathematically respectable candidates for the incipient infinite cluster [59,86], using appropriately defined conditional probabilities.

(i) Take $p > p_c$ and work with conditional probabilities, conditioning on the event that the origin is part of an infinite cluster. Then take the limit $p \downarrow p_c$.

(ii) Take $p = p_c$ and work with conditional probabilities, conditioning on the event that the origin belongs to a connected cluster that reaches the boundary of a box of side length $2n$ centered on the origin. Then take the limit as $n \to \infty$.

For bond percolation on the square lattice, these two apparently different definitions have been proved consistent [86]. Moreover, for this specific problem, it can be shown that the expected number of sites of the incipient infinite cluster in a box of side $2n$ is (to within a slowly-varying prefactor) $n^{2-\eta}$, where the exponent η governs the decay of the probability that the origin is connected to a box of side $2n$. It has been proved that for the triangular lattice bond problem, $\eta = \frac{5}{24}$ [148], and this should be generally true for two dimensions. In physicists' terminology, this shows that the fractal dimension of the incipient infinite cluster in two dimensions is $d_{\text{iic}} = \frac{43}{24} \approx 1.792$, which is outside the 1983 estimates $d_{\text{iic}} = 1.90 \pm 0.1$ [130] and $d_{\text{iic}} = 1.900 \pm 0.009$ [81].

The theory of the incipient infinite cluster and its relation to finite-size scaling considerations are completely resolved in two dimensions [23,76]. Some illuminating if less complete conclusions are available in higher dimensions [23]. Physicists' scaling theories suggest that $d_{\text{iic}} = d - \beta/\nu$ for $2 \le d \le 6$ [155]. However, it is not the incipient infinite cluster but rather the backbone that is core to the determination of the conductivity exponent, so that these results do not go far enough for the present purposes.

Random Motion in a Random Environment

One may replace the steady-state transport and conduction processes discussed in Sect. "Continuum Models: Steady-State Phenomena" and "Lattice Models: Steady-State Phenomena" for continua and lattices respectively by time-dependent analogues. Our discussion of the continuum version is very brief.

Continuum Problems

As noted in Sect. "Caveats to the Electrical Interpretation", problems of diffusion in random media are easily defined. An account of the homogenization of the diffusion Eq. (5), including references to earlier work, will be found in Jikov et al. [79]. In particular for random media subject a uniform ellipticity condition (equivalent to bounding the local diffusivity away from zero) and with a spatially stationary distribution of the local diffusivity, the system can be homogenized for almost all realizations of the random diffusivity distribution, and the corresponding homogenized diffusivity is independent of the realization. Percolative problems, where the diffusivity is zero at a given arbitrary point with nonzero probability are more difficult to analyze, but Jikov et al. [79] give a proof that for the random chessboard (squares with diffusivities 0 or 1 with probabilities $1 - p$ and p respectively), the scaled displacement $\mathbf{X}(t)$ of a diffusion process commencing in the conducting phase converges in distribution to a zero mean, isotropic bivariate normal random variable. If D_0 denotes the homogenized diffusivity for the steady-state problem treated like a steady conduction problem, then the diffusivity governing the time-dependent problem is $D_0/P_\infty(p)$, where $P_\infty(p)$ is the density of the infinite conducting cluster (and indeed equal to the percolation probability for site percolation on the square lattice).

For a discussion of many aspects and applications of diffusion in condensed matter physics, an area that has sustained interest in the properties of heterogeneous and randomly microstructured materials for a long time, see the collection edited by Heitjans and Kärger [71]. One interesting diffusion problem that we do not address, since it does not manifest percolation properties, arises when one phase acts as an irreversible trap. The survival probability diffusing objects in the presence of dilute random traps decays as $\exp(-kt^{3/5})$ at large times t in three dimensions rather than the naively expected $\exp(-kt)$, due to the unexpected statistical importance of rare, large trap-free regions [58,74,80].

Lattice Problems

The lattice-based models for stochastic transport processes in random environments that we address may loosely be described as *random walks*, since they derive conceptually from the random walk problems first posed by in 1905 by Pearson [126] and in 1919 by Pólya [128,129], but the precise meaning of the phrase *random walk* varies widely in the literature. The classic account of the traditional theory of discrete time, translationally invariant random walks on $\mathbb{Z}^d$ is Spitzer [150]; substantial extensions to the theory needed for more general problems will be found in Doyle and Snell [40], Hughes [74,75], Telcs [163] and Woess [169]. The most recent comprehensive rigorous reviews of random walks in random environments are the papers by Zeitouni [172,173]. For other discussions of random walks in random environments see the books by Hughes [75] and Révész [134].

Nearest-Neighbour Stepping Discrete-Time Random Walk We consider the case in which the probability that a walker presently at site $\mathbf{s}'$ next steps to site $\mathbf{s}$ is $p(\mathbf{s}|\mathbf{s}')$, nonzero only when $\mathbf{s}$ is a nearest neighbor of $\mathbf{s}'$. The walk is called *recurrent* if there is probability 1 that the walker eventually returns to the starting site and *transient* otherwise. A recurrent walker is certain to visit all sites accessible to it, and visits its own starting site infinitely often (with probability 1). A transient walker revisits the starting site at most finitely many times.

The walk is of Pólya type if $p(\mathbf{s}|\mathbf{s}') = 1/z(\mathbf{s}')$, where $z(\mathbf{s}')$ is the coordination number of $\mathbf{s}'$, that is, all nearest-neighbor steps are equally likely. Pólya's most famous result is that for Pólya walk on $\mathbb{Z}^d$, the walk is recurrent for $d = 1$ and $d = 2$, but transient for $d \geq 3$. Translationally invariant walks are well-suited to Fourier analysis. This is how much of the classical theory is derived, and the discrete time evolution is simplified by generating function methods [74,150]. In particular, for Pólya walks on $\mathbb{Z}^d$, the position distribution of the random walker is asymptotically Gaussian (normal) at large times and the probability $p_n(\mathbf{s}_0)$ that the walker will be found at the starting site $\mathbf{s}_0$ after n steps decays in proportion to $n^{-d/2}$.

The number S_n of distinct sites visited in the first n steps is of interest in a number of contexts [74]; in the probability literature this quantity is sometimes misleadingly called the range of the random walk. For classical Pólya walks on $\mathbb{Z}^d$, the mean number of distinct sites visited has the asymptotic behavior [115]

$$\langle S_n \rangle \sim \begin{cases} (8n/\pi)^{1/2}, & d = 1\,, \\ \pi n/\ln n, & d = 2\,, \\ (1-R)n, & d \geq 3\,, \end{cases} \tag{65}$$

where R is the probability of eventual return to the starting site. The following more general results hold [74] for translationally invariant walks on periodic lattices. For transient walks, $\langle S_n \rangle \sim (1-R)n$. For recurrent walks, if $p_n(\mathbf{s}_0) \sim \text{constant} \times n^{-H/2}$ with $0 < H < 2$, or equivalently,

$$\sum_{n=0}^{\infty} p_n(\mathbf{0})\xi^n \sim \text{constant} \times (1-\xi)^{H/2-1} \quad \text{as } \xi \uparrow 1\,, \tag{66}$$

then

$$\langle S_n \rangle \sim \text{constant} \times n^{H/2}\,. \tag{67}$$

The case $H = 2$ induces logarithmic prefactors. The exponent H is variously described as the *harmonic dimension* [74], *spectral dimension* or *fraction dimension* [2], and $H = d$ for the simplest problems on $\mathbb{Z}$ or $\mathbb{Z}^2$.

For random walk problems where the generating function and Fourier analysis techniques used to derive the preceding results are not available, the important questions to addressed in other ways are as follows.

(i) Is the walk recurrent or transient?
(ii) Is the walk diffusive (large-n Gaussian or normal limiting behavior) and if so, what is the value of diffusion constant?
(iii) In non-diffusive cases, how does the mean-square displacement grow with n?
(iv) What is the value of the harmonic dimension?

Canonical Models for Random Environments Random environments for random walkers to experience may be constructed in various ways. One simple way is to assign to each bond of the lattice $\mathbb{Z}^d$ (or some other periodic lattice) an independent nonzero weight, which might be interpreted as the conductance of a random resistor. If $G_{\mathbf{r},\mathbf{s}} = G_{\mathbf{r},\mathbf{s}}$ denotes the conductance of a bond joining nearest-neighbor sites $\mathbf{r}$ and $\mathbf{s}$, then the transition probability may be defined to be

$$p(\mathbf{s}|\mathbf{s}') = \frac{G_{\mathbf{s},\mathbf{s}'}}{\sum_{\mathbf{s}''} G_{\mathbf{s}'',\mathbf{s}'}}\,, \tag{68}$$

the sum over $\mathbf{s}''$ being restricted to nearest neighbors of $\mathbf{s}'$. If all bonds emanating from a given site have equal conductance, the walk is of Pólya type.

Consider the following two problems on the infinite conducting lattice just introduced:

- a discrete-time random walk, governed by (68) starting from site $\mathbf{s}_0$;
- electrical conduction between site $\mathbf{s}_0$ and infinity.

Then it can be shown [40] that the walk is transient if and only if the total resistance between $\mathbf{s}_0$ and infinity is finite. This result, and various other relations between random walks and electric networks [40,75,117], represent one of the most important avenues for progress in the study of random walks in random environments.

Pemantle and Peres [127] have shown that for independent, identically distributed conductances, the question of recurrence or transience of this model can be settled (for all realizations of the environment save for a set of zero probability) by an analysis of Pólya random walk on the random lattice arising from the bond percolation on the same lattice. The original walk is transient if and only if for some p with $p_c < p < 1$ the Pólya walk on the infinite cluster in the bond percolation problem is transient.

Master Equations and Generalized Master Equations Differential-difference equations of the form

$$\frac{\mathrm{d}}{\mathrm{d}t}c(\mathbf{s},t) = \sum_{\mathbf{s}'} W(\mathbf{s},\mathbf{s}')c(\mathbf{s}',t) - M(\mathbf{s})c(\mathbf{s},t) \qquad (69)$$

describe a process in which the concentration of a mobile substance at site $\mathbf{s}$ evolves by transfer of substance from other sites (gaining substance at rate $W(\mathbf{s},\mathbf{s}')c(\mathbf{s}',t)$ from site $\mathbf{s}'$) and loss of substance to other sites (total rate of loss $M(\mathbf{s})c(\mathbf{s},t)$ to all other sites). If the substance is to be globally conserved, one needs

$$M(\mathbf{s}) = \sum_{\mathbf{s}'} W(\mathbf{s}',\mathbf{s}) \qquad (70)$$

and if

$$p(\mathbf{s},t) = \frac{c(\mathbf{s},t)}{\sum_{\mathbf{s}'} c(\mathbf{s}',t)} \qquad (71)$$

denotes the normalized concentration then what physicists call the *master equation* [122],

$$\frac{\mathrm{d}}{\mathrm{d}t}p(\mathbf{s},t) = \sum_{\mathbf{s}'}[W(\mathbf{s},\mathbf{s}')p(\mathbf{s}',t) - W(\mathbf{s}',\mathbf{s})p(\mathbf{s},t)]\,, \qquad (72)$$

results. This equation is interpreted as the law governing the probability of the position of some type of random walk process in continuous time, and indeed is a standard equation from the theory of Markov processes.

To obtain a richer class of possible behaviors, physicists have also considered *generalized master equations* [84], where the transition rates $W(\mathbf{s},\mathbf{s}')$ are replaced by memory kernels $W(\mathbf{s},\mathbf{s}',t)$:

$$\frac{\mathrm{d}}{\mathrm{d}t}p(\mathbf{s},t) = \int_0^t \sum_{\mathbf{s}'}[W(\mathbf{s},\mathbf{s}',t-t')p(\mathbf{s}',t') - W(\mathbf{s}',\mathbf{s},t-t')p(\mathbf{s},t')]\mathrm{d}t'\,. \qquad (73)$$

For Eqs. (72) and(73) the transition rates or memory kernels are often nonzero only for nearest-neighbor sites. Simple models of random media arise by imposing symmetry,

$$W(\mathbf{s},\mathbf{s}') = W(\mathbf{s}',\mathbf{s}) \quad \text{or} \quad W(\mathbf{s},\mathbf{s}',t) = W(\mathbf{s}',\mathbf{s}',t),$$

and making the rate coefficients $W(\mathbf{s},\mathbf{s}')$ or parameters in the memory kernels $W(\mathbf{s},\mathbf{s}',t)$ independent random variables. If we introduce Laplace transforms, writing

$$\widehat{f}(u) = \int_0^\infty e^{-ut} f(t)\mathrm{d}t\,, \qquad (74)$$

then the transformed master and generalized master equations for a process started at the origin site $\mathbf{0}$ become

$$u\widehat{p}(\mathbf{s},u) - \delta_{\mathbf{s},\mathbf{0}} = \sum_{\mathbf{s}'} W(\mathbf{s},\mathbf{s}')[\widehat{p}(\mathbf{s}',u) - \widehat{p}(\mathbf{s},u)], \qquad (75)$$

$$u\widehat{p}(\mathbf{s},u) - \delta_{\mathbf{s},\mathbf{0}} = \sum_{\mathbf{s}'} \widehat{W}(\mathbf{s},\mathbf{s}',u)[\widehat{p}(\mathbf{s}',u) - \widehat{p}(\mathbf{s},u)]. \qquad (76)$$

In both cases, the Laplace transform equations are able to be interpreted as the equations governing a random resistor network, with all sites having an additional connection to zero potential (an earth connection) of conductance u. If we attempt to match Eq. (75), with random rates $W(\mathbf{s},\mathbf{s}')$, to an equivalent uniform system with rates W_*, then it should be anticipated that W_* is a function of the variable u, since the relative importance of the earth connection at $\mathbf{s}$ compared to its connections to other sites will fluctuate over the lattice. Consequently, as discussed in Sect. "Exactly and Approximately Solved Continuous-Time Problems", the appropriate real-time description of the system may be expected to correspond to a uniform memory kernel generalized master equation, rather than a simple, uniform transition rate master equation.

Exactly Solved Discrete-Time Problems Elegant exact results are scarce for random processes in random environments, with the strongest and most informative results limited to one dimension (that is, on $\mathbb{Z}$), where percolative problems become essentially trival: for $p < 1$ a Pólya walker is confined to a finite interval and essentially its position has a limiting distribution (to be more precise, the positions after even or odd numbers of steps have limiting distributions, which may be different). Averaging over all realizations of the environment we find that the mean-square displacement after n steps is $o(n)$. This unusual behavior is an artifact of averaging: as n increases, in more and more realizations the walker's displacements have saturated and only the effects of increasingly rare large intervals contribute to the continued growth of the mean-square displacement, and various properties of the system can be deduced by appropriate averaging over the positions of the left and right boundary sites [121].

A less trivial one-dimensional model introduced in 1972 by Temkin [164] brings out the subtle possibilities for random walks in random environments. Consider the stepping law

$$p(l|l') = A_{l'}\delta_{l,l'+1} + (1 - A_{l'})\delta_{l,l'-1}\,, \qquad (77)$$

where $\{A_l\}$ is a set of independent, identically distributed random variables. Let an overbar denote an average over all realizations of the set $\{A_l\}$. Solomon [149] has shown that: a walker initially stepping right is certain to return if and only if $\overline{\log[(1-A)/A]} \geq 0$; a walker initially stepping left is certain to return if and only if $\overline{\log[A/(1-A)]} \geq 0$, and the walk is recurrent if and only if $\overline{\log[A/(1-A)]} = 0$. In 1982, Sinai [146] produced the astonishing result that in the recurrent case, on the additional assumption that A_l is bounded away from 0 and 1, the mean-square displacement is $O(\ln^4 n)$, in place of the standard $O(n)$ for one-dimensional Pólya walkers.

Exactly and Approximately Solved Continuous-Time Problems Alexander et al. [3] have discussed exactly solvable one-dimensional master equations with independent, identically distributed random transition rates. If the probability density function for the rates is denoted by $f(w)$, they show that the mean-square displacement grows as $2W_0 t$, and the random system is equivalent in its long-time properties to a uniform system in which all transition rates are W_0, where

$$\frac{1}{W_0} = \int_0^\infty \frac{f(w)\mathrm{d}w}{w} \,, \tag{78}$$

so long as the integral on the right is finite. When this is not the case, the random motion is *sub-diffusive* : if $f(w) \to f(0) > 0$ as $w \to 0$ then the mean-square displacement grows as $t/\ln t$, while if $f(w) \propto w^{-\alpha}$ as $w \to 0$ the mean-square displacement grows as $t^{(2-2\alpha)/(2-\alpha)}$ (distribution-induced nonuniversality). There are several of other approaches to exactly solvable one-dimensional master equation problems, including asymmetric rate problems [75].

A number of authors have extended the idea of an effective medium approximation from the random resistor problem (Sect. "Effective Medium Approximations") or other contexts to the problem of random master equations. For historical details and a full account of the analysis see Sahimi et al. [142] or Hughes [74]. As noted in Sect. "Master Equations and Generalized Master Equations", in the Laplace transform domain, the master equation with random coefficients is equivalent to a random resistor network, and the uniform transition rate produced by the matching procedure is a function of the transform variable, so that the approximately equivalent uniform system is governed by a generalized master equation. In the percolative case in which the rate coefficient associated with a bond is nonzero only with probability $p < 1$, the approximately equivalent uniform system does not support motion if $p < 2/z$ (the predicted percolation threshold, where z is the coordination number of the underlying lattice on which the percolation process is realized). For $p \downarrow 2/z$, the effective diffusion constant $D(p)$ (a constant multiple of the time derivative of the mean-square displacement) is predicted to vanish linearly with $p - 2/z$ for the standard case where all nonzero rate coefficients are equal, but the exponent is predicted to change in more general cases if the average of W^{-1} is infinite, where W is the random rate associated with an arbitrary bond, conditional on the rate being nonzero.

In one dimension, the effective medium approximation reproduces a number of the exact results of Alexander et al. [3]. Its predictions for higher-dimensional systems, while not of great accuracy, do have one interesting aspect. Generalized master equations with memory kernels $W(\mathbf{s}, \mathbf{s}', t) = \phi(t)p(\mathbf{s}|\mathbf{s}')$ are naturally associated with continuous-time random walk processes in which the walker waits for a random time with probability density function $\psi(t)$ between successive steps, and then moves with the stepping law $p(\mathbf{s}|\mathbf{s}')$. The classic exponential waiting time density $\psi(t) = \kappa \exp(-\kappa t)$ arises if and only $\phi(t) = \kappa\delta_+(t)$ and the generalized master equation reduces to the ordinary master equation in this case. In general, the connection between ϕ and ψ is most simply expressed in terms of the Laplace transform: $\widehat{\psi}(u) = \widehat{\phi}(u)/[u + \widehat{\phi}(u)]$ [74,85]. Any form of nondiffusive behavior that may arise is naturally associated with a non-exponential waiting time density, and for $p < 2/z \approx p_c$ the associated waiting time is predicted to be defective, that is,

$$\int_0^\infty \psi(t)\mathrm{d}t < 1 \tag{79}$$

and the equivalent continuous time random walker takes only finitely many steps. An alternative approach to modeling nondiffusive behavior of possible relevance to percolative systems can be developed using fractional calculus ideas [107,108].

The Ant in the Labyrinth

We conclude our survey of transport and conduction in random environments, with a discussion for discrete-random walks of the problem of the ant in the labyrinth, introduced in 1975 by Brandt [24] and proposed by de Gennes [33] as a probe of the geometry of percolation. The ant, a random walker, moves through a random labyrinth generated by applying site or bond percolation to a periodic lattice [24,33,75,110,111,113]. Because the analogue of a strong ellipticity condition is not satisfied for these percolative problems, many of the more general results from rigorous analyzes of random walks in random environments [172,173] do not apply.

Models Let the original lattice from which the labyrinth is made have coordination number z. Then at a site $\mathbf{s}$ of the labyrinth, the coordination number will be $Z_\omega(\mathbf{s}) \leq z$, where $Z_\omega(\mathbf{s})$ is determined by the specific realization ω of site or bond percolation used in constructing the labyrinth. There are two canonical choices for the ant's mode of stepping through the labyrinth, the distinction between them having been clearly drawn by Mitescu and Roussenq [111] and Majid et al. [99].

myopic ant (Pólya case) —On arrival at site $\mathbf{s}$, the ant looks at the $Z_\omega(\mathbf{s})$ adjacent sites onto which it is permitted to step, assigns each of them probability $1/Z_\omega(\mathbf{s})$ and chooses one of them at random.

blind ant —On arrival at site $\mathbf{s}$, the ant attempts to move to one of the z adjacent sites on the original lattice. If this move is not allowed for the labyrinth, the ant remains at site $\mathbf{s}$.

In a given time interval, a blind ant visits fewer distinct sites than a myopic ant.

It is generally believed that the qualitative properties of myopic (Pólya) ants and blind ants are similar, but there is an important difference when the ant is introduced on a finite cluster [111]: the "equilibrium" probability distributions of the ant, approached asymptotically as the number of steps grows without bound, differ for the two models. The existence of equilibrium probability distributions on finite clusters can be discussed from the point of view of Markov chains [46], where such distributions are called "invariant measures".

Simulations suggest [41,113,125,145] that when the mean-square displacement $\langle R_n^2 \rangle$ is averaged over environments, as $n \to \infty$ we have

$$\overline{\langle R_n^2(p) \rangle} = \begin{cases} R_\infty^2 - A(p)\exp\{[-n/\theta(p)]^w\} + \cdots\,, & p < p_c\,, \\ Bn^{2k} + \cdots\,, & p = p_c\,, \\ CD(p)n + \cdots\,, & p > p_c\,, \end{cases} \tag{80}$$

where any dependence of a quantity on p or n is explicitly indicated. Here $D(p)$ is an effective diffusion constant and the exponent k, which would be 1/2 for classical diffusion, is dimension-dependent, with $k < 1/2$ in low-dimensional systems. In particular, estimates of k for the simple cubic lattice are 0.20 ± 0.01 [125] and 0.200 ± 0.002 [41]. The value of the exponent w was initially believed close to 1 [113] in three dimensions, but later evidence [125] suggests that $w \approx 0.4$ in three dimensions.

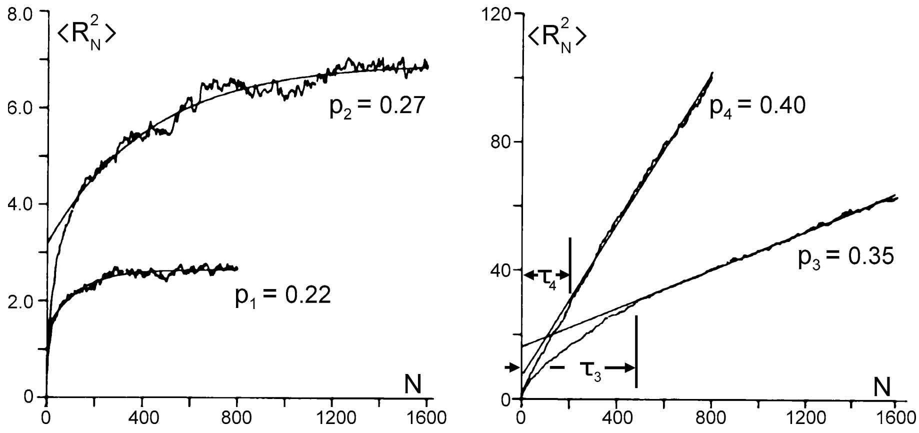
In the mathematical literature, careful distinctions are drawn between results that apply to the *annealed* case (corresponding to averaging over all realizations of the disordered system) and the *quenched* case (involving statements about realizations ω of the disorder. For $p \leq p_c$ the ant commences with probability 1 on a cluster of finite size, and in any individual realization ω of the system, the mean-square displacement will converge to a finite value (blind case) or oscillate between two finite values (myopic case for some lattices, where oscillations can occur if the cluster divides into sites accessible only after an even number of steps and sites accessible only after an odd number of steps). For $p = p_c$, at a given value of n the displacement will have saturated (that is, be close to its asymptotic value) in some environments but not in others. This partitioning of the realizations of the environments, and the tortuous structure of large clusters that are not yet fully explored by the ant, give rise to the nonclassical exponent $k < 1/2$.

Scaling Theory for the Ant in the Labyrinth Heuristic work [9,69,75,124,155] raises attractive possible connections between exponents characterizing the asymptotic behavior of the ant in the labyrinth and the geometrical exponents of percolation theory. A number of rigorous scaling relations involving various exponents that characterize random walk and electrical conduction on lattices have been derived by Telcs [163], but these are not sufficiently informative to establish rigorously the results now briefly described or to enable exponent values to be predicted.

We shall denote averages for walks, conditioned on the walks taking place on clusters of m sites, by $\langle \cdot \rangle_m$. Consider first the expected number of distinct sites visited. At the percolation threshold, if there is some kind of effective harmonic dimension for large clusters (cf. Sect. "Lattice Problems"), which one might loosely call the harmonic dimension of the incipient cluster (cf. Sect. "The Incipient Infinite Cluster") and denote by H_{iic}, then the expected number of distinct sites visited by a walker on a cluster of m sites should evolve as $\langle S_n \rangle_m \propto n^{H_{\mathrm{iic}}/2}$ for $1 \ll \langle S_n \rangle_m \ll m$. The scaling hypothesis [124] $\langle S_n \rangle_m \approx n^{H_{\mathrm{iic}}/2}\phi(m/n^{H_{\mathrm{iic}}/2})$ and the asymptotic law $P_m(p) \propto m^{-1-1/\delta}$ for the cluster size distribution gives a simple prediction [6,124] for the mean number of distinct sites visited, averaged both over cluster sizes and over walks on individual clusters:

$$\overline{\langle S_n \rangle} \approx \sum_{m=1}^{\infty} m^{-1-1/\delta}\, n^{H_{\mathrm{iic}}/2}\phi(m/n^{H_{\mathrm{iic}}/2}) \approx n^{(1-1/\delta)H_{\mathrm{iic}}/2}\,; \tag{81}$$

the last result arises from approximating the sum by an integral. Three-dimensional simulations give $\overline{\langle S_n \rangle} \propto n^{0.54 \pm 0.02}$ [124].



Conduction and Diffusion in Percolating Systems, Figure 3

Simulations of the ant in the labyrinth [113]: myopic ants (Pólya walkers) on the simple cubic lattice under site percolation ($p_c \approx 0.31$) for four values of p. Simulation data (*erratic curves*) shows the mean-square displacement after N steps, averaged over realizations of the environment when a fraction p of all sites are occupied: a shows $p < p_c$ ($p_1 = 0.22$, $p_2 = 0.27$), with the smooth curves least-squares fits to $R_\infty^2 - A(p)\exp[-n/\theta(p)]$; b shows $p > p_c$ ($p_1 = 0.35$, $p_4 = 0.40$), with the straight-line asymptotes corresponding to effectively diffusive behaviour and τ_k corresponding to the number of steps needed for diffusive behaviour to be manifest for $p = p_k$ (Figure reproduced with permission from [114])

A similar analysis may be performed for the mean-square displacement at the percolation threshold [54,75]. If the fractal dimension of the incipient infinite cluster is denoted by d_{iic} (cf. Sect. "The Incipient Infinite Cluster") one may propose that the mean-square displacement on clusters of size m is $\langle R_n^2 \rangle_m \propto n^{2\nu_{\text{iic}}}$ for $1 \ll \langle R_n^2 \rangle_m^{1/2} \ll m^{1/d_{\text{iic}}}$. The naturally associated scaling assumption $\langle R_n^2 \rangle_m \approx n^{2\nu_{\text{iic}}} \psi(m^{1/d_{\text{iic}}}/n^{2\nu_{\text{iic}}})$ predicts the mean-square displacement averaged both over cluster sizes and over walks on individual clusters to be

$$\begin{aligned}\overline{\langle R_n^2 \rangle} &\approx \sum_{m=1}^{\infty} m^{-1-1/\delta} n^{2\nu_{\text{iic}}} \psi(m^{1/d_{\text{iic}}}/n^{2\nu_{\text{iic}}}) \\ &\approx n^{2\nu_{\text{iic}}[1-d_{\text{iic}}/(2\delta)]} .\end{aligned} \tag{82}$$

The accepted scaling relations $d_{\text{iic}} = (\beta + \gamma)/\nu$ and $\gamma = \beta(\delta - 1)$ give the alternative form $\overline{\langle R_n^2 \rangle} \propto n^{2\nu_{\text{iic}}[1-\beta/(2\nu)]}$ and simulation data is consistent with this picture [68].

A conjecture of Alexander and Orbach [2] published in 1982 suggesting that $H_{\text{iic}} = 4/3$ for all dimensions d briefly raised the possibility that the conductivity exponent t could be simply related to geometrical exponents in percolation theory, and that other dynamical exponents related to random walk processes could be determined. Given the known geometrical exponents in two dimensions, the Alexander–Orbach conjecture predicted that $t = 91/72 \approx 1.2639$ in two dimensions. It is now generally accepted that the Alexander–Orbach conjecture, while an excellent approximation, is not precisely correct [9,116].

A number of other observable quantities can be estimated by scaling arguments [9,75,155]. For example, just below the percolation threshold, it is predicted [154] that the mean-square displacement (averaged over all walks and realizations) has the limiting value $R_\infty^2 \propto (p_c - p)^{2\nu-\beta}$.

Rigorous Results for Discrete Time The most important rigorous result is probably the following theorem, which shows that Pólya's simple criterion for transience $d \geq 3$ is not destroyed by the percolation process, provided the system is above the percolation threshold, and the ant starts on the infinite cluster [60].

Theorem 1 (Theorem of Grimmett, Kesten and Zhang) *For myopic ants (Pólya walkers) walking on the infinite cluster generated by bond percolation on the simple hypercubic lattice at $p > p_c$, the walk is transient with probability 1 if $d \geq 3$.*

As with most rigorous results in this area, the proof is of antisocial length. However, Rayleigh's Monotonicity Law and the correspondence between random walks and electric circuits makes it relatively straightforward to show that the recurrence of the ordinary Pólya walk on the square lattice $\mathbb{Z}^2$ ensures the recurrence of myopic ant motion on every realization of an infinite cluster in bond or site percolation on the square lattice.

For walks on the incipient infinite cluster, a nebulous concept made precise by either of the equivalent approaches of Kesten discussed in Sect. “The Incipient Infinite Cluster”, it is known [86] that the general behavior is subdiffusive ($|\mathbf{X}_n| = O(n^{1/2-\epsilon})$ for some $\epsilon > 0$) for the square lattice bond problem, but the exact exponent characterizing the growth of $|\mathbf{X}_n|$ is unknown.

Rigorous Results for Continuous Time For the natural master-equation analogue of the myopic ant (corresponding to a myopic ant executing a continuous-time random walk with an exponential waiting time density of mean waiting time 1 at all sites) several exact results that mirror known results for Pólya walks on periodic lattices are available. In stating these results, we assume that our labyrinth is generated by bond percolation on $\mathbb{Z}^d$ with $d \geq 2$ and $p > p_c$, we write C^ω_∞ to denote the (unique with probability 1) infinite cluster in the realization ω of the random environment, and we assign coordinates such that the the origin $\mathbf{0}$ is a site of the infinite cluster. We write $\Pr^\omega$ to denote probabilities associated with random walks in the fixed realization ω of the environment. The position at time t of a random walker starting from the origin at time 0 is $\mathbf{X}_t$. We say that a result holds for almost all environments if it holds with probability 1, where probability is measured with respect to the realizations of bond percolation for the given value of p.

The following results, published in 2004 [7,103], go further than results previously established only for $d = 2$ [35,36] and show that there is no anomalous behavior above the percolation threshold for the myopic ant problem for all $d \geq 2$: in the long time limit, the process strongly resembles classical diffusion.

Mathieu and Remy [103] have proved that there exists $c_1(p, d)$ (independent of time or the realization ω of the environment) such that for almost all environments, the quenched bound

$$\sup_{\mathbf{y} \in C^\omega_\infty} \Pr{}^\omega\{\mathbf{X}_t = \mathbf{y}\} \leq \frac{c_1(p,d)}{t^{d/2}} \tag{83}$$

holds. This result confirms the transience of the walk for $d \geq 2$, a result already known from the theorem of Grimmett, Kesten and Zhang [60] for the discrete-time walk, stated in Sect. “Rigorous Results for Discrete Time”. Mathieu and Remy also establish the analogous result to (83) for site percolation on the two-dimensional square lattice, and an annealed lower bound proportional to $t^{-d/2}$ for bond percolation on $\mathbb{Z}^d$.

Barlow [7] has constructed upper and lower bounds for the quenched transition density

$$q^\omega_t(\mathbf{x}, \mathbf{y}) = \frac{1}{Z^\omega(\mathbf{y})} \Pr{}^\omega\{X_{t+\tau} = \mathbf{y} \,|\, X_\tau = \mathbf{x}\} \tag{84}$$

that hold with probability 1 for sufficiently large time t:

$$\begin{aligned} &\frac{c_1(d,p)}{t^{d/2}} \exp\left[-\frac{c_2(d,p)}{t}|\mathbf{x}-\mathbf{y}|_1^2\right] \leq q^\omega_t(\mathbf{x},\mathbf{y}) \\ &\leq \frac{c_3(d,p)}{t^{d/2}} \exp\left[-\frac{c_4(d,p)}{t}|\mathbf{x}-\mathbf{y}|_1^2\right] . \end{aligned} \tag{85}$$

Here if $\mathbf{x} = (x_1, x_2, \ldots, x_d)$ and $\mathbf{y} = (y_1, y_2, \ldots, y_d)$, one defines

$$|\mathbf{x}-\mathbf{y}|_1 = \sum_{k=1}^{d} |x_k - y_k| \, . \tag{86}$$

Sufficiently large t is quantified by $t \geq \sup\{|\mathbf{x}-\mathbf{y}|_1, S^\omega_\mathbf{x}\}$, where the finite but realization-dependent quantities $S^\omega_\mathbf{x}$ deal with problems associated with an initial period of potentially anomalous behavior. Barlow’s results establish the essentially diffusive asymptotic behavior of the walk. For further results in the quenched case, see Berger and Biskup [13].

The above results pertain only to walks of Polyá type on the infinite cluster for $p > p_c$. For a discussion of biased random walks on the infinite cluster in two-dimensional percolation, see Berger et al. [14].

Future Directions

Problems of transport and conduction in random systems subject to the kinds of uniform ellipticity restrictions that preclude percolation phenomena have become increasingly well understood, though the address by Zeitouni [171] at the 2002 International Congress of Mathematicians summarizes a number of areas in which progress on the problem of random walk in a random environment remains to be made. Moreover, an adequate theoretical understanding does not entirely remove the tedious problem of accurately estimating overall system properties.

The situation concerning truly percolative problems remains less satisfactory. The generally classical behavior of such systems above the percolation threshold means that, for modeling purposes in science and technology, one often may reasonably replace the random system by a uniform analogue, in much the same way as one can do this for systems with ellipticity restrictions, but with the important caveat that close to the percolation threshold, the length or time scales at which the uniform treatment is accurate may in practice be unacceptably large. A fuller understanding therefore of processes at or near the percolation threshold remains the greatest challenge.

There has been spectacular progress since the late 1970s with the understanding (both heuristic and rigorous) of the geometrical side of percolation theory, especially for lattices. We have elegant results on the existence of classical or mean-field behavior for large dimension d, and the knowledge (though gaps in rigor remain) that mean-field behavior applies for $d \geq 7$ and in a slightly weaker sense for $d = 6$ but not for smaller d. More importantly, through rigorous work on conformal invariance and on Schramm–Loewner evolution processes, exact two-dimensional values of geometrical critical exponents and exact two-dimensional scaling relations are now properly established. An analogous rigorous account of dynamical exponents characterizing transport in two-dimensional percolating systems is perhaps not too much to ask for, though the way is not yet clear. It would be surprising indeed if there were significant progress in the short term on the rigorous analysis of three-dimensional systems at or near the percolation threshold.

Article Outline

Glossary

Thalamocortical system The network of highly interconnected cortical areas and thalamic nuclei that comprises a large part of the mammalian brain. The cortex is the wrinkled surface of the brain, the thalamus is a small walnut-sized structure at its center. An intact thalamocortical system is essential for normal conscious experience.

Theory of neuronal group selection (TNGS) A large-scale selectionist theory of brain development and function with roots in evolutionary theory and immunology. According to this theory, brain dynamics shape and are shaped by selection among highly variant neuronal populations guided by value or salience.

Neural correlate of consciousness Patterns of activity in brain regions or groups of neurons that have privileged status in the generation of conscious experience. *Explanatory* correlates are neural correlates that in addition account for key properties of consciousness.

Dynamic core A distributed and continually shifting coalesence of patterns of activity among neuronal groups within the thalamocortical system. According to the TNGS, neural dynamics within the core are of high neural complexity by virtue of which they give rise to conscious discriminations.

Neural complexity A measure of simultaneous functional segregation and functional integration based on information theory. A system will have high neural complexity if each of its components can take on many different states and if these states make a difference to the rest of the system.

Small-world networks Networks in which most nodes are not neighbors of one another, but most nodes can be reached from every other by a small number of hops or steps. Small-world networks combine high clustering with short path lengths. They can be readily identified in neuroanatomical data, and they are well suited to generating dynamics of high neural complexity.

Metastability Dynamics that are characterized by segregating and integrating influences in the temporal domain; metastable systems are neither totally stable nor totally unstable.

Definition of the Subject

How do conscious experiences, subjectivity, and apparent free will arise from their biological substrates? In the mid 1600s Descartes formulated this question in a form that has persisted ever since [1]. According to Cartesian dualism consciousness exists in a non-physical mode, raising the difficult question of its relation to physical interactions in the brain, body and environment. Even in the late twentieth century, consciousness was considered by many to be outside the reach of natural science [2], to require strange new physics [3], or even to be beyond human analysis altogether [4]. Over the last decade however, there has been heightened interest in attacking the problem of consciousness through scientific investigation [5,6,7,8,9]. Succeeding in this inquiry stands as a key challenge for twenty-first century science.

Conventional approaches to the neurobiology of consciousness have emphasized the search for so-called 'neural correlates': Activity within brain regions or groups of neurons that has privileged status in the generation of conscious experience [10]. An important outcome of this line of research has been that consciousness is closely tied to neural activity in the thalamocortical system, a network of cortical areas and subcortical nuclei that forms a large part of the vertebrate brain [11,12]. Yet correlations by themselves cannot supply explanations, they can only constrain them. A promising avenue toward explanation is to focus on key properties of conscious experience and to identify neural processes that can account for these properties; we can call these processes *explanatory correlates*. This article clarifies some of the issues surrounding this approach and describes ways of characterizing quantitatively the *complexity* of neural dynamics as a candidate explanatory correlate.

Complexity is a central concept within many branches of systems science and more generally across physics, statistics, and biology; many quantitative measures have been proposed and new candidates appear frequently [13,14,15]. The complexity measures described in this article are distinguished by focusing on the extent to which a system's dynamics are *differentiated* while at the same time *integrated*. This conception of complexity accounts for a fundamental feature of consciousness, namely that every conscious experience is composed of many different distinguishable components (differentiation) and that every conscious experience is a unified whole (integration). According to the theoretical perspective described here, the combination of these features endows consciousness with a discriminatory capability unmatched by any other natural or artificial mechanism.

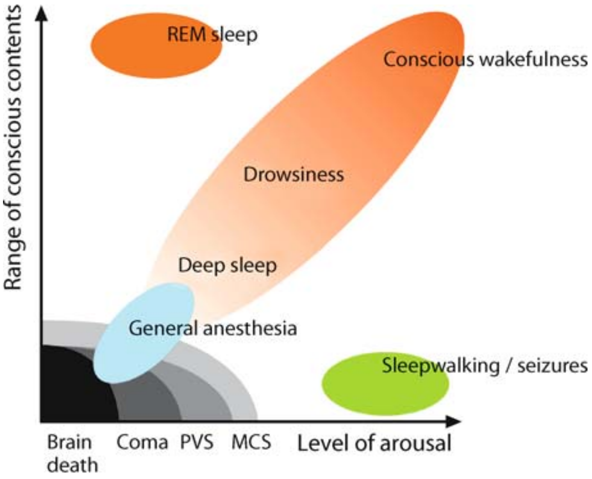
While the present focus is on consciousness and its underlying mechanisms, it is likely that the measures of complexity we describe will find application not only in neuroscience but also in a wide variety of natural and artificial systems.

Introduction

Consciousness

Consciousness is that which is lost when we fall into a dreamless sleep and returns when we wake up again. As William James emphasized, consciousness is a *process* and not a 'thing' [5]. Conscious experiences have content such as colors, shapes, smells, thoughts, emotions, inner speech, and the like, and are commonly accompanied by a sense of self and a subjective perspective on the world (the 'I'). The phenomenal aspects of conscious content (the 'redness' of red, the 'warmth' of heat, etc.) are in philosophical terminology called *qualia* [16].

It is important to distinguish between conscious *level*, which is a position on a scale from brain-death and coma at one end to vivid wakefulness at the other, and conscious *content*, which refers to composition of a conscious scene at a given (non-zero) conscious level. Obviously, conscious level and conscious content are related inasmuch as the range of possible conscious contents increases with conscious level (see Fig. 1). It is also possible to differentiate *primary* (sensory) consciousness from *higher-order* (meta) consciousness [6,17]. Primary consciousness refers to the presence of perceptual conscious content (colors, shapes, odors, etc.). Higher-order consciousness (HOC) refers to the fact that we are usually conscious of being conscious; that is, human conscious contents can refer to ongoing primary conscious experiences. HOC is usually associated with language and an explicit sense of selfhood [18] and good arguments can be made that primary consciousness can exist in principle in the absence of HOC, and that in many animals it probably does [19,20].



Consciousness and Complexity, Figure 1
Conscious level is correlated with the range of possible conscious contents. PVS = persistent vegetative state, MCS = minimally conscious state. Adapted from [21]

Consciousness as Discrimination

There are many aspects of consciousness that require explanation (see Table 1). However, one especially salient aspect that has been too often overlooked is that every conscious scene is both *integrated* and *differentiated* [22]. That is, every conscious scene is experienced 'all of a piece', as unified, yet every conscious scene is also composed of many different parts and is therefore one among a vast repertoire of possible experiences: When you have a particular experience, you are distinguishing it from an enormous number of alternative possibilities. On this view, conscious scenes reflect informative discriminations in a very high dimensional space where the dimensions reflect all the various modalities that comprise a conscious

Consciousness and Complexity, Table 1

Thirteen features of consciousness that require theoretical explanation. Items 1–6 are to some degree open to quantitative measurement whereas items 7–13 are more readily understood through logical and qualitative analysis. This list is drawn from [23] and a related list appears in [17]

1	Consciousness is accompanied by irregular, low-amplitude, fast (12–70 Hz) electrical brain activity.
2	Consciousness is associated with activity within the thalamocortical complex, modulated by activity in subcortical areas.
3	Consciousness involves distributed cortical activity related to conscious contents.
4	Conscious scenes are unitary.
5	Conscious scenes occur serially – only one conscious scene is experienced at a time.
6	Conscious scenes are metastable and reflect rapidly adaptive discriminations in perception and memory.
7	Conscious scenes comprise a wide multimodal range of contents and involve multimodal sensory binding.
8	Conscious scenes have a focus/fringe structure; focal conscious contents are modulated by attention.
9	Consciousness is subjective and private, and is often attributed to an experiencing 'self'.
10	Conscious experience is reportable by humans, verbally and non-verbally.
11	Consciousness accompanies various forms of learning. Even implicit learning initially requires consciousness of stimuli from which regularities are unconsciously extracted.
12	Conscious scenes have an allocentric character. They show intentionality, yet are shaped by egocentric frameworks.
13	Consciousness is a necessary aspect of decision making and adaptive planning.

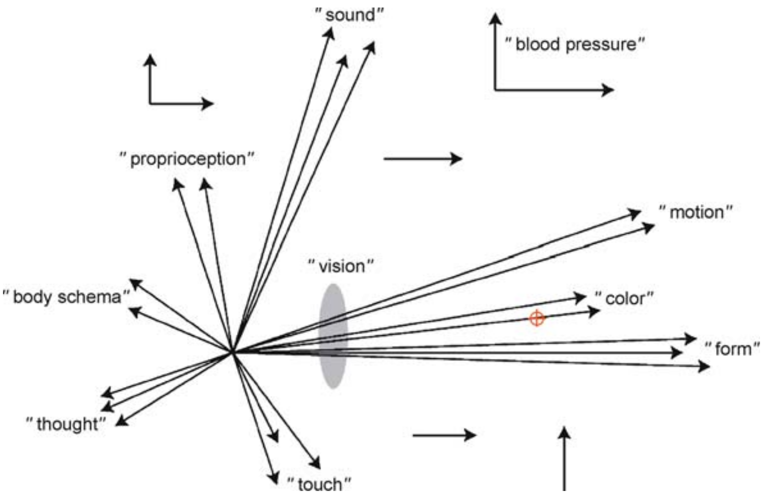
experience: sounds, smells, body signals, thoughts, emotions, and so forth (Fig. 2).

Because the above point is fundamental, it is useful to work through a simple example (adapted from [22,24]). Consider a blank rectangle that is alternately light and dark (Fig. 3a,b). Imagine that this rectangle is all there is, that you are seated in front of it, and that you have been instructed to say "light" and "dark" as appropriate. A simple light-sensitive diode is also in front of the screen and beeps whenever the screen is light. Both you and the diode can perform the task easily, therefore both you and the diode can discriminate these two states: lightness and darkness. But each time the diode beeps, it is entering into one of a total of two possible states. It is minimally differentiated. However, when you say "light" or "dark" you are reporting one out of an enormous number of possible experiences. This point is emphasized by considering a detailed image such as a photograph (Fig. 3c). A conscious person will readily see this image as distinct both from the blank rectangle and from a scrambled version of the same image (Fig. 3d). The diode, however, would classify both images and the rectangle as "light" (depending on its threshold), because it is insufficiently differentiated to capture the differences between the three.

Consider now an idealized digital camera. The electronics inside such a camera will enter a different state for the scrambled image than for the non-scrambled image; indeed, there will be a distinct state for any particular image. A digital camera is capable of much greater differentiation than the diode, but it is still not capable of discrimination because it is minimally *integrated*. In idealized form it is a collection of many independent light-sensitive diodes that must, to a good approximation, remain functionally independent from each other. From the perspective of this camera the image and the scrambled image are equivalent. *We* (as conscious organisms) can tell the difference between the two is because we integrate the many different parts of the image to form a coherent whole. We perceive each part of the image in relation to all the other parts, and we perceive each image in relation to all other possible images and possible conscious experiences that we may have. Successful discrimination therefore requires *both* integration *and* differentiation, and it can be hypothesized that it is this balance that yields the unity and diversity central to conscious experience.

Experimental evidence as well as intuition testifies to the fundamental nature of integration and differentiation in consciousness. A striking example is provided by so-called 'split brain' patients whose cortical hemispheres have been surgically separated. When presented with two independent visuospatial memory tasks, one to each hemisphere, they perform both very well [25]. In contrast, normal subjects cannot avoid integrating the independent signals into a single conscious scene which yields a much harder problem, and performance is correspondingly worse. In general, normal subjects are unable to perform multiple tasks simultaneously if they both require conscious input and they cannot make more than one conscious decision within the so-called 'psychological refractory period', a short interval of a few hundred milliseconds [26].

A loss of differentiation can be associated with the impoverishment of conscious contents following brain trauma. In 'minimally conscious' or 'persistent vegetative' states the dynamical repertoire of the thalamocortical system is reduced to the extent that adaptive behavioral responses are excluded [21]. In less dramatic cases focal cortical lesions can delete specific conscious contents; for example, damage to cortical region V4 can remove color



Consciousness and Complexity, Figure 2
The figure shows an *N*-dimensional neural space corresponding to the dynamic core (see Sect. "Consciousness and Complexity"). *N* is the number of neuronal groups that, at any time, are part of the core, where *N* is normally very large (much larger than is plotted). The appropriate neural reference space for the conscious experience of 'pure red' would correspond to a discriminable point in the space (marked by the *red cross*). Focal cortical damage can delete specific dimensions from this space

dimensions from the space of possible experiences (cerebral achromatopsia [27]; c.f., Fig. 2). Reportable conscious experience is also eliminated during generalized epileptic seizures and slow-wave sleep. Neural activity in these states is again poorly differentiated, showing hypersynchrony (epilepsy) or a characteristic synchronous 'burst pause' pattern (sleep) [22].

Consciousness and Complexity

The Dynamic Core Hypothesis

The notion that consciousness arises from neural dynamics that are simultaneously differentiated and integrated is expressed by the *dynamic core hypothesis* (DCH). This hypothesis has two parts [22,28]:

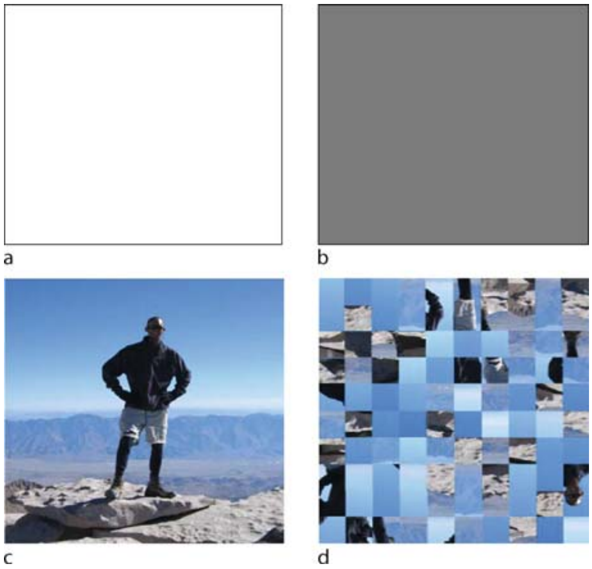
- A group of neurons can contribute directly to conscious experience only if it is part of a distributed functional cluster (the dynamic core) that, through reentrant interactions in the thalamocortical system, achieves high integration in hundreds of milliseconds.
- To sustain conscious experience, it is essential that this functional cluster be highly differentiated, as indicated by high values of complexity.

The concept of a *functional cluster* refers to a subset of a neural system with dynamics that displays high statistical dependence internally and comparatively low statistical dependence with elements outside the subset: A functional cluster 'speaks mainly to itself' [29]. Conceiving of the dynamic core as a functional cluster implies that the boundaries of the neural substrates of consciousness are continually shifting, with neuronal groups exiting and entering the core according to the flow of conscious contents and the corresponding discriminations being made. *Reentry* refers to the recursive exchange of signals among neural areas across massively parallel reciprocal connections and which in the context of the DCH serve to bind the core together. It is important to distinguish reentry from 'feedback' which refers to the recycling of an error signal from an output to an input [30,31]. The interpretation of *complexity* in the context of the DCH is the subject of Sect. "Neural Complexity"; for now we remark that it provides a quantitative measure of neural dynamics that is maximized by simultaneous high differentiation and high integration.

The Theory of Neuronal Group Selection

The DCH emerged from the theoretical framework provided by the 'theory of neural group selection' (TNGS), otherwise known as 'neural Darwinism' [18,32,33]. This section summarizes some of this essential background.

The TNGS is a biological perspective on brain processes with roots in evolutionary theory and immunology. It suggests that brain development and dynamics are *selectionist* in nature, and not instructionist, in contrast to computers which carry out explicit symbolic instructions. Four aspects of selectionist processes are emphasized: di-



Consciousness and Complexity, Figure 3

a A light-colored rectangle. b A dark-colored rectangle. c A detailed image (the summit of Mount Whitney, California). d A scrambled version of the same image. A simple light-sensitive diode would be able to discriminate a from b, but not among a, c, and d, since all these images would appear as 'light'. An idealized digital camera would enter a different state for each image a, b, c, and d, but would not discriminate between c and d because the camera does not integrate the various parts of each image to form a coherent whole. We can discriminate among all images because (i) our brain is capable of sufficient differentiation to enter a distinct state for each image, and (ii) our brain is capable of integrating the various parts of each image to form a coherent whole

versity, amplification/reproduction, selection, and degeneracy. *Diversity* in the brain is reflected in highly variant populations of neuronal groups where each group consists of hundreds to thousands of neurons of various types. This variation arises as a result of developmental and epigenetic processes such as cell division, migration, and axonal growth; subsequent strengthening and weakening of connections among cells (synapses) via experience and behavior generates further diversity. *Amplification* and *selection* in the brain are constrained by *value*, which reflects the salience of an event and which can be positive or negative as determined by evolution and learning. Value is mediated by diffuse ascending neural pathways originating, for example, in dopaminergic, catecholaminergic, and cholinergic brainstem nuclei [34]. As a result of value-dependent synaptic plasticity, connections among neuronal groups that support adaptive outcomes are strengthened, and those that do not are weakened. Finally, *degeneracy* emphasizes that in adaptive neural systems many structurally different combinations can perform the same function and yield the same output. Degeneracy is a key feature of many biological systems that endows them with adaptive flexibility [35,36]. It is conspicuously absent in artificial systems that are correspondingly fragile (some artificial systems make use of 'redundancy' which differs from degeneracy in that specific functional units are explicitly duplicated; redundancy provides the robustness but not the flexibility of degeneracy).

According to the TNGS, primary consciousness arises when brain areas involved in ongoing perception are linked via reentry to brain areas responsible for a value-based memory of previous perceptual categorizations. On this view, primary consciousness manifests as a 'remembered present' (akin to William James' 'specious present') by which an animal is able to exploit adaptive links between immediate or imagined circumstances and that animal's previous history of value-driven behavior (Fig. 4).

The TNGS and the dynamic core hypothesis are closely related [17,18]. They share the general claim that the neural mechanisms underlying consciousness arose in evolution for their ability to support multimodal discriminations in a high-dimensional space. In addition, the reentrant interactions linking immediate perception to value-category memory are precisely those that are suggested to bind together the dynamic core. Finally, the vast diversity of neural groups is central both to the original TNGS in providing a substrate for selection and to the DCH, in providing an essential component of neural complexity.

Consciousness and the Dynamic Core

We can now summarize the DCH and its origin in the TNGS. Consciousness is entailed by extensive reentrant interactions among neuronal populations in the thalamocortical system, the so-called dynamic core. These interactions, which support high-dimensional discriminations among states of the dynamic core, confer selective advantages on the organisms possessing them by linking current perceptual categorizations to value-dependent memory. The high dimensionality of these discriminations is proposed to be a direct consequence of the rich complexity of the participating neural repertoires. Just as conscious scenes are both differentiated and integrated at the phenomenal level to yield high-dimensional discriminations, so too are the reentrant dynamics of their underlying neural mechanisms differentiated and integrated. Critically according to the TNGS, conscious qualia *are* the high-dimensional discriminations entailed by this balance of differentiation and integration as reflected in high complexity.

Consciousness and Complexity, Figure 4

Primary consciousness and HOC in the TNGS. Signals related to value and signals from the world are correlated and produce value-category memories. These memories are linked by reentry to current perceptual categorization, resulting in primary consciousness. Higher-order consciousness depends on further reentry between value-category memory and current categorization via areas involved in language production and comprehension. Reprinted from [17]

Any theory of consciousness must confront the question of whether conscious experiences have causal effects in the physical world [37]. Responding positively reflects common sense but it seems contrary to science to suggest non-physical causes for physical events. Responding negatively respects the causal closure of the physical world but appears to suggest that conscious experiences are 'epiphenomenal' and could in principle be done without (an implication that may be particularly troubling for experiences of 'free will' [38]). The TNGS addresses this quandary via the notion of *entailment*. According to the TNGS, dynamic core processes entail particular conscious experiences in the same way that the molecular structure of hemoglobin entails its particular spectroscopic properties: it simply could not be otherwise [18]. Therefore, although consciousness does not cause physical events, there exist particular physical causal chains (the neural mechanisms underlying consciousness) that by necessity entail corresponding conscious experiences: The conscious experience cannot be 'done without'.

Measuring Consciousness and Complexity

Having covered basic elements of the DCH and its origin in the TNGS, we turn now to the issue of measuring complexity in neural dynamics. To be useful in this context, candidate measures should satisfy several constraints. We have already mentioned that a suitable measure should reflect the fact that consciousness is a dynamic process [5], not a thing or a capacity. This point is particularly important in light of the observation that conscious scenes arise ultimately from transactions between organisms and environments, and these transactions are fundamentally processes [39]. (This characterization does not, however, exclude 'off-line' conscious scenes, for example those experienced during dreaming, reverie, abstract thought, planning, or imagery). A suitable measure should also take account of causal interactions within a neural system, and between a neural system and its surroundings – i. e., bodies and environments. Finally, to be of practical use, a suitable measure should also be computable for systems composed of large numbers of neuronal elements.

Obviously, the quantitative characterization of complexity can constitute only one aspect of a scientific theory of consciousness. This is true at both the neural level and at the level of phenomenal experience. At the neural level, no single measure could adequately describe the complexity of the underlying brain system (this would be akin, for example, to claiming that the complex state of the economy could be described by the gross domestic product alone). At the phenomenal level, conscious scenes have many diverse features [18,19], several of which do not appear to be readily quantifiable (see Table 1). These include subjectivity, the attribution of conscious experience to a self, and intentionality, which reflects the observation that consciousness is largely about events and objects. A critical issue nevertheless remains: how can measurable aspects of the neural underpinnings of consciousness be characterized [32,132]?

Neural Complexity

A fundamental intuition about complexity is that a complex system is neither fully ordered (e. g., a crystal) nor fully disordered (e. g., an ideal gas). This intuition is compatible with the central theme of the DCH, namely that the neural dynamics within the dynamic core should be both integrated and differentiated. The following definition of *neural complexity* (C_N), first proposed in 1994 [40], satisfies these intuitions and provides a practical means for assessing the complexity of neural and other systems.

Mathematical Definition

Consider a neural system X composed of N elements (these may be neurons, neuronal groups, brain regions, etc.). A useful description of the dynamical connectivity of X is given by the joint probability distribution of the activities of its elements. Assuming that this function is Gaussian, this is equivalent to the covariance matrix of the system's dynamics COV(X). Importantly, COV(X) captures the total effect of all (structural) connections within a system upon deviation from statistical independence of the activities of a pair of elements, and not just the effect of any direct anatomical connection linking them [41]. Given COV(X) and assuming that the dynamics of X are covariance stationary (i. e., having unchanging mean and variance over time) the entropy of the system $H(\mathrm{X})$ is given by:

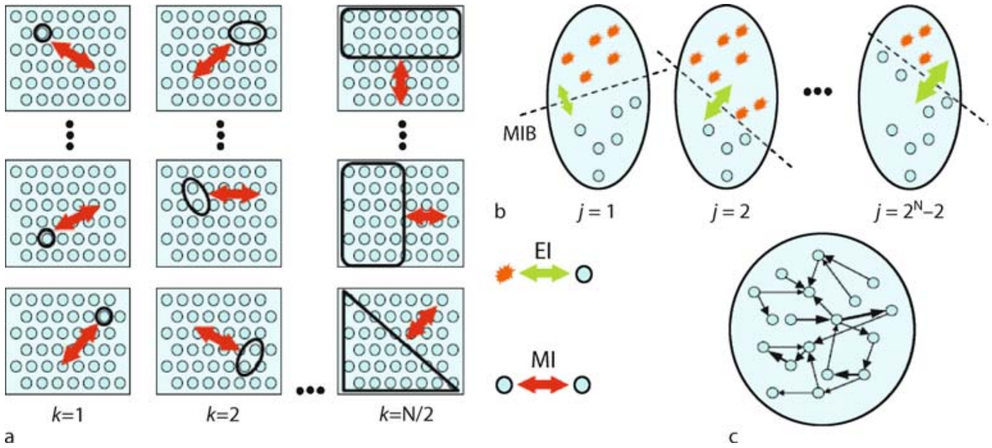
$$H(\mathrm{X}) = \tfrac{1}{2}\ln\left((2\pi \mathrm{e})^N \left|\mathrm{COV(X)}\right|\right)$$

where |.| denotes the matrix determinant [42]. $H(\mathrm{X})$ measures the overall degree of statistical independence exhibited by the system; i. e., its degree of differentiation. Knowing the entropy of a system allows calculation of the mutual information (MI) between two systems, or between two subsets of a single system. The MI between systems (or subsets) A and B measures the uncertainty about A that is accounted for by the state of B and is defined as $\mathrm{MI(A;B)} = H(\mathrm{A}) + H(\mathrm{B}) - H(\mathrm{AB})$ [43].

The integration of X, $I(\mathrm{X})$, measures the system's overall deviation from statistical independence. All elements in a highly integrated system are tightly coupled in their activity. With x_i denoting the ith element of X, $I(\mathrm{X})$ can be calculated as:

$$I(\mathrm{X}) = \sum_{i=1}^{N} H(x_i) - H(\mathrm{X}) \, .$$

$I(\mathrm{X})$ is equivalent to the measure 'multi-information' which was introduced several decades ago [44]. Having ex-



Consciousness and Complexity, Figure 5
Measuring integration and differentiation in neural dynamics. a Neural complexity C_N is calculated as the ensemble average mutual information (MI) between subsets of a given size and their complement, summed over all subset sizes (k) (adapted from Fig. 2 in [46]). *Small circles* represent neuronal elements and *red arrows* indicate MI between subsets and the remainder of the system. b Information integration Φ is calculated as the effective information (EI) across the 'minimum information bipartition' (MIB). To calculate EI for a given bipartition (j), one subset is injected with maximally entropic activity (*orange stars*) and MI across the partition is measured. c Causal density c_d is calculated as the fraction of interactions that are causally significant according to a multivariate Granger casuality analysis. A weighted (and unbounded) version of causal density (c_{dw}) can be calculated as the summed magnitudes of all significant causal interactions (depicted schematically by *arrow width*). Reprinted with permission from [132]

pressions for MI, $H(\mathrm{X})$, and $I(\mathrm{X})$ allows $C_{\mathrm{N}}(\mathrm{X})$ to be expressed in two equivalent ways. First, $C_{\mathrm{N}}(\mathrm{X})$ can be calculated by summing the average MI between subsets of various sizes, for all possible bipartitions of the system:

$$C_{\mathrm{N}}(\mathrm{X}) = \sum_k \left\langle MI\left(\mathrm{X}_j^k; \mathrm{X} - \mathrm{X}_j^k\right)\right\rangle , \qquad (1)$$

where X_j^k is the jth bipartition of size k, and $\langle . \rangle$ is the average across index j (Fig. 5a). $C_{\mathrm{N}}(\mathrm{X})$ can also be expressed in terms of integration:

$$C_{\mathrm{N}}(\mathrm{X}) = \sum_k \left(\frac{k}{n} I(\mathrm{X}) - \left\langle I\left(\mathrm{X}_j^k\right)\right\rangle\right) , \qquad (2)$$

where $\langle I(\mathrm{X}_j^k)\rangle$ is the average integration of all subsets of size k. $C_{\mathrm{N}}(\mathrm{X})$ will be high if small subsets of the system show high statistical independence, but large subsets show low statistical independence. In other words, $C_{\mathrm{N}}(\mathrm{X})$ will be high if each of its subsets can take on many different states and if these states make a difference to the rest of the system.

Because the full $C_{\mathrm{N}}(\mathrm{X})$ can be computationally expensive to calculate for large systems, it is useful to have an approximation that considers only bipartitions consisting of a single element and the rest of the system. There are three mathematically equivalent ways of expressing this approximation, which is denoted $C(\mathrm{X})$:

$$\begin{aligned} C(\mathrm{X}) &= H(\mathrm{X}) - \sum_{k=1}^{N} H\left(x_i | \mathrm{X} - x_i\right) \\ &= \sum_i MI(x_i; \mathrm{X} - x_i) - I(\mathrm{X}) \\ &= (n-1)\, I(\mathrm{X}) - n\, \langle I(\mathrm{X} - x_i)\rangle , \qquad (3) \end{aligned}$$

where $H(x_i|\mathrm{X} - x_i)$ denotes the conditional entropy of each element x_i given the entropy of the rest of the system $\mathrm{X} - \mathrm{X}_i$. These three expressions are equivalent for all X, whether they are linear or non-linear, and neither $C_{\mathrm{N}}(\mathrm{X})$ nor $C(\mathrm{X})$ can adopt negative values.

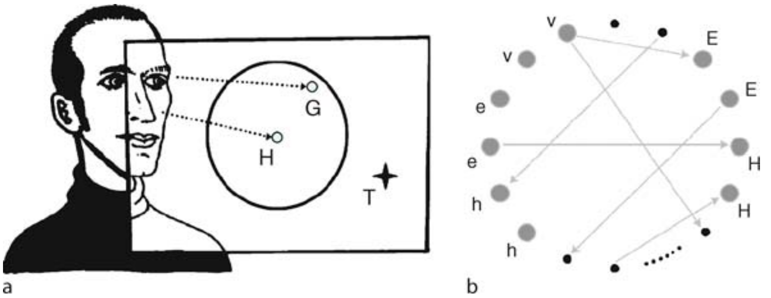
Recently, De Lucia et al. [45] have developed a different approximation to $C_{\mathrm{N}}(\mathrm{X})$ that is calculated directly from topological network properties (i. e., without needing covariance information). Their measure of 'topological $C_{\mathrm{N}}(\mathrm{X})$' is based on the eigenvalue spectrum of the connectivity matrix of a network. While topological $C_{\mathrm{N}}(\mathrm{X})$ offers substantial savings in computational expense it carries the assumption that the network is activated by independent Gaussian noise and therefore cannot be used to measure neural complexity in conditions in which a network is coupled to inputs and outputs (see Subsect. "Complexity and Behavior" below).

Connectivity and Complexity

There is a growing consensus that features of neuroanatomical organization impose important constraints on the functional dynamics underlying cognition [47,48]. Accordingly, several studies have addressed the relationship between structural connectivity and neural complexity [49,50,51,52,53].

One useful approach employs evolutionary search procedures (genetic algorithms [54]) to specify the connection structure of simple networks under various fitness (cost) functions. A population of networks $\mathrm{X}_1 \ldots \mathrm{X}_{\mathrm{N}}$ is initialized ('generation zero') with each member having random connectivity. Each network X_i is then evaluated according to a fitness function [for example, maximize $C(\mathrm{X})$] and those that score highly, as compared to the other networks in the population, are subjected to a small amount of random 'mutation' (i. e., small random changes in connectivity) and proceed to the next 'generation'. This procedure is repeated for many generations until the population contains networks that score near-optimally on the fitness function, or until the experimenter is satisfied that no further improvement is likely.

Sporns and colleagues applied a version of evolutionary search to find distinctive structural motifs associated with $H(\mathrm{X})$, $I(\mathrm{X})$, and $C(\mathrm{X})$ [49]. In this study, the initial population consisted of ten networks each with $N = 32$ nodes and $K = 256$ connections and with fixed identical positive weights w_{ij}. The fitness function was determined by the value of $H(\mathrm{X})$, $I(\mathrm{X})$, or $C(\mathrm{X})$ calculated from the covariance matrix of each network, assuming activation by covariance-stationary Gaussian noise. In each case they found that the resulting networks had distinctive structural features, as revealed both by simple visual inspection and by analysis using a variety of graph-theoretic measures. Networks optimized for $H(\mathrm{X})$ contained mostly reciprocal connections without any apparent local clustering. Networks optimized for $I(\mathrm{X})$ were highly clustered (i. e., neighboring nodes connect mainly to each other [55]) and had a long characteristic path length (i. e., a high mean separation between any two nodes in terms of number of intervening nodes). Finally, networks optimized for $C(\mathrm{X})$ had high clustering (and high reciprocal connectivity) coupled with a short characteristic path length. Strikingly, these networks were very similar to the so-called 'small world' class of network in which dense groups of nodes are connected by a relatively small number of reciprocal 'bridges' [55]. These networks also had a high proportion of 'cycles' (routes through the network that return to their starting point) and very low wiring lengths [49].



Consciousness and Complexity, Figure 6

Target fixation model. a The agent controls head-direction (H) and eye-direction (not shown) in order to move a gaze point (G) towards a target (T). b Neural network controller. The six input neurons are shown on the *left* and the four output neurons on the *right*. Each pair of inputs (v,e,h) responds to x, y displacements: 'v' neurons to displacements of G from T, 'h' neurons to displacements of H from an arbitrary origin ('straight ahead'), and 'e' neurons to displacements of H from the eye-direction. The four output neurons control head direction (H) and eye-direction relative to the head (H). For clarity only four of the 22 interneurons are shown. *Thin gray lines* show synaptic connections. Only a subset of the 256 connections are shown. Adapted from [59]

Sporns et al. extended the above findings by calculating $C(\mathrm{X})$ for networks reflecting the known cortical connectivity of both the macaque visual cortex and the entire cat cortex. In both cases covariance matrices were obtained by assuming linear dynamics, equal connection strengths, and activation by covariance-stationary Gaussian noise. They found that both networks gave rise to high $C(\mathrm{X})$ as compared to random networks with equivalent distributions of nodes and connections. Indeed, the networks seemed to be near-optimal for $C(\mathrm{X})$ because random rewiring of connections led in almost all cases to a reduction in $C(\mathrm{X})$ [49].

In a separate study using a non-linear neuronal network model including excitatory and inhibitory units, Sporns showed that regimes of high $C(\mathrm{X})$ coincided with 'mixed' connection patterns consisting of both local and long-range connections [56]. This result lines up with the previous study [49] in suggesting an association between small-world properties and complex dynamics. In addition, Sporns and Kötter found that networks optimized for the number of functional 'motifs' (small repeating patterns) had high $C(\mathrm{X})$ but those optimized for structural motifs did not [57] suggesting that high complexity reflects the presence of large functional repertoires. Finally, $C(\mathrm{X})$ seems to associate with fractal patterning, but not in a simple sense that fractal networks are optimal for complexity [53,58]. Rather, fractality seems to be one among several structural attributes that contribute to the emergence of small-world features and complex dynamics. Together, these results indicate that only certain classes of network are able to support dynamics that combine functional integration with functional segregation and that these networks resemble in several ways those found in neuroanatomical systems.

Complexity and Behavior

An important claim within the DCH is that complex dynamics provide adaptive advantages during behavior. To test this claim, Seth and Edelman examined the relationship between behavior and neural complexity in a simple agent-based computational model [59]. They evolved networks similar to those in [49] ($N = 32$, $K = 256$) by selecting for their ability to guide target fixation behavior in a simulation model requiring coordination of 'head' and 'eye' movements (Fig. 6). Networks were evolved in both 'simple' and 'complex' environments where environmental complexity was reflected by unpredictable target movement and by variation in parameters affecting head and eye movement. Consistent with the DCH, networks supporting target fixation in rich environments showed higher $C(\mathrm{X})$ than their counterparts adapted to simple environments. This was true both for dynamics exhibited during behavior in the corresponding environments ('interactive' complexity), and for dynamics evoked with Gaussian noise ('intrinsic' complexity).

Sporns and Lungarella explored the relationship between $C(\mathrm{X})$ and behavior in a different way [60]. As in [59], networks acted as neural controllers during performance of a task (in this case, control of a simulated arm to reach for a target). However, instead of evolving for successful behavior, networks were evolved directly for high $C(\mathrm{X})$. Strikingly, selecting for high $C(\mathrm{X})$ led to networks that were able to perform the task, even though performance on the task had not been explicitly selected for. Finally, Lungarella and Sporns asked how $C(\mathrm{X})$ depends on sensorimotor coupling by comparing neural dynamics of a robotic sensory array in two conditions: (i) unperturbed foveation behavior, and (ii) decoupling of sensory input and motor output via 'playing back' previously recorded motor activity [61]. They found significantly higher $C(\mathrm{X})$ when sensorimotor coupling was maintained.

Taken together, the above results suggest a strong link between high neural complexity and flexible, adaptive behavior. Of course, in none of these studies is any claim made that the corresponding networks are in any sense conscious.

Extensions and Limitations

The concept of neural complexity has been extended to characterize the selectional responses of neural systems to inputs in terms of 'matching' complexity C_{M} [62]. C_{M} measures how well the intrinsic correlations within a neural system fit the statistical structure of a sensory stimulus. Simulations show that C_{M} is high when intrinsic connectivity is modified so as to differentially amplify those intrinsic correlations that are enhanced by sensory input, possibly reflecting the capacity of a neurally complex system to 'go beyond the information given' in a stimulus [62]. Despite this possibility C_{M} has not been investigated as thoroughly as has C_{N}.

C_{N} has several limitations. In its full form it is computationally prohibitive to calculate for large networks, but in approximation it is less satisfying as a measure. Also, C_{N} does not reflect complexity in the temporal domain since functional connections are analyzed at zero-lag [23]. Finally, C_{N} does not take into account *directed* (causal) dynamical interactions for the simple reason that MI is a symmetric measure. This last point is addressed by the alternative measures described below.

Information Integration

The most prominent alternative to C_{N} is 'information integration' (Φ) [24,63]. Unlike C_{N}, Φ reflects causal interactions because it is based on 'effective information' (EI), a directed version of MI that relies on the replacement of the outputs of different subsets of the studied system with maximum entropy signals.

Mathematical Definition

Φ is defined as the effective information across the informational 'weakest-link' of a system, the so-called *minimum information bipartition* (MIB; Fig. 5b). It is calculated by the following procedure [63].

Given a system of N elements, identify all possible bipartitions of the system. For each bipartition $A|B$, replace the outputs from A by uncorrelated noise (i. e., maximally entropic activity), and measure how differentiated are the responses of its complement (B). This is the effective information (EI) between A and B:

$$\mathrm{EI}(A \to B) = \mathrm{MI}(A_{H\max}; B)\ ,$$

where $\mathrm{MI}(A_{H\max}; B)$ is the mutual information between A and B when the outputs from A have maximal entropy. $\mathrm{EI}(A{\to}B)$ measures the capacity for causal influence of partition A on its complement B (i. e., all possible effects of A on B). Given that $\mathrm{EI}(A{\to}B)$ and $\mathrm{EI}(B{\to}A)$ are not necessarily equal, one can define:

$$\mathrm{EI}(A \leftrightarrow B) = \mathrm{EI}(A \to B) + \mathrm{EI}(B \to A)\ .$$

The minimum information bipartition (MIB) is the bipartition for which the normalized $\mathrm{EI}(A \leftrightarrow B)$ is lowest. Normalization is accomplished by dividing $\mathrm{EI}(A \leftrightarrow B)$ by $\min\{H_{\max}(A); H_{\max}(B)\}$, so that effective information is bounded by the maximum entropy available. The resulting MIB corresponds to the informational weakest link of the system, and the Φ value of the system is the non-normalized $\mathrm{EI}(A{\leftrightarrow}B)$ across the MIB.

A further stage of analysis has been described [63] in which a system can be decomposed into 'complexes' by calculating Φ for different subsets of elements; a complex is a subset having $\Phi > 0$ that is not included in a larger subset with higher Φ. For a given system, the complex with the maximum value of Φ is called the 'main complex'.

Information Integration, Connectivity, and Complexity

As with neural complexity it is useful to explore what kinds of network structure lead to high values of Φ. Because of computational constraints only comparatively small networks have been investigated for their ability to generate high Φ (i. e., $N = 8$, $K = 16$ as opposed to $N = 32$, $K = 256$ as in [49]). In an initial study, networks optimized for Φ had highly heterogeneous connectivity patterns with no two elements having the same sets of inputs and outputs [63]. At the same time, all nodes tended to emit and receive the same number of connections. These two properties arguably subserve functional segregation and integration, respectively [63].

Although both Φ and C_{N} depend on a combination of functional integration and segregation, they are sensitive to different aspects of network dynamics. C_{N} reflects an average measure of integration that, unlike Φ, does not require heterogeneous connectivity. On the other hand, unlike C_{N}, Φ is determined by the value of an informational measure (EI) across only a single bipartition (the MIB) and is not modified by dynamical transactions across the remainder of the network. Finally, as mentioned above, Φ but not C_N is sensitive to causality.

Limitations and Extensions

As with C_N, Φ does not measure complexity in the temporal domain [23]. There are also substantial limitations attending measurement of Φ for non-trivial systems. First, it is not possible in general to replace the outputs of arbitrary subsets of neural systems with uncorrelated noise. An alternative version of Φ can be envisaged in which 'transfer entropy' (TE) [64], a directed version of MI, is substituted for EI. TE can be calculated from the dynamics generated by a neural system during behavior and therefore does not require arbitrary perturbation of a system; it measures the *actual* causal influence across partitions whereas EI measures the *capacity* for causal influence. However, a version of Φ based on TE does not in general find the informational 'weakest link' (MIB) of a system since the MIB depends on capacity and not on transient dynamics.

Second, unlike C_N there is presently no well-defined approximation for Φ that removes the need to examine all possible bipartitions of a system. However, it may be possible to make use of some informal heuristics. For example, bipartitions for which the normalized value of EI will be at a minimum will be most often those that cut the system in two halves, i. e., midpartitions [63]. Similarly, a representative rather than exhaustive number of perturbations may be sufficient to obtain at least an estimated value of Φ [63].

The Information Integration Theory of Consciousness

Φ occupies a central place in the 'information integration theory of consciousness' (IITC, [24]). According to this theory, consciousness *is* information integration as measured by Φ. The nature of the conscious content in a system with high Φ is determined by the particular informational relationships within the main complex (the complex with the highest Φ). While there are many similarities between the DCH and the IITC, most obviously that both make strong appeal to a measure of complexity, there are also important differences of which we emphasize two:

(i) Because Φ measures the capacity for information integration, it does not depend on neural activity per se. The IITC predicts that a brain where no neurons were active, but in which they were potentially able to react, would be conscious (perhaps of nothing). Similarly, a brain in which each neuron were stimulated to fire as an exact replica of your brain, but in which synaptic interactions had been blocked, would *not* be conscious [24]. The DCH has neither of these implications.

(ii) On the IITC Φ is an adequate measure of the 'quantity' of consciousness, therefore any system (biological or artificial) with sufficiently high Φ would necessarily be conscious. According to the DCH, high C_N is necessary but not sufficient for consciousness.

Point (ii) is particularly important in view of the finding that an arbitrarily high Φ can be obtained by a system as simple as a Hopfield network, which is a fully connected network with simple binary neuronal elements [23]. By choosing the synaptic strengths according to an exponential rule it can be shown that the corresponding Φ value scales linearly with network size, such that $\Phi(\mathrm{X}) = N$ bits for a network X of size N nodes. On the IITC this result leads to the counterintuitive conclusion that a sufficiently large Hopfield network will be conscious. Another challenge for the IITC in this context is the fact that the probability distributions determining entropy values (and therefore by extension Φ values) depend on subjective decisions regarding the spatial and temporal granularity with which the variables in a system are measured ([23,65] but see [24]).

Causal Density

A balance between dynamical integration and differentiation is likely to involve dense networks of causal interactions among neuronal elements. Causal density (c_d) is a measure of causal interactivity that captures both differentiated and integrated aspects of these interactions [23,66]. It differs from C_N by detecting causal interactions, differs from Φ by being sensitive to dynamical interactions across the whole network, and differs from both by being based not on information theory but instead on multivariate autoregressive modeling.

Mathematical Definition

Causal density (c_d) measures the fraction of interactions among neuronal elements in a network that are causally significant (Fig. 5c). It can be calculated by applying 'Granger causality' [67,68], a statistical concept of causality that is based on prediction: If a signal x_1 causes a signal x_2, then past values of x_1 should contain information that helps predict x_2 above and beyond the information contained in past values of x_2 alone [67]. In practice, Granger causality can be tested using multivariate regression modeling [69]. For example, suppose that the temporal dynamics of two time series, $x_1(t)$ and $x_2(t)$ (both of length T), can be described by a bivariate autoregressive model:

$$x_1(t) = \sum_{j=1}^{p} A_{11,j} x_1(t-j) + \sum_{j=1}^{p} A_{12,j} x_2(t-j) + \xi_1(t)$$
$$x_2(t) = \sum_{j=1}^{p} A_{21,j} x_1(t-j) + \sum_{j=1}^{p} A_{22,j} x_2(t-j) + \xi_2(t) \tag{4}$$

where p is the maximum number of lagged observations included in the model (the model order, $p < T$), A contains the coefficients of the model, and ξ_1, ξ_2 are the residuals (prediction errors) for each time series. If the variance of ξ_1 (or ξ_2) is reduced by the inclusion of the x_2 (or x_1) terms in the first (or second) equation, then it is said that x_2 (or x_1) *G-causes* x_1 (or x_2). In other words, x_2 G-causes x_1 if the coefficients in A_{12} are jointly significantly different from zero. This relationship can be tested by performing an F-test on the null hypothesis that $A_{12,j} = 0$, given assumptions of covariance stationarity on x_1 and x_2. The magnitude of a significant interaction can be measured either by the logarithm of the F-statistic [70] or, more simply, by the log ratio of the prediction error variances for the restricted (R) and unrestricted (U) models:

$$gc_{2\to 1} = \begin{cases} \log \dfrac{\operatorname{var}(\xi_{1R(12)})}{\operatorname{var}(\xi_{1U})}\,, & \text{if } gc_{2\to 1} \text{ is significant} \\ 0\,, & \text{otherwise,} \end{cases}$$

where $\xi_{1R(12)}$ is derived from the model omitting the $A_{12,j}$ (for all j) coefficients in Eq. (4) and ξ_{1U} is derived from the full model, where $gc_{2\to 1}$ refers to G-causality from x_2 to x_1.

Importantly, G-causality is easy to generalize to the multivariate case in which the G-causality of x_1 is tested in the context of multiple variables $x_2 \ldots x_N$. In this case, x_2 G-causes x_1 if knowing x_2 reduces the variance in x_1's prediction error when the activities of all other variables $x_3 \ldots x_n$ are also included in the regression model. Both bivariate and multivariate G-causality have been usefully applied to characterizing causal interactions in simulated [71,72] and biological [73] neural systems.

Following a Granger causality analysis, both normalized (c_d) and non-normalized (c_{dw}) versions of causal density of a network X with N nodes can be calculated as:

$$c_d(\mathrm{X}) = \frac{\alpha}{N(N-1)}\,,$$
$$c_{dw}(\mathrm{X}) = \frac{1}{N(N-1)} \sum_{i=1}^{N} \sum_{j=1}^{N} gc_{j\to i}$$

where α is the total number of significant causal interactions and $N(N-1)$ is the total number of pairwise interactions among elements. While normalized causal density is bounded to the range [0,1] the non-normalized version is unbounded.

High causal density indicates that elements within a system are both globally coordinated in their activity (in order to be useful for predicting each others activity) and at the same time dynamically distinct (reflecting the fact that different elements contribute in different ways to these predictions). Therefore, as with both C_N and Φ, c_d reflects both functional integration and functional segregation in network dynamics.

Conditions Leading to High Causal Density

In terms of connectivity, computational models show that both fully connected networks (having near-identical dynamics at each node) and a fully disconnected networks (having independent dynamics at each node) have low c_d and c_{dw}; by contrast, randomly connected networks have much higher values [71]. More detailed connectivity studies remain to be conducted.

An initial attempt to analyze behavioral conditions leading to high causal density was made by [66] revisiting the model of target fixation described previously [59]. To recapitulate, in this model networks were evolved in both 'simple' and 'complex' environments where environmental complexity was reflected by unpredictable target movement and by variation in parameters affecting head and eye movement (Fig. 6). Causal density in this model was calculated from first-order differenced time series of the ten sensorimotor neurons and it was found that highest values of causal density occurred for networks evolved and tested in the complex environments. These results mirrored those obtained with C_N, indicating an association between a high value of a complexity measure and adaptive behavior in a richly structured environment.

Extensions and Limitations of Causal Density

A practical problem for calculating causal density is that multivariate regression models become difficult to estimate accurately as the number of variables (i. e., network elements) increases. For a network of N elements, the total number of parameters in the corresponding multivariate model grows as pN^2, and the number of parameters to be estimated for any single time series grows linearly (as pN), where p is the model order (Eq. (4)). We note that these dependencies are much lower than the factorial dependency associated with Φ and C_N, and may therefore be more readily circumvented. One possible approach may involve the use of Bayesian methods for limiting the number of model parameters via the introduction of prior constraints on significant interactions [74]. In neural systems, such prior constraints may be derived, for example, on the basis of known neuroanatomy or by anatomically based clustering procedures.

Several other extensions to causal density are suggested by enhancements to the statistical implementation of Granger causality:

- Non-linear G-causality methods based, for example, on radial-basis-function kernels allow causal density to detect both linear and non-linear causal interactions [75,76].
- Partial G-causality (based on partial coherence) enhances robustness to common input from unobserved variables, supporting more accurate estimates of causal density in systems that cannot be fully observed [77].
- G-causality has a frequency-dependent interpretation [70,73] allowing causal density to be assessed in specific frequency bands.

Causal Density and Consciousness

Although causal density is not attached to any particular theory of consciousness, it aligns closely with the DCH because it is inherently a measure of process rather than capacity. Causal density cannot be inferred from network anatomy alone, but must be calculated on the basis of explicit time series representing the dynamic activities of network elements during behavior. It also depends on all causal interactions within the system, and not just on those interactions across a single bipartition, as is the case for Φ. Finally, causal density incorporates the temporal dimension more naturally than is the case for either C_N or Φ; while the latter measures functional interactions at zero-lag only, causal density incorporates multiple time lags as determined by the order parameter p (Eq. (4)).

The foregoing descriptions make clear that although existing formal measures may have heuristic value in identifying functional integration and functional segregation in neural dynamics, they remain inadequate in varying degrees. C_N can reflect process, can be computed for large systems in approximation, but does not capture causal interactions. Φ captures causal interactions, is infeasible to compute for large neural systems, and can be shown to grow without bound even for certain simple networks. Also, Φ is a measure of capacity rather than process but this is a deliberate feature of the IITC. c_d reflects all causal interactions within a system and is explicitly a measure of process, but it also is difficult to compute for large systems. An additional and important practical limitation of C_N, Φ, and c_d is that they apply only to statistically stationary dynamics.

Empirical Evidence

We turn now to empirical evidence relevant to the DCH. Much of this evidence comes from patients with focal brain lesions and neuroimaging of healthy subjects using functional magnetic resonance imaging (fMRI), electroencephelography (EEG) and magnetoencephalography (MEG). Although current experimental methods are not sufficiently powerful to confirm or refute the DCH, their application, separately and in combination, yields much useful information. A detailed review appears in [17]; below we select some pertinent features.

Involvement of the Thalamocortical System

A wealth of experimental evidence attests to thalamocortical involvement in consciousness, as demonstrated by both clinical studies and by experiments using normal subjects. Clinical studies show that damage to non-specific (intralaminar) thalamic nuclei can abolish consciousness in toto [78], whereas damage to cortical regions often deletes specific conscious features such as color vision, visual motion, conscious experiences of objects and faces, and the like [79]. No other brain structures show these distinctive effects when damaged.

Conscious functions in normal subjects are usefully studied by comparison with closely matched controls who perform the function unconsciously, an approach known as 'contrastive analysis' [80,81,82]. An emerging consensus among contrastive studies is that conscious contents correspond to widespread thalamocortical activation as compared to unconscious controls [81]. For example, Dehaene and colleagues have shown widespread fMRI activation peaks in parietal, prefrontal, and other cortical regions for conscious perception of visual words, as compared to unconscious inputs which activated mainly primary visual cortex [83]. Along similar lines, a recent fMRI study of motor sequence learning showed a shift from widespread cortical involvement during early learning (when conscious attention is required) to predominantly subcortical involvement during later learning phases (when skill production is comparatively 'automatic') [84].

Dynamical Correlates: Binocular Rivalry

A classical example of contrastive analysis makes use of the phenomenon of binocular rivalry, in which different images are projected to each eye [85]. Despite the integrative nature of consciousness these images, if sufficiently different, are not combined into a single composite; rather, conscious experience alternates between them. Srinivasan and colleagues used magnetoencephalography to measure brain responses to flickering visual stimuli under rivalrous conditions [86,87]. A vertical grating flickering at one frequency was presented to one eye and a horizontal grating flickering at another frequency was presented to the other; these different frequencies allowed stimulus-specific brain responses to be isolated in the neuromagnetic signal, a technique known as 'frequency tagging' [88]. As expected for such stimuli, subjects perceived only one grating at any given time. It was found that the power of the frequency-tag of a stimulus was higher by 30–60% across much of the cortical surface when that stimulus was perceptually dominant compared to when it was perceptually suppressed. Moreover, there was a large increase in coherence among distant brain regions, consistent with the idea that conscious perception is associated with widespread integration of neural dynamics mediated by reentry. Although this coherence increase is not a direct test of the DCH it is consistent with the theory and underscores the value of looking for *dynamical* correlates of consciousness.

Cosmelli and colleagues have used a similar paradigm to show that development of a perceptual dominance period arises in neural terms as an extended dynamical process involving the propagation of activity throughout a distributed brain network beginning in occipital regions and extending into more frontal regions [89]. Such a 'wave of consciousness' might reflect underlying integrative processes that lead to the formation of a dynamic core [90]. Chen and colleagues modified the rivalry paradigm so that subjects saw both gratings with both eyes but had to differentially *pay attention* to one or the other [91]. Power increases but not coherence increases were found for the attended stimulus, suggesting that attention may not involve the same global integrative processes implicated in consciousness. Finally, Srinivasan has shown that coherence increases during dominance are due partly to increased phase locking to the external stimulus and partly to increased synchrony among intrinsic network elements, again in line with the idea that consciousness involves coalescence of a distributed functional cluster within the brain [92].

Sleeping, Waking, and Anesthesia

Binocular rivalry involves constant conscious level and changing conscious *content*. Experimental evidence relevant to conscious *level* comes from studies involving transitions between sleeping and waking, anesthesia, epileptic absence seizures and the like. Many studies have tracked changes in endogenous activity across these various transitions but direct assessments of specific complexity measures are mostly lacking. Nonetheless, current findings are broadly consistent with the DCH. As noted in Subsect. "Consciousness as Discrimination", absence seizures and slow-wave sleep (but not rapid-eye-movement sleep) are characterized by hypersynchronous neural activity that may correspond to reduced functional segregation [22]. Anesthesia has particular promise for further experimental study because global anesthetic states can be induced via a wide variety of pharmacological agents having diverse physiological effects. Moreover, proposed unifying frameworks, such as Mashour's 'cognitive unbinding' theory [93], share with the DCH the idea that loss of consciousness can arise from diminished functional integration. In line with Mashour's proposal, John and colleagues have observed at anesthetic loss-of-consciousness (i) functional disconnection along the rostrocaudal (front-to-back) axis and across hemispheres (measured by coherence changes), and (ii) domination of the EEG power spectrum by strongly anteriorized low frequencies [94].

The development of transcranial magnetic stimulation (TMS) has opened the possibility of studying effective (causal) connectivity in the brain. TMS non-invasively disrupts specific cortical regions by localized electromagnetic induction. Massimini and colleagues combined high-density EEG with TMS to test whether effective connectivity among distant brain regions is diminished during sleep [95]. Applying a TMS pulse to premotor cortex during quiet wakefulness led to a sequence of waves propagating throughout the cortex, but this widespread propagation was mostly absent during non-rapid eye movement (slow wave) sleep. While these results do not allow calculation of any specific complexity measure they are consistent with both the IITC and the DCH.

In summary, it is clear that enhanced experimental and analytical methods are needed in order to test adequately whether C_N (or other specific measures) are modulated as predicted by the DCH. Initial attempts to calculate C_N directly from neural dynamics have not been successful (see [96] for a review) although a link to complexity is suggested by the discovery of small-world networks in functional brain dynamics [96,97].

Related Theoretical Proposals

Dynamical Systems Theory and Metastability

We have already mentioned that the measures of complexity discussed in this article apply only to statistically stationary dynamics (Subsect. "Causal Density and Consciousness"). This restriction contrasts sharply with an alternative tradition in theoretical neuroscience that focuses on non-stationary brain dynamics and which emphasizes the tools of dynamical systems theory. This alternative tradition can be traced back to early suggestions of Turing [98] and Ashby [99] and was concisely expressed by Katchalsky in 1974: "… waves, oscillations, macrostates emerging out of cooperative processes, sudden transitions, patterning, etc., seem made to order to assist in the understanding of integrative processes in the nervous system" [100]. More recently the dynamical systems approach has been championed in neuroscience by, among others, Haken [101] under the rubric 'coordination dynamics' and Freeman who has produced a steady stream of papers exploring dynamical principles in brain activity [102,103]. Valuable reviews of work in this tradition can be found in [104,105,106].

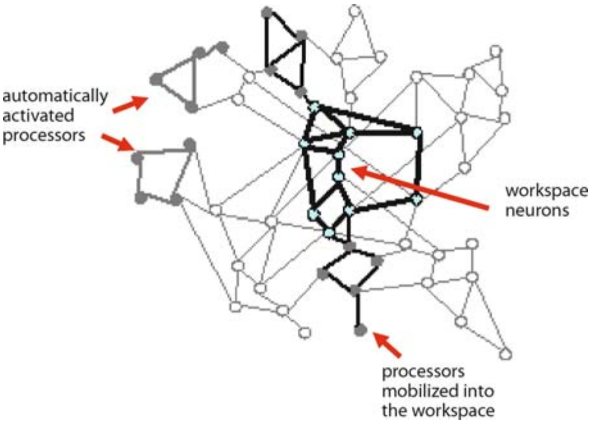
A key concept in the dynamical systems approach is 'metastability' which describes dynamics that are "distinguished by a balanced interplay of integrating and segregating influences" (see p. 26 in [107]). While this definition is obviously similar to the intuition driving neural complexity, metastability has been fleshed out, not in the concepts of information theory or time-series analysis, but instead in the language of attractor dynamics. A dynamical system inhabits a metastable regime when there are no stable fixed points but only partial attraction to certain phase relationships among the system variables. At the level of neural dynamics metastability may reflect the ongoing creation and dissolution of neuronal assemblies across distributed brain regions [105,107,108]. A now classical experimental example of metastability comes from a study in which subjects were asked to flex a finger in response to a periodic tone, initially in a syncopated manner [107]. As the frequency of the tone increases, the syncopated response becomes harder to maintain until a critical point is reached at which the subject switches to a synchronous mode of response. Strikingly, this behavioral phase transition is accompanied by a corresponding transition in the patterning of neuromagnetic cortical signals. At the critical point, where there is partial attraction to both syncopated and synchronous response modes, both behavioral and neural dynamics are dominated by metastability. For other evidence of metastability in the brain see [109].

Metastability characterizes an important aspect of conscious experience, namely that conscious events are rapidly adaptive and fleeting [17]. Consciousness is remarkable for its present-centeredness [5,6]. Immediate experience of the sensory world may last at most a few seconds and our fleeting cognitive present is surely less than half a minute in duration. This present-centeredness has adaptive value for an organism by allowing time enough to recruit a broad network of task-related neural resources while permitting neural dynamics to evolve responses to subsequent events. Thus, conscious experience can be described by an interplay of segregating and integrating influences in both the temporal (metastability) and spatial (complexity) domains. A key theoretical challenge is to work out in greater detail the relationship between these two concepts.

Global Workspace Theory

Beginning in 1988 [80] Baars developed a cognitive theory of consciousness under the rubric 'global workspace (GW) theory' [80,81,110]. The cornerstone of GW theory is the idea that consciousness involves a central resource (the GW) which enables distribution of signals among numerous otherwise informationally encapsulated and functionally independent specialized processors. GW theory states that mental content becomes conscious mental content when it gains access to the GW such that it can influence a large part of the brain and a correspondingly wide range of behaviors. A key aspect of GW theory is that conscious contents unfold in an integrated, serial manner but are the product of massively parallel processing among the specialized processors. The integrated states of the GW follow each other in a meaningful but complex progression that depends on multiple separate processes, each of which might have something of value to add to the ongoing constitution of the GW. Although these notions are compatible with the DCH, they do not by themselves specify dynamical properties to the same level of detail.

A dynamical approach to GW theory has been pursued by Wallace [112] and separately by Dehaene, Changeux and colleagues [111,113,114]. Wallace adopts a graph-theoretic perspective proposing that the GW emerges as a 'giant component' among transient collections of otherwise unconscious processors. The formation of a giant component in graph theory denotes a phase transition at which multiple sub-networks coalesce to form a large network including the majority of network nodes [115]. Dehaene and colleagues have built a series of computational models inspired by GW theory, to account for a variety of psychological phenomena including 'attentional blink' [111], 'inattentional blindness' [114], and effortful cognitive tasks [113]. These models are based on the concept of a 'neuronal global workspace' in which sensory stimuli mobilize excitatory neurons with long-range cortico-cortical axons, leading to the genesis of global activ-



Consciousness and Complexity, Figure 7
A schematic of the neuronal global workspace. A central global workspace, constituted by long-range cortico-cortical connections, assimilates other processes according to their salience. Other automatically activated processors do not enter the global workspace. Adapted from [111]

ity patterns among so-called 'workspace neurons' (Fig. 7). This model, and that of Wallace both, predict that consciousness is 'all or nothing' – i. e., a gradual increase in stimulus visibility should be accompanied by a sudden transition (ignition) of the neuronal GW into a corresponding activity pattern. As with Wallace, although some dynamic properties of the neuronal GW have been worked out and are compatible with the DCH, a rigorous account of how the model relates to neural complexity has not been attempted.

Neuronal Synchrony and Neuronal Coalitions

The association of neural synchrony with consciousness arose from its proposed role as a mechanism for solving the so-called 'binding problem', which in general terms refers to the problem of coordinating functionally segregated brain regions. The binding problem is most salient in visual perception for which the functional and anatomical segregation of visual cortex contrasts sharply with the unity of a visual scene. Since the 1980s a succession of authors have proposed that the binding problem is solved via neuronal synchronization [116,117] and both experimental evidence [118,119] and computational models have borne out the plausibility of this mechanism [31]. In the 1990s, starting with an early paper by Crick and Koch [7], this proposal grew into the hypothesis that consciousness itself is generated by transient synchronization among widely distributed neuronal assemblies, with particular emphasis on oscillations in the gamma band ($\sim$ 40 Hz) [39,120]. In support of this idea we have already seen that conscious perception correlates with increased synchrony of a (non-gamma-band) visual 'frequency tag' [87], and several studies have reported associations between gamma-band synchrony and consciousness [121,122,123]. However, synchrony-based theories of binding (and by extension consciousness) remain controversial [124] and there is not yet evidence that disruptions of gamma-band synchrony lead to disruptions of conscious contents [12].

From the perspective of the DCH a deeper concern with the synchrony hypothesis is that it accounts only for integration, and not for the combination of integration and differentiation that yields the discriminatory power of consciousness. In a recent position paper [125], Crick and Koch reversed their previous support for gamma-band synchrony as a sufficient mechanism for consciousness, favoring instead the notion of competition among 'coalitions' of neurons in which winning coalitions determine the contents of consciousness at a given time. Such neuronal coalitions bear similarities to the decades-old notion of Hebbian assemblies [126] on a very large and dynamic scale. They also suggest that unconscious processing may consist largely of feed-forward processing whereas consciousness may involve standing waves created by bidirectional signal propagation, a proposal advanced as well by Lamme [127]. Crick and Koch note that the 'coalition' concept is similar to the dynamic core concept [125] although lacking in the detailed formal specification of the latter.

A possible role for gamma-band synchrony in both the DCH and in Crick and Koch's framework is that it may facilitate the formation but not the ongoing activity of the core (or a coalition) [125]. In this light it is suggestive that correlations between gamma-band synchrony and consciousness tend to occur at early stages of conscious perception [121,122].

Outlook

Scientific accounts of consciousness continue to confront the so-called 'hard problem' of how subjective, phenomenal experiences can arise from 'mere' physical interactions in brains, bodies, and environments [128,129]. It is possible that new concepts will be required to overcome this apparent conceptual gap [130]. It is equally likely that increasing knowledge of the mechanisms underlying consciousness will lead these philosophical conundrums to fade away, unless they have empirical consequences [81,125]. In short, to expect a scientific resolution to the hard problem as it is presently conceived may be to misunderstand the role of science in explaining nature. A scientific theory cannot presume to replicate the experience that it describes or explains; a theory of a hurricane is not a hurricane [18]. If the phenomenal aspect of experience is irreducible, so is the fact that physics has not explained why there is something rather than nothing, and this ontological limit has not prevented physics from laying bare many mysteries of the universe.

The approach described in this article is one of developing *explanatory correlates* of consciousness, namely properties of neural dynamics that are experimentally testable and that account for key properties of conscious experience. Thanks to accelerating progress in experimental techniques and increased attention to theory, the outlook for this approach is healthy. We close by suggesting some key areas for further study:

Development of a large-scale model of a dynamic core Although progress in large scale neural network modeling has been rapid [131], we currently lack a sufficiently detailed model of environmentally coupled thalamocortical interactions needed to test the mechanistic plausibility of the DCH. Having such a model should also allow substantive connections to be drawn between the DCH and GW theory.

Development of new experimental methods New methods are needed to track neuronal responses at sufficient spatio-temporal resolutions to support accurate estimation of C_N and other complexity measures during different conscious and unconscious conditions. Among current methods fMRI has poor time resolution and measures neural activity indirectly, while MEG/EEG lacks spatial acuity and is unable to record details of thalamic responses.

Complexity and metastability New theory is needed to relate the class of complexity measures described in this article to metastability, which analyzes functional segregation and integration in the temporal domain.

Emergence and 'downward causality' New theory is also needed to better understand how global dynamical states arise from their basal interactions and how these global states can constrain, enslave, or otherwise affect properties at the basal level [39]. Applied to consciousness and to cognitive states in general, such downward causality can suggest functional roles and may even help reconcile the phenomenology of free-will with physiological fact.

Jerusalem, Israel

Article Outline

Glossary

Site percolation Assuming a lattice in which the sites can be occupied, with a probability p^{s}, two sites are assumed locally connected if they are nearest neighbors and occupied. A group of sites in which each of its' sites is occupied and locally connected to at least one other site in the group is called a connected cluster. If there is a cluster that connects the edges of an "infinite" lattice, the cluster is called the percolation cluster. The lowest p^{s} for which such a cluster is found is called the percolation threshold, $p_{\mathrm{c}}^{\mathrm{s}}$.

Bond percolation Assuming a lattice, the segment between nearest neighbor sites is called a bond. A bond can be occupied with a probability p^{b}. Two bonds are locally connected if they are both occupied and have a common site. A group of bonds in which each is connected to at least one other bond is called a connected cluster of bonds. If the span of this cluster is infinite we have a "percolation cluster" and the lowest p^{b} for which such a cluster is formed is called the bonds percolation threshold, $p_{\mathrm{c}}^{\mathrm{b}}$.

Critical behavior Percolation can be modeled as a phase transition and thus various properties have a power-low dependence on $|p - p_{\mathrm{c}}|$ for small values of $|p - p_{\mathrm{c}}|/p_{\mathrm{c}}$. The exponent that describes this dependence is called the critical exponent.

Universal and non universal behavior If the critical exponent depends only on the dimensionality of the system, we say that the critical behavior is universal. If the exponent depends on other parameters of the system, we say that the behavior is non universal.

Continuum percolation In a system of objects one can define a local connectivity criterion such as the overlap of pores in porous media. The objects are assumed to be randomly distributed in space, they may have various and variable shapes and sizes and they may interact with each other. A group of objects such that each object is locally connected to at least one other object in the group is a connected cluster. The cluster that has an infinite span is the "percolating" cluster in the continuum and the lowest concentration of objects that yield such a cluster defines the percolation threshold.

Critical fractional volume The content of the objects at the onset of global connectivity, i. e. the percolation threshold, is usually characterized in the continuum by the measurable fractional volume content of the objects of interest in the system. This volume at the percolation threshold is the critical fractional volume.

Excluded volume In the case where the local connectivity is determined by a partial overlap of the volumes of two equal objects, the volume in space in which the two centers of the two objects can be, and must be, in order to have such an overlap is defined as the excluded volume of the object. If the objects are not equal one has to define a corresponding average.

Average bonds per object The average number of objects that are locally connected to a given object in the system. This quantity, at the percolation threshold, B_c, is the quantity that characterizes topologically the onset of global connectivity i. e. the onset of percolation.

"Pointedness" The parameter that can be defined qualitatively as the degree of deviation from sphericity of a given object. The manifestation of this property for different objects, that have the same excluded volume, is that with its increase the value of B_c decreases.

Critical behavior of dynamical properties The critical behavior of a property that has to do with flow in the system, such as electrical conductivity and fluid permeability. In the continuum, it is related to the distribution of the local values of the dynamical parameter associated with a given bond. If the average of this parameter effects the global critical behavior of the system, its contribution is added to the "universal" critical behavior that is found in lattices.

The random void and the inverted random void systems A system of pores or topologically similar systems which are reminiscent of the "Swiss Cheese". In the random void (RV) case one is concerned with the network excluding the pores. The mirror image of this system, i. e. when one is concerned with the network that consists of the pores (or particles that can coalesce) is called the inverted random void (IRV) system. In these systems the "neck" formed by the separation (RV) or the overlap (IRV) of two adjacent pores determines the local dynamical property.

Tunneling percolation The conduction process in a system where the "local connectivity" is not determined by a geometrical contact but is determined electronically. This is in particular by inter-object tunneling. The corresponding connected system exhibits a percolation-like critical behavior of the dynamical properties.

"Physically controlled percolation" When an externally applied quantity, such as an electric field or mechanical pressure, affects the parameters that characterize the percolation-like behavior, one may call the corresponding phenomena "physically controlled percolation".

Definition of the Subject

In this review we will describe the two main features that are very different in lattice percolation and in continuum percolation and which bring about new concepts that are not encountered in the "more traditional" and well developed theory of percolation in lattices [121]. The origin of the difference is that in continuum percolation we are dealing with "real" objects that have sizes and shapes, and that are randomly distributed in space, while in lattices we are dealing with abstract mathematical objects such as dots and line segments in a priori defined locations. The result is that in the continuum we have to use different quantities to describe the percolation threshold and we obtain a much richer variability of the corresponding behaviors of the dynamical properties, such as the electrical transport. To equip the reader with the basic concepts needed for the discussion of continuum percolation we also include a short introduction to the relevant principles of lattice percolation and then we discuss in some detail the very basic concepts and achievements in continuum percolation. Finally, we discuss open questions and possible future developments associated with this field.

Percolation theory is concerned with the effects of local and global connectivity on the geometrical and dynamical properties of systems. Within the limited scope of this review we cannot discuss the numerous systems and many properties associated with continuum percolation and we deal only with the principles of this field. However, in order to illustrate the great variety of systems and properties that constitute this area of research, we mention now single, typical, examples of the most conspicuous of those.

Continuum percolation encompasses all the many body systems from the smallest, the elementary particles systems [104], to the largest, the galactic-cosmological systems [109]. Correspondingly continuum percolation was applied to discuss and describe structures and phenomena in physics, chemistry, earth sciences and biology, as well as communication and traffic networks. As some typical examples, let us mention, the electrical properties of numerous composites [128], porous media [125], microemulsions [36,69], disordered semiconductors [137], disordered superconductors [91], molecular [75] and macromolecular [39] liquids, nano-tubes in composites [45,64] and suspensions [64], quantum dot composites [27], thin metal films [118], layered materials [47], quasi-crystals [98], chemical networks [92] and transport in them [96], biological networks [134] and flow in them [117], bioinformatics [99], and ecological systems [132]. Then there are the properties associated with the flow of charge carriers, such as electrical conductivity [10], the flow of liquids such as the permeability [88], as well as corresponding processes [77] such as displacements [133], drainage [6], dispersion [107], hydrological flows [31] and diffusion [130]. Very closely related is the class of rheological properties [57] such as the viscosity [84]. The possible variation in the local ("bond strength") parameters makes the concepts of continuum percolation also applicable to information and traffic management [135]. Finally, there are the related areas of the elastic [81], the dielectric [67] and the magnetic [122] properties, and their relation to electrical properties [28,85,93].

In this review we will limit ourselves to a discussion of the percolation threshold and electrical conductivity, as they are the most studied properties in "real systems", with the hope that the principles that are understood to govern this property will be sufficient for approaching the understanding of the various systems and properties such as those mentioned above. In particular this review is expected to be also helpful for the analysis of related behaviors such as the electrical noise [127], piezoresistivity [71,128], magneto-transport [29], alternating current conductivity [43], and the effects of interplay between electrical and elasto-thermal properties [8]. An example of a generalization of the concepts used in the discussion of the electrical conductivity to other properties is the extension of the theory [127] and the experimental analysis [102] of the electrical conductivity to the electrical noise.

Turning to the historical highlights of the development of lattice percolation theory and continuum percolation theory we realize that by the very nature of this limited and subjective review there will be many important works that will not be mentioned here and need to be summarized in a more expanded review. We point out however that our previous reviews [11,17,26,32] cover the basic understanding of the present subject for the corresponding years.

The history of percolation theory is usually considered to begin with the works of Flory in 1941 [60] and Stockmayer in 1943 [123] on gelation, and, by definition, as a flow problem in the work of Broadbent and Hammersley in 1957 [33], who also coined the name of the corresponding processes as percolation phenomena [136]. These works were followed by very many works that consolidated the concepts associated with the theory of percolation on lattices. Excellent general reviews on lattice percolation were given by Zallen in 1983 [136], Stauffer and Aharony in 1992 [121], and Sahimi in 1994 [105] and some aspects of it were considered in more specialized reviews such as by Kirkpatrick in 1973 [80], Shklovskii and Efros in 1984 [114], Isichenko in 1992 [77] and Sahimi in 1998 [106].

The principal concepts, that were developed for lattices were the site and bond occupation probabilities, p, and the resulting clusters, that are groups of occupied sites or bonds that are connected by having pairs of occupied sites (or bonds) when the latter are nearest neighbors. The corresponding theory was concerned with the properties of the clusters that enable this connectivity, and in particular those of the infinite-spanning cluster, when it exists. The onset of this cluster at a given occupation probability, p_c, is associated with the onset of global connectivity as well as with the possible onsets of "flows" through the systems. The major developments of percolation theory were then along two lines that will be emphasized in this review: the determination of the onset of global connectivity, and the variation of geometrical and dynamical properties of such systems as the percolation threshold is approached. The corresponding developments in the 1960's culminated in the 1969 work of Kasteleyn and Fortuin (that is detailed in Fortuin and Kasteleyn [62]). They were able to show that the p transition through p_c can be described as a second order phase transition [119], thus justifying a posteriori the previous findings that the above various properties behave as power laws of $|p - p_c|$, with powers that are only dimensionally dependent. The latter behavior as $p \to p_c$ is known as the critical behavior, and the independence of the exponents on other system parameters is referred to as the universal critical behavior of the quantities in percolation systems. While the initial motivation to consider percolation problems was to account for the behavior of "real" systems, the considerations of such systems and the realization that they cannot be simply discussed using the terms of lattice systems was postponed to the 1970's. Since "real" systems are made of objects and these are randomly dispersed in the continuum, the corresponding research field of "real" systems became synonymous with the later coined concept of "continuum" percolation.

The first major step in trying to account generally for more realistic systems can be considered the finding of Scher and Zallen (hereafter S&Z) in 1970 [108]. They found that for properly placed hard core spheres in lattice points, the onset of global connectivity will take place at a volume fraction of the objects in the system, τ_c, that is nearly a constant for all possible lattices in a given dimension D. This is in contrast with the relatively wide range of p_c values for the various lattices in the same D, thus suggesting that at τ_c there is an onset of a fundamental topological connectivity. Similar invariants were found by Powell in 1979 [97] who essentially used a model in which "conducting" and "non-conducting" spheres fill a box under "gravitation". Another approach, which relates to problems of flow via porous-like media or impurity band conduction-like systems, was taken by Holcomb and Rehr in 1969 [76], and Pike and Seager in 1974 [95]. They considered essentially the fractional occupied volume of spherical pores, when the local connectivity is defined by partial overlap of the pores, at the onset of global connectivity. They also found invariants in the case for systems for which no volume can be attached to the object such as widthless sticks in a two dimensional system [25]. A very significant insight into the problem of percolation thresholds of systems in the continuum was provided by Shante and Kirkpatrick (hereafter S&K) in 1971 [112]. They confirmed that the underlying topology of the connected objects, i. e. the average number of connected permeable spheres, per given sphere, at the onset of percolation, is the same as that of the "fine grid" lattice. It took then more than a decade until Balberg and co-workers in 1983 [14,20] and 1984 [21,22] provided the generalization of the above concepts to zero-volume and "soft-core" non-parallel objects. They systematically established the concepts of the average excluded volume, $\langle V_{\text{ex}} \rangle$, and the number of bonds per object, B_c. Consequently the quantity $B_c = \rho_c \langle V_{\text{ex}} \rangle$, where ρ_c is the number of objects per unit volume at the onset of percolation, became the guide for *the phenomenological theory* of the percolation threshold in the continuum [131] and its application [30]. For example, these concepts of $\langle V_{\text{ex}} \rangle$ and B_c have enabled the explanation of the nearly zero volume of the conducting phase needed for the onset of percolation in many systems [9] and the analysis of the various cases where the objects are not entirely permeable [17].

The first step towards a rigorous derivation of results in continuum percolation is probably the suggestion of Coniglio, DeAngelis and Forlani who developed, in 1977 [44], a series expansion in the objects density, ρ, to describe the average size of the finite clusters in fluid systems. This utilization of liquid theory [74] was translated to the prediction of the ρ_c values for partially permeable spheres by DeSimone, Stratt and Demoulini in 1986 [49], and to an analytic prediction of trends, in the B_c dependence on the type of the objects, by Bug, Safran and Webman in 1985 [34]. Extension of the latter approach and the application of extrapolation methods (by fitting the results to the known average cluster size dependence on $|\rho - \rho_c|$) finally yielded very accurate predictions for B_c [3,53]. In particular the work of Drory et al. in 1997 [56] has lent a firm basis for a rigorous theory for percolation thresholds in the continuum, which followed Drory's works in 1996 [50,51] and 1997 [52] that proved that continuum percolation is also a second order-like phase transition. An insight concerning the variation of B_c (that is much less straightforward than the variation of ρ_c) from a system of one type of objects to a system of another type of objects was suggested by Alon, Balberg and Drory who introduced the concept of "*pointedness*" in 1991 [4]. Recently, some works on permeable systems in high dimensions have shown that applying intuition for the prediction of various specific behaviors is not always justified [63,68]. The case at hand was the finding of Wagner, Balberg and Klein, in 2006 [131], that for $D \to \infty$ the value of B_c can become smaller than the intuitively expected unity [136].

Turning to the critical behavior of percolation systems in the continuum, we note that the study of the dynamical properties, and in particular the study of the electrical resistivity, became an intensive area of research in the 1970's. The first work to test experimentally the predicted properties on "real" systems can be considered to be the study of Abeles, Pinch and Gittleman in 1975 [2] regarding the critical behavior of the electrical resistivity of granular metals [1] at the onset of metallic conduction. They found that the conductivity exponent that characterizes the critical behavior, t, was 1.9 in accordance with the universal values predicted for lattices. This was followed by numerous works that yielded the same conclusion on other electrical properties, such as the electrical noise [40]. In fact various experiments on "real" systems have also confirmed the lattice-like geometrical-structural exponents, such as the correlation length exponent, ν [18,79] and the fractal dimension of the percolation cluster, D_f [113]. In parallel, the developments in computers and consequent computer simulations in the 1980's have enabled quite accurate simulations for the determination of the critical exponents in continuum systems, yielding again very good agreement with the universal predictions [20]. On the other hand, the many experimental results that did not conform with the universal predictions [7,94] were largely ignored by the mainstream of the research. Even the "toy" model of non-universal behavior of the electrical resistivity, proposed by Kogut and Straley (hereafter K&S) in 1979 [82], was bypassed for a few years, until it became the cornerstone of the understanding of non universal behavior of the dynamical properties. This overlooking of the theory of K&S was apparently for a good reason, since all that time there was no known link to connect the features of the continuum system with the parameters of their "toy" model. This "missing" link was provided by the work of Halperin, Feng and Sen in 1985 [72]. They showed that non universality can be a fundamental property of dynamical properties in continuum systems. By finding the distribution function of the pore sizes, in sedimentary rock-like systems, they were able to show its immediate consequence regarding the resistors value distribution, and thus the appearance of non universality in accordance with the model of K&S. Their finding opened the way then to the understanding of the many dynamical properties in the various continuum systems that were mentioned above. In particular, soon after these findings, in 1987, Balberg showed [10] that tunneling conduction in random systems can also be mapped onto a K&S-like resistor distribution. This realization has enabled, at least, the qualitative interpretation of the numerous experimental results in the broadest group of studied continuum systems, i. e. composite materials, and the broadest group of studied properties, i. e. the various electrical transport properties. The very simple theoretical predication that was derived for the latter case yielded, however, critical exponents that were much larger than the many experimentally observed values that were reported in the literature [26]. The other difficulty with the corresponding physical picture was that it did not explain how is it that systems in which all the particles are electrically connected on the one hand, and in which there is no geometrical connectivity, between any pair of them, on the other hand, yield behaviors that are identical to those obtained in bona fide percolation systems [13]. The two problems have been resolved in principle only very recently, the first by Grimaldi and Balberg in 2006 [70], and the other by Toker et al. in 2003 [124]. These developments will be described in more detail below.

Introduction

Percolation phenomena are associated with the consequences of the connectivity in systems composed of elementary members that are distributed in some random manner, after a criterion for the connectivity between two such elements is defined. The corresponding theory that deals with those phenomena tries to describe geometrical structures of connected parts in those systems as well as their dynamical properties. The most interesting and consequently the most studied manifestations of percolation phenomena are those taking place in the close proximity to the onset of global connectivity in the system. This onset is known as the percolation threshold, and the behavior of the geometrical and dynamical properties in the vicinity of this threshold is known as the critical behavior of the percolation system. It was shown that this critical behavior can be described as a second-order phase transition and thus, close enough to the percolation threshold, the various properties are given by power laws [121] that are reminiscent of the dependencies found in the most well-known phase transitions [119] such as the simplest magnetic transitions [116].

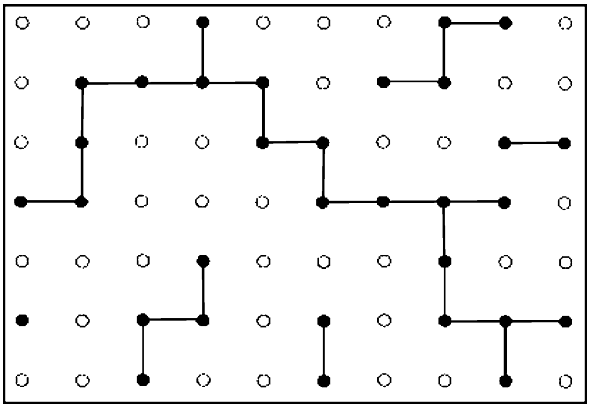
There are thousands of papers that have been written on the theory and the applications of percolation in the continuum. These applications are found in very many fields of physics, chemistry, biology, geophysics and communications, and there are very many relevant properties that are discussed in terms of the concepts of this theory. Since all these cannot be summarized within the framework of the present review we will concentrate here on the theory and the understanding of the principal concepts and on the major experimental manifestations of the theory and its consequences. In particular we will focus on the central essential concept of the *percolation threshold* in the continuum and on the dynamical property that was studied more than any other property in corresponding systems, i. e., the *electrical conductivity*.

Since the fundamental concepts that are used for the description of percolation in the continuum are based on the great advancements made in the theory of lattice percolation, we will start this review by briefly outlining the principles of the latter theory. Following the fact that there are excellent textbooks [106,121,136] and many review articles on lattice percolation, this background will be given very briefly in Sect. "Lattice Percolation". It is expected that this brief background will be sufficient for the understanding of the basic ideas of continuum percolation that will be discussed then in more detail here, in Sects. "Principal Issues in Continuum Percolation", "Percolation Thresholds in the Continuum", and "The Critical Behavior of the Dynamical Properties in the Continuum". In those sections we will put emphasis on the properties of continuum percolation that cannot be extrapolated simply from their lattice counterparts. For example, the almost zero-percolation threshold as well as the non universal behavior of various physical properties do not follow the scenarios of, and expectations from, lattice percolation. Finally, in Sect. "Future Directions" we consider the major issues in continuum percolation the solution of which seem to be important in order to deepen our understanding of this and related fields of research. In Sect. "Bibliography" we provide a rather very limited list of papers relevant to the subjects considered here with the hope that this will be sufficient as a guide for the application of continuum percolation theory in various and many related research areas.

Lattice Percolation

To introduce the above mentioned basic concepts we start by considering the very simple model of the two dimensional square lattice that is illustrated in Fig. 1. Let us assume a probability, p, that a lattice site is occupied, and denote the occupied sites by full circles. The step that is very important here, and will be very crucial when we discuss continuum percolation, is the definition of the local connectivity between members in a given system. In the present lattice these members are the occupied sites and two such sites are defined to be connected if they are first nearest neighbors. In the particular case shown in Fig. 1 the number of nearest neighbors of a given site (the coordination number of the lattice), z, is 4. We can now define a (connected) cluster size as the number of sites such that each of them is connected to at least one (same or other) occupied site in the cluster. In Fig. 1 we see then clusters of size 1, size 2, size 4 and a larger cluster that connects opposite edges of the system. The latter is called the spanning cluster. In percolation theory we are concerned mainly with "infinite" systems, i. e. with systems where the details (e. g. the sites themselves and the intersite distances) are much smaller than the size of the system. Correspondingly, in an "infinite" system we call the spanning cluster, the percolation, or the infinite, cluster. The illustration given in Fig. 1 reflects then a finite (small) portion of the infinite system. Such small portions are used below for the description and definitions of local and global quantities of the system, but it has to be remembered that quantitative characterizations of the various properties are considered meaningful only in the (statistically sufficient) "infinite" system limit.

From Fig. 1 it is easy to appreciate that the number of clusters and their sizes will grow as the site occupation, p, increases, as can be derived quantitatively by various models and simulations [121,136]. The most important consequence, however, is that there will be a value of p, that is known in the literature as p_c, such that for $p < p_c$ there will be no percolation cluster, while for $p \geq p_c$ there will be such a cluster. This p_c is known as the *percolation threshold* of the lattice. The behavior of the various geometrical or physical properties for p values in the close proximity of p_c is known as the *critical behavior*. The above mentioned considerations of the percolation as a phase transition yield then that these properties will be well described by power laws of the proximity to the threshold $|p - p_c|/p_c$. For example, the average cluster size, S, is defined usually [121] as the average number of sites in a cluster, per an occupied site in the lattice. The average that is thus found for the finite clusters in the lattice, behaves, for both, $p > p_c$ and $p < p_c$, as



Continuum Percolation, Figure 1
A two dimensional illustration of a portion of an infinite lattice. The open circles represent lattice sites and the full circles represent occupied lattice sites. The segments connecting two nearest neighbor occupied sites represent a local connection or a bond. In this illustration there are finite clusters of connected sites (of size 1, 2 and 4) and a "spanning" cluster that connects two opposite edges of the system. In a system of infinite size the latter is known as the "infinite" or the "percolation" cluster. (From [32])

$$S \propto |p - p_c|^{-\gamma} \,. \tag{1}$$

In particular, the phase transition-like behavior yields that exponents, such as γ, depend only on the lattice dimension D, and are thus independent of the details (e. g. the lattice type) of the system. This property is known as the *universality* and the corresponding dependence on $|p - p_c|$ as the *universal behavior*. The universal values of γ are, for example, 2.4 for $D = 2$ and 1.8 for $D = 3$. The other important property of the clusters is their geometrical extent, i. e. their effective (e. g. gyration) radius (say, in units of the lattice spacing). The corresponding average for the finite clusters in the lattice (e. g., per sites connected to a given site in the cluster; Stauffer and Aharony [121]) defines then the "connectivity" length in the system, ξ. This length, as to be expected from the above discussion, behaves as

$$\xi \propto |p - p_c|^{-\upsilon} \,, \tag{2}$$

where ν is a "universal" exponent. The quantity ξ, known also as the *correlation length*, is the most important parameter of the system since it characterizes its connectivity and provides the basic length scale for dealing with the behavior of the properties of interest in the system. The well known values of υ are 1.33 for $D = 2$ and 0.88 for $D = 3$.

We note in passing that in Fig. 1 we may also consider the occupancy of the bonds (i. e. the segments between the sites) for which the local bond connectivity criterion is the occupation of two bonds that share a site [129]. It is obvious that for a given lattice there is a simple numerical factor that relates the site occupancy, p^s, and the bond occupancy, p^b [136]. Below, we will use then the more general p concept to describe both quantities except when the difference between the two types of occupancy needs to be emphasized.

Turning to the dynamic properties associated with the connectivity of the system in lattices we consider now the global conductance of a system, G. This is the dynamic property that we will discuss in Sect. "The Critical Behavior of the Dynamical Properties in the Continuum". for continuum systems. Viewing then the system shown in Fig. 1 as consisting of "bonds" (between two occupied sites), let us assume that each bond is a resistor bar of a given resistance value. In such a system there will be electrical conduction from right to left or from top to bottom, only if there is a spanning cluster. Examining the system illustrated in Fig. 1 from this point of view, we see that only a fraction of the 18 resistor-bonds in this cluster (15 from left to right or 11 from top to bottom) will participate in the conduction in the respective direction. On the other hand, there will be a few resistance-bonds (3 from left to right, or 7 from top to bottom) that do not participate in the conduction process. The bonds of the first type belong to the *backbone* of the percolation cluster while the others are known as the *"dead ends"* of the percolation cluster.

Let us consider now the structure of the backbone net. We can imagine the backbone as (say, a cubic) net of "links" and "nodes". These "links" intersect then at the "nodes" that define the corresponding net. The average length of the links is easily appreciated to be of the order of ξ, since the "holes" in the backbone net can encapsulate only finite clusters, and these, as we saw above, have their diameter distributed around ξ. Turning to the structure of the links, we can look at it from a geometrical point of view or an electrical point of view. In the first picture let us consider those bonds in the link that connect two sites in the link such that there is no other "indirect" connection between them within the distance ξ (i. e. when only the members of the link) are included. We call the corresponding bond a "*singly connected bond*". From the electrical point of view the latter bonds are simply those that carry the same current as the link (say, through a plane that intersects the link, but only through members of the link). The parts of the backbone that are confined between two adjacent "singly connected bonds" are known as the "blobs" of the backbone. Hence, since the system will conduct only for $p > p_c$, the backbone can be envisioned as consisting of, say, a square or a cubic, network of "links" that are made of series connections of "singly connected bonds" and "blobs". The model described here is known as the *links-nodes-blobs* (the LNB) model [32,114,120,121].

Considering the expected resistance of a cubic (or hypercubic) LNB network let us assume that the resistance of a link is R_ξ. If the sample size is L we have then, on the average, L/ξ links that connect one edge of the sample with its counterpart. Correspondingly, there will be $(L/\xi)^{D-1}$ parallel links between these "opposite-edges", where D is the dimensionality of the system. Since the link's resistance is R_ξ, the resistance of the whole network $\mathbf{R}_L$ will be given by

$$\mathbf{R}_L = R_\xi (\xi/L)^{D-2} \,. \tag{3}$$

The crucial step here is then "only" to estimate the value of R_ξ [32,114]. The corresponding easiest approach (that can be termed also the lattice approach) is to assume that all the bond-resistors have the same resistance value $\mathbf{r}_0$ [121,122]. In passing we note that when the resistors' values come from a distribution, even if a lattice structure is assumed as the platform of the resistors network, the problem is classified as a problem in continuum percolation. This follows of course the fact that in "real" (or continuum) systems a distribution in the resistance values of the local resistors is usually expected (see Sect. "The Local Resistors and Their Distributions"). The deviation from the simple $\mathbf{r}_0$ assumption that is used in lattice models will be shown in Sect. "The Critical Behavior of the Dynamical Properties in the Continuum" to lead to the very different and rich behaviors that are encountered in continuum percolation.

However, with the above assumption of all resistors having the same value $\mathbf{r}_0$, we can estimate the value of R_ξ in the LNB model as follows. We saw that the link consists of singly connected bonds and blobs. Let us determine first how many singly connected bonds we expect to have in a link of length ξ. Assuming a lattice with $p > p_c$ and assuming that there are L_1 such bonds in this link [114], let us cut out $(p - p_c)/p$ of the bonds in the whole lattice. The number of singly connected bonds that will be cut in a link will be then $L_1(p - p_c)/p$. If, upon the increase of L_1 as $p \to p_c$, this quantity reaches unity, there will be on the average one singly connected bond missing in a link and "all" the links will not conduct. In the limit of $\xi \to \infty$ (i. e. $(p - p_c)/p_c \ll 1$) we approach then the onset of "no percolation" with $L_1 \propto (p - p_c)^{-1}$. If we neglect the blobs (that, following the above, are aggregates of parallel resistors and thus have lower resistance than the same length chain of singly connected resistors), the resistance of the link can be estimated by its lower bound of $R_\xi = \mathbf{r}_0 L_1 \propto (p - p_c)^{-1}$. Since the blobs do contribute to the resistance of the link, one expects that $R_\xi > \mathbf{r}_0 L_1$ and that R_ξ will behave as $(p - p_c)^{-\zeta}$ where ζ is an exponent that is dimensional-dependent. While the calculation of the value of ζ is not straightforward [122], it can be well approximated by fractal models [48]. That the value of ζ is larger, but not much larger, than unity is to be expected, since, as in the "dilution" of the network of links (when $p \to p_c$), there is also a dilution in the local structure of the blobs, and the links will approach the limit of a chain of singly connected bonds. In other words as $p \to p_c$ the resistance $\mathbf{R}_L$ will be affected by both the dilution of the links in the network Eq. (3) and the dilution of the resistors in the blobs. The latter effect means a "stronger" (in comparison with the one that would be encountered in a link that is made only of "singly connected bonds") divergence of the sample resistance as $p \to p_c$ and thus it is manifested by ζ that are, for $D < 6$, larger than 1. Indeed, it was found that $\zeta \approx 1.3$ for $D = 2$ and $\zeta \approx 1.1$ for $D = 3$ [121]. All the above results can be summarized now by presenting the critical behavior of the global resistance, $\mathbf{R}_L$, in a percolation system of size L, by

$$\mathbf{R}_L (\equiv 1/G) \propto (p - p_c)^{-t} , \qquad (4)$$

where t is the critical exponent of the global conductance G, that is given, in view of the above, by

$$t = (D - 2)\nu + \zeta . \qquad (5)$$

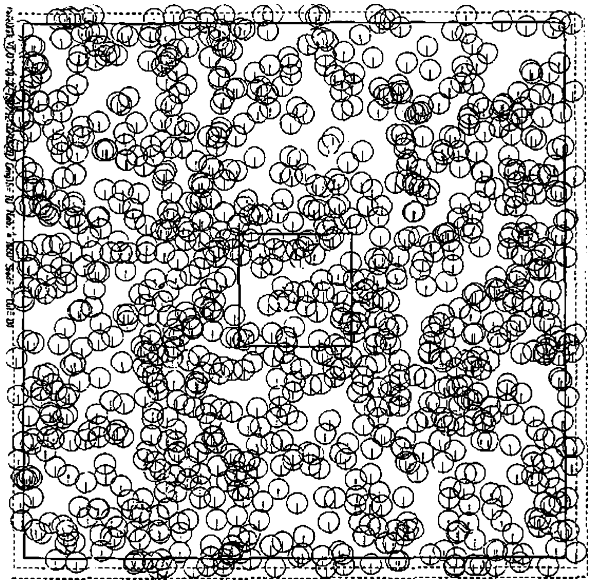
The numerical t values that were derived by various corresponding analytical approximations, or Monte Carlo simulations, are known as the universal values of the conductivity exponent, t_{un}. These values are, in particular [121,136], 1.3 for $D = 2$ and ≈ 2 for $D = 3$. The deviation from these "lattice" values that represent the behavior of the "global network" in lattices will be discussed in Sect. "The Critical Behavior of the Dynamical Properties in the Continuum".

Principal Issues in Continuum Percolation

In the previous section we have briefly reviewed the principal concepts of lattice percolation where the systems have sites (or bonds) on lattices and these can be empty or occupied with a probability $p^s(p^b)$. This yields a percolation threshold p_c that depends on the particular lattice of interest. The physical properties on the other hand, all of which are associated with the existence of the corresponding bonds in the system, are all characterized by the same single-valued physical parameters. In continuum percolation the system is composed of objects (or structures) that are *randomly placed in space*, that may be of *various sizes and various shapes* and, if non-spherical, may have a *distribution of their orientations*. Correspondingly, the physical parameters that characterize the bonds may vary from one bond to another in a manner that may or may not be determined solely by the local geometry and environment of the bond. The two most significant issues that are of concern in continuum percolation are then the connectivity of the system, as reflected by the percolation threshold, in systems of objects, and the possibility of a different critical behavior of the geometrical and physical properties in comparison with that of lattices.

To make this general discussion more specific, we start by an illustration of a well known prototype of a two dimensional continuum percolation system which consists of randomly distributed circles, as shown in Fig. 2. The circles in this model can be described as permeable, overlapping, interpenetrating, or of "soft core". Such a system can represent a metal sheet in which holes have been drilled at random. In this case the electrical conduction between opposite edges of the sample is carried by the "background" (the sample without the holes) of the sheet. We call this "interpretation" of the system, the random void (RV), or the "Swiss Cheese" model. The system shown in Fig. 2 can be also considered as representing a mirror image of the RV system, i. e. to be taken to represent pores (filled, say, with a conducting liquid) in a porous medium, or a collection of isolated and fused metallic grains embedded in an insulating matrix as in granular metals. In these cases, the conducting parts are the pores or the grains, and their network provide the global conductivity of the system. The transport in the latter system can be of course of a liquid or an electrical charge. Correspondingly, this view of the system is known as the inverted random void (IRV) model.

In the latter model the criterion for local connectivity (that is equivalent to the simple bond connection in lattice percolation) is rather simple; two circles are connected if they partially overlap. While (as we will see later) the local



Continuum Percolation, Figure 2
A two dimensional illustration of a continuum system. The circles are distributed randomly and two of them are considered connected if they partially overlap. There are finite clusters here as well as an "infinite" cluster of connected circles. A small finite portion of the system is enclosed in the square shown at the center. (From [130])

connectivity criterion is not always so simple in continuum systems, this one is easy to understand intuitively and thus it is the most abundant model in continuum percolation. In what follows, and in particular, for the discussion of the "connecting criteria" and their interpretation in the continuum, we will usually illustrate our arguments by figures that show small portions of the infinite system, such as the area enclosed in the square that confines the center of Fig. 2.

It is already the first examination of the system shown in Fig. 2 that makes one appreciate the fundamental questions of continuum percolation: how to define quantitatively the percolation threshold in such a system (there is no apparent meaning to p), and how the local degree of objects overlap determines the local and global geometrical and dynamical properties of the system. We will discuss these two issues in Sects. "Percolation Thresholds in the Continuum" and "The Critical Behavior of the Dynamical Properties in the Continuum" of our review. In contrast, we will not describe here the numerous natural and artificial systems for which the consequences of these issues are of great significance, leaving these for more specific reviews to come. We provided, however, a small representative list of such systems in Sect. "Definition of the Subject".

Percolation Thresholds in the Continuum

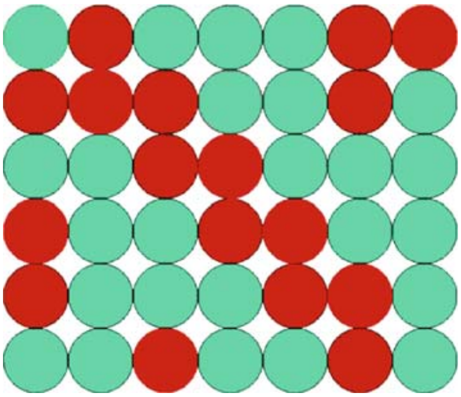
The Basic Concepts

The first attempt to characterize the percolation threshold in the continuum, which is usually credited as the beginning of the field of continuum percolation, was the 1970 [108] work of Scher and Zallen (S&Z), who based their argument on the "behavior" of a regular lattice, such as the one shown in Fig. 3. There, the red (say, the conducting) spheres occupy lattice sites, with a probability p^{s}, as in the lattice models described in Sect. "Lattice Percolation". The green (insulating) spheres correspond to empty sites in the lattice. The local connectivity criterion here is simply the red spheres occupation of nearest neighbor sites, as in the lattice, but here, if we consider the spheres as objects, the connectivity between two adjacent spheres, can be looked upon, as defined by a *single point contact* between two such spheres. Hence, if the diameter of the hard core spheres is equal to the lattice spacing the connectivity of the network stays the same as in the corresponding lattice. We can consider then the fractional volume of the conducting (red) phase which is simply given by $\phi = p^{\mathrm{s}} f$, where f is the filling factor of the system (the maximum fraction of the volume in a given lattice that can be filled by hard spheres of equal volume). Correspondingly, one can define the percolation threshold by the total occupied volume fraction of the conducting spheres, i. e. $\phi_{\mathrm{c}} = p_{\mathrm{c}}^{\mathrm{s}} f$. It is obvious then that $\phi - \phi_{\mathrm{c}} \propto p^{\mathrm{s}} - p_{\mathrm{c}}^{\mathrm{s}}$, and that the critical behavior of a given property Ξ in this case will be determined by

$$\Xi \propto (\phi - \phi_{\mathrm{c}})^{\chi} \,, \tag{6}$$

where χ is the corresponding-lattice critical exponent. S&Z noticed that ϕ_{c}, unlike $p_{\mathrm{c}}^{\mathrm{s}}$ (or $p_{\mathrm{c}}^{\mathrm{b}}$), is nearly a dimensional invariant, yielding values very close to 45 (area %) for all 2D lattices and very close to 16 (vol.%) for all 3D lattices. This brought them to the important realization that if we "shake" the system shown in Fig. 3 to yield a disordered system of touching spheres, its topology will not be significantly modified, and following the above close invariance, both ϕ and ϕ_{c} will be as good parameters for the characterization of the disordered arrangement of spheres, as p^{s} and $p_{\mathrm{c}}^{\mathrm{s}}$ are for lattices. The latter system can be also envisioned as a result of randomly dropping red and green spheres "gravitationally" into a container so that the "gravitation" secures the (single point) contacts between adjacent spheres [97]. Following the above concluded topology, it was of no surprise then that the latter approach confirmed the ideas and the results of S&Z.

We note of course that the above systems is by no means general or a prototype of a continuum system.



Continuum Percolation, Figure 3

A small portion of a square lattice that is comprised by "conducting" (red) and "insulating" (green) circles. The local connectivity is defined here by the "single point" contact of two red circles, and the global connectivity is determined by the spanning cluster of touching red circles

Rather, it represent an example of simple mapping of a continuum problem onto a lattice problem. While *the use of the fractional volume as a parameter*, which is equivalent in a way to p^s in lattices, was an important step in launching a theory for continuum percolation, their ϕ_c values were misused later, and to this date, for the characterization of continuum systems that are very different than the ones for which these, very particular values (secured single-point contacts), were calculated. For example, consider a system of red spheres that are embedded randomly in a continuous insulating matrix. Such a system represents many common composites (see Sect. "The Critical Behavior of the Dynamical Properties in the Continuum"). It can be easily appreciated that $\phi_c = 16$ vol.% in such a system of hard spheres yields a very sparse composite [1] and that the metallic (touching grain) conduction will be set at a much higher vol.% (of the order of 50 vol.% in the granular metals that constitute in fact an IRV system; Fonseca and Balberg [61]). Moreover, in practice there is no random system in which the "contact" or the "bond" between non permeable elements is "automatically" provided (if at all, it is approached only at the very high close packing limit of $\phi > 64$ vol.% [136,138]. Hence, there is no resemblance between the abundant common composite (with a continuous insulating matrix) and the models of S&Z and Powell, and thus the value of $\phi_c = 16$ vol.% is by no means a general approximate-invariant. This problem was discussed in more detail by Balberg and Binenbaum in 1987 [17].

In 1971 [112] Shante and Kirkpatrick (S&K) approached the percolation problem from the opposite end, i. e., considering permeable objects as in the case shown in Fig. 2. Like S&Z, it was obvious to S&K that the most promising approach to continuum systems was to try and map them onto a lattice problem, for which the theory was quite developed in the 1970's. They took what may be considered the most important single step in correlating lattice percolation and continuum percolation, proving that, at least in a specific systems, the topology of the two can be mapped onto each other. Their approach took into account an earlier empirical observation of Dalton, Domb and Sykes in 1964 [46] that in lattices, where z (the coordination number of the sites) approaches infinity, the value of zp_c^s extrapolates to 4.5 in 2D and to 2.8 in 3D. The quantity zp_c^s is, however, the average number of near-neighbors that are connected to a given site and it can be considered then as the number of occupied "bonds" per site. Hence, the quantity zp_c^s can be interpreted simply as the number of the occupied neighbor sites of a given site at the onset of percolation in the $z \to \infty$ limit. On the other hand, if one considers a system of permeable objects one can "implant" them anywhere in space. In particular for permeable spheres, the density of the possible centers of spheres which overlap a given sphere is also unlimited.

Following this observation, S&K conjectured that the topology of the $z \to \infty$ lattice and the continuum of permeable spheres is the same at the onset of percolation, i. e., that the number of "occupied" bonds per site, or the number of overlapping spheres for a given sphere, will be the same. Topologically, then, these two systems are expected to have the same onset of global connectivity. To test this idea, S&K considered the fact that the probability of randomly choosing a geometrical point that will be out of a given sphere of a volume v, in a unit size system, is $(1 - v)$. The probability that this point will be out of all the ρ_c spheres in this unit volume system, at the percolation threshold, is $(1 - v)^{\rho_c}$. In a large system that is statistically sufficient (i. e., $v \ll 1$ but $\rho_c \to \infty$) we can write the latter quantity as $e^{-v\rho_c}$. On the other hand, the probability of a point to be in any of the spheres (at the onset of percolation) is simply ϕ_c, the fractional volume that is covered by the ρ_c spheres. Hence, $\phi_c = 1 - e^{-v\rho_c}$. For a permeable sphere of radius a, in order not to overlap "another" sphere, its center has to be at a distance of $2a$ from the center of the "first" sphere. Correspondingly, the volume in which the center of the second sphere is not "allowed" to be (if no overlap is permitted) is not v but, rather, $8v$, or for hyperspheres in a D dimensional system it is, $v2^D$. On the other hand, the average number of centers of spheres that overlap a given sphere is simply $\rho_c v 2^D$. We have then that the quantity $\rho_c v 2^D$, is the critical number of bonds per sphere (or center, or site), B_c. Applying now their above conjecture, i. e. that $B_c = z p_c^s(z \to \infty)$ one finds that

$$\phi_{Dc} = 1 - \exp(-B_c/2^D)\,, \tag{7}$$

for a system of hyperspheres of dimension D.

Using the above mentioned "lattice" values of B_c for $D = 2$ and $D = 3$, with the prediction of Eq. (7), S&K found an excellent agreement with the Monte Carlo findings of $\phi_{2c} = 68$ area % and $\phi_{3c} = 29$ vol.%. In fact the B_c values were confirmed directly for permeable spheres later (in 1987 [16]) by Balberg and Binenbaum. The most important step of S&K was then the recognition of the fact that the number of bonds per site is the proper topological parameter to describe the connectivity in continuum as well as in lattice systems. In passing we note that following the above argument for any system of parallel aligned "regular objects" (such as boxes or cylinders) the relation $B_c = \rho_c v 2^D$ is expected to be obeyed [21,115].

In 1984 [22] Balberg et al. realized that the ideas of S&K can be generalized to non spherical objects, and even to objects that have no "volumes" of their own. Such is the case of two dimensional "widthless sticks" [20,25], where the local connectivity criterion is the intersection of two sticks, and the onset of percolation does not require any area of the sticks. This is in contrast with the systems mentioned so far. The way this generalization was conducted [9] followed the procedure of S&K with the topological expectation that for any system (regardless of the particular objects) B_c is the meaningful general topological parameter, and as such, it is expected to be a finite invariant. Following the B_c values in lattices of various dimensions [136], their values are intuitively expected to be between 1 and 5. In particular, B_c is always the number of the "other" objects centers (or sites) within the "excluded volume" V_{ex} of a given object, where the latter is the volume in which the centers of two objects must be in order for them to overlap. As such, the quantity V_{ex} is well defined for any permeable (or partially permeable object, see below). This yields that, in general, $B_c = V_{ex}\rho_c$. Naturally, the simple relation we had above for spheres Eq. (7) can be generalized now to all dimensions and for all types of permeable objects of a finite volume. This is done by noting that we can write ϕ_c by using, instead of $v\rho_c$ as above, the relation, $v\rho_c V_{ex}/V_{ex} = vB_c/V_{ex}$ for an object of hypervolume v and a hyper-excluded volume, V_{ex}, thus yielding that

$$\phi_c = 1 - e^{-B_c(v/V_{ex})}\,. \tag{8}$$

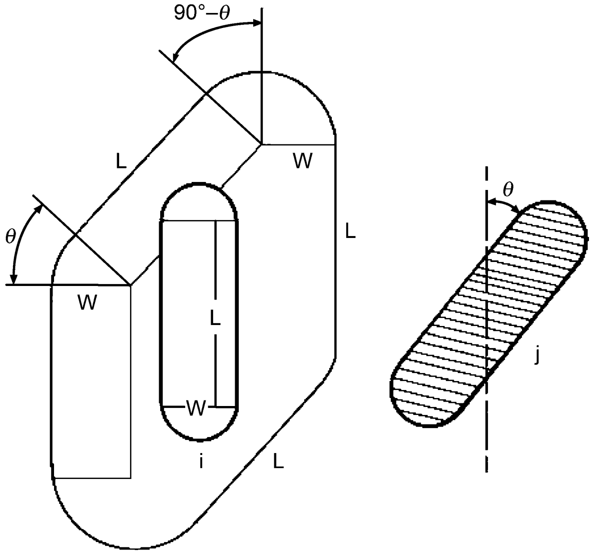
In 1986 [9] Balberg noted that Eq. (8) has far-reaching consequences, since it says that we can have a connected system with very minute content of the "percolating" or "conducting" phase ($v\rho_c$ or ϕ_c) involved. This follows from the fact, seen in Eq. (8), that ϕ_c can be as small as desired provided that v/V_{ex} is very as small as requireds. Indeed, this result was able to explain the $\phi_c \to 0$ values in porous systems, such as sedimentary rocks [7,110] and geological cracks [58], as well as in cermets such as cellular composites [94,128] in which the conducting phase is arranged along lines or planes [101]. Moreover, the fact that for lattices we have always finite p_c^s (or p_c^b) values that are larger than 0.3 for 2D and larger than 0.1 for 3D, made this result, of ϕ_c values as small as desired, quite surprising, and demonstrated that the mapping of the continuum onto lattices is not as simple as might have been conjectured from the pioneering works of S&Z and S&K (who were concerned only with systems of spheres).

The above generalization is also very useful for systems with distributions of object sizes, shapes and orientations, when a proper determination of the average excluded volume of the system, $\langle V_{ex}\rangle$, is carried out [22,53]. Hence, the above $B_c = \rho_c V_{ex}$ relation can be generalized to:

$$B_c = \rho_c\langle V_{ex}\rangle\,. \tag{9}$$

This result is very significant and important from the point of view of applications since if B_c is nearly an invariant (as to be expected topologically in view of the above, i. e. its value changes only in a very limited range, see also Sect. "The Origin of the Different **B**$_c$ Values in Systems of Different Objects" below) for various objects, one can predict the variation of ρ_c with the variation of the $\langle V_{ex}\rangle$ values in a group of objects. Hence, by assuming a constant B_c, trends in the behavior of percolation thresholds, ρ_c, as a function of the object's parameters, can be evaluated readily [9,37,83,103]. Moreover, one can predict the actual vol.% of the conducting phase (ϕ_c or $\rho_c v$) by just knowing the values of B_c and $\langle V_{ex}\rangle$ that can be well approximated by models (see below).

It turns out that the application of the concepts exhibited by Eqs. (8) and (9), beyond the very simple solution of $V_{ex} = 2^D v$ suggested for spheres (and for parallel convex shaped objects by Pike and Seager [95], and by Skal and Shklovskii, in 1974 [115]), has enabled the application of the above considerations to very many continuum systems. This was done in particular by the use and/or modification of the most celebrated model of non trivial systems, i. e., that of the three dimensional continuum system of capped cylinders [22]. These capped cylinders (of length L, radius W/2 and two capped spheres of radius W/2) span objects from spheres to cylinders with a single "close to an invariant" (see Sect. "The Origin of the Different B_c Values in Systems of Different Objects"), value of B_c. The basis of this model has been applied recently by Berham



Continuum Percolation, Figure 4
The volume and the excluded volume of two adjacent capped cylinders. The latter is for two cylinders (*i* and *j*) the angle between which is θ. (From [22])

and Sastry in 2007 [30] even to rather non-regular "wavy" shaped objects. The system of capped cylinders became then the prototype of continuum percolation systems of "non trivial" (non spherical) permeable and non-permeable objects. The volume of this capped cylinder is simply $v = (4\pi/3)(W/2)^3 + \pi(W/2)^2 L$, but its average excluded volume, shown in Fig. 4, is given by

$$\langle V_{\text{ex}}\rangle = (32\pi/3)(W/2)^3 + 8(W/2)^2 L + 4(W/2)L^2\langle\sin\theta\rangle\,, \tag{10}$$

where θ is the angle between the two of possible intersecting cylinders, and the average is over the particular distribution of the θ values [22,89]. The "non trivial" aspect is manifested by the fact that $\langle V_{\text{ex}}\rangle$ is not proportional to v, and that in the large aspect ratio case (i. e. $L \gg W$) we have that $v/\langle V_{\text{ex}}\rangle \propto W/L$, while for the small aspect ratio case we recover the above mentioned, trivial $v/V_{\text{ex}} = 1/8$ result for spheres. The system described here can be shown to represent very many natural and artificial systems where the objects are elongated [38] or have a negligible volume [101]. We note also that another system that is very helpful for the description of various systems is that of disks with a radius a, and a thickness t. These disks have a volume $v = \pi a^2 t$, while their excluded volume, in the isotropic orientation case, is given by $V_{\text{ex}} = \pi^2 a^3$ [37]. It is apparent that in the thin disk limit ($t \ll a$), we get that $v/V_{\text{ex}} \propto t/a$, explaining the very small ϕ_c values observed, as mentioned above, in sedimentary rocks, in systems of geological cracks and in cellular composites. In passing we note that the low dimensionality of the conducting phase inclusions in these systems explains the correlation between low percolation thresholds and the high critical conductivity-exponents (that are associated with low dimensional tunneling systems, see Sect. "The Average Resistance in the Case of Tunneling-Percolation").

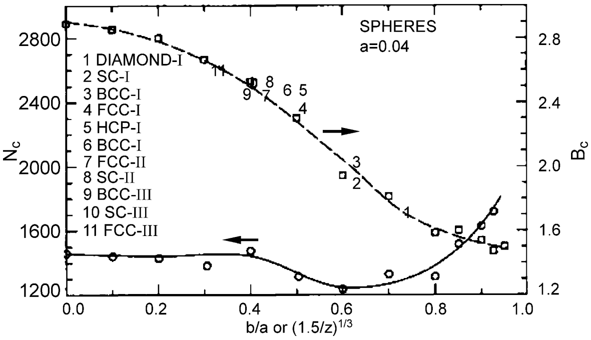
Following the above, let us try and guess now the possible variations of B_c as one goes from systems that consist of permeable (soft-core) spheres to quasi-permeable spheres with a hard core of radius b and a wrapping soft shell with a thickness of $a - b$. We mentioned already that B_c is 2.8 in the 3D soft core limit. We also know then, as found directly [17], that the value of B_c decreases, in the transition with the increase b, towards a value of 1.5. What we have available empirically are, those limits, the fact that what influences the behavior are volume quantities, and the above expectation that B_c will decrease between the two limits as $b/a \to 0$. Hence, we can simply expect empirically that

$$B_c = 1.5 + 1.3\left[1 - (b/a)^3\right]\,. \tag{11}$$

Considering the above mentioned topological meaning of B_c we recall that for lattices we realized already that in the $z \to \infty$ limit, $B_c = 2.8$, and we note that for the other limit we can apply the conjecture of Ziman in 1979 [138] (following the fact that zp_c^b is an invariant in lattices such that $zp_c^b = 1.5$ in 3D) that the smallest z (existing or imaginary) needed for percolation in 3D lattices, is 1.5. In this case we expect then that the approximation:

$$B_c = 1.5 + 1.3\left[1 - (1.5/z)\right]\,, \tag{12}$$

will be reasonable for lattices. If the connecting topology in the continuum and in lattices is the same (as found to be the case in the $b/a \to 0$ limit by S&K), B_c should scale equally well with $(b/a)^3$ or $1.5/z$. Indeed, as is clearly seen in Fig. 5, Monte Carlo simulations on a series of systems that represent the "soft core" to the "hard core" transition [17] have confirmed this mapping of the continuum system onto the lattice system. This establishes that, indeed, the underlying connectivity is the same in lattices and in continuum systems of partially permeable spheres (i. e., beyond the soft core S&K limit). A reproduction of the corresponding B_c values themselves can be achieved and explained phenomenologically as we will see in the following section. We noted already that from the practical point of view, one can generally predict the percolation threshold ρ_c once one knows the value of B_c (or an approximate of it) and the value of V_{ex}. In the present case we have the value of B_c (Eq. (11)) and



Continuum Percolation, Figure 5
Monte Carlo results for the dependence of the critical number of spheres in the system, N_c (denoted by circles, solid curve) and B_c (denoted by squares, dashed curves) on the spheres' b/a ratio in a continuum system of semi-permeable spheres. Also shown is the dependence of B_c on $(1.5/z)^{1.3}$ for three dimensional lattice systems. (From [16])

$V_{ex} = (32\pi/3)(a^3 - b^3)$. Hence, as the hard core limit is approached, and B_c gets the value of 1.5, we expect that ρ_c ($= N_c$ for a system of a unit volume) will diverge (of course up to the close packing limit that is possible). This is well exhibited by the Monte Carlo determination of N_c that is shown in Fig. 5. We note that the above derived phenomenological behavior does not tell us why the value of B_c itself decreases in the $b/a \to 1$ and $z \to 1.5$ limits (see Sect. "The Origin of the Different B_c Values in Systems of Different Objects").

A somewhat different view of the hard core-soft shell problem leads us to examine continuum percolation properties that can be considered to be even more remote from those of lattice systems. A conspicuous case of such a property is the effect of objects interaction due to a potential associated with the objects [41,90]. To introduce this scenario, we can consider the above hard core-soft shell sphere as being composed of a region of infinite repulsive interaction at distances r (from its center) smaller than $2b$, and a shell of zero potential for $r > 2b$. We may further look at the problem as a one in which the density of the objects is not uniform around an object (here e. g. $\rho = 0$ for $r < 2b$ and $\rho = \rho_s$ for $r > 2b$). If we use then the corresponding radial distribution function $g_R(r)$ of the particles (or objects' centers), the average number of bonds per site will be given by $B = \langle\rho\rangle \int_0^{2a} g_R(r) \mathrm{d}^3 r$, where $\langle\rho\rangle$ is the average density of objects in the whole system and a is the radius of the soft shell (that determines the local connectivity of the system). If we have a more complicated potential (i. e. when $g_R(r)$ has values different from 0 or 1 as above), B, and thus B_c, will depend on the parameters of this distribution, such as on the interaction potential that determines the $\rho(r)$ dependence [4]. A case that was considered in detail and is relevant, for example, to microemulsions [69], is that of an attractive potential shell that "wraps" the hard core ($b \leq r \leq (1 + \lambda)b$) and has a constant, non-zero value, in the interval of λb. In that case, it has been shown first by Bug et al. [35] (and later by Drory, Balberg and Berkowitz [54,55]) that interactions can raise or lower the percolation thresholds, i. e., the value of the global ρ_c value, according to the details of the magnitude of the potential and the ratios between b, λ and a.

Physically, this competition is not too surprising, since the attractive potential will cause the increase of the density of objects in the attractive potential region, but for a globally given ρ, it will cause a reduction of the density outside this region. The two effects will be manifested by an increased probability for the formation of the connected clusters, on the one hand, but by the reduction of the connectivity between different clusters, on the other hand. The interesting observations are then the non-trivial results of the interplay between these two effects that is determined by the system parameters, i. e. by the dependence of the values of B_c and ρ_c on them.

From the point of view of continuum percolation theory, the important conclusion is that even in this explicit interaction case we can characterize the system by its B_c value, correlate it with system parameters, and apparently generalize it to systems where the mapping onto lattice models is, conceptually and/or computationally, not obvious. On the other hand, it is apparent that such derivations can account for general connectivity problems where ρ or other "bonding strength" parameters are not uniform in space or in the network.

The Generalized Thresholds and the Critical Behavior in the Continuum

Let us turn now to see how the above mentioned quantities play a role in the determination of the most important parameter in the study of the critical behavior, i. e. the proximity to the percolation threshold. Following the fact that $B_c = \rho_c \langle V_{ex} \rangle$, we simply have the relation $B - B_c \propto \rho - \rho_c$. Hence, for B very close to B_c and ϕ very close to ϕ_c (which is the interesting "critical" range), we can further generalize this relation (by using Eq. (8)) to

$$\phi - \phi_c \propto B - B_c \propto \rho - \rho_c \,. \tag{13}$$

This relation is a very important one from the practical point of view, since ϕ is the only parameter that one can determine readily in experimental studies. However, the requirement for small $\phi - \phi_c$ values must be kept then in mind when the critical behavior is studied in continuum systems. In fact, another very important precaution has to be taken into account when studying the critical behavior as a function of $\phi - \phi_c$. We saw above that in many (e. g. sedimentary rocks and cellular composites) systems, ϕ_c can be very small. Hence, a small $\phi - \phi_c$ (with respect to unity) does not actually tell us about the proximity to the threshold. The parameter that one should consider is a normalized proximity to the threshold, such as $(\phi - \phi_c)/\phi_c$. We note that the latter problem is not severe in lattices of the "practical" ($D = 2$ or $D = 3$) dimensions because p_c^s and p_c^b for all these lattices are larger than 0.12 [136]. On the other hand, as noted by Grimaldi and Balberg in 2006 [70], the overlooking of the above two precautions is one of the reasons that when considering experimental results, improper comparisons with lattice-like critical behavior have been suggested. Following the above discussion on the soft core-hard core transition we also note that in the small $B - B_c$ limit, Eq. (13) covers all systems, including those where ϕ represents te hard core fractional volume in partially permeable (hard-core/soft-shell) objects. This is easy to appreciate since at the close vicinity of the percolation threshold the ratio of the hard core volume to the entire (hard core and soft shell) volume can be considered a constant and since we know that the relation given by Eq. (13) holds in limit as shown by the S&Z case. Indeed, many computer simulations on many continuum systems [15,65,66], where the systems are well defined (and ϕ_c can be approached much more closely than in the experimental studies on "real" systems), have revealed the critical behavior of lattices. This is quite an important realization when one tries to explain the critical behavior in composites, considering the fact that the rigorous development that we described above was given for permeable objects.

From our above discussion we can expect then *the same critical behavior* for all types of objects, and may further conjecture that this is the case when other local connectivity criteria are applied. In fact, thus far all Monte Carlo simulations have confirmed these expectations. We note, however, that a high precision study of ϕ_c and the critical exponents of a system of permeable spheres, was claimed to indicate a small variations with respect to the corresponding lattice values of the same exponents [100]. This conclusion can be contrasted by the fact that rigorous exact mapping of the permeable circles system onto the fine grid lattice system was demonstrated by McCarthy already in 1987 [86]. As of now, however, further work will be needed in order to determine whether the above small deviation is a matter of accuracy or proximity to ϕ_c (see the discussion following Eq. (13) above), or if there is still something more fundamental here that has not been satisfactorily studied thus far.

The Origin of the Different B_c Values in Systems of Different Objects

So far we have taken B_c to be an empirical parameter, as are the p_c^s and p_c^b quantities in lattice percolation, and the application of the relation given by Eq. (9) was proven extremely useful for the determination of trends in the variation of measurable percolation thresholds (i. e., ρ_c) when a constant (system independent, for a class of materials, e. g. boxes with a different aspect ratio) B_c value was assumed. However, the various values of B_c, while being confined to the 1–5 range (see above) are not the same for systems of objects of different shapes. These differences are important to understand since, as we discussed above, this is the only parameter that accounts for the global topological connectivity of percolation systems in the continuum. We note in passing that while the B_c values can be derived rigorously (see Sect. "Rigorous Determination of the Percolation Threshold"), their relation to the particular objects in the system under consideration is not a priori transparent from the corresponding derivations. At this point we concentrate then on the reasons for the different B_c values for different "types" of objects. For example, B_c *is 2.8 for permeable spheres and is only 2.6 for parallel permeable cubes*. While this difference seems minute (in comparison with the larger differences to be mentioned below), it is a convenient case for the illustration of the concept of "pointedness" that enables to explain the observed differences in the B_c values.

The reason for the above mentioned variations in the B_c values had hardly been considered prior to the work of Alon, Balberg, and Drory in 1991 [4] that yielded an insight into the apparent "different topology" associated with different objects. They derived this understanding using a heuristic or "semi-rigorous" argument, which will be illustrated here by the different B_c values for spheres and cubes, as well as by the variation of B_c in the soft core to hard core transition.

Let us consider then a system of permeable spheres of radius r_0 and a system of parallel permeable cubes with an edge a_0. Choosing their size such that they have the same excluded volume $\langle V_{ex} \rangle$ (in this case, also the same volume), we note that $\langle V_{ex} \rangle = (4\pi/3)(2r_0)^3 = (2a_0)^3$. Now let us consider the maximum distance between the centers of two spheres that can overlap. This distance is $2r_0$, and thus the possible distances, l, between the centers of two partially overlapping spheres is in the range $0 \le l \le 2r_0$. In contrast, for three dimensional cubes that are also connected by a partial overlap (and have the same $\langle V_{\mathrm{ex}} \rangle$), the corresponding range is $0 \leq l \leq \sqrt{3}a_0$, i. e., $0 \leq l \leq 2.7r_0$. Hence, since the density of the centers of the objects is uniform in both cases, on the average, two partially overlapping cubes can "on the average span" a larger distance than that of partially overlapping spheres. Correspondingly, in order to span an "infinite" cluster, we will need a smaller number of cubes than spheres, i. e., the value of ρ_c will be smaller in the case of cubes compared with the case of spheres. Since we have chosen V_{ex} to be the same in the above two systems, the corresponding value of ρ_c and thus the value of $B_c (= \rho_c V_{\mathrm{ex}})$ will be lower in the case of the cubes. Of course, the exact ratio between the B_c values of the two systems cannot be derived from the qualitative-simple illustration given here, but a more refined argument has been shown to heuristically yield such ratios exactly [4].

Since the apparent difference between the cube and the sphere is that the former has corners ("points"), one can say that the "pointedness" (that was defined by Alon, Balberg and Drory accurately) brings about the lower value of B_c. We can correspondingly conclude that since the average "covered" l "per excluded volume" will be larger with a higher aspect ratio of elongated objects, such as boxes that are isotropically distributed in space, we can further expect that for elongated boxes, of the same $\langle V_{\mathrm{ex}} \rangle$, the value of ρ_c will decrease with this ratio. For these, as mentioned above, the corresponding trend of the decrease of B_c with the aspect ratio was confirmed both rigorously and computationally [53,131] to decrease from about 2.7 to 1.2 for aspect ratios between 1 and 500. The latter trend was confirmed also for other types of permeable elongated objects [30,103].

A similar argument can apply for spheres of a hard core of radius b and a soft shell with a wrapping thickness of $a - b$. The "local span" of the two objects' in the $b = 0$ case is in the $0 \leq l \leq 2a$ range, while for the hard-core sphere with a soft shell it is $2b \leq l \leq 2a$, so that the average l value is larger in the latter case. Correspondingly, for the same average ρ in the system, the "span" of larger-hard core spheres will be larger, or the value of ρ_c will be smaller in the hard core-soft shell case, suggesting the decrease of B_c from 2.8 to 1.5, as we saw already in Fig. 5. The above result is of great conceptual importance, since it shows that while the phenomenological theory of the excluded volume theory was developed for permeable objects, *all consequences regarding the trends* in the values of the percolation thresholds (such as the effect of the aspect ratio) *apply also upon the approach to the hard core limit*. This can be illustrated simply by replacing W by $W - 2b$, where b is the hard core radius, in Eq. (10), and noting that as the aspect ratio increases the last term will eventually become the dominant term for any $2b/W$ ratio. In fact from the above arguments concerning the aspect ratio and the soft core to hard core transition, we conclude that the two effects can be compounded. This is also important from the practical point of view, since one can be guided, for example, for "real" composites that are composed of hard core objects [19], by the many works and the numerous simulations [21] that were concerned with the corresponding (easier to study) systems of permeable objects. A case in point is the decrease of the percolation threshold in carbon-black-polymer composites as the conducting particles become elongated (or, as better known, of "higher structure" [10,11,102]).

Rigorous Determination of the Percolation Threshold

Thus far we have considered the derivation of the concepts and the empirical trends in the behavior of the percolation thresholds as a function of the correlation between, and the properties of, the individual objects, as well as the corresponding global averages such as the anisotropy of a system. However, as we saw above, the particular fundamental values of the thresholds were either derived from lattice quasi-invariants (notably $p_c^s z$ for $z \to \infty$), heuristic arguments or computer simulations. Noting that a "complete" theory with a firm basis requires a rigorous derivation of the fundamental quantities from first principles, it is always a challenge to achieve such a derivation and the theoretical justification for the experimental and computational observations and their trends. This challenge was recognized also for the problem at hand, i. e., the rigorous finding of the "fundamental-topological" percolation threshold B_c (e. g., $B_c = 4.5$ for circles and $B_c = 2.8$ for spheres), which we encountered in the previous sections.

The above challenge was appreciated in 1977 [73] when Haan and Zwanzig considered the existence of bonds, defined by the overlap of permeable objects, and applied a graph theory for the analogous lattice-bond percolation problem. This attempt, which involved a lengthy cluster enumeration and high-order overlap integrals, has not been followed however by others, probably because of the latter reasons. The breakthrough in trying to find a rigorous route which is physically more transparent can be attributed then to the work of Coniglio, DeAngelis and Forlani in that year#160;[44]. They applied for the above purpose the formalism of the connectedness functions that is well known in the theory of liquids [74]. For the sake of brevity we will describe here their approach by the following simple "intuitive" arguments.

If we define a local (direct) connectedness criterion (e. g., overlap between permeable spheres) and a global connectedness (e. g., being on the same cluster), we can derive a direct connectedness function $C(\boldsymbol{x}, \boldsymbol{y})$, such that if $\boldsymbol{r}$ is the vector $\boldsymbol{x} - \boldsymbol{y}$ connecting "directly" the two objects at $\boldsymbol{x}$ and at $\boldsymbol{y}$, $\rho(\boldsymbol{r})C(\boldsymbol{r})\mathrm{d}^3 r$ is the probability that given a particle at $\boldsymbol{r} = \boldsymbol{0}$, there will be a particle, in the volume $\mathrm{d}^3 r$ around $\boldsymbol{r}$, that is locally connected to the particle at $\boldsymbol{r} = \boldsymbol{0}$. Here, $\rho(\boldsymbol{r})$ is the particles' (or objects') density in the system. The quantity $C(\boldsymbol{x}, \boldsymbol{y})$ accounts, in addition to the direct connection, for all possible additional "indirect" connections between the "directly connected" these two particles, and thus it can be presented by corresponding "closed diagrams" [56]. Similarly, one can define a "total" pair connectedness function $g(\boldsymbol{z}, \boldsymbol{y})$ between two objects (say, at $\boldsymbol{z}$ and at $\boldsymbol{y}$) which involves all the connecting (direct and indirect) routes between them. The function $g(\boldsymbol{r})$ (where $\boldsymbol{r} = \boldsymbol{y} - \boldsymbol{z}$) can be defined then by the probability, $\rho(\boldsymbol{r})g(\boldsymbol{r})\mathrm{d}^3 r$, of finding a particle in the volume element $\mathrm{d}^3 r$ around $\boldsymbol{r}$, which is connected (i. e., belonging to the same cluster) to the particle that is given to exist at $\boldsymbol{r} = \boldsymbol{0}$. Since $g(\boldsymbol{x}, \boldsymbol{y})$ is composed of "direct" connectivity steps such as $C(\boldsymbol{x}, \boldsymbol{z})$ and $C(\boldsymbol{z}, \boldsymbol{y})$, the "total" $g(\boldsymbol{x}, \boldsymbol{y})$ function can be expressed by the corresponding (Ornstein-Zernike) "chain" rule

$$g(\mathbf{x}, \mathbf{y}) = C(\mathbf{x}, \mathbf{y}) + \int \rho(\mathbf{z})C(\mathbf{x}, \mathbf{z})g(\mathbf{z}, \mathbf{y})\mathrm{d}^3 z\,, \tag{14}$$

where $\rho(\boldsymbol{z})$ is the density of particles (or centers of objects) in a volume of $\mathrm{d}^3 z$ around $\boldsymbol{z}$. For simplicity we will assume in the following that $\rho(\mathbf{z}) = \rho$, where ρ is a constant-uniform density in our problem. The crucial step that connects relation (14) with the present continuum percolation problem, i. e. with the average cluster size, is the consideration of its Fourier transform. For a "wave vector" $\boldsymbol{k}$ this relation yields that for the transformed functions $C(\boldsymbol{k})$ and $g(\boldsymbol{k})$ we will have that $g(\mathbf{k}) = C(\mathbf{k})/(1 - \rho C(\mathbf{k}))$. If we are interested in the integral $\int g(\boldsymbol{r})\mathrm{d}^3 r$, i. e. in the Fourier transform $g(\boldsymbol{0}) \equiv g(\boldsymbol{k} = \boldsymbol{0})$, we get in particular that

$$g(\mathbf{0}) = C(\mathbf{0})/(1 - \rho C(\mathbf{0}))\,. \tag{15}$$

The new important step made in the work of Coniglio, DeAngelis and Forlani in 1977 [44] was that, as can be appreciated intuitively, the average cluster size S in the system is simply given by

$$S = 1 + \int \rho g(\boldsymbol{r})\mathrm{d}^3 r\,, \tag{16}$$

where the unity here represents the given initial object (with a center at, say, $\boldsymbol{r} = \boldsymbol{0}$), $\rho\mathrm{d}^3 r$ is the probability of finding an object center in the space element $\mathrm{d}^3 r$, and $g(\boldsymbol{r})$ is essentially the percolation correlation function [121], i. e., the probability that, if there are objects centers at $\boldsymbol{r} = \boldsymbol{0}$ and $\boldsymbol{r}$, they will be on the same cluster. From Eq. (16) we have that $\rho g(\boldsymbol{0}) = S - 1$ and thus using Eq. (15), we obtain that

$$S = 1/(1 - \rho C(\mathbf{0}))\,. \tag{17}$$

Hence, knowing that at the threshold $S \to \infty$, we get that $\rho_c = 1/C(\mathbf{0})$, and thus, in principle, "all that is left" is to calculate $C(\mathbf{0})$.

There are basically two approaches for the calculation of $C(\mathbf{0})$. The first one is immediately called for by Eq. (14), from which it is apparent that if another relation between $g(\boldsymbol{x}, \boldsymbol{y})$ and $C(\boldsymbol{x}, \boldsymbol{y})$ is known, one can solve both functions and then find the value of S. Such a relation can be derived from corresponding approximations. One of these approximations, known as the Percus–Yevick closure [74]), was used for the solution of the problem at hand. Since the application of this closure was of a limited success [49]), and since it would require a deviation from the simple outline of our main argument regarding the rigorous derivation of ρ_c, it will not be detailed here.

The conceptually simpler and physically more transparent approach to the problem can be attributed to the suggestion of Bug, Safran and Webman in 1985 [34]. They were able to determine the initial terms in a (diagrammatic) series expansion of the form $C(\mathbf{0}) = \sum c_n \rho^n$, and to relate the initial coefficients to the concept of the excluded volume. This already enabled them to derive the trends in the behavior of the thresholds. However, this use, of what one may call an order-by-order (or series) approach, did not yield (in that work) actual values for the thresholds. The full utilization of this order-by-order approach came in the work of Drory and coworkers in 1990 [3], 1991 [53] and 1997 [56]. In passing we note that Drory also got in 1996 [51] and 1997 [52] a firm basis for the conjecture that continuum percolation is a phase transition, as proven previously [62] to be the case of lattice percolation.

Turning to the utilization of the latter approach we noticed already that in principle, $C(\mathbf{0}) = 1/\rho_c$. However, in practice, this does not provide directly an accurate enough value for ρ_c for the rather short series that were obtained thus far. On the other hand a more successful, albeit biased, approximation has yielded, as mentioned below, very accurate results. For the description of the latter we start then from Eq. (17) using the well understood relation that we had considered before, i. e., replacing ρ by $B = \rho V_{\mathrm{ex}}$. Hence, the aim of the procedure is to determine the, by now, well understood and well-characterized parameter B_c. Following the above, we can write S in terms of a power series of the form $S = \sum a_n B^n$, which is similar to the form used for the derivation of S by a power series of p in lattice percolation [121] In the present case, having the quantity $C(\mathbf{0})$ expressed as a power series of the form $C(\mathbf{0}) = \sum b_n B^n$ enables the comparison of the coefficients on both sides of Eq. (17), yielding then relations between the coefficients a_n and b_n. Here, for example, $a_0 = 1$, $b_0 = 0$, $a_1 = b_1$, $a_2 = b_2 + b_1 a_1$, $a_3 = b_3 + b_2 a_1 + b_1 a_2$, and $a_4 = b_4 + b_3 a_1 + b_2 a_2 + b_1 a_3$. Having these relations and implementing the fact (see Eq. (1)) that S has a critical behavior of the form

$$S \propto |B - B_c|^{-\gamma} , \tag{18}$$

where γ is the well-established critical exponent for lattices and, as expected from universality, also for the continuum (see above), one can fit the series of S to the behavior described by Eq. (18), in order to find the value of B_c. Of course the "only" input needed for the implementation of this procedure is then the determination of, as many b_n coefficients as possible and a good extrapolation of S. However, the derivation of the coefficients b_n is not trivial and becomes more and more complicated with increasing n [53]. So far these values of b_n have been determined up to $n = 5$ for permeable hyperspheres, yielding, however, very accurate values for B_c that are only a few % off the Monte Carlo estimates for corresponding $D = 2$ to $D = 6$ systems [3]. Similar successes for systems of elongated boxes [53] and hard core-soft shell cubes [56] have been already obtained. In spite of those achievements, further basic and computational developments in the study of this subject are called for. These will be outlined in Sect. "Future Directions".

The Critical Behavior of the Dynamical Properties in the Continuum

As we pointed out above, within the limited framework of this review, it will not be possible to consider all the many various dynamical properties (mentioned in Sect. "Definition of the Subject") that are determined by the added locally variable features in continuum systems and compare their behaviors with those derived for lattices. Correspondingly, we will confine our discussion to the conceptually most conspicuous representative, which is also the most studied, dynamical property, i. e., the electrical conductivity. It can be shown, as done by Rubin et al. in 1999 [102] for the electrical noise, that the basic arguments associated with the critical behaviors of the other properties are similar in principle, and that the specific details of those behaviors can be derived along the same lines that are used here for the electrical conductivity.

In the previous sections, we saw that one property that makes continuum percolation an area of a much wider diversity and application, in comparison with what one finds in lattice percolation, is the percolation threshold. The global properties of a percolation system were own there to depend on the details of the systems, where these may vary in many respects from one system to another. On the other hand, as far as the critical behavior is concerned, we have seen that the global behaviors of the geometrical-statistical properties are expected to be exactly the same as those found in lattices, provided that one uses the topological concept of bonds per site. In those cases a simple mapping, which is intuitively straightforward, of the "percolating phase" content onto the lattice occupation probability, can be made. Following the fact that for a given lattice there is a constant ratio between p^{b} and p^{s} [136], we will simply use here p and p_c as a generalized "conducting phase" content and describe the critical behavior of the dynamical properties in the continuum using these parameters. When needed however, the relation between these and the commonly measurable quantities, such as the corresponding partial volume contents of the conducting phase, τ and τ_c, will be emphasized.

Does the above behavior of the geometrical-statistical properties give us a hint as to the critical behavior of the dynamic (or "physical") properties of the system? To answer this question, let us consider the two possible features that are fixed in lattices, and may be random (or follow another distribution) in the continuum. This is easy to do by reexamining the system shown in Fig. 2 as a system of permeable spheres. In this figure we can see that the continuum randomness is manifested by the positions of the centers of the spheres and the random-like degrees of overlap between two adjacent spheres. If these spheres are envisioned as pores filled with a conducting fluid, the latter feature determines the local resistance between a pair of them. This will yield a distribution in the resistance values of the actual resistors that connect pairs of pores in the system. The simplest approach to evaluate the contribution of the latter effect (that has no counterpart in lattice percolation) to the global conductance of the system is to assign a resistor, with a resistance value that is taken from the corresponding distribution, to the occupied bonds on a given lattice [111]. A more direct simulation of the system that involves also the random "implantation" of the spheres has also been shown [23] to yield the predicted results that will be given below. The purpose of the following discussion is then to show how corresponding distributions of the local resistance values can guide us to the determination of the critical behavior in "real" continuum systems.

The simplest system to realize then is the lattice system of Fig. 1, when one assumes that the "bond" or the conducting "bar" between two occupied nearest neighbor sites corresponds to a resistor, the value of which is taken from a given distribution. A priori, one does not foresee too much of a surprise here, and a "universal" (lattice-like) behavior of the conductivity is expected, except that the individual local resistance value, $\mathbf{r}_0$ (associated with R_ξ; see Eq. (3)), will be replaced now by an average value of the local resistors, $\langle \mathbf{r} \rangle$. In fact, the finding of a universal value for t in many "real" systems [2,19,25] suggested that this distribution-effect will not yield a critical behavior that is different from the behavior in lattices, as appears to be the case for the geometrical-statistical properties. Considering this problem Kogut and Straley (K&S) developed in 1979 [82] a simple "toy" model that suggested that for some distributions, the above universality will hold, while for others, it will not. It took six years, however, until the missing link of the "toy" distribution and "real", or continuum, systems was made by Halperin, Feng and Sen in 1985 [72], and attention was given finally to the results of K&S. The work of K&S, which can be considered as the cornerstone of the field of "non-universal" behavior of dynamical properties in the continuum, will be reviewed below, after a modified-generalized account of the basic physics that is involved in their model will be given.

What apparently took the above-mentioned six years in order to understand, even in principle, the emerging numerous experimental observations of non-universal t values in the 1970's and 1980's (i. e., $t \neq t_{\text{un}}$; [10,11,94]), and to appreciate the theory of K&S, was *the unsatisfied need to find a distribution function* of the resistors values in a given "real", natural or artificial, system. This breakthrough came then with the work of Halperin, Feng and Sen in 1985 [72], who were able to show that in sedimentary rocks the values of the local resistors are essentially distributed according to the "toy model" function of K&S. In fact, it will be emphasized all along this part of the review that the determination of the resistors distribution function is the crucial step for the understanding of the critical behavior of the electrical conductivity (or other dynamical properties) in a given continuum system. The basic physics of this key issue, which has not been reviewed before, will be described below in some detail.

The Basic Physics of the Non-universal Behavior of the Conductivity

The physics of the critical behavior of the global resistance in continuum systems can be described as follows. Suppose we have a distribution $f(g)$ of the values of the individual conductors (the resistors that occupy the bonds) in our infinite lattice. Let us assume that the system has a fractional bond occupation p and that the percolation threshold is p_c such that $p > p_c$.

We have seen that in lattice percolation (Sect. "Lattice Percolation") the resistance of the system can be written as

$$\mathbf{R}_L = \mathbf{r}_0 A_R L_1^{\xi} (L/\xi)^{2-D} \, , \tag{19}$$

where A_R is some constant (i. e., ξ, or $p - p_c$, independent) parameter that accounts for the local and global geometry of the system and $\mathbf{r}_0$ is the resistance value of the individual occupied bond in the system. The question of interest here is then the behavior of $\mathbf{R}_L$, when we have a distribution of the individual resistance values (as expected in continuum systems) rather than a single $\mathbf{r}_0$ value. Let us denote the conductance of the individual resistor by g, so that the local value of the resistance is given by g^{-1}. Now suppose that the g values are taken from a distribution $f(g)$ that is confined to the range $g_1 \leq g \leq g_2$. Let us also assume that in our system there is a largest possible g_2 value (e. g., a zero distance tunneling or a complete overlap of IRV spheres; see Sect. "The Local Resistors and Their Distributions", below). The most important assumption in the following consideration is however that there is no correlation between the location of the resistor in space and its value, and thus one would expect that if there is such a distribution, $\mathbf{r}_0$ in Eq. (19) should be simply replaced by $\langle \mathbf{r} \rangle$ where

$$\langle \mathbf{r} \rangle = \langle g^{-1} \rangle = \int_{g1}^{g2} g^{-1} f(g) \mathrm{d}g \, . \tag{20}$$

We note in passing that such an average is meaningful if it is taken on $1/g$ (rather than on g), since it is the series connection of resistors that determines the resistance of the link (see Eq. (3)).

In principle, g_1 can be any value in the interval $0 < g_1 \leq g_2$ (a $g_1 = 0$ value corresponds to an unoccupied bond), and it is apparent that for a well defined finite-constant $g_1 > 0$ value, the critical behavior described by Eq. (19), with $\langle \mathbf{r} \rangle$ replacing $\mathbf{r}_0$, will be the same as in Eqs. (3)–(5), i. e., the universal (lattice-like) critical behavior will be obtained. What if $g_1 \to 0$ (but $g_1 \neq 0$; see above)? In this case it is apparent that the result will depend on $f(g)$. If $f(g)$ decreases as $g \to 0$, the value of the average $\langle \mathbf{r} \rangle$, as defined by Eq. (20), will be finite, as above. On the other hand, if $f(g)$ is a constant or it increases towards $g = 0$ (i. e. $f(g)$ diverges at $g = 0$), the value of $\langle \mathbf{r} \rangle$ will be ∞. In other words, if there are "enough" $g \to 0$

conductors in the system, the average will be determined by them and we will also get that $\mathbf{R}_L \to \infty$.

To consider however the behavior of $\mathbf{R}_L$ in more detail (i. e. the way in which $\langle \mathbf{r} \rangle$ diverges) for a non-decreasing $f(g)$ distribution as $g \to 0$, we use the following estimate of $\langle \mathbf{r} \rangle$ for the $g_1 \to 0$ case as follows. Let us list the values of the local conductances in the system in a descending order. Now, electrical conductance in the system is only possible if $p > p_c$, and thus we can choose the fraction (or subset), p_c of the p local conductors in the system, that contains the "top" g, p_c-values from that list. Following our basic assumption that there is no correlation between the location of the bond and its attached g value, we can use the fact that any randomly selected subset of p_c conductors is, by definition, a percolating cluster, and conclude that the above chosen p_c subset of the top value conductors constitute a percolation cluster. Of course, the largest conductance value in the system, g_2, is also the largest possible g value in the so chosen subset. For convenience let us choose now the value of g_2, by the relation $F(g_2) = 1$, where $F(g)$ is the indefinite integral of the function $f(g)$. This is done without loss of generality since all other g values in the system can be normalized accordingly. Then, the lowest g value of the conductors in the above subset p_c of p has the corresponding normalized value g_c. Mathematically, this g_c value is given then by

$$p\left[\int_{\mathrm{gc}}^{g2} f(g)\mathrm{d}g\right] = p_c \,. \tag{21}$$

This yields that $F(g_c) = (p - p_c)/p$, and thus that $g_c = F^{-1}[(p - p_c)/p]$, where F^{-1} is the inverse function of F. We have then a very significant result that connects the conductors' values in the system with the proximity to the percolation threshold. In particular, it is the nature of the F^{-1} function that determines the "pace" at which $g_c \to 0$, as p is made to become closer to p_c. The very important observation here is that for $p = p_c$ we have to exhaust all the resistors in the system and thus $g_c = 0$. The question that we would like to resolve is, following the variation of g_c as p approaches p_c, how will $\langle \mathbf{r} \rangle$ change as a consequence of this variation.

As above, we can distinguish here between three cases, but now we can also get some physical insight as to the corresponding critical behaviors. If $f(g)$ is a constant (in the $0 \leq g \leq 1$ interval) g_c will approach 0 at exactly the same "pace" as $p - p_c$. If $f(g)$ increases as $g \to 0$ (i. e. $f(g)$ diverges as $g \to 0$), g_c will approach $g = 0$ "faster" than $p - p_c$, and if $f(g)$ decreases toward $g = 0$, g_c will approach $g = 0$ at a "slower pace" than p approaches p_c. In other words, $1/g_c$ which is a measure of the resistors that determine the value of $\langle \mathbf{r} \rangle$ (see below), will not diverge in the latter case when $p \to p_c$. On the other hand, if $1/g_c$ diverges as $p \to p_c$ there is a possibility that a dynamic property that depends on g will also diverge then. Correspondingly then the above $p - p_c$ dependence of $1/g_c$ on $p - p_c$ dependence of $\langle \mathbf{r} \rangle$ may contribute to a non universal behavior of $\mathbf{R}_L$.

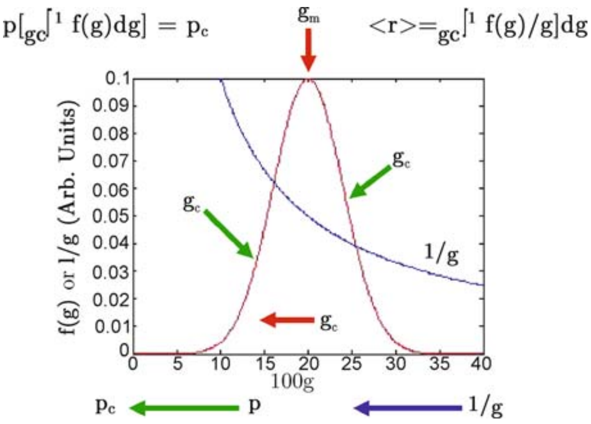
In order to derive a quantitative determination of the critical behavior of $\mathbf{R}_L$ let us try now to evaluate the behavior of $\langle \mathbf{r} \rangle$. Above, we have selected a subset of the conductors in the system (i. e. a subset of the resistors that participate in the conduction process). The average resistance of this subset is

$$\langle \mathbf{r_c} \rangle = \int_{\mathrm{gc}}^{g2} g^{-1} f(g)\mathrm{d}g \,. \tag{22}$$

Any other subset of p_c resistors will have an $\langle \mathbf{r} \rangle$ which is larger than $\langle \mathbf{r_c} \rangle$ (or equal to it), and thus $\langle \mathbf{r_c} \rangle$ yields the lowest estimate of $\langle \mathbf{r} \rangle$ that can be inserted in Eq. (19) instead of the $\mathbf{r}_0$ value in Eq. (19). Considering the fact that we are concerned with $p \to p_c$ and that $g_c \to 0$, the contribution of the very low g-values (with values of $g < g_c$) to the "measured" network resistance becomes negligible as $g_c \to 0$. This is in particular so if the values of g are changing by orders of magnitude as $g \to 0$ [87]. Hence, this $\langle \mathbf{r_c} \rangle$ of the "bypassing" network becomes a "more and more" accurate estimate for the value of $\langle \mathbf{r} \rangle$ in the $g_c \to 0$ limit, and consequently a reasonable replacement for $\mathbf{r}_0$ in Eq. (19).

Let us try and get a physical feeling for the correspondingly expected critical behavior, i. e., for the dependence of $\mathbf{R}_L$ on $(p - p_c)$. For that purpose we follow the dependence of $\langle \mathbf{r_c} \rangle$ on $(p - p_c)$ by considering the behavior of $1/g_c$ when $p \to p_c$. The above mentioned "list" of conductors, as p is made to decrease (i. e., some of these occupied bonds are eliminated as p_c is approached), we have to go "down the list" of the conductors in the system, in order to choose p_c bonds from the new p, so that the smallest g_c involved is smaller (or at most equal) in comparison with the g_c value of the larger (i. e. "former") p. Of course, it is not enough that g_c will just become smaller as $p \to p_c$, since if the availability of these low-value g_c conductors becomes scarce as $p \to p_c$, they will not contribute significantly to the network (or to the average $\langle \mathbf{r_c} \rangle$) and there will be an effective constant $\langle \mathbf{r_c} \rangle$ value (which is independent of $p - p_c$) that will determine the resistance $\langle \mathbf{r} \rangle$ and thus the global resistance of the system (see examples below, and in the following sections). If this is not the case, the effect of $\langle \mathbf{r} \rangle$ on $\mathbf{R}_L$ is clear then; not only changes of the network connectivity (Eq. (19)) take place as $p \rightarrow p_c$, but also, the average resistor value that contributes to the conduction can diverge, yielding an additional $p - p_c$ divergence to the "universal" contribution of Eq. (19). Hence, a compounded, non-universal (or non lattice-like) behavior can be obtained.

For a more quantitative illustration of the above discussion let us consider the simple case of $f(g) = 1$ in the interval $0 \leftarrow g \leq 1$. In this case we have from (Eq. (22)) that $\langle \mathbf{r_c} \rangle \propto \log(1/g_c)$ and from (Eq. (21)) that $g_c \propto p - p_c$. Hence, substituting $\langle \mathbf{r_c} \rangle$ instead of $\mathbf{r}_0$ in Eq. (19) will provide a logarithmic divergence to $\mathbf{R}_L$, as $p \rightarrow p_c$, in addition to the power law divergence of the global or the "lattice-like" contribution. It is also apparent then that it is enough that when $f(g)$ increases towards $g = 0$ (i. e., $f(g)$ diverges as $g \rightarrow 0$), a stronger (say, power law) divergence of $\langle \mathbf{r_c} \rangle$ with $p - p_c$ will be obtained. On the other hand, there will be no divergence of $\langle \mathbf{r_c} \rangle$ if $f(g)$ decreases (in this case $f(g)$ diminishes) towards $g = 0$. In the latter case we have that the approach of p to p_c is associated with the "disappearance" of the large $(1/g)$ resistors, while in the former, this approach is associated with the "appreciable" availability of these resistors ("at the expense" of the smaller $(1/g)$ resistors). From the above analysis we see that the crossover between the diverging and non diverging $\langle \mathbf{r_c} \rangle$, as $p \rightarrow p_c$, occurs when $f(g)$ "overcomes" the increase in the "summation" of the resistors, as reflected by the $(\mathrm{d}g/g)$ term in Eq. (22). This is easy to comprehend in the LNB picture as a competition between the possible introduction of large $(1/g)$ resistors in the links (the $f(g)$ effect), and the rate of increase in the "weighted" values of the "needed" individual resistors in the link (the $\mathrm{d}g/g$ effect) as the links become longer (i. e. as $p \rightarrow p_c$). This scenario of the "need to supply enough high-resistance resistors" in order to get the divergence of $\langle \mathbf{r_c} \rangle$ as $p \rightarrow p_c$, will be important as we turn to consider "real" continuum systems. Physically, we found here an important principle of the $\langle \mathbf{r_c} \rangle$ behavior, the appearance of non universal behavior will be determined by the competition between the $f(g)$ and the $\mathrm{d}g/g$ effects. One notes is passing that for other dynamical properties (that are described by functions of g other that $1/g$) the "$\mathrm{d}g/g$" effect will be changed accordingly [42].



Continuum Percolation, Figure 6
An illustration of a peaked distribution of the local conductances in a continuum system, as well as the variation of the participating g-values as $g \rightarrow 0$. The relation between the approach of g_c to the $g \rightarrow 0$ limit and the corresponding direction of the $p - p_c$ variations is indicated by the arrows in the figure. The principal equations that determine g_c and the approximated average resistor in the sample $\langle r \rangle$ are also given

In "real" systems, however, the $f(g)$ distributions may be more complicated than described above, yielding behaviors that were not accounted for in the literature until very recently [70,71]. To illustrate such a distribution and to summarize the above discussion, let us consider an $f(g)$ function that is peaked at some value g_m and diminishes towards both, $g = 1$ and $g = 0$. Such a distribution from $g_2 = 0.4$ to $g_1 = 0$ is illustrated in Fig. 6. As p is decreased towards p_c, the g_c values "move first" along the $f(g)$ part where $f(g)$ increases faster than $1/g$. Over this range, i. e. $0.4 \leq g_c \leq g_m$, we have (see above) the conditions that yield a diverging-like behavior of $\langle \mathbf{r_c} \rangle$. Hence, as the decrease of p is associated with the decrease of g_c, we will get an apparent non universal behavior. Continuing with the decrease of p to the p-range for which $f(g)$ decreases with $1/g$ (i. e. the $0 \leftarrow g \leq g_m$ range), the apparent behavior of $\langle \mathbf{r_c} \rangle$ will become of the type that does not have a divergence and will thus yield a universal-like behavior of the system in the corresponding p-range. We note that while, strictly speaking, the critical behavior (i. e., at the $p \rightarrow p_c$ limit) is universal for this $f(g)$, in "practice", i. e., when the p values are somewhat removed from p_c, the behavior observed (i. e. for $g > g_m$) may be characterized as non universal. In fact, considering the increase in the "pace" in which $f(g)$ varies with $1/g$ in the $g > g_m$ regime, one would expect for the large g (or large p) values, a behavior that is close to the universal behavior, and then that this behavior will turn to a more pronounced non universal-like behavior as g and p are decreasing (but still for $g > g_m$). This pronounced behavior will be weakened however, as g_m will be approached, until upon the decrease of $f(g)$ for $g < g_m$ a universal behavior is obtained. Hence, a peak in the "local" t value is expected for some p (i. e. at the inflection point of $f(g)$ in the $g_m < g < 0.4$ interval) and a transition from a non universal-like to a universal behavior will be obtained at some lower p. Examining the various experimental data in the literature [128] that suggested a non universal behavior for cases where $f(g)$ is expected to be of the form shown in Fig. 6, one must conclude that the p value that corresponds to the g_{m} peak lies below the p values-limit available in the acquisition of the experimental data. In fact, the range of the g values between g_2 and g_{m} usually consists of a few orders of magnitude in the variation of g [70] and thus the experimental data that is fitted to a range of a few orders of magnitude in $\mathbf{R}_L$, while appearing to represent a single "non universal" t value, does not disclose the variation in the value of t as $p \to p_{\mathrm{c}}$, due to the relatively limited range of the latter (see also Sect. "The Average Resistance in the Case of Tunneling-Percolation" below).

The Model of Kogut and Straley and Beyond

As we have shown above, the crucial factor in the determination of the critical behavior of an average dynamical property is the variation of its extreme value as $p - p_{\mathrm{c}} \to 0$. K&S have proposed a particular distribution of the local conductances in a system which can exhibit the three basic behaviors that we mentioned above. This distribution (which as we show below turned out to be very useful for the description of best known real systems) yielded then analytic expressions for the diverging or non diverging $\langle \mathbf{r}_{\mathrm{c}} \rangle$ values as $p \to p_{\mathrm{c}}$. The distribution that they suggested was

$$f(g) = 1/(1-\alpha) g^{-\alpha} \,, \tag{23}$$

which is normalizable for $\alpha < 1$, in the range $1 > g > 0$. For this distribution one gets from Eq. (21) that

$$g_{\mathrm{c}} = \left[(p - p_{\mathrm{c}})/p\right]^{1/(1-\alpha)} \tag{24}$$

and from Eq. (22), that

$$\langle \mathbf{r}_{\mathrm{c}} \rangle = \left[(1-\alpha)/\alpha\right]\left[g_{\mathrm{c}}^{-\alpha} - 1\right] . \tag{25}$$

We see here the three behaviors described above as follows. If $\alpha = 0$ we have that $f(g) = 1$ as discussed above. If $\alpha < 0$, $\langle \mathbf{r}_{\mathrm{c}} \rangle$ is not diverging as $p \to p_{\mathrm{c}}$ and it is the constant $(1-\alpha)/(-\alpha)$, i. e., the system behaves in the $g \to 0$ limit as if it is made of local resistors all having the latter value. If $\alpha > 0$, we get that in the interesting regime of $p \to p_{\mathrm{c}}$ (i. e., where $g_{\mathrm{c}} \to 0$),

$$\langle \mathbf{r}_{\mathrm{c}} \rangle \approx \left[(1-\alpha)/\alpha\right] g_{\mathrm{c}}^{-\alpha} \propto \left[(p - p_{\mathrm{c}})\right]^{-\alpha/(1-\alpha)} . \tag{26}$$

We recall that the resistance of the sample is approximated by $\mathbf{R}_L \propto \langle \mathbf{r}_{\mathrm{c}} \rangle (p - p_{\mathrm{c}}) -^{t_{\mathrm{un}}}$, where t_{un} describes the effect of the connectivity of the global network of the system (Eqs. (3)–(5)). Correspondingly, the critical behavior of the electrical conductivity of the system, which determines the critical exponent t (see Eq. (4)), will be given now by

$$t = t_{\mathrm{un}} + \alpha/(1-\alpha) \,. \tag{27}$$

In what follows we will show that the mapping of the most conspicuous systems in the continuum onto the K&S distribution is possible and that it is associated with the corresponding local geometrical parameters. We will also note the very important case where this mapping is not simple and other approaches must be taken in order to determine $\langle \mathbf{r} \rangle$ and thus the $\mathbf{R}_L$ dependence on $p - p_{\mathrm{c}}$, as the percolation threshold is approached. For example, the application of the Effective Medium Approximation (EMA) by Grimaldi and Balberg in 2006 [70] yielded the confirmation of the rather more complicated behavior that was discussed above in relation to Fig. 6, on the one hand, and which explained the moderate $t - t_{\mathrm{un}}$ (that are in the 1–10 range) values that were obtained in numerous composites [128], on the other hand.

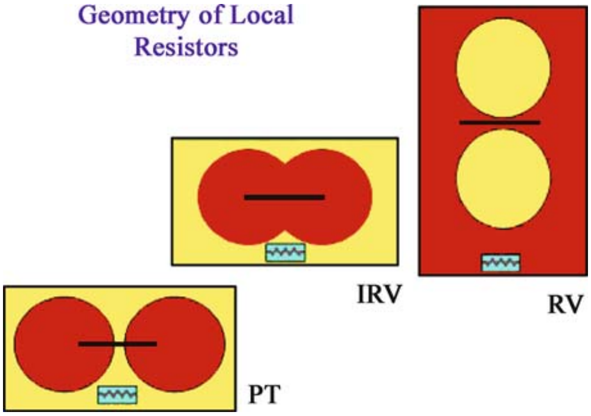
The Local Resistors and Their Distributions

As pointed out above, the conductors' distribution, as given by K&S was considered to be quite abstract until this resistors value distribution was suggested for some real systems by Halperin, Feng and Sen in 1985 [72]. Once this distribution is given, its mapping onto the K&S distribution is, as shown below [12], quite straight forward. Another way to derive the corresponding critical behavior was based on the use of a physically more transparent and more rigorous approach [59]. The corresponding findings were the very crucial steps that have finally explained the universal and non universal behaviors of "real" systems. In passing, we note that a posteriori, the critical behavior estimated by the above consideration of $\langle \mathbf{r}_{\mathrm{c}} \rangle$, is also confirmed by the latter approach, as will be shown below.

Since both approaches have been given in detail in the literature, we will only outline here the principal steps in their utilization for the determination of the corresponding t values. Starting then with the first approach, let us assume that the resistance of a local resistor in the system, $1/g$, is determined by a single local geometrical parameter, ε, and that the distribution of the ε values in the system, $h(\varepsilon)$, is known. The distribution function of the local conductor values, $f(g)$ is simply given then by [10]

$$f(g) = h(\varepsilon)(\mathrm{d}\varepsilon/\mathrm{d}g) \,. \tag{28}$$

"All one has to find" then, from the local configuration that occur in the system, are the $h(\varepsilon)$ function (which is usually not easy to do; see below) and the function $\varepsilon(g)$ (which is usually easy to do).



Continuum Percolation, Figure 7
The three major configurations of "real" systems in the continuum. The red color represents the conducting phase, and the yellow color represents the insulating phase in the systems. The bars and the resistors represent the "necks" and the corresponding dominant local resistors in the system. The configurations represent, from right to left, the random void, the inverted random void and the percolation tunneling models

There are three principal local configurations that were studied in detail. Let us discuss these configurations and consider the single geometrical parameter, ε, that describes them. These three configurations are illustrated in Fig. 7, where the "conducting" phase is colored in red and the "insulating" phase is colored in yellow. Starting from the random void (RV, sedimentary rock-like system, or a metallic bulk in which holes were punched out), that is also known as the Swiss cheese-like system, we can assume that the distance between the surfaces of the spherical pores is ε, and there is a "neck" of volume $(2\sqrt{b\varepsilon})C_D\varepsilon^{D-1}$ between them. Here, b is the radius of the pore and C_D is a constant (which is 1 in $D = 2$ and $\pi/4$ in $D = 3$). This neck determines the resistance of the neck that is associated with the two adjacent spheres [72] since beyond this "neck" the local resistance in the system is relatively small. The value of the local resistor in the system is well approximated then by the resistance of the "neck" which is given by $\rho_0(2\sqrt{b\varepsilon})/C_D\varepsilon^{D-1}$, where ρ_0 is the resistivity of the conducting medium. Hence, the resistance of the local resistor is varied with ε as $1/g \propto \varepsilon^{3/2-D}$ (i. e., the local conductance can be expressed by $g \propto \varepsilon^{D-3/2}$).

In the second configuration, known as the inverted random void (IRV) system, such as a granular metal above the onset of metallic conductivity [61], or a system of pores filled with a conducting liquid [32,59] the overlap between two spheres can be characterized by the parameter $\varepsilon = 2b - r$, where r is the distance between the centers of the adjacent spheres. Correspondingly, the neck for conduction here is approximated to be $2\sqrt{\varepsilon b}$ long, and it has a cross section of $C_D(b\varepsilon)^{(D-1)/2}$ ($C_D = 2$ in $D = 2$ and $C_D = \pi$ in $D = 3$), yielding that $g \propto \varepsilon^{D/2-1}$. For the above two cases we have then that $g \propto \varepsilon^m$, where $m = D - 3/2$ in the RV model and $m = D/2 - 1$ in the IRV model.

The third case is that of conduction between two spheres that do not overlap for which the distance between their centers is r and the distance between their surfaces is $r - 2b$. In that case, the conduction between the two spheres is by tunneling and the charge transfer probability between the surfaces is expected to decrease as $\exp[-(r - 2b)/2d]$, where $2d$ is the effective (say, the WKB) tunneling decay coefficient. This percolation-tunneling (PT) case will be considered in Sects. "The Tunneling Percolation Problem", "The Average Resistance in the Case of Tunneling-Percolation".

Let us turn now to the corresponding $h(\varepsilon)$ and $f(g)$ distributions in the first two cases. Noting that the derivation, theoretically or experimentally, of these distributions is the most difficult part (see above and below) in our problem, one can consider the first suggestion of a "real" $h(\varepsilon)$ dependence, and its use in the present context, to be the breakthrough that lead to the understanding of the non universal behavior of the dynamic properties in "real" systems. This was achieved, as pointed out already, in the 1985 [72] work of Halperin Feng and Sen, who showed that in porous media $h(\varepsilon)$ is a constant, h_0, for $\varepsilon \to 0$. The corresponding distribution is, however, normalizable since $h(\varepsilon)$ tapers off with increasing ε, above a certain value of ε (as is obvious from the finite size of the system, see below). Being interested in the smallest ε values, i. e., the largest resistors in the system, one can easily apply the "recipe" given by Eq. (28). Using then the general $g \propto \varepsilon^m$ relation, where m is the relevant exponent, we have that $f(g) \propto dg/d\varepsilon \propto h_0 g^{(1-m)/m}$ and thus, that the α value of K&S is $1 - 1/m$. In the above RV case, for which $m = D - 3/2$, we have then that $t - t_{\text{un}} = \alpha/(1 - \alpha) = m - 1 = D - 5/2$. Hence, from the consideration of K&S, it is easy to conclude that for $D = 2$ a universal behavior will be found, while for $D = 3$, a value of $t - t_{\text{un}} = 1/2$ is predicted, as confirmed indeed by the corresponding simulations of Sen, Roberts and Halperin in 1985 [111].

The above procedure was generalized by Balberg in 1998 [12] for any power law distribution of the $h(\varepsilon) \propto \varepsilon^{-\omega}$ type which, following the above, yields that $f(g) \propto g^{(1-m-\omega)/m}$ and correspondingly (see Eq. (27)) that $t - t_{\text{un}} = (m + \omega - 1)/(1 - \omega)$. Of course we note that we must have that $\omega < 1$, so that the distribution is normalizable. For the three dimensional RV case we will generally get then that $t - t_{\text{un}} = (D - 5/2 + \omega)/(1 - \omega)$. It is important to note that if ω varies from one ε range to another, the behavior obtained will be more complicated. In particular, transitions between universal-like and non universal-like behaviors may be obtained as $p \to p_c$. Such a variation, with the consequences of a none monotonic $h(\varepsilon)$, and thus a non monotonic $f(g)$, has not been considered in the literature for this case. However, following the above discussion of Fig. 6, one can account for now such transitions. In fact, a similar situation in principle, was evaluated very recently for the percolation tunneling problem, that will be described in Sect. "The Average Resistance in the Case of Tunneling-Percolation". A mapping similar to that of the RV model was obtained for the IRV model [12,23] yielding that $\alpha \leq 0$ for $D \leq 4$, and thus the divergence of the conductance is obtained (for the $\omega = 0$ case) only for $D \geq 5$.

Let us derive now these results in a physically more transparent manner [59,72]. We start by assuming the LNB model and try to find the relation between the parameter ε, that is relevant to the value of the resistors, and the proximity parameter $p - p_c$, so that a relation such as that of the K&S model can be found between the average local resistance $\langle \mathbf{r_c} \rangle$ and $p - p_c$. For the $\varepsilon \to 0$ limit, which corresponds to the larger $1/g$ resistors (that must be included in the network when $p \to p_c$), we assume, as above, that $h(\varepsilon) = h_0$ and that $g \propto \varepsilon^{-m}$. The corresponding $\langle \mathbf{r_c} \rangle$ is determined then by

$$\langle \mathbf{r_c} \rangle \propto \int_{\delta}^{\Delta} h_0 \varepsilon^{-m} \, \mathrm{d}\varepsilon \,, \tag{29}$$

where Δ is the ε value above which $h(\varepsilon)$ tapers off with increasing ε, and δ is the smallest ε value (which is associated with the smallest g value), in a typical link, that is made of L_1 singly connected bonds. The probability that ε will be larger than a given δ for a bond in this link is simply $1 - \int_0^\delta h_0 \, \mathrm{d}\varepsilon$, and thus for all L_1 bonds in the link it is $(1 - \int_0^\delta h_0 \, \mathrm{d}\varepsilon)^{L1} = \exp(-\delta L_1 h_0)$. This means that at $\delta \approx 1/L_1 h_0$ this probability starts to become significantly smaller than unity, and thus this relation provides a good estimate of δ, i. e. that $\delta \propto 1/L_1$. Having this value and considering that $\delta \ll \Delta$ and that $m > 1$ (see above), we get from Eq. (29) that

$$\langle \mathbf{r_c} \rangle \propto h_0 \delta^{-m+1} \approx h_0^m L_1^{m-1} \propto (p_- p_c)^{1-m} \,. \tag{30}$$

This result yields, as above, (see Eqs. (26) and (27)) that $t = t_{\mathrm{un}} + (m-1)$. As we saw for the RV model, $m = D - 3/2$, and thus for the corresponding three dimensional system we get $t = t_{\mathrm{un}} + 1/2$, in accordance with the above result that was obtained from the K&S model. Similarly, for the IRV model we got that $m = D/2 - 1$, and thus for $D = 3$, we have that $m < 1$ and $\alpha < 0$ yielding that $t = t_{\mathrm{un}}$. We can further attach the distribution term $\varepsilon^{-\omega}$ as above and get that instead of the relation of $\delta L_1 h_0 \approx 1$ we will have that $\delta^{(1-\omega)} L_1 h_0/(1-\omega) \approx 1$ and thus, that in the more general case, $\langle \mathbf{r_c} \rangle \propto h_0 \delta^{-m+1-\omega} \approx h_0^m L_1^{(\omega+m-1)/(1-\omega)} \propto (p_- p_c)^{-(\omega+m-1)/(1-\omega)}$ or $t = t_{\mathrm{un}} + (m+\omega-1)/(1-\omega)$, where ω is as above [12].

The Tunneling Percolation Problem

Before turning to the problem of the average value of the local resistor in the case of tunneling percolation, let us examine the unique relation between tunneling and percolation [13]. Tunneling is essentially the principal mechanism of electrical conduction in most classes of composite materials. This is to be distinguished from the cases that involve a coalescence of particles encounters one that in granular metals [2], porous media (the IRV model; see above) and microemulsions [69], where the onset of a continuous geometrical network is associated with the onset of a global "metallic" conductivity. In most other cases, such as in granular metals in the dielectric regime [1] and in various semiconductor composites [26,27], the conductivity between the particles (or objects) is generally controlled by tunneling.

As one considers the tunneling in the percolation-systems context, one notices that it challenges our above understanding of continuum percolation as follows. In lattices (S&Z-like), or in the above RV and IRV systems, the geometrical connectivity and the electrical connectivity are very clear and both are associated with the geometrical continuity of the conducting phase. This is also the case when we can define a soft shell that wraps the hard-core so that the overlaps of the soft shells provides a continuous conducting phase, as can be envisioned to be the case in microemulsions [35]. When the conductivity is provided only by tunneling, there is no geometrical connectivity (or continuity) but there is electrical connectivity. The latter connectivity, however, is problematic, since all the conducting objects are connected electrically to each other (albeit with a different "strength" that is determined by the exponential decay of the tunneling probability). Hence, the system has a "zero span" of the geometrical connectivity and an "infinite span" of the electrical connectivity. It appears then to be quite surprising [13] that systems corresponding to this "counter" percolation configuration, such as many types of composites, exhibit computational [24,78] or experimental [128] well-defined percolation thresholds with a universal or a non universal critical behavior. This problem was essentially clarified only recently as to be described below. We note then in passing that until quite recently the very many experimental or computational studies on numerous composite systems that were discussed in terms of a bona-fide percolation critical behavior have done so with no justification.

The first explanation for the above paradox was given only very recently by Toker et al. in 2003 [124]. They concluded, by examining the fractal dimension of the "electrical" percolation network (that was derived from local probe microscopy on real composites), that if the tunneling decay parameter is very small compared with the size of the objects (say, spheres), in practice, only the network of adjacent neighbors (see above) determines the global measurable conductivity of the system. In that case the percolation threshold is simply associated with by the concentration of "near neighbor" objects, such as in the case of a system of objects of a "large" hard-core and a thin soft shell. In this case the percolation tunneling problem can be mapped onto such a model. The dynamical properties are determined then by the local resistors distribution (see also Sect. "The Average Resistance in the Case of Tunneling-Percolation") as in the above given discussion.

When this is not the case, i. e. when the tunneling distance is of the order of the size of the conducting objects, such as the case in granular metals [1,26,124] or quantum dot semiconductors [27] in the dielectric regime, the observation of a percolation threshold and a critical behavior is less obvious. It turns out that the solution to this problem can be based on the same model as in the above case if we take into account the accumulated information that we have on the radial distribution (RDF), $G(r)$, of a collection of hard spheres. This function that is defined [138] as the probability $G(r)\mathrm{d}r$ to find a particle center within the interval r and $r + \mathrm{d}r$ from a given particle, shows that there is an evolution of the peak of "nearly touching" particles as we go from the dilute, or small b, limit to the (hard core) dense spheres limit, i. e. as the particles size and/or density increase. In particular, the common conclusion of all the corresponding models is that the larger the particles phase content (i. e. the particles density and/or their size) the narrower the "tail" of the near neighbors separations. This is equivalent in the present context to the statement that more particles will overlap their neighbors within the narrow shell, d, that is of the order of the tunneling distance. In other words, the way the hard spheres arrange themselves yields a preferred conduction network that can be looked upon as made of an IRV system with the soft shell, the thickness of which is of the order of the tunneling decay constant. Hence, the model is much like the one proposed above for the $b >> d$ case. It is of course appreciated that as the system becomes very dilute it also becomes reminiscent of the near neighbor hopping model [114]. Indeed, a close examination of the dependence of the conductivity on the conducting phase content in granular metals [26] reveals a density regime in which both, percolation and hopping, can simultaneously account for the experimental data, while only a percolation model can account for the data obtained on the "large spheres" system of Carbon black-Polymer composites [102].

The Average Resistance in the Case of Tunneling-Percolation

The determination of the average local resistance in the tunneling-percolation problem was solved thus far accurately only for the 1D (or quasi 1D; see below) systems [10,11]. At higher dimensions, the lack of analytic expressions for the $f(g)$ distribution does not enable a simple evaluation of the corresponding critical behavior. However, with the information already available [5,126] it is possible, as described below, to obtain a good physical understanding and derive semi-quantitative results for the critical behavior [78].

We start then with the simple case of a linear chain of geometrically, but not electrically, isolated "metallic" spheres [71], the hard core radius of which is b and the average distance between which is $2a$ ($= 1/N_1$, where N_1 is the average number of spheres per unit length). The random distribution of the distances of the centers of the nearest neighbor spheres from a given sphere center in the corresponding 1D system is the well-known 1D Hertz distribution [10,11,126] that can be written as [26]

$$h_1(r) = \big[1/(2a - 2b)\big]\exp\big[-(r - 2b)/(2a - 2b)\big] , \quad (31)$$

where r is the distance from the center of the reference sphere. On the other hand, the local tunneling conductance between two such spheres is simply given by

$$g = g_0 \exp\big[-(r - 2b)/2d\big] , \quad (32)$$

where g_0 is a corresponding geometrical-physical constant and $2d$ is the tunneling decay constant. For the calculation of the average value of the local resistance we will neglect the resistance between "non-adjacent" spheres, i. e., we assume that $b \gg d$. Applying Eqs. (28), (31) and (32), we get that for the nearest neighbor connections (or bonds; [10,11,26])

$$f_1(g) \propto \exp\big[(r - 2b)/2d\big]\big[1 - d/(a - b)\big] \propto g^{-\alpha} , \quad (33)$$

where,

$$\alpha = 1 - d/(a - b) . \quad (34)$$

Following the above K&S prediction (Eq. (27)) for the exponent t we get then that

$$t - t_{\text{un}} = (a - b)/d - 1 \, . \tag{35}$$

Considering the discussion in Sect. "The Basic Physics of the Non-universal Behavior of the Conductivity", regarding Eq. (22), we see that if d is larger than $(a - b)$, there is not "enough" supply of distant neighbors, or large resistors ("the $f(g)$ effect"), to overcome the needed $1/g$ resistors ("the $\mathrm{d}g/g$ effect") and thus to yield the diverging $\langle \mathbf{r_c} \rangle$. In contrast, if $d < a - b$, even though the "supply" (Eq. (31)) decreases with increasing r (i. e. with decreasing g values), this "supply" is enough for the "fastly" increasing $1/g$ values, to yield an increase in $f(g)$ as $g \to 0$. This is an important observation that results from the fact that we have two terms in Eq. (28) so that the behavior of $f(g)$ is not necessarily the behavior expected by just examining $h_1(r)$. Physically then, as above, in the $d < a - b$ case the decrease in the available small g values (or the large r values) is slower than the increase in the value of the large resistors, $1/g$, as $r \to \infty$ or (Eq. (32)). Correspondingly, one obtains the divergence of $f(g)$ (Eq. (33)) as $g \to 0$ i. e., when p approaches p_c. This description is manifested quantitatively of course by the above mapping of the tunneling resistor problem onto the K&S model, with an α value that determines the transition between a non-diverging to a diverging distribution, i. e. $\alpha = 0$, which in the present case corresponds to $d/(a - b) = 1$ (Eq. (34)).

For completeness, let us present the physically more transparent procedure for the determination of $t - t_{\text{un}}$, such as the one of Halperin, Feng and Sen in 1985 [72], which we outlined in Sect. "The Local Resistors and Their Distributions", but this time for the tunneling-percolation problem. This approach [102] is similar then to the one considered for the RV and IRV models, but for the present problem we assume that the largest distance between two adjacent spheres in the link is s (rather than the smallest distance, δ, in the RV and IRV problems). We are above interested then in the probability that the largest r in the link of L_1 singly connected resistors is smaller than some prechosen s. This probability (following Eq. (31) and the procedure given in Sect. "The Local Resistors and Their Distributions") is simply $\{1 - \exp[-(s - 2b)/(2a - 2b)]\}^{L1} = \exp\{-L_1 \exp[(s - 2b)/(2a - 2b)]\}$. Correspondingly, this probability starts to be small at a value of about $\exp(-1)$, and thus the condition for s being the largest "bond-length" in the link is that $L_1 \approx 1/\exp[(s - 2b)/(2a - 2b)]$. On the other hand, the average resistance in the link, $\langle \mathbf{r_c} \rangle$, is now proportional to $\int_{2b}^{s} \exp\{[(r - 2b)/(2a - 2b)] - [(r - 2b)/2d]\}\mathrm{d}r$. The dominant term in the integral is then $\exp\{[(s - 2b)/(2a - 2b)][1 - (a - b)/d]\}$, or in view of the above, the dominant term of $\langle \mathbf{r_c} \rangle$ is $L_1^{-[1-(a-b)/d]} \propto (p - p_c)^{1-[(a-b)/d]}$. Correspondingly, we get (as we already found above from our mapping of the problem onto the K&S distribution) that in this relatively simple 1D case, $t - t_{\text{un}} = (a - b)/d - 1$.

This finding has been adopted not only for the relativle simple 3D cases where the above $h_1(r)$ distribution is still appropriate [71] but also, very recently, to general 3D random systems. The simpler cases include cellular composites in which the system can be assumed to be made of insulating (say, cubic) blocks, and of conducting channels with a diameter just wider than $2b$ which include metallic spheres of diameter $2b$. The channels are further assumed to coincide with the edges of the insulating cubes [71,78]. In practice, however, the comparison of the prediction of Eq. (35) with experimental observations on "real" cellular composites [128] shows that the above predictions yield t values that are very exaggerated. If one tries to provide then a "more realistic" model of such a composite, one must also assume that the chains are not infinite and that thier number per unit length, N_1, (and thus a) may vary from one chain to the other, according to the make of the composite. This is even to the degrees that $(a - b)/d$ may be larger or smaller than unity in different chains. The corresponding distribution of N_1 in the chains may affect then the critical behavior by yielding an effective "global" α. For this case that was considered in detail by Grimaldi et al. in 2003 [71], it is obvious that the chains' $N_1(= 1/2a)$ values will contribute to a universal behavior (high N_1) or to a non universal (low N_1) behavior of the system. The global behavior will be determined then finally by the distribution of the various N_i's values in the system.

A priori one may think that this model of Grimaldi et al. should apply to systems of higher dimensions as one approaches the percolation threshold, since in the Links, Nodes, Blobs (LNB) model we consider a conducting network of such large chains that are, at first sight, one dimensional in nature. At second sight one notices two problems with that assumption. First, the distribution function of the nearest neighbor sites in the $D > 1$ case, $h_D(r)$, is different from the one given in Eq. (31) and, second, and more severe, the LNB link is made of singly connected bonds that are determined by the connectivity of the $D > 1$ network and not (necessarily) by the first nearest neighbors, as in the simple 1D case.

Before giving the recent "exact" solution to the problem [78] let us see the basic underlying physics of it. The global conductance as $p \to p_c$ can be concluded semi-quantitatively by noting that for the very large $(r - 2b)$ values (that are relevant to the critical behavior), the $h_3(r - 2b)$ distribution function is expected to decrease as $\exp[-(r/2a)^3]$ for all neighbors [5]. Here, a is the average (see below) distance between neighboring sphere centers in the above 3D system. Hence, "finally" (i. e., for the largest r's or smallest g's) the "supply" of the g's (i. e. the function $h_3(r-2b)$) will not meet the "demand" of Eq. (32). This situation is different then from the situation described above (Eq. (33)) for the 1D case of $d < a-b$, for any value of $d/(a-b)$. Correspondingly, as demonstrated below, for these large r's, $f(g)$ will be a decreasing function of $1/g$. Strictly speaking, for the general 3D system the "ultimate" (i. e. at the $p \to p_c$ limit) the critical behavior will be universal as discussed in Sect. "The Basic Physics of the Non-universal Behavior of the Conductivity". However, the latter limit is rather experimentally [70] and so far computationallay [78] a non accessible (see below) and thus there is a great interest in the critical behavior of the system on route to this limit. To consider the latter behavior let us use the 1990 [126] result of Torquato, Lu and Robinstein for the 3D distribution function of the inter-particle distances of the first nearest neighbors, $h_3(r)$. The latter result can guide us in predicting the behavior of the more general $D > 1$ systems.

The relevant dominant term that as implied by their $h_3(r)$ is

$$H_3(r-2b) \propto A(\rho)(r-2b)^2 \exp\left\{-\left[8A(\rho)/b^3\right]\left[r^3-(2b)^3\right]\right\} , \quad (36)$$

where, $A(\rho) = [\rho v(1+\rho v)/(1-\rho v)^3]$, v is the hard core spheres volume $(4\pi/3)b^3$ in a system of a unit volume and ρ is their concentration (i. e., per unit volume of the sample). This concentration is related to the above $2a(> 2b)$ parameter (i. e. the average distance between the sphere-centers of two nearest neighbors) that, we simply define it here by $\int_{2b}^{\infty} h_3(r) r \mathrm{d}r$ [70]. A very rough, but geometrically more transparent, estimate of a (which is enough for the present discussion of the basic physics of the problem) can be given by assuming that the spheres are implanted randomly (as in the $a \gg b$ case). In this case a is associated with the average "territory" of a sphere, and is thus given by the relation

$$(4\pi/3)a^3\rho = 1 . \quad (37)$$

Returning to Eq. (36), we can follow the behavior of $f(g)$ by applying Eqs. (28), (32) and (36) in a way that yielded Eq. (33). The first feature that we encounter in $H_3(r-2b)$, and which has no counter part in $h_1(r-2b)$, is a peak at some r_m that is of the order of $2(a-b)$. For $r < r_m$ both $H_3(r-2b)$ and the resistance term $1/g \propto \exp[(r-2b)/2d]$ increase with increasing r and thus $f(g)$ increases with $1/g$. The rate of this increase may be very large for the small $r-2b$ values due to the dominance of the $(r-2b)^2$ term in Eq. (36) that can be translated to a $g^{-\alpha}$ behavior with $\alpha > 1$ for a limited g range, in some cases [24]. Of course, this strong dependence will be weakened for larger r's (smaller g's) as follows. Since $H_3(r-2b)$ stops increasing at r_m it is obvious that the maximum rate of the increase of $f(g)$ with $1/g$ will be obtained at some intermediate value r_p that is smaller than r_m. This yields then a corresponding g_p value (Eq. 32) such that $g_p > g_m$. However, the increase of $f(g)$ with $1/g$ does not necessarily stop at g_m. To see that let us now consider the $r > r_m$ regime. The dominant term of $H_3(r-2b)$ there is the exponential decrease of this function and thus, using the procedure suggested by Eqs. (33) and (36), we can express $f(g)$ now as $f(g) \propto g^{-\alpha(r)}$ where now we have a "local α" that is given by:

$$\alpha(r) = 1 - \left\{2d\left[8A(\rho)/b^3\right]\left[r^2+br+(2b)^2\right]\right\} . \quad (38)$$

Noting that r is a measure of $1/g$ we have here then, unlike the constant α of the 1D case, a "locally" varying $\alpha(r)$. Hence, for the $r > r_m$ regime we will have that for small (in comparison with $2a-2b$), $r-2b$ values, $\alpha(r) > 0$, i. e. $f(g)$ will still be increasing with increasing $1/g$. For larger r's however, $\alpha(r)$ will "eventually" become negative and thus $f(g)$ will decrease with $1/g$. Denoting the r value, at which $\alpha(r) = 0$, by r_t, we can summarize the behavior of $f(g)$ as follows. For small $1/g$ values $f(g)$ increases with g, obtaining a maximum rate of this increase at some g_p which is larger than g_m. Then, at some g_t (such that $g_t < g_m$) $f(g)$ will decrease as a function of $1/g$. Following now the premise of our model (as described in Sect. "The Basic Physics of the Non-universal Behavior of the Conductivity") i. e. the increase of $1/g_c$ with the decrease of $p-p_c$) we can now predict the critical behavior of the global conductance of the system and in particular the corresponding critical exponent as p approaches p_c. For p far above p_c, $\langle \mathbf{r_c} \rangle$ will have a diverging-like behavior with $p-p_c$ and thus a non universal value will be obtained for t. The value of this non universal t will reach its maximum at a p value, p_p, and then, for still smaller p values, it will decrease until at a low enough p value, p_t, it will become the universal value t_{un}. Hence, as we saw above, strictly speaking, the critical (i. e. in the $p \to p_c$ limit) behavior of the general $D > 1$ systems will always be the universal behavior.

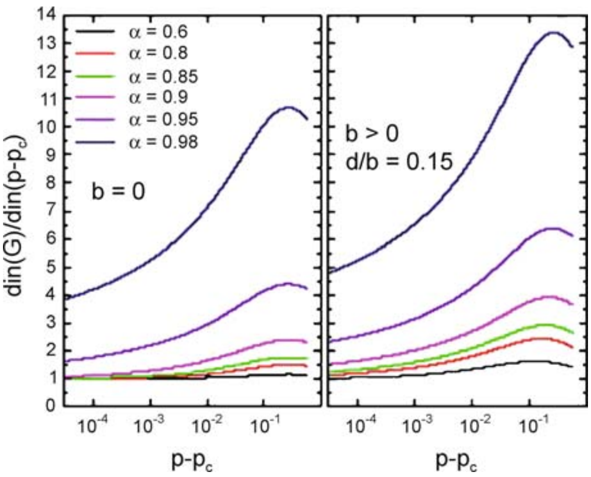
Since the value of $1/g_c$ and thus the values of $\langle \mathbf{r_c} \rangle$ and $\langle \mathbf{r} \rangle$ diverge as $p-p_c \to 0$, minute variations in the value of p cause very strong (orders of magnitude) variations in the former quantities. This implies that the variations that we described above for $1/g$, and thus for $f(g)$, actually take place over a narrow range of p when it is close to p_c. The first implication of that is that the use of a constant a (say, the one that applies to p_c) in the above equations (e. g. Eq. (37)) is a very good approximation. The second implication is that the "locally" (r range, g range or p range, see also Eq. (38)) determined value of t should be defined differentially as

$$t = \mathrm{d}[\ln G]/\,\mathrm{d}[\ln(p - p_c)] \,, \tag{39}$$

where G is the global conductance of the system. Using this definition and the g_c dependence on $p - p_c$, the above behavior of $f(g)$ can be translated to a p (or a $p - p_c$) dependence of t. We concluded above that far from p_c, t will increase with decreasing $p - p_c$ until it obtains its maximum, and from there on (i. e. for smaller p values) it will decrease until it reaches the corresponding universal value. The questions that arise are, of course, at what p, and for what value of $t - t_{\text{un}}$ will the peak t-value and the t-value transition happen, and how does this behavior depend on the parameters of the system [78]. The mathematical expression for the above described behaior has been developed very recently by Johner et al. [78] using the application of the Effective Medium Approximation (EMA). In that case, one essentially usses a lattice model, but with a distribution of bond or g-values taken by using the $f_3(g)$ function that is obtained by applying Eqs. (28), (32) and (36) to the basic EMA equation. They were able to show then that:

$$t - t_{\text{un}} = \left[(a-b)/d\right] \left\{\ln\left[yp/\left(p - p_c\right)\right]\right\}^{-2/3} \,, \tag{40}$$

where, $y = \exp[2b/(2a - 2b)]^3$. It is easy to appreciate that this expression follows the expected behavior as otlined above.



Continuum Percolation, Figure 8

The dependence of the (differential) conductivity exponent as calculated using the Effective Medium Approximation for a system of spheres, where 2*b* is their diameter and 2*d* is the tunneling decay constant. The results are presented for various values of the 1D parameter *α*, such that the higher the values of *α*, the smaller the local conductance values that are involved in the global conductance. (From [70])

Following our above discussion and the result given in Eq. (40), it is apparent that we cannot have a simple-complete mapping of the $D > 1$ systems (Eq. (38)) onto the K&S model as we had for the 1D model (Eq. (33)). On the other hand, the constant parameter α, of Eqs. (33) and (34), can be applied for the characterization of the above general $D > 1$ systems, since the three relevant length scales for all ($D \geq 1$) tunneling models are still the same i. e., a (see above), b and d. Using then $\alpha = 1 - d/(a - b)$ as the system characterization parameter, we show in Fig. 8 the above differential $t(p - p_c)$ dependence, as obtained by the application of the Effective Medium Approximation (EMA) to the 3D percolation tunneling system [70]. In this approximation, one notes that $t_{\text{un}} = 1$, but this (EMA value) is not important in the present context, since we are interested here in $t - t_{\text{un}}$. The results shown in Fig. 8, confirm then the above mentioned expectations and in particular that (as in the 1D case) the larger the value of α (in the $0 \leq \alpha \leq 1$ interval), i. e. the smaller the tunneling decay range in comparison with the inter-particle distances r (or, the smaller the corresponding g-values that are involved in the conduction), the more pronounced the non universal-like behavior (the larger the t values) that accompanies the conduction process. However, in contrast with the $D = 1$ case, the $t > t_{\text{un}}$ values are maintained only over a limited $p - p_c$ range, and "eventually" (as $p \to p_c$) a decrease of t towards the value of t_{un} takes place. In addition to this main result, i. e., the confirmation of the peak in the t dependence on p and its decrease to t_{un}, as p approaches p_c, we can derive further conclusions regarding the α dependence of the curves. First, for very small values of α, a non universal behavior will hardly be observed, and second, even though the shift of the $t(p)$ peak with increasing α is very small, it is obvious from our comparison of Eqs. (32) and (36) that this increase shifts the peak towards lower $p - p_c$ values. As to the meaning of this shift in practice, let us note that for a given type of a system (i. e., b and d fixed), the larger the value of a (the smaller the value of p), the more dilute the system. Correspondingly, as apparent from the smaller g values involved in the conduction process then, the decay of $H_3(r)$ in Eq. (36) will be "slower", and the non universal behavior will be also emphasized by the extension of the non universal behavior values into the lower $p - p_c$ regime. A similar argument can be derived from Eq. (38)

since the smaller the value of d/b the larger the value of $\alpha(r)$ i. e. the value of t for a given r. In passing, we also note that the parameters that determine the critical behavior can be controlled externally. For example, a voltage application effect on d, or a pressure application and temperature change on a, will change the value of α and thus the value of t. In that case, we expect to get a new class of phenomena that may be called "physically controlled percolation".

Considering the corresponding numerous data in the literature [128], one finds that there is no convincing direct experimental or Monte Carlo evidence, on a genuine continuum system, for the variation of $t(p)$ as predicted in Fig. 8, but there is some indirect evidence for that behavior (see below). The main reason for not observing the peaked $t(p)$ dependence in the experimental and computational works seems to be the accuracy of these data, or more importantly, the limited $p - p_c$ range that is actually accessible in the corresponding studies. For the experimental data, the latter effect can be appreciated as follows [70]. The proximity to the percolation threshold is usually given, as in Fig. 8, by the parameter $p - p_c$. However, this is not a good parameter for that purpose of the description of the proximity to the threshold in continuum systems. If both p and p_c are small, a small $p - p_c$ does not mean that the system is in close proximity to the critical regime. Rather, a quantity such as $(p - p_c)/p_c$ is a better indication of the proximity to the threshold. The problem is not too severe in lattices when one considers the resistors distribution imposed on lattices [88,111] since the p_c values are larger than 0.1 for two and three dimensions. This problem may be very severe, however, when one interprets experimental data in the continuum, where the proximity parameter is given in terms of the fractional occupied volume τ, and the corresponding critical fractional volume τ_c, i. e. by $(\tau - \tau_c)$. Here, while both, τ and τ_c can be very small, $(\tau - \tau_c)/\tau_c$ can be quite large, indicating that the system is far from the critical region. In this case, single, high, non universal-like, t values, are not too surprising in view of the above discussion, and the limited $(\tau - \tau_c)/\tau_c$ range hardly enables one to detect deviations from a single t value [70]. Computer simulations, on the other hand, "suffer" from finite size effects, and while a variable $t(p)$ behavior has been found [24,78], it has not yet been established to be beyond the influence of such effects.

However, more convincing, though indirect, confirmation of the t value variation with $p - p_c$ seems to be indicated by the experimental data on other electrical properties such as the resistance noise. For this property, the variation of the corresponding exponent, as a function of $\tau - \tau_c$, was found to indicate the decrease of t as τ approaches τ_c [40,42,85]. Hence, in view of the above, the transitions from a non universal behavior to a universal behavior seem to be well understood and well accounted for semiquantitatively, but further work is needed in order to examine this effect more quantitatively.

Future Directions

The relevance of the connectivity to the many areas of science mentioned in Sect. "Definition of the Subject", makes the achievements in the theory of continuum percolation of great importance to numerous natural and artificial systems. In particular, the understanding and conclusions derived from this theory in the last forty years serve as guides to the analysis and understanding of the various properties of these systems. Naturally then, future studies of continuum percolation are expected to proceed along two directions. The first is the further development of the theory itself and issues of principle and depth of understanding, such as the ones emphasized in the present review. The other direction is the application of the general conclusions and principles derived from the first direction for the understanding of the systems and properties such as those mentioned in Sect. "Definition of the Subject". The latter direction deserves quite a few reviews that will center on particular types of systems (say, solid composites and porous media) or particular properties (such as electrical noise and heterogeneous-fluid viscosity). Considering the wide scope of these many issues, we will mention here, as examples, only a couple of them that are relevant to systems and properties that became of wide interest only very recently.

On the very basic-scientific level, the establishment of continuum percolation as a phase transition that can be mapped onto the lattice percolation phase transition is desired, in order to determine rigorously and conclusively that the critical behavior of the geometrical-statistical properties is the same. Another fundamental theoretical problem is the derivation of the percolation thresholds and critical exponents rigorously. The first question that arises in that context is whether this can be done by another approach than the common one used thus far, i. e., the application of the theory of liquids, and whether such an approach can yield better results than that of the latter application. The second question is whether within the rather developed application of the theory of liquids, one can find a way to facilitate its implementation to the degree that will enable unbiased determination of percolation thresholds and critical exponents, as well as its application for "less trivial" objects than those considered thus far. On the more fundamental level of the latter problem, it is very interesting to know why this application is so successful for the description of the percolation behavior, even though the theory of liquids was not designed for the study of phase transitions.

Considering the empirical approach to the theory we note that the usefulness and the generalization of the concept of "pointedness" have not been studied extensively, in spite of its impressive predications concerning trends in the behavior of percolation thresholds in the continuum. The transparent physical-geometrical meaning of this concept calls then for its further utilization on the one hand, and for trying to understand the reasons for its success on the other hand. In particular we note that at present, the latter approach can be used much more readily and for many more systems than the above mentioned rigorous approach that is based on the theory of liquids. A specific problem that needs attention in order to derive a more complete understanding of the percolation threshold in continuum percolation is the value of B_c at the hardcore limit

Turning to the behavior of the dynamical properties, it appears that most of the basic principles of the corresponding theory are well understood by now. However, the problem of variable "bond strengths" is not well accounted for, in general, and beyond the "strong-interaction" limit (e. g., tunneling only to nearest neighbors) in particular. The meaning of the percolation threshold in corresponding systems and the predictions of the corresponding critical behaviors, are still open. In particular, the evaluation of the "residual" conductivity in comparison with the dominant percolation-like subnetwork has not been given thus far. For this, there is the need for the other corresponding parameters that characterize the charge, the mass, or energy, transfer between the objects in the system. It further appears however, that the most important information that one needs, when these principles are applied for the understanding of particular continuum systems, is the distribution function of the sizes and shapes of the objects in the system, as well as their separations. As emphasized in this review, this information is usually scarce, thus limiting the possible applications of the general understanding and principles outlined in Sect. "The Critical Behavior of the Dynamical Properties in the Continuum" to specific systems. Here, the utilization of very modern experimental characterization techniques, such as local probe microscopies, should provide the link needed for the above application. On the theoretical-computational end, the distribution functions associated with the structure, and thus with the dynamical physical properties, need to be derived, in order to appreciate trends in the critical behavior (i. e., the values of the critical exponents) in various systems. These trends will become amenable for examination, however, only with the ability to produce or find systems where the percolation threshold can be approached much more closely than at present, in the experiments, and to create much larger systems (in order to avoid finite size effects) in the computations. Such developments are expected to yield the (generally missing so far) information on the dependence of the critical exponents on the proximity to the percolation threshold. It appears then that the meaning of the percolation threshold, when farther than closest neighbors are involved (such as in the case of tunneling-percolation systems where the "interaction" range is not much smaller than the size of the objects), as well as the critical behavior of such systems, beyond the intuitive picture suggested in Sect. "The Critical Behavior of the Dynamical Properties in the Continuum", is very much called for.

Let us now turn to outline a few typical (of the numerous) questions associated with specific systems, in order to illustrate the issues and systems whose understanding rests on the concepts mentioned above. Such are the effects of charging and quantum confinement within corresponding particles that are embedded in a percolating system. The understanding of the interplay between these effects and the effects of the neighboring network is still in its infancy. This interplay has been shown recently to have pronounced effects not only on the transport, but also on the phototransport in such systems. Also, the effects of special features of the network, such as its fractal dimension, on the dynamical behavior are still a matter of controversy. Again, local probe microscopy, on the experimental end, and corresponding theoretical-computational work, on the other end, may resolve the corresponding problems. Another issue of great interest is the consideration of objects that are more complicated in their shape than the convex objects dealt with in the present review. Such are the systems that are of great present interest, i. e., carbon nanotube composites, where the objects can be described as having a "wavy" shape. One question that arises there, and that was dealt with only very recently, is the effect of this "wavyness" on the percolation threshold. A broader issue that is relevant to many systems, but for which no systematic discussion has been given thus far, is the relation between the trends in the critical behavior of the electrical, mechanical and rheological properties, in corresponding solids or molten composites. These are of great importance in the fields of chemical-material and electrical-material engineering.

Finally, a subject that has not been discussed in the context of continuum percolation, and, as we saw above, is mainly concerned with global properties of systems, is the statistics of finite clusters where there is, or there is no, interaction between the objects. This is of great importance for systems where the finite clusters as such determine the properties of interest, such as in cases where there is a charge transfer by a delocalization process. This is of importance, for example, in the cases of illumination-generated charge carriers, since there, the local connectivity of the system around the particle, in which the carriers were optically generated, determines the probability of their separation and thus the "deconfinement" and corresponding elimination of the radiative recombination.

Acknowledgments

The present review could not have been written without the stimulation and the intensive collaboration that I had with the many colleagues and students, whose papers that were co-authored with me, are cited in this review. In particular, I would like to thank Dr. C. Grimaldi and Dr. N. Wagner for the on going collaboration and for the critical reading of the present manuscript. This work was supported by the Israel Science Foundation (ISF). The author holds the Enrique Berman chair in Solar Energy Research at the Hebrew University.

Article Outline

Glossary

Degree of freedom (Sub)set of a physically reconfigurable system whose configuration can always be specified by a single variable.

Kinematics Geometric (and differential geometric) models of mechanical systems, not including effects of dynamics (masses, forces, inertias, etc.).

Robot A physically reconfigurable system that has multiple degrees of freedom and is (at least partially) computer-controlled.

Actuators Devices used to transfer mass (herein portions of a robot system) from one place to another within the system's environment.

Sensors Devices used to infer information, usually either about the internal state of a system, or about external environment surrounding that system.

Control Use of sensors and actuators to reconfigure a system (herein robots) according to a desired plan.

Continuum Continuous in nature; herein usually the backbone/core of a robot.

OctArm Continuum robot manipulator inspired by octopus arms.

AWE ("Animated Work Environment") Reconfigurable environment featuring continuum robot components, focused on work environments featuring computing.

Definition of the Subject

In this article, we discuss some of the key issues involved in the design and implementation of the emerging class of "invertebrate-like" continuum robots. Using two case studies of continuum robots developed recently at Clemson University, we overview the issues involved in realizing continuum robots and their deployment. The potential of these types of robots for enhanced productivity in novel applications is discussed.

In the first case study, we describe the design of the "OctArm" continuum manipulator robot hardware, and discuss the results of field testing of these novel "trunk-like" robots. OctArm robots are able to adapt their shape to their environment, to access difficult-to-reach areas, and to perform adaptive grasping using their entire arms. Lessons learned and implications for future robot manipulators in the field are discussed.

In the second case study, we describe the new "Animated Work Environment" (AWE) concept. AWE is an articulated, programmable, interior environment and chassis, embedded with integrated digital technologies. Featuring a continuum, morphing robot surface controlled by a user-friendly interface, AWE is characterized as adaptive and robust when applied to a range of work activities and working populations currently not accommodated by robotics.

The OctArm and AWE were selected as case studies to represent the potential broad range of application of continuum robots: the former suggests how continuum robots might operate in environments too harsh and hazardous for routine human activity, and the latter offers the promise of continuum robots in everyday interior environments supporting human collaboration and productivity.

Introduction

Industrial robot manipulators typically feature a small finite number (typically 4–6) of serially-connected rigid links. This is well-matched to factory "pick-and-place" applications, but such manipulators have not been generally successful in tackling more complex tasks (such as interacting with humans) in less structured environments. A frequently considered question in robot manipulator research is: "what happens as the number of joints becomes much larger, and ultimately increases towards infinity?" Examples of serial rigid-link systems with many joints exist in nature (snakes, mammalian and fish backbones, for example), and these biological "existence proofs" have provided motivation and insight for robot analysts and hardware designers for many years. This interest has resulted in the development of several special sub-classes of manipulators, collectively known as *redundant manipulators* [86].

A manipulator is said to be (kinematically) *redundant* if its configuration (joint) space degrees of freedom exceed its task space degrees of freedom. Hence, since spatial (end effector) task motions are generally six-dimensional, seven or eight degree of freedom spatial rigid-link manipulators are usually considered to be redundant. A manipulator is generally considered to be *hyperredundant* if its configuration (joint) space degrees of freedom greatly exceed its task space degrees of freedom. Hyperredundant manipulators have enhanced potential to use their extra joints for whole arm grasping/manipulation and maneuvering within tight obstacle fields. Their anticipated applications therefore include operations in congested environments (disaster relief, medical applications, etc.).

The field of hyperredundant manipulators has evolved in two major directions: "vertebrate-like" rigid-link designs, and "invertebrate-like" continuum manipulators [86]. Here we describe recent developments in continuum robots. Continuum robots are most typically defined by their "continuous backbone structures" – structures without the skeletal design of traditional rigid-link, robot manipulators [66,78]. Defined by this unusual structure, continuum robots may be described as "invertebrate-like" as opposed to the "vertebrate-like" nature of traditional robots [33]. Much research in the area takes inspiration from biology, and has often been strongly influenced by the design and functionality of invertebrate structures such as octopus arms [46,50,79,81] and elephant trunks [19,30,46,76,85]. As continuum designs can be scaled down to very small sizes [69,72,73], potential applications include medicine [4,12,68,75,82].

The main feature of continuum structures is their inherent smoothness. Instead of bending at discrete points (joints, or "elbows") along the "backbone", they can smoothly bend anywhere along their structure. Several designs, including the OctArm robots discussed in this article, additionally feature the ability to extend (elongate) along the length of the backbone. Almost all continuum robot designs exhibit significant compliance, i. e. they inherently present a "soft" rather than "stiff" interface to the environment.

Two functions in particular define the potential advantages of continuum robots: operation in congested environments and whole-arm grasping. In congested environments, the lack of "elbows" and the ability to bend at many locations allows continuum structures to "snake" in and through very tight obstacle fields. (Snakes are vertebrates, but their "links" are small and many, and their general movements match that of continuum structures.) There are numerous important arenas in which key applications of traditional robotics are currently impractical (many surgical applications, search and rescue operations in collapsed buildings, etc.) and where the effective deployment of continuum structures exhibiting snake-like behaviors would make a significant contribution to Society.

In whole-arm grasping, continuum robots again prove their potential advantage: their smooth and compliant nature allows them to gently interact with the world by adapting their shape to that of environmental objects (i. e.

contact along a continuum of the robot) [67]. Note that this is the form of adaptive manipulation used by biological continuum structures such as elephant trunks and octopus arms.

In the following case studies, we outline the design and development of two very different types of continuum robot design, the "OctArm" series of manipulator, and the "AWE" continuum surface. In both cases, the ability of the continuum robot structures to bend smoothly is key to enabling the innovative application scenarios.

Case Study 1: Trunk Continuum Robots – OctArm

Introduction to Octarm Robots

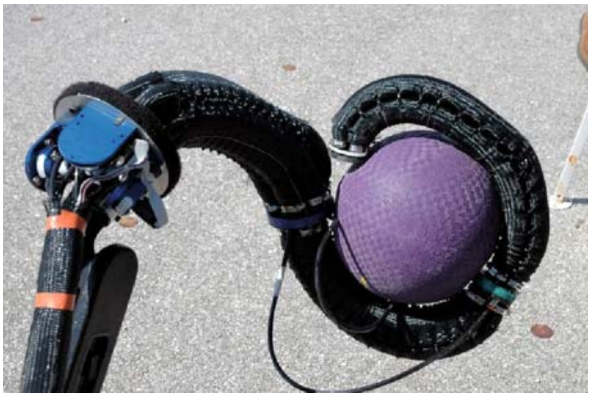
Continuum robot hardware designs can be sub-divided (via their means of actuation) into the categories of "extrinsically actuated" and "intrinsically actuated". Extrinsically actuated continuum robots have their actuators located outside the continuum structure itself, and typically transmit power to the continuum structure though tendons. Intrinsically actuated continuum robots have the actuators embedded in the continuum structure.

At Clemson, we have developed continuum robot hardware actuated both extrinsically and intrinsically. In this section, we discuss the OctArm series of intrinsically actuated continuum arms developed over the past several years under funding from DARPA. The OctArm design was significantly influenced by the underlying design of octopus arms [46,50,70]. Key OctArm design goals were to keep the arm as "soft" and compliant as possible, while incorporating the actuators in the body of the arm.

The resulting robots feature a serially arranged set of "sections". Each section corresponds roughly to a link in a conventional rigid link robot [71]. The variables determining changes in shape of each section correspond conceptually to "joint angles" in conventional robot arms. However, the shape of each section in the OctArm design is determined by two or more variables in a coupled nonlinear relationship. A series of kinematic models have been developed in order to command the OctArms into desired shapes. These models are easily generalized to a wide variety of previously proposed and constructed continuum robots.

Overview of Octarm Robots

The OctArm series of continuum robots feature three (or four) sections, each section having three degrees of freedom, for a total of nine (or twelve) degrees of freedom per arm (see Fig. 1, showing a three-section version) [64]. Each section has two degrees of bending freedom, and one degree of extension. The bending and extension in a section are achieved via variation of pressure in three "air muscles" (McKibben actuators) built into the system (in fact, the air muscles – tubes in the figure – form the majority of the arm structure).



Continuum Robots, Figure 1
Three-section Octarm V continuum robot

The arms are approximately one meter long, with a roughly circular cross-sectional profile, and are tapered from base to tip. The air pressure in the actuators is controlled via commercial pressure regulators, which form the inner loop of the feedback control system. At a higher level, commands to the pressure regulators are provided via a real-time kernel on a PC-104 system, with wireless interface to an operator control PC/joystick. The control code is written in C+. Algorithm development and user interface code utilize Matlab and Simulink modules [20].

The shape of the arms is measured via cables integrated into the arm. The cables change length as the arm moves; changes in cable length are then measured by encoders at the base; and the shape of the arm is inferred by changes in the cable length, following a geometric model. This approach gives a good approximate shape of the arm, which is displayed to the operator via a graphical interface, driven by the sensor information in real-time.

Related Work

Continuum robot hardware designs (usually arms/trunks or fingers/whiskers, though some robot snake/worm [33] designs also fit the classification) have appeared in the literature since the early 1960's [2]. Although there have been many proposed continuum robot designs [51], and numerous hardware realizations [3,10,15,29,35,36,37,47,53,61,62,84], until recently they have largely been "laboratory curiosities", used for a few "proof-of-concept" demonstrations and then abandoned. The main reason for this has been a lack of underlying theory, corresponding to traditional robot kinematics and dynamics, to enable the coordination of their degrees of freedom. This deficiency meant that even "simple" tasks such as moving the tip of the robots in a straight line were difficult if not impossible to achieve. This in turn has made it very difficult to apply continuum robots to real tasks.

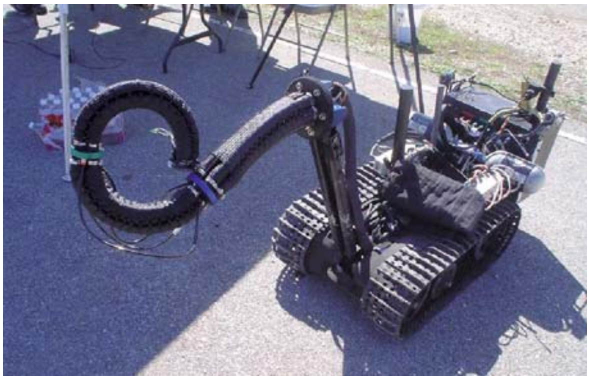
However, in the last ten years, a complete and general body of theory (at least for kinematics) has been established [38,39,40,58,59]. Our group at Clemson University has been a major contributor to this theory [24,25,26,30, 31,32,41,43,44,45,74,80] building on existing pioneer efforts [13,14,16,17,83]. This emerging body of understanding now enables the consistent coordination of the degrees of freedom within general continuum structures. Programming of continuum robots can now theoretically be done in terms of "task space" and "configuration space" in an analogous way to that for conventional robots.

At Clemson, the first author's group has demonstrated the ability for the "OctArm" continuum robot hardware to successfully maneuver through complex obstacle fields and grasp and manipulate objects of many different shapes over a wide range (orders of magnitude) of size and weight, and with widely different physical characteristics (rigid, soft, flexible ...) [8,9,18]. The following section describes the deployment of the OctArm hardware in realistic field trials.

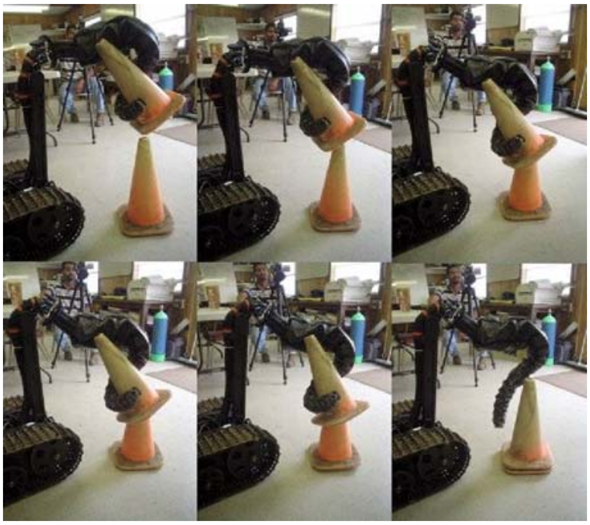
Example Octarm Field Trials

The OctArm system underwent extensive field trials in the spring of 2005 and 2006 at the Southwest Research Institute (SwRI) in San Antonio, Texas, USA [42,52]. The SwRI testbed is specially designed for the systematic evaluation of robotic systems in the field. The test environment includes rubble piles and a dry riverbed which can be flooded to create turbulent conditions. The main goal for the trials was to evaluate the ability of the OctArm system to stably and adaptively grasp a wide range of objects under a variety of conditions. For the field tests, OctArm V was mounted on a Foster–Miller TALON platform (shown in Fig. 2).

The OctArm base was attached to the second link of the TALON robot arm. The control valves and two air tanks provided nine channels of controlled pneumatic pressure. The control computer was mounted on the back of the TALON. The TALON and arm were controlled via wireless connection. The system was operated under joystick control via the wireless link and in view of the operator. More details of the user interface used are described in [20].



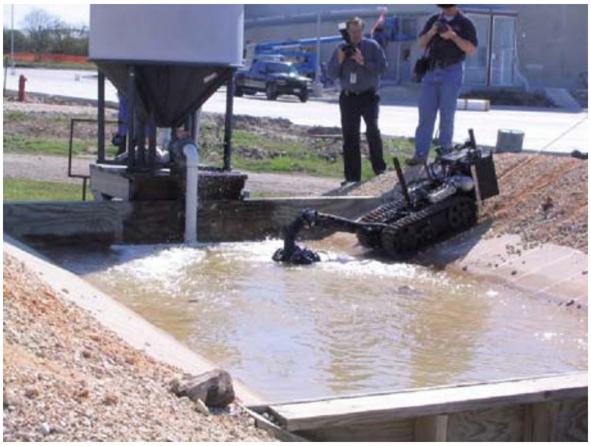
Continuum Robots, Figure 2
OctArm V mounted on Foster–Miller TALON system



Continuum Robots, Figure 3
Cone stacking task

Tasks included stacking and unstacking traffic cones (see Fig. 3). The ability of the system to grasp objects, such as spheres and cylinders, over a wide range of scales was recorded. These tasks are inherently problematic for traditional parallel jaw-end effectors. The operations were timed, videotaped, and recorded in detail to provide a baseline performance measure for continuum robots under the above conditions.

The system was also operated in water. Submerged in water (shown in Fig. 4), the OctArm attempted to grasp various payloads and to maintain grasps under turbulent flow. This tested the potential of the system for robust grasping under disturbances. The system was operated as well alongside rubble piles. This provided an initial benchmark for remote operation in congested environments.



Continuum Robots, Figure 4
Grasp in turbulent water

During the trials, the OctArm grasped and manipulated various sized cylinders and spheres. The system was able to successfully conform to the varying shapes of these payloads, demonstrating an ability to adapt to environmental conditions not found in traditional manipulators. The continuum system was able to successfully grasp both spherical (balls) and elongated objects (pieces of wood) within the underwater environment, and to maintain the grasps despite significant flow.

The results of the trials clearly demonstrated that continuum robot arms exhibit more adaptive and versatile operation than do conventional robot manipulators. Note that the continuum arm in these trials featured no shape sensing; the shapes displayed to the user was inferred only from the pressures at the actuator input valves. This proved a highly inaccurate estimate, as external effects such as sag due to gravity or external loading were not accounted for in any way. Shortly after the trials described in this section were performed, we integrated shape sensors into the design in order to reduce this inaccuracy.

Case Study 2: Continuum Robot Surfaces – AWE

Introduction to AWE

Our second case study features a novel robotic system where the continuum "trunk" is expanded into a continuum "surface". The surface forms a key part of our "Animated Work Environment" (AWE), aimed at work activities and working populations currently not accommodated by robotics [27,28].

A recent trend in the nature, place and organization of working life is the growing complexity of work, the emergence of new working populations (older workers, under-skilled workers, telecommuters and flexible shift workers), and the increasing likelihood that workers are working, at least part-time, at home. As the home becomes more an office, the office is becoming more a home, where "hot desks," lounges, sofas, WI-FI and internal networks have replaced office cubicles and hard-wired, isolated workstations. These dramatic transformations in the nature of work, combined with unprecedented new technologies associated with working life, suggest a re-evaluation of the relations between workers, their technologies and their work environments, and a redesign of the work environment itself as a socially and technologically responsive system occupying both home and office.

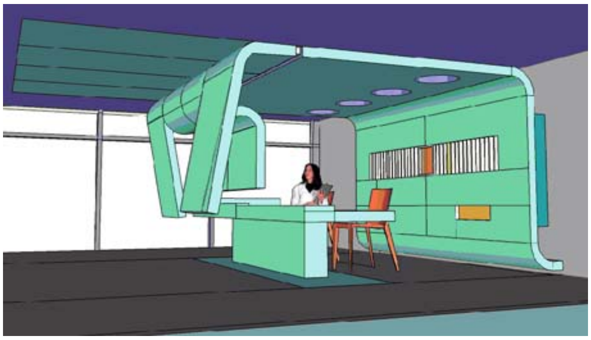
While investigators continue to realize promising components of the "intelligent" work environment – projectors, screens, tablets, sensors, actuators and other digital devices – our collaborative team is focused upon a novel but wholly compatible aspect of the "intelligent" work environment: the physical work space itself. The AWE concept challenges knowledge and understanding in both Architecture and Engineering by defining the "robot as a room" and the "room as a robot." This is a redefinition of what constitutes Architecture and Robotics and is not only a conceptual leap in the respective disciplines, but a fully appropriate, even necessary response to a condition in working life that is both social and technological.

The need to "program the room" both stimulates and is enabled by existing and ongoing efforts in Information Technology and "intelligent environments." More broadly, AWE challenges present understanding in both Architecture and Computer and Information Science and Engineering by recognizing computer software, networks and devices not as isolated aspects of a digital society but as constituents of an integral environmental system, far more productive and more accessible than any of its parts. In this way, the AWE concept aims to expand the vision of researchers, developers and manufacturers of information technologies to recognize the physical environment as an integral and necessary part of the dynamic interaction between people and the digital realm.

Overview of AWE

The ongoing dramatic transformation in working life, including the introduction of ever new digital technologies, presents problems and opportunities to all workers, particularly to segments of the working population that are emerging and neglected: telecommuters, flexible shift workers, single parents, elders, recent immigrants, the obese, the handicapped and, other individuals requiring special accommodations.

Continuum Robots, Figure 5
AWE concept – SLEEPING



Continuum Robots, Figure 6
AWE concept – COMPOSING

This dramatic shift in the nature, place and organization of working life motivates our research which, in the simplest of terms, involves the designing, prototyping, demonstrating and evaluating of a prototypical "robot-room" with embedded Information Technologies that we call an "Animated Work Environment" (AWE) (Figs. 5 and 6).

The strength of AWE is made clearer by recognizing what it isn't: it isn't a building, or a room, or a "stand-alone" device, or a software application, or a piece of furniture. Instead, AWE is a user-friendly, programmable environment, both digital and analog, high-tech and low-tech, fitted to home and office, that users adjust along a continuum, providing the sense of being more "at home" or more "at work," more leisurely or more productive, more efficient or more innovative, while facilitating multiple activities.

In concept, AWE is envisioned as an information-rich environment featuring the ability to continuously "morph" its continuum surfaces to accommodate a wide range of user needs. At the core of this environment (though not exclusively comprising it) are smooth, continuously deformable "smart" continuum surfaces whose configuration, and hence functionality, are user-controllable. In addition to this novel aspect, AWE embodies a range of "off-the-shelf" Information Technology (IT) components: embedded commercially-available sensors that, when suitably exploited, make AWE user-friendly and intelligent; radio-frequency identification (RFID) tags that allow AWE to associate printed and digital materials; and integrated display screens, scanners, projectors, keyboards and audio speakers that make AWE useful as a total work environment programmable to suit a range of work needs and situations.

Related Work

Few precedents for AWE are found in the work environments being researched and developed by IT and the architectural design industries. The most promising of these efforts are perhaps IBM's "Blue Space" [34] and IDEO's "Q" [65], both important steps towards integrating IT and Design. Compared to our vision of AWE, however, "Blue Space" contains fewer and more timid "smart" components and a narrower range of embedded IT peripherals; and "Q," accommodates only one user who must be seated, supports a far more limited range of work activities, and cannot be reconfigured in the way AWE promises. A more enticing integration of design and IT is found in numerous efforts offered by Phillips as "Ambient Intelligence" 0; but as single products rather than complex environments, these too fall short of AWE's promise.

Additionally, while numerous research efforts in ubiquitous computing [6,7,22,23,60] are viewed by the AWE team as significant, compatible, and parallel efforts to our own research, the difference between the AWE project and these efforts is made clear by a compelling research project from University of Massachusetts titled "NeTS: Animated Spaces for the Digital Society" [60]. While this project's title and broad objective to "bridge the gap between the physical and digital worlds" sounds strikingly similar to our own, "NeTS" focuses on employing Radio Frequency Identification to link objects with their placement in a room, rather than creating, as envisioned for AWE, the physical room itself, rendered intelligent and embedded with a range of IT technologies. Our AWE research effort focuses less on developing and interfacing individual IT elements that might be embedded in AWE, and more on cultivating the dynamic, reinforcing and reconfigurable relationships between the digital and physical (i. e. environmental) realms responsive to workers and working life in a digital society.

Precedents that most significantly impact our development of AWE, a robot-room, are those few where Architectural and CISE researchers collaborate to realize intelligent physical environments. In broad theoretical terms, the AWE team is inspired by two such convergences drawn from William Mitchell's trilogy of books on IT and the built environment [55,56,57]. The first is Mitchell's vision of the building as a computer: "The building of the near future will function more and more like large computers" [56]. The second is Mitchell's vision of the building as a robot: "Our buildings will become … robots for living in" [56].

It is worth noting that Mitchell moves easily between MIT's School of Architecture and its Media Lab, and that his vision of the building-as-robot is not altogether radical when we recognize that the first known treatise of architecture, by Vitruvius, laid claims to machine design as the proper domain of architecture [49,77]. Indeed, the "smart house" projects by Mitchell's group [48] and others, and, more significantly, the programmable, robotic wall by dECOi [21] and robotic pavilions by Kas Oosterhuis [63], hint at the promise of converging architectural design, interface design and robotic design. AWE draws from these precedents the open source, chassis/plug-in strategy of MIT's *House* [48], the seamless integration of IT and architecture suggested by the MIT/FPC *Media House* [54], and the real-time configurability of the programmable *WEB* pavilion of Oosterhuis [63].

However as "houses," "walls," and "pavilions," these significant precedents for our research, by definition, are not explicitly designed for specified human activities and so, suffer from being too diffuse; whereas AWE, operating at the smaller scale of the room, employing novel morphing surfaces, and devoted to facilitating working life, makes more of its association of new technologies, the physical environment and very particular social conditions.

Example AWE Scenario

The following scenario begins to illustrate the operation and promise of AWE.

Situation Laura, a single-mother/biologist, presents her research proposal before a committee in two weeks. Laura's proposal draws significantly from documents in digital format, notes from a recent conference, a video she made, and several books. She is working on her proposal mostly at home but also at her faculty office. Meanwhile Laura's nephew Roberto, a college student, is visiting from Latin America.

Before AWE Laura's documents are spread over the desk, computer, floor, and filing cabinet of her home office. Books are opened, face-down, to critical pages. One of these books and two of the digital papers are most important to her proposal. She's periodically disrupted by her four-year old child, Eric, who pulls materials off Laura's desk when he wants her attention. Laura senses that her nephew Roberto has a real interest in science, but she doesn't know how to sustain this interest over his visit, and, anyhow, he's on vacation – easily distracted and easily bored.

Working with AWE for the first time AWE is installed and ready to operate in Laura's living room (Fig. 5). It looks to her more like a dining room table than an office desk, a cubicle, or a work station. Laura quickly recognizes six prominent icons on AWE's work surface that read: COMPOSING, PRESENTING, COLLABORATING, MEETING, VIEWING, PLAYING.

As Laura urgently needs to work on her research proposal, she imagines COMPOSING best defines her needs and engages that icon. Quickly and steadily, four ribbons descend from the ceiling, each embedded with a computer screen arrayed at eye level when seated at the work surface (Fig. 6). The four screens light-up and a keyboard and mouse pop up from the work surface. In the short time that AWE sets itself up for COMPOSING, Laura discovers a toggle option marked SMART / PROGRAM and decides on toggling SMART mode. Nothing happens; that is, until Laura has organized her printed materials and coffee cup on AWE's work surface and sits before its array of four lit screens.

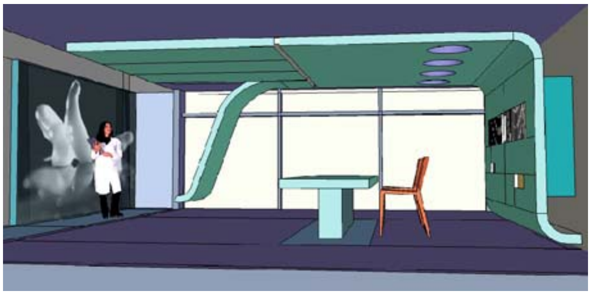
Laura takes notice of a slowly moving curtain encircling one end of AWE's work surface to provide privacy and sound dampening for COMPOSING. Laura's scientific mind correctly infers that AWE, in its simple intelligence, has recognized that she is presently seated, COMPOSING, and so is likely to require this kind of gentle enclosure to facilitate her work. She also senses that AWE has adjusted its overhead lighting to facilitate her focused work. But the desk is too low for Laura's height. Laura moves her hand towards the work surface where she sees the outline of a hand, marked RISE, at which point the surface rises to a height at which Laura is comfortable. The surface stops rising when Laura removes her hand. Laura now presses and holds the COMPOSING button to save this particular setting and then types "Laura – Research Presentation" to define this personal setting. At a later occasion, Laura can simply press COMPOSING to return AWE to this configuration.

Laura now assigns four digital documents to the four digital screens: two screens display the two most important articles, a third displays the video, and the fourth screen displays the titles of some non-digital documents Laura is using to compose the presentation – her handwritten conference notes, nine printed articles, and four books. Laura clicks on the title of a particular printed article she's soon to need, and the screen reports to her that this article (with attached RFID tag), is located in slot-24 of AWE's physical filing system. The lit door over file slot-24 helps Laura quickly locate and retrieve the article.

Laura now touches, one at a time, the two screens displaying the two most important articles for her proposal and these, in AWE's simple intelligence, follow Laura's hand, extending and slightly twisting to a more accessible position for her. In a like manner, Laura sends the two screens displaying the video and the non-digital documents a short distance away and above her so that she is aware of, but not distracted by them.

Forty minutes into her work, Laura becomes aware of her son Eric, growing restless. But Eric, seeing his mother intently working through AWE's translucent privacy curtain, entertains himself for another five minutes. Then, the inevitable: Eric, intent on getting his mother's attention, lunges for the printed article Laura has just retrieved. At that moment, Laura toggles the icon on AWE's work surface labeled COVER/UNCOVER to COVER. A thin but sturdy surface originates from below, covering Laura's materials that had been distributed methodically by her across the work surface. The new surface provides space for Laura and Eric to color some pictures for ten minutes – their pact.

After ten minutes of coloring, Eric seems content to entertain himself for a little while longer, and Laura toggles UNCOVER to reveal the organization of her work surface again. Laura decides it's time to rehearse the first segment of her presentation. Simply engaging the PRESENTING icon establishes the new configuration (Fig. 7). (Alternatively, Laura could select INTENT INFERENCING in AWE's set-up menu, so that AWE begins configuring the PRESENTING mode when it recognizes Laura standing in a location where one would give a presentation.) In PRESENTING mode, three of AWE's display screens retract into the ceiling and the fourth screen, displaying Laura's developing *Powerpoint* presentation, spins 180 degrees to face her. Three projectors also are turned on: one projects the *Powerpoint* presentation on the wall surface next to Laura while the other two projectors display, on two adjacent walls, the visual sensation of a small lecture hall where one might make a presentation. AWE's lighting and acoustics are likewise adjusted to simulate the atmosphere of the hall.



Continuum Robots, Figure 7
AWE concept – Presenting

After 30 minutes of rehearsing, Laura remembers its time she drop Eric at the day care and then, to return to her faculty office for a scheduled appointment. Before leaving the house, Laura withdraws, from a USB port in AWE, a portable storage device containing the digital information held in her home-based AWE system.

Stopped at a red traffic light on her way to the University, Laura has an epiphany about her developing proposal. Upon entering her faculty lab where AWE is also installed, Laura inserts the portable storage device into AWE to quickly match the AWE configuration she left at home. Without having to reach for a notepad and without losing the time of transcription, Laura is easily integrating her "epiphany" into the developing presentation. Laura also adjusts AWE's on-screen ATMOSPHERE settings to better approximate, for her next rehearsal, the sense of the conference room where she will finally present her proposal.

At home, Roberto employs AWE to view materials that Laura has given him access to. Among these is a recording of Laura's earlier conversation with Roberto about AWE and her developing work, presented by AWE as a video for Roberto to review and examine. Roberto, a college student, prefers lounging in an upholstered chair to sitting at a desk. Using AWE's simple intelligence, Roberto adjusts AWE's work surface from the default VIEWING configuration to a slightly tilted and lower configuration that better suits his lounging. As well, Roberto elects to bring the single screen displaying Laura's video more proximate to him, guiding the screen with his hand. Roberto saves this VIEWING figuration as, simply, "Roberto" for future retrieval.

When Laura returns from the University, Roberto excitedly announces to his aunt that using AWE, he's discovered a curious link between something she's considering in her research and research activities occurring in his native country, which he discovered on the internet.

When Roberto grows tired from all his explorations facilitated by AWE, Laura, with a simple activation of the COMPOSING option, recovers the physical organization of her materials as before, and continues developing her presentation.

In sum, AWE affords responsiveness to needs – particular and dynamic, cognitive and kinesthetic – of individual users in fluid social organizations and work patterns.

Summary

The two case studies discussed in this article demonstrate the potential for continuum structures to transform the nature of robot applications. The OctArm continuum robots described herein have successfully grasped and manipulated objects over a wide range of sizes and scales in the laboratory, demonstrating the ability to adapt their shape to that of a wide variety of payloads. Additionally, the field tests demonstrated the ability of the continuum robots to operate successfully in realistic application environments, both in air and in water, and to maintain grasp-stability under dynamic disturbances.

AWE, by recognizing the physical environment as an integral aspect of the dynamic interaction between people and the digital realm, constitutes an early, socially significant initiative featuring continuum robots by a team of "collaborative environment designers," defined by Mark Burry as "architects" working "along with their new collaborating experts … in computer science … and engineering" [11].

Future Directions

The AWE environment, featuring continuum robot surfaces, is a "look at the future" for continuum robotics. AWE is a direct extension of the activities within Clemson University's *Animated Architecture Lab*, a research and teaching body founded by the second author in which engineering, architecture and the social sciences converge. The AWE project is currently being realized, as a result of these efforts, as a working prototype at full-scale.

Our ongoing efforts with the OctArm robots focus on enhanced designs incorporating significantly higher arm strength, and on the integration of sensors to guide remote operation in congested obstacle fields. We anticipate "multi-arm" versions of the hardware being developed in the near future.

Glossary

$\mathbb{R}$ denotes the **real line**, $\mathbb{R}^n$ the n-dimensional Euclidean space, $x \cdot y$ stands for the Euclidean scalar product of $x, y \in \mathbb{R}^n$, and $|x|$ for the norm of x.

State variables quantities describing the state of a system; in this note they will be denoted by u; in the present setting, u will be either a function defined on a subset of $\mathbb{R} \times \mathbb{R}^n$, or a function of time taking its values in an Hilbert space H.

Space domain the subset of $\mathbb{R}^n$ on which state variables are defined.

Partial differential equation a differential equation containing the unknown function as well as its partial derivatives.

State equation a differential equation describing the evolution of the system of interest.

Control function an external action on the state equation aimed at achieving a specific purpose; in this note, control functions they will be denoted by f; f will be used to denote either a function defined on a subset of $\mathbb{R} \times \mathbb{R}^n$, or a function of time taking its values in an Hilbert space F. If the state equation is a partial differential equation of evolution, then a control function can be:

1. *distributed* if it acts on the whole space domain;
2. *locally distributed* if it acts on a subset of the space domain;
3. *boundary* if it acts on the boundary of the space domain;
4. *optimal* if it minimizes (together with the corresponding trajectory) a given cost;
5. *feedback* if it depends, in turn, on the state of the system.

Trajectory the solution of the state equation u_f that corresponds to a given control function f.

Distributed parameter system a system modeled by an evolution equation on an infinite dimensional space, such as a partial differential equation or a partial integro-differential equation, or a delay equation; unlike systems described by finitely many state variables, such as the ones modeled by ordinary differential equations, the information concerning these systems is "distributed" among infinitely many parameters.

$\mathbb{1}_A$ denotes the **characteristic function** of a set $A \subset \mathbb{R}^n$, that is,

$$\mathbb{1}_A(x) = \begin{cases} 1 & x \in A \\ 0 & x \in \mathbb{R}^n \setminus A \end{cases}$$

∂_t , ∂_{x_i} denote **partial derivatives** with respect to t and x_i, respectively.

$L^2(\Omega)$ denotes the **Lebesgue space** of all real-valued square integrable functions, where functions that differ on sets of zero Lebesgue measure are identified.

$H^1_0(\Omega)$ denotes the **Sobolev space** of all real-valued functions which are square integrable together with their *first order* partial derivatives in the sense of distributions in Ω, and vanish on the boundary of Ω; similarly $H^2(\Omega)$ denotes the space of all functions which are square integrable together with their *second order* partial derivatives.

$H^{-1}(\Omega)$ denotes the dual of $H^1_0(\Omega)$.

$\mathcal{H}^{n-1}$ denotes the $(n-1)$-dimensional **Hausdorff measure**.

H denotes a **normed spaces** over $\mathbb{R}$ with norm $\|\cdot\|$, as well as an **Hilbert space** with the scalar product $\langle\cdot,\cdot\rangle$ and norm $\|\cdot\|$.

$L^2(0, T; H)$ is the space of all square integrable functions $f\colon [0, T] \to H$; $C([0, T]; H)$ (continuous functions) and $H^1(0, T; H)$ (Sobolev functions) are similarly defined .

Given Hilbert spaces F and H, $\mathcal{L}(F, H)$ denotes the (Banach) space of all bounded linear operators $\Lambda\colon F \to H$ with norm $\|\Lambda\| = \sup_{\|x\|=1} \|\Lambda x\|$ (when $F = H$, we use the abbreviated notation $\mathcal{L}(H)$); $\Lambda^*\colon H \to F$ denotes the adjoint of Λ given by $\langle \Lambda^* u, \phi\rangle = \langle u, \Lambda\phi\rangle$ for all $u \in H, \phi \in F$.

Definition of the Subject

Control theory (abbreviated, CT) is concerned with several ways of influencing the evolution of a given system by an external action. As such, it originated in the nineteenth century, when people started to use mathematics to analyze the perfomance of mechanical systems, even though its roots can be traced back to the calculus of variation, a discipline that is certainly much older. Since the second half of the twentieth century its study was pursued intensively to address problems in aerospace engineering, and then economics and life sciences. At the beginning, CT was applied to systems modeled by ordinary differential equations (abbreviated, ODE). It was a couple of decades after the birth of CT—in the late sixties, early seventies—that the first attempts to control models described by a partial differential equation (abbreviated, PDE) were made. The need for such a passage was unquestionable: too many interesting applications, from diffusion phenomena to elasticity models, from fluid dynamics to traffic flows on networks and systems biology, can be modeled by a PDE.

Because of its peculiar nature, control of PDE's is a rather deep and technical subject: it requires a good knowledge of PDE theory, a field of enormous interest in its own right, as well as familiarity with the basic aspects of CT for ODE's. On the other hand, the effort put into this research direction has been really intensive. Mathematicians and engineers have worked together in the construction of this theory: the results—from the stabilization of flexible structures to the control of turbulent flows—have been absolutely spectacular.

Among those who developed this subject are A. V. Balakrishnan, H. Fattorini, J. L. Lions, and D. L. Russell, but many more have given fundamental contributions.

Introduction

The basic examples of controlled partial differential equations are essentially two: the heat equation and the and the wave equation. In a bounded open domain $\Omega \subset \mathbb{R}^n$ with sufficiently smooth boundary Γ the *heat equation*

$$\partial_t u = \Delta u + f \quad \text{in } Q_T \doteq (0,T)\times\Omega \tag{1}$$

describes the evolution in time of the temperature $u(t,x)$ at any point x of the body Ω. The term $\Delta u = \partial^2_{x_1} u + \cdots + \partial^2_{x_n} u$, called the Laplacian of u, accounts for heat diffusion in Ω, whereas the additive term f represents a heat source. In order to solve the above equation uniquely one needs to add further data, such as the initial distribution u_0 and the temperature of the boundary surface Γ of Ω. The fact that, for any given data $u_0 \in L^2(\Omega)$ and $f \in L^2(Q_T)$ Eq. (1) admits a unique weak solution u_f satisfying the boundary condition

$$u = 0 \quad \text{on} \quad \Sigma_T \doteq (0,T)\times\Gamma \tag{2}$$

and the initial condition

$$u(0,x) = u_0(x) \quad \forall x = (x_1,\dots,x_n) \in \Omega \tag{3}$$

is well-known. So is the maximal regularity result ensuring that

$$u_f \in H^1\left(0,T;L^2(\Omega)\right) \cap C\left([0,T];H^1_0(\Omega)\right) \cap L^2\left(0,T;H^2(\Omega)\right) \tag{4}$$

whenever $u_0 \in H^1_0(\Omega)$. If problem (1)–(3) possesses a unique solution which depends continuously on data, then we say that the problem is *well-posed*.

Similarly, the *wave equation*

$$\partial_t^2 u = \Delta u + f \quad \text{in} \quad Q_T \tag{5}$$

describes the vibration of an elastic membrane (when $n=2$) subject to a force f. Here, $u(t,x)$ denotes the displacement of the membrane at time t in x. The initial condition now concerns both initial displacement and velocity:

$$\forall x \in \Omega \qquad \begin{cases} u(0,x) = u_0(x) \\ \partial_t u(0,x) = u_1(x)\,. \end{cases} \tag{6}$$

It is useful to treat the above problems as a first order *evolution equation* in a Hilbert space H

$$u'(t) = Au(t) + Bf(t) \quad t \in (0,T)\,, \tag{7}$$

where $f(t)$ takes its valued in another Hilbert space F, and $B \in \mathcal{L}(F,H)$. In this abstract set-up, the fact that (7) is related to a PDE translates into that the closed linear operator A is not defined on the whole space but only on a (dense) subspace $D(A) \subset H$, called the *domain* of A; such a property is often referred to as the *unboundedness* of A.

For instance, in the case of the heat equation (1), $H = L^2(\Omega) = F$, and A is defined as

$$\begin{cases} D(A) = H^2(\Omega) \cap H^1_0(\Omega) \\ Au = \Delta u\,, \quad \forall u \in D(A)\,, \end{cases} \tag{8}$$

whereas $B = I$.

As for the wave equation, since it is a second order differential equation with respect to t, the Hilbert space H should be given by the product $H^1_0(\Omega)\times L^2(\Omega)$. Then, problem (5) is turned into the first order equation

$$U'(t) = \mathcal{A}U(t) + Bf(t) \quad t \in (0,T)\,,$$

where

$$U = \begin{pmatrix} u \\ v \end{pmatrix}, \quad B = \begin{pmatrix} 0 \\ I \end{pmatrix}, \quad F = L^2(\Omega)\,.$$

Accordingly, $\mathcal{A}\colon D(\mathcal{A}) \subset H \to H$ is given by

$$\begin{cases} D(\mathcal{A}) = \left(H^2(\Omega)\cap H^1_0(\Omega)\right)\times H^1_0(\Omega) \\ \mathcal{A}U = \begin{pmatrix} 0 & I \\ A & 0 \end{pmatrix} U = \begin{pmatrix} v \\ Au \end{pmatrix} \quad \forall U \in D(\mathcal{A})\,, \end{cases}$$

where A is taken as in (8).

Another advantage of the abstract formulation (7) is the possibility of considering locally distributed or boundary source terms. For instance, one can reduce to the same set-up the equation

$$\partial_t u = \Delta u + \mathbb{1}_\omega f \quad \text{in} \quad Q_T\,, \tag{9}$$

where $\mathbb{1}_\omega$ denotes the characteristic function of an open set $\omega \subset \Omega$, or the nonhomogeneus boundary condition of Dirichlet type

$$u = f \quad \text{on} \quad \Sigma_T\,, \tag{10}$$

or Neumann type

$$\frac{\partial u}{\partial \nu} = f \quad \text{on} \quad \Sigma_T\,, \tag{11}$$

where ν is the outward unit normal to Γ. For Eq. (9), B reduces to multiplication by $\mathbb{1}_\omega$—a bounded operator on $L^2(\Omega)$; conditions (10) and (11) can also be associated to suitable linear operators B—which, in this case, turn out to be unbounded. Similar considerations can be adapted to the wave equation (5) and to more general problems.

Having an efficient way to represent a source term is essential in control theory, where such a term is regarded as an external action, the *control function*, exercised on the *state variable* u for a purpose, of which there are two main kinds:

- *positional*: $u(t)$ is to approach a given target in X, or attain it exactly at a given time $t > 0$;
- *optimal*: the pair (u, f) is to minimize a given functional.

The first criterion leads to *approximate* or *exact controllability* problems in time t, as well as to *stabilization* problems as $t \to \infty$. Here, the main tools will be provided by certain estimates for partial differential operators that allow to study the states that can be attained by the solution of a given controlled equation. These issues will be addressed in Sects. "Controllability" and "Stabilization" for linear evolution equations. Applications to the heat and wave equations will be discussed in the same sections.

On the other hand, *optimal control problems* require analyzing the typical issues of optimizations: existence results, necessary conditions for optimality, sufficient conditions, robustness. Here, the typical problem that has been successfully studied is the Linear Quadratic Regulator that will be discussed in Sect. "Linear Quadratic Optimal Control".

Control problems for nonlinear partial differential equations are extremely interesting but harder to deal with, so the literature is less rich in results and techniques. Nevertheless, among the problems that received great attention are those of fluid dynamics, specifically the *Euler equations*

$$\partial_t u + (u \cdot \nabla)u + \nabla p = 0$$

and the *Navier–Stokes equations*

$$\partial_t u - \mu\Delta u + (u \cdot \nabla)u + \nabla p = 0$$

subject to a *boundary control* and to the incompressibility condition $\operatorname{div} u = 0$.

Controllability

We now proceed to introduce the main notions of controllability for the evolution equation (7). Later on in this section we will give interpretations for the heat and wave equations.

In a given Hilbert space H, with scalar product $\langle \cdot, \cdot \rangle$ and norm $\| \cdot \|$, let

$$A \colon D(A) \subset H \to H$$

be the *infinitesimal generator* of a *strongly continuous semigroup* e^{tA}, $t \geq 0$, of bounded linear operators on X. Intuitively, this amounts to saying that $u(t) \doteq e^{tA} u_0$ is the unique solution of the Cauchy problem

$$\begin{cases} u'(t) = Au(t) & t \geq 0 \\ u(0) = u_0 \,, \end{cases}$$

in the classical sense for $u_0 \in D(A)$, and in a suitable generalized sense for all $u_0 \in H$. Necessary and sufficient conditions in order for an unbounded operator A to be the infinitesimal generator of a strongly continuous semigroup are given by the celebrated Hille–Yosida Theorem, see, e. g. [99] and [55].

Abstract Evolution Equations

Let F be another Hilbert space (with scalar product and norm denoted by the same symbols as for H), the so-called *control space*, and let $B \colon F \to H$ be a linear operator, that we will assume to be bounded for the time being. Then, given $T > 0$ and $u_0 \in H$, for all $f \in L^2(0, T; F)$ the Cauchy problem

$$\begin{cases} u'(t) = Au(t) + Bf(t) & t \geq 0 \\ u(0) = u_0 \end{cases} \tag{12}$$

has a unique *mild solution* $u_f \in C([0, T]; H)$ given by

$$u_f(t) = e^{tA} u_0 + \int_0^t e^{(t-s)A} Bf(s) \quad \forall t \geq 0 \tag{13}$$

Note 1 Boundary control problems can be reduced to the same abstract form as above. In this case, however, B in (12) turns out to be an unbounded operator related to suitable fractional powers of $-A$, see, e. g., [22].

For any $t \geq 0$ let us denote by $\Lambda_t \colon L^2(0, t; F) \to H$ the bounded linear operator

$$\Lambda_t f = \int_0^t e^{(t-s)A} Bf(s)\, ds \quad \forall f \in L^2(0, t; F)\,. \tag{14}$$

The *attainable* (or *reachable*) set from u_0 at time t, $\mathcal{A}(u_0, t)$ is the set of all points in H of the form $u_f(t)$ for some control function f, that is

$$\mathcal{A}(u_0, t) \doteq e^{tA} u_0 + \Lambda_t L^2(0, t; F)\,.$$

We introduce below the main notions of controllability for (7). Let $T > 0$.

Definition 1 System (7) is said to be:

- **exactly controllable** in time T if $\mathcal{A}(u_0, T) = H$ for all $u_0 \in H$, that is, if for all $u_0, u_1 \in H$ there is a control function $f \in L^2(0, T; F)$ such that $u_f(T) = u_1$;
- **null controllable** in time T if $0 \in \mathcal{A}(u_0, T)$ for all $u_0 \in H$, that is, if for all $u_0 \in H$ there is a control function $f \in L^2(0, T; F)$ such that $u_f(T) = 0$;
- **approximately controllable** in time T if $\mathcal{A}(u_0, T)$ is dense in H for all $u_0 \in H$, that is, if for all $u_0, u_1 \in H$ and for any $\varepsilon > 0$ there is a control function $f \in L^2(0, T; F)$ such that $\|u_f(T) - u_1\| < \varepsilon$.

Clearly, if a system is exactly controllable in time T, then it is also null and approximately controllable in time T. Although these last two notions of controllability are strictly weaker than strong controllability, for specific problems—like when A generates a strongly continuous group—some of them may coincide.

Since controllability properties concern, ultimately, the range of the linear operator Λ_T defined in (14), it is not surprising that they can be characterized in terms of the adjoint operator $\Lambda_T^*\colon H \to L^2(0, T; F)$, which is defined by

$$\int_0^T \langle \Lambda_T^* u(s), f(s)\rangle \mathrm{d}s = \langle u_0, \Lambda_T f\rangle \qquad \forall u \in H\,,\ \forall f \in L^2(0, T; F)\,.$$

Such a characterization is the object of the following theorem. Notice that the above identity and (14) yield

$$\Lambda_T^* u(s) = B^* \mathrm{e}^{(T-s)A^*} u \quad \forall s \in [0, T]\,.$$

Theorem 1 *System (7) is:*

- ***exactly controllable*** *in time T if and only if there is a constant $C > 0$ such that*
$$\int_0^T \left\|B^* e^{tA^*} u\right\|^2 dt \geq C\|u\|^2 \quad \forall u \in H\,; \tag{15}$$
- ***null controllable*** *in time T if and only if there is a constant $C > 0$ such that*
$$\int_0^T \left\|B^* e^{tA^*} u\right\|^2 dt \geq C\left\|e^{TA^*} u\right\|^2 \quad \forall u \in H\,; \tag{16}$$
- ***approximately controllable*** *in time T if and only if, for every $u \in H$,*
$$B^* e^{tA^*} u = 0 \quad t \in [0, T] \ a.e. \implies u = 0\,. \tag{17}$$

To benefit the reader who is more familiar with optimization theory than abstract functional analysis, let us explain, by a variational argument, why estimate (16) implies null controllability. Consider, for every $\varepsilon > 0$, the penalized problem

$$\min\left\{J_\varepsilon(f) \,:\, f \in L^2(0, T; H)\right\},$$

where

$$J_\varepsilon(f) = \frac{1}{2}\int_0^T \|f(t)\|^2 \,\mathrm{d}t + \frac{1}{2\varepsilon}\|u_f(T)\|^2 \qquad \forall f \in L^2(0, T; H)\,.$$

Since J_ε is strictly convex, it admits a unique minimum point f_ε. Set $u_\varepsilon = u_{f_\varepsilon}$. Recalling (13) we have, By Fermat's rule,

$$0 = J'_\varepsilon(f_\varepsilon)g = \int_0^T \langle f_\varepsilon(t), g(t)\rangle \,\mathrm{d}t + \frac{1}{\varepsilon}\langle u_\varepsilon(T), \Lambda_T g\rangle \quad \forall g \in L^2(0, T; H)\,. \tag{18}$$

Therefore, passing to the adjoint of Λ_T,

$$\int_0^T \left\langle f_\varepsilon(t) + \frac{1}{\varepsilon}\left(\Lambda_T^* u_\varepsilon(T)\right)(t), g(t)\right\rangle \mathrm{d}t = 0 \qquad \forall g \in L^2(0, T; H)\,,$$

whence, owing to (14),

$$f_\varepsilon(t) = -\frac{1}{\varepsilon}\left(\Lambda_T^* u_\varepsilon(T)\right)(t) = -B^* v_\varepsilon(t) \qquad \forall t \in [0, T]\,, \tag{19}$$

where $v_\varepsilon(t) \doteq \frac{1}{\varepsilon}\mathrm{e}^{(T-t)A^*} u_\varepsilon(T)$ is the solution of the *dual problem*

$$\begin{cases} v' + A^* v = 0 & t \in [0, T] \\ v(T) = \frac{1}{\varepsilon} u_\varepsilon(T)\,. \end{cases}$$

It turns out that

$$\frac{1}{2}\int_0^T \|f_\varepsilon(t)\|^2 \,\mathrm{d}t + \frac{1}{\varepsilon}\|u_\varepsilon(T)\|^2 \leq C\|u_0\|^2 \qquad \forall \varepsilon > 0 \tag{20}$$

for some positive constant C. Indeed, observe that, in view of (19),

$$\begin{cases} \left\langle u'_\varepsilon - Au_\varepsilon + BB^* v_\varepsilon\,,\, v_\varepsilon\right\rangle = 0\,, & u_\varepsilon(0) = u_0 \\ \left\langle v'_\varepsilon + A^* v_\varepsilon\,,\, u_\varepsilon\right\rangle = 0\,, & v_\varepsilon(T) = \frac{1}{\varepsilon} u_\varepsilon(T)\,. \end{cases}$$

So,

$$\int_0^T \left[\frac{\mathrm{d}}{\mathrm{d}t} \langle u_\varepsilon \, , \, v_\varepsilon \rangle + \left\| B^* v_\varepsilon \right\|^2 \right] dt = 0 \, ,$$

hence

$$\frac{1}{\varepsilon} \| u_\varepsilon(T) \|^2 + \int_0^T \left\| B^* v_\varepsilon \right\|^2 \, \mathrm{d}t \; = \; \langle u_0 \, , \, v_\varepsilon(0) \rangle \, . \qquad (21)$$

Now, apply estimate (16) with $u = \frac{u_\varepsilon(T)}{\varepsilon}$ and note that $v_\varepsilon(T - t) = \mathrm{e}^{tA^*} \frac{u_\varepsilon(T)}{\varepsilon}$ to obtain

$$\int_0^T \left\| B^* v_\varepsilon(t) \right\|^2 \, \mathrm{d}t \geq C \, \| v_\varepsilon(0) \|^2$$

for some positive constant C. Hence, (20) follows from (21) and (19).

Finally, from (20) one deduces the existence of a weakly convergent subsequence f_{ε_j} in $L^2(0, T; F)$. Then, called f_0 the weak limit of f_{ε_j}, $u_{\varepsilon_j}(t) \to u_{f_0}(t)$ for all $t \in [0, T]$. So, owing to (20), $u_{f_0}(T) = 0$.

Heat Equation

It is not hard to see that the heat equation (9) with Dirichlet boundary conditions (2) fails to be exactly controllable. On the other hand, one can show that it is null controllable in any time $T > 0$, hence approximately controllable. Let ω be an open subset of Ω such that $\overline{\omega} \subset \Omega$.

Taking

$$H = L^2(\Omega) = F \, , \quad Bf = \mathbb{1}_\omega f \quad \forall f \in L^2(\Omega)$$

and A as in (8), one obtains that, for any $u_0 \in L^2(\Omega)$ and $f \in L^2(Q_T)$, the initial-boundary value problem

$$\begin{cases} \partial_t u = \Delta u + \mathbb{1}_\omega f & \text{in } \; Q_T \\ u = 0 & \text{on } \; \Sigma_T \\ u(0, x) = u_0(x) & x \in \Omega \end{cases} \qquad (22)$$

has a unique mild solution $u_f \in C([0, T]; L^2(\Omega))$. Moreover, multiplying both sides of equation (9) by u and integrating by parts, it is easy to see that

$$\partial_{x_i} u \in L^2(Q_T) \quad \forall i = 1, \ldots, n \, . \qquad (23)$$

Notice that the above property already suffices to explain why the heat equation cannot be exactly controllable: it is impossible to attain a state $u_1 \in L^2(\Omega)$ which is not compatible with (23).

On the other hand, null controllability holds true in any positive time.

Theorem 2 *Let $T > 0$ and let ω be an open subset of Ω such that $\overline{\omega} \subset \Omega$. Then the heat equation (9) with homogeneous Dirichlet boundary conditions is null controllable in time T, i. e., for every initial condition $u_0 \in L^2(\Omega)$ there is a control function $f \in L^2(Q_T)$ such that the solution u_f of (22) satisfies $u_f(T, \cdot) \equiv 0$. Moreover,*

$$\iint_{Q_T} |f|^2 dx dt \leq C_T \int_\Omega |u_0|^2 dx$$

for some positive constant C_T.

The above property is a consequence of the abstract result in Theorem 1 and of concrete estimates for solutions of parabolic equations. Indeed, in order to apply Theorem 1 one has to translate (16) into an estimate for the heat operator. Now, observing that both A and B are self-adjoint, one promptly realizes that (16) reduces to

$$\int_0^T \int_\omega |v(t, x)|^2 \mathrm{d}x\mathrm{d}t \geq C \int_\Omega |v(T, x)|^2 \mathrm{d}x \qquad (24)$$

for every solution v of the problem

$$\begin{cases} \partial_t v = \Delta v & \text{in } \; Q_T \\ v = 0 & \text{on } \; \Sigma_T \, . \end{cases} \qquad (25)$$

Estimate (24) is called an *observability inequality* for the heat operator for obvious reasons: problem (25) is not well-posed since the initial condition is missing. Nevertheless, if, "observing" a solution v of such a problem on the "small" cylinder $(0, T) \times \omega$, you find that it vanishes, then you can conclude that $v(T, \cdot) \equiv 0$ in the whole domain Ω. Thus, $v(0, \cdot) \equiv 0$ by backward uniqueness.

In conclusion, as elegant as the abstract approach to null controllability may be, one is confronted by the difficult task of proving observability estimates. In fact, for the heat operator there are several ways to prove inequality (24). One of the most powerful, basically due to Fursikov and Imanuvilov [65], relies on global *Carleman estimates*. Compared to other methods that can be used to derive observability, such a technique has the advantage of applying to second order parabolic operators with variable coefficients, as well as to more general operators.

Global Carleman estimates are a priori estimates in weighted norms for solutions of the problem

$$\begin{cases} \partial_t v = \Delta v + f & \text{in } \; Q_T \\ v = 0 & \text{on } \; \Sigma_T \, . \end{cases} \qquad (26)$$

regardless of initial conditions. The weight function is usually of the form

$$\psi_r(t, x) \doteq \theta(t) \big(\mathrm{e}^{2r\|\phi\|_{\infty,\Omega}} - \mathrm{e}^{r\phi(x)} \big) \quad (t, x) \in Q_T \, , \; (27)$$

where r is a positive constant, ϕ is a given function in $C^2(\overline{\Omega})$ such that

$$\nabla\phi(x) \neq 0 \quad \forall x \in \overline{\Omega}\,, \tag{28}$$

and

$$\theta(t) \doteq \frac{1}{t(T-t)} \quad 0 < t < T\,.$$

Note that

$$\theta > 0\,, \quad \theta(t) \to \infty \quad t \to 0\,, T$$

$$\psi_r > 0\,, \quad \psi_r(t,x) \to \infty \quad t \downarrow 0\,, t \uparrow T\,.$$

Using the above notations, a typical global Carleman estimate for the heat operator is the following result obtained in [65]. Let us denote by $\nu(x)$ the outword unit normal to Γ at a point $x \in \Gamma$, and by

$$\frac{\partial\phi}{\partial\nu}(x) = \nabla\phi(x)\cdot\nu(x)$$

the normal derivative of ϕ at x.

Theorem 3 *Let Ω be a bounded domain of $\mathbb{R}^n$ with boundary of class C^2, let $f \in L^2(Q_T)$, and let ϕ be a function satisfying (28). Let v be a solution of (26). Then there are positive constants r, s_0 and C such that, for any $s > s_0$,*

$$\begin{aligned} s^3 \iint_{Q_T} & \theta^3(t)|v(t,x)|^2 e^{-2s\psi_r} dx dt \\ & \leq C \iint_{Q_T} |f(t,x)|^2 e^{-2s\psi_r} dx dt \\ & + Cs \int_0^T \theta(t) dt \\ & \quad \times \int_\Gamma \frac{\partial\phi}{\partial\nu}(x) \left|\frac{\partial v}{\partial\nu}(t,x)\right|^2 e^{-2s\psi_r} \mathrm{d}\mathcal{H}^{n-1}(x) \end{aligned} \tag{29}$$

It is worth underlying that, thanks to the singular behavior of θ near 0 and T, the above result is independent of the initial value of v. Therefore, it can be applied, indifferently, to any solution of (26) as well as to any solution of the *backward problem*

$$\begin{cases} \partial_t v + \Delta v = f & \text{in } Q_T \\ v = 0 & \text{on } \Sigma_T\,. \end{cases}$$

Moreover, inequality (29) can be completed adding first and second order terms to its left-hand side, each with its own adapted power of s and θ.

Instead of trying to sketch the proof of Theorem 3, which would go beyond the scopes of this note, it is interesting to explain how it can be used to recover the observability inequality (24), which is what is needed to show that the heat equation is null controllable. The reasoning—not completely straightforward—is based on the following topological lemma, proved in [65].

Lemma 1 *Let $\Omega \subset \mathbb{R}^n$ be a bounded domain with boundary Γ of class C^k, for some $k \geq 2$, and let $\omega \subset \Omega$ be an open set such that $\overline{\omega} \subset \Omega$.*

Then there is function $\phi \in C^k(\overline{\Omega})$ such that

$$\begin{cases} (i) \quad \phi(x) = 0 \quad \text{and} \quad \frac{\partial\phi}{\partial\nu}(x) < 0 \quad \forall x \in \Gamma \\ (ii) \quad \{x \in \Omega | \nabla\phi(x) = 0\} \subset \omega\,. \end{cases} \tag{30}$$

Now, given a solution v of (25) and an open set ω such that $\overline{\omega} \subset \Omega$, let $\omega' \subset\subset \omega'' \subset\subset \omega$ be subdomains with smooth boundary. Then the above lemma ensures the existence of a function ϕ such that

$$\{x \in \Omega | \nabla\phi(x) = 0\} \subset \omega'\,.$$

"Localizing" problem (25) onto $\Omega' \doteq \Omega \setminus \omega'$ by a cutoff function $\eta \in C^\infty(\mathbb{R}^n)$ such that

$$0 \leq \eta \leq 1\,, \quad \eta \equiv 1 \quad \text{on } \mathbb{R}^n \setminus \omega''\,, \quad \eta \equiv 0 \quad \text{on } \omega'\,,$$

that is, taking $w = \eta v$, gives

$$\begin{cases} \partial_t w = \Delta w + h & \text{in } Q'_T \doteq (0,T)\times\Omega' \\ w(t,\cdot) = 0 & \text{on } \partial\Omega' = \partial\Omega \cup \partial\omega'\,, \end{cases} \tag{31}$$

with $h := -v\Delta\eta + 2\nabla\eta\cdot\nabla u$. Since $\nabla\phi \neq 0$ on Ω', Theorem 3 can be applied to w on Q'_T to obtain

$$\begin{aligned} s^3 \iint_{Q'_T} & \theta^3 |w|^2 \mathrm{e}^{-2s\psi_r} \mathrm{d}x\mathrm{d}t \\ & \leq C \iint_{Q'_T} |h|^2 \mathrm{e}^{-2s\psi_r} \mathrm{d}x\mathrm{d}t \\ & + Cs \int_0^T \theta \mathrm{d}t \int_\Gamma \frac{\partial\phi}{\partial\nu} \left|\frac{\partial w}{\partial\nu}\right|^2 \mathrm{e}^{-2s\psi_r} d\mathcal{H}^{n-1} \\ & + Cs \int_0^T \theta \mathrm{d}t \int_{\partial\omega'} \frac{\partial\phi}{\partial\nu} \left|\frac{\partial w}{\partial\nu}\right|^2 \mathrm{e}^{-2s\psi_r} d\mathcal{H}^{n-1} \\ & \leq C \iint_{Q'_T} |h|^2 \mathrm{e}^{-2s\psi_r} \mathrm{d}x\mathrm{d}t \end{aligned}$$

for s sufficiently large. On the other hand, for any $0 < T_0 < T_1 < T$,

$$s^3 \iint_{Q'_T} \theta^3 |w|^2 \mathrm{e}^{-2s\psi_r} \mathrm{d}x\mathrm{d}t \geq s^3 \int_{T_0}^{T_1} \mathrm{d}t \int_{\Omega\backslash\omega} \theta^3 |w|^2 \mathrm{e}^{-2s\psi_r} \mathrm{d}x\mathrm{d}t \geq \int_{T_0}^{T_1} \mathrm{d}t \int_{\Omega\backslash\omega} |v|^2 \mathrm{d}x$$

Therefore, recalling the definition of h,

$$\begin{aligned} \int_{T_0}^{T_1} \mathrm{d}t \int_{\Omega\backslash\omega} |v|^2 \mathrm{d}x &\leq C \iint_{Q'_T} |h|^2 \mathrm{e}^{-2s\psi_r} \mathrm{d}x\mathrm{d}t \\ &\leq C \int_0^T \mathrm{d}t \int_{\omega''\backslash\omega'} \left[|\nabla^2 \eta|^2 v^2 + |\nabla \eta|^2 |\nabla v|^2 \right] \mathrm{e}^{-2s\psi_r} \mathrm{d}x \\ &\leq C \int_0^T \mathrm{d}t \int_\omega |v|^2 \mathrm{d}x + C \int_0^T \mathrm{d}t \\ &\quad \times \int_{\omega''\backslash\omega'} |\nabla v|^2 \mathrm{e}^{-2s\psi_r} \mathrm{d}x \,. \end{aligned}$$

Now, fix $T_0 = T/3\,,\ T_1 = 2T/3$ and use Caccioppoli's inequality (a well-known estimate for solution of elliptic and parabolic PDE's)

$$\int_0^T \mathrm{d}t \int_{\omega''\backslash\omega'} |\nabla v|^2 \mathrm{e}^{-2s\psi_r}\, \mathrm{d}x \leq C \int_0^T \mathrm{d}t \int_\omega |v|^2 \mathrm{e}^{-2s\psi_r}\, \mathrm{d}x \,,$$

to conclude that

$$\int_{T/3}^{2T/3} \mathrm{d}t \int_{\Omega\backslash\omega} |v|^2\, \mathrm{d}x \leq C \int_0^T \mathrm{d}t \int_\omega |v|^2\, \mathrm{d}x$$

or

$$\int_{T/3}^{2T/3} \mathrm{d}t \int_\Omega |v|^2\, \mathrm{d}x \leq (1 + C) \int_0^T \mathrm{d}t \int_\omega |v|^2\, \mathrm{d}x$$

for some constant C. Then, the dissipativity of the heat operator (that is, the fact that $\int_\Omega |v(t,x)|^2 \mathrm{d}x$ is decreasing with respect to t) implies that

$$\begin{aligned} \int_\Omega v^2(T,x)\, \mathrm{d}x &\leq \frac{3}{T} \int_{T/3}^{2T/3} \mathrm{d}t \int_\Omega v^2(t,x)\, \mathrm{d}x \\ &\leq (1 + C) \frac{3}{T} \int_0^T \mathrm{d}t \int_\omega v^2(t,x)\, \mathrm{d}x \,, \end{aligned}$$

which is exactly (24).

Wave Equation

Compared to the heat equation, the wave equation (5) exhibits a quite different behavior from the point of view of exact controllability. Indeed, on the one hand, there is no obstruction to exact controllability since no regularizing effect is connected with wave propagation. On the other hand, due to the finite speed of propagation, exact controllability cannot be expected to hold true in arbitrary time, as null controllability does for the heat equation.

In fact, a typical result that holds true for the wave equation is the following, where a boundary control of Dirichlet type acts on a part $\Gamma_1 \subset \Gamma$, while homogeneous boundary conditions are imposed on $\Gamma_0 = \Gamma \setminus \Gamma_1$:

$$\begin{cases} \partial_t^2 u = \Delta u & \text{in } Q_T \\ u = f \mathbb{1}_{\Gamma_1} & \text{on } \Sigma_T \\ u(0,x) = u_0(x)\,, \partial_t u(0,x) = u_1(x) & x \in \Omega \end{cases} \qquad (32)$$

Observe that problem (32) is well-posed taking

$$\begin{aligned} u_0 &\in L^2(\Omega)\,, \quad u_1 \in H^{-1}(\Omega) \\ f &\in L^2(0,T; L^2(\Gamma)) \\ u &\in C([0,T]; L^2(\Omega)) \cap C^1([0,T]; H^{-1}(\Omega))\,. \end{aligned}$$

Theorem 4 *Let Ω be a bounded domain of $\mathbb{R}^n$ with boundary of class C^2 and suppose that, for some point $x_0 \in \mathbb{R}^n$,*

$$\begin{cases} (x - x_0) \cdot \nu(x) > 0 & \forall x \in \Gamma_1 \\ (x - x_0) \cdot \nu(x) \leq 0 & \forall x \in \Gamma_0\,. \end{cases}$$

Let

$$R = \sup_{x \in \Omega} |x - x_0|\,.$$

If $T > 2R$, then, for all $(u_0, u_1), (v_0, v_1) \in L^2(\Omega) \times H^{-1}(\Omega)$ there is a control function $f \in L^2(0,T; L^2(\Gamma))$ such that the solution u_f of (32) satisfies

$$u_f(T,x) = v_0(x)\,, \quad \partial_t u_f(T,x) = v_1(x)\,.$$

As we saw for abstract evolution equations, the above exact controllability property is proved to be equivalent to an observability estimate for the dual homogeneous problem using, for instance, the Hilbert Uniqueness Method (HUM) by J.-L. Lions [86].

Bibliographical Comments

The literature on controllability of parabolic equations and related topics is so huge, that no attempt to provide a comprehensive account of it would fit within the scopes of this note. So, the following comments have to be taken as a first hint for the interested reader to pursue further bibliographical research.

The theory of exact controllability for parabolic equations was initiated by the seminal paper [58] by Fattorini and Russell. Since then, it has experienced an enormous development. Similarly, the multiplier method to obtain observability inequalities for the wave equation was developed in [17,73,74,77,86]. Some fundamental early contributions were surveyed by Russell [108]. The next essential progress was made in the work by Lebeau and Robbiano [83] and then by Fursikov and Imanuvilov in a series of papers. In [65] one can find an introduction to global Carleman estimates, as well as applications to the controllability of several ODE's. In particular, the presentation of this paper as for observability inequalities and Carleman estimates for the heat operator is inspired by the last monograph. General perspectives for the understanding of global Carleman estimates and their applications to unique continuation and control problems for PDE's can be found in the works by Tataru [113,114,115,116]. Usually, the above approach requires coefficients to be sufficiently smooth. Recently, however, interesting adaptations of Carleman estimates to parabolic operators with discontinuous coefficients have been obtained in [21,82].

More recently, interest has focussed on control problems for nonlinear parabolic equations. Different approaches to controllability problems have been proposed in [57] and [44]. Then, null and approximate controllability results have been improved by Fernandez–Cara and Zuazua [61,62]. Techniques to produce insensitizing controls have been developed in [117]. These techniques have been successfully applied to the study of Navier–Stokes equations by several authors, see e. g. [63].

Fortunately, several excellent monographs are now available to help introduce the reader to this subject. For instance, the monograph by Zabczyk [121] could serve as a clean introduction to control and stabilization for finite- and infinite-dimensional systems. Moreover, [22,50,51], as well as [80,81] develop all the basic concepts of control and system theory for distributed parameter systems with special emphasis on abstract formulation. Specific references for the controllability of the wave equation by HUM can be found in [86] and [74]. More recent results related to series expansion and Ingham type methods can be found in [75]. For the control of Navier–Stokes equations the reader is referred to [64], as well as to the book by Coron [43], which contains an extremely rich collection of classical results and modern developments.

Stabilization

Stabilization of flexible structures such as beams, plates, up to antennas of satellites, or of fluids as, for instance, in aeronautics, is an important part of CT. In this approach, one wants either to derive feedback laws that will allow the system to autoregulate once they are implemented, or study the asymptotic behavior of the stabilized system i. e. determine whether convergence toward equilibrium states as times goes to infinity holds, determine its speed of convergence if necessary or study how many feedback controls are required in case of coupled systems.

Different mathematical tools have been introduced to handle such questions in the context of ODE's and then of PDE's. Stabilization of ODE's goes back to the work of Lyapunov and Lasalle. The important property is that trajectories decay along Lyapunov functions. If trajectories are relatively compact in appropriate spaces and the system is autonomous, then one can prove that trajectories converge to equilibria asymptotically. However, the construction of Lyapunov functions is not easy, in general.

This section will be concerned with some aspects of the stabilization of second order hyperbolic equations, our model problem being represented by the wave equation with distributed damping

$$\begin{cases} \partial_{tt}u - \Delta u + a(x)u_t = 0 & \text{in } \Omega \times \mathbb{R}\,, \\ u = 0 & \text{on } \Sigma = (0,\infty) \times \Gamma \\ (u, \partial_t u)(0) = (u^0, u^1) & \text{on } \Omega\,, \end{cases} \tag{33}$$

in a bounded domain $\Omega \subset \mathbb{R}^n$ with a smooth boundary Γ. For $n = 2$, $u(t,x)$ represents the displacement of point x of the membrane at time t. Therefore, equation (33) describes an elastic system. The energy of such a system is given by

$$E(t) = \frac{1}{2} \int_\Omega \left[|u_t(t,x)|^2 + |\nabla u(t,x)|^2 \right] \mathrm{d}x\,.$$

When $a \geq 0$, the *feedback* term $a(x)u_t$ models friction: it produces a loss of energy through a dissipation phenomenon. More precisely, multiplying the equation in (33) by u_t and integrating by parts on Ω, it follows that

$$E'(t) = -\int_\Omega a(x)|u_t|^2 \, \mathrm{d}x \leq 0\,, \quad \forall t \geq 0\,. \tag{34}$$

On the other hand, if $a \equiv 0$, then the system is *conservative*, i. e., $E(t) = E(0)$ for all $t \geq 0$.

Another well-investigated stabilization problem for the wave equation is when the feedback is localized on a part Γ_0 of the boundary Γ, that is,

$$\begin{cases} \partial_{tt}u - \Delta u = 0 & \text{in } \Omega \times \mathbb{R} \\ \frac{\partial u}{\partial \nu} + u_t = 0 & \text{on } \Sigma_0 = (0,\infty) \times \Gamma_0 \\ u = 0 & \text{on } \Sigma_1 = (0,\infty) \times (\Gamma \setminus \Gamma_0) \\ (u, \partial_t u)(0) = (u^0, u^1) \end{cases} \tag{35}$$

In this case, the dissipation relation (34) takes the form

$$E'(t) = -\int_{\Gamma_0} |u_t|^2 \, \mathrm{d}\mathcal{H}^{n-1} \leq 0\,, \quad \forall t \geq 0\,.$$

In many a situation—such as to improve the quality of an acoustic hall—one seeks to reduce vibrations to a minimum: this is why stabilization is an important issue in CT. We note that the above system has a unique stationary solution—or, *equilibrium*—given by $u \equiv 0$. Stabilization theory studies all questions related to the convergence of solutions to such an equilibrium: existence of the limit, rate of convergence, different effects of nonlinearities in both displacement and velocity, effects of geometry, coupled systems, damping effects due to memory in viscoelastic materials, and so on.

System (33) is said to be:

- **strongly stable** if $E(t) \to 0$ as $t \to \infty$;
- **(uniformly) exponentially stable** if $E(t) \leq Ce^{-\alpha t}E(0)$ for all $t \geq 0$ and some constants $\alpha > 0$ and $C \geq 0$, independent of u^0, u^1.

This note will focus on some of the above issues, such as geometrical aspects, nonlinear damping, indirect damping for coupled systems and memory damping.

Geometrical Aspects

A well-known property of the wave equation is the so-called *finite speed of propagation*, which means that, if the initial conditions u^0, u^1 have compact support, then the support of $u(t,\cdot)$ evolves in time at a finite speed. This explains why, for the wave equation, the geometry of Ω plays an essential role in all the issues related to control and stabilization.

The size and localization of the region in which the feedback is active is of great importance. In this paper such a region, denoted by ω, is taken as a subset of Ω of positive Lebesgue measure. More precisely, a is assumed to be continuous on $\overline{\Omega}$ and such that

$$a \geq 0 \quad \text{on} \quad \Omega \quad \text{and} \quad a \geq a_0 \quad \text{on} \quad \omega\,, \tag{36}$$

for some constant $a_0 > 0$. In this case, the feedback is said to be *distributed*. Moreover, it is said to be *globally* distributed if $\omega = \Omega$ and *locally* distributed if $\Omega \setminus \omega$ has positive Lebesgue measure.

Two main methods have been used or developed to study stabilization, namely the *multiplier method* and *microlocal analysis*. The one that gives the sharpest results is based on microlocal analysis. It goes back to the work of Bardos, Lebeau and Rauch [17], giving geodesics sufficient conditions on the region of active control for exact controllability to hold. These conditions say that each ray of geometric optics should meet the control region. Burq and Gérard [25] showed that these results hold under weaker regularity assumptions on the domain and coefficients of the operators (see also [26,27]). These geodesics conditions are not explicit, in general, but they allow to get decay estimates of the energy under very general hypotheses.

The multiplier method is an explicit method, based on energy estimates, to derive decay rates (as well as observability and exact controllability results). For boundary control and stabilization problems it was developed in the works of several authors, such as Ho [38,73], J.-L. Lions [86], Lasiecka–Triggiani, Komornik–Zuazua [76], and many others. Zuazua [123] gave an explicit geometric condition on ω for a semilinear wave equation subject to a locally distributed damping. Such a condition was then relaxed K. Liu [87] (see also [93]) who introduced the so-called piecewise multiplier method. Lasiecka and Triggiani [80,81] introduced a sharp trace regularity method which allows to estimate boundary terms in energy estimates. There also exist intermediate results between the geodesics conditions of Bardos–Lebeau–Rauch and the multiplier method, obtained by Miller [95] using differentiable escape functions.

Zuazua's multiplier geometric condition can be described as follows. If a subset O of $\overline{\Omega}$ is given, one can define an ε-neighborhood of O in $\overline{\Omega}$ as the subset of points of Ω which are at distance at most ε of O. Zuazua proved that if the set ω is such that there exists a point $x_0 \in \mathbb{R}^n$—an *observation* point—for which ω contains an ε-neighborhood of $\Gamma(x^0) = \{x \in \partial\Omega\,,\ (x - x^0) \cdot \nu(x) \geq 0\}$, then the energy decays exponentially. In this note, we refer to this condition as (MGC).

If a vanishes for instance in a neighborhood of the two poles of a ball Ω in $\mathbb{R}^n$, one cannot find an observation point x_0 such that (MGC) holds. K. Liu [87] (see also [93]) introduced a piecewise multiplier method which allows to choose several observation points, and therefore to handle the above case.

Introduce disjoint lipschitzian domains Ω_j of Ω, $j = 1, \dots, J$, and observation points $x^j \in \mathbb{R}^N$, $j = 1, \dots, J$ and define

$$\gamma_j(x^j) = \{x \in \partial\Omega_j \, , \, (x - x^j) \cdot \nu_j(x) \geq 0\}$$

Here ν_j stands for the unit outward normal vector to the boundary of Ω_j. Then the piecewise multiplier geometrical condition for ω is:

$$\omega \supset \mathcal{N}_\varepsilon \left(\cup_{j=1}^J \gamma_j(x^j) \cup \left(\Omega \setminus \cup_{j=1}^J \, \Omega_j \right) \right) \qquad \text{(PWMGC)}$$

It will be denoted by (PWMGC) condition in the sequel.

Assume now that a vanishes in a neighborhood of the two poles of a ball in $\mathbb{R}^n$. Then, one can choose two subsets Ω_1 and Ω_2 containing, respectively, the two regions where a vanishes and apply the piecewise multiplier method with $J = 2$ and with the appropriate choices of two observation points and ε. The multiplier method consists of integrating by parts expressions of the form

$$\int_t^T \int_\Omega \left(\partial_t^2 u - \Delta u + a(x) u_t \right) Mu \, \mathrm{d}x \, \mathrm{d}t = 0 \qquad \forall 0 \leq t \leq T \, ,$$

where u stands for a (strong) solution of (33), with an appropriate choice of Mu. Multipliers have generally the form

$$Mu = (m(x) \cdot \nabla u + c\, u)\, \psi(x) \, ,$$

where m depends on the observation points and ψ is a cut-off function. Other multipliers of the form $Mu = \Delta^{-1}(\beta u)$, where β is a cut-off function and Δ^{-1} is the inverse of the Laplacian operator with homogeneous Dirichlet boundary conditions, have also used.

The geometric conditions (MGC) or (PWMGC) serve to bound above by zero terms which cannot be controlled otherwise. One can then prove that the energy satisfies an estimate of the form

$$\int_t^T E(s) \, \mathrm{d}s \leq cE(t) + \int_t^T \left(\int_\Omega a(x)|u_t|^2 + \int_\omega |u_t|^2 \right) \mathrm{d}s \qquad \forall t \geq 0 \, . \quad (37)$$

Once this estimate is proved, one can use the dissipation relation to prove that the energy satisfies integral inequalities of Gronwall type. This is the subject of the next section.

Decay Rates, Integral Inequalities and Lyapunov Techniques

The Linear Feedback Case Using the dissipation relation (34), one has

$$\int_t^T \int_\Omega a|u_t|^2 \, \mathrm{d}x \, \mathrm{d}s \leq \int_t^T -E'(s) \, \mathrm{d}s \leq E(t) \qquad \forall \; 0 \leq t \leq T \, .$$

On the other hand, thanks to assumption (36) on a

$$\int_t^T \int_\omega u_t^2 \, \mathrm{d}x \, \mathrm{d}s \leq \frac{1}{a_0} \int_t^T \int_\Omega a|u_t|^2 \, \mathrm{d}x \, \mathrm{d}s \leq \frac{1}{a_0} E(t) \quad \forall 0 \leq t \leq T \, .$$

By the above inequalities and (37), E satisfies

$$\int_t^T E(s) \, \mathrm{d}s \leq cE(t) \, , \quad \forall 0 \leq t \leq T \, . \qquad (38)$$

Since E is a nonincreasing function and thanks to this integral inequality, Haraux [71] (see also Komornik [74]) proved that E decays exponentially at infinity, that is

$$E(t) \leq E(0) \exp\left(1 - t/c\right) , \quad \forall t \geq c \, . \qquad (39)$$

This proof is as follows. Define

$$\phi(t) = \exp(t/c) \int_t^\infty E(s) \, \mathrm{d}s \quad \forall t \geq 0 \, .$$

Thanks to (38) ϕ is nonincreasing on $[0, \infty)$, so that

$$\phi(t) \leq \phi(0) = \int_0^\infty E(s) \, \mathrm{d}s \, .$$

Using once again (38) with $t = 0$ in this last inequality and the definition of ϕ, one has

$$\int_t^\infty E(s) \, \mathrm{d}s \leq cE(0) \exp(-t/c) \quad \forall t \geq 0 \, .$$

Since E is a nonnegative and nonincreasing function

$$cE(t) \leq \int_{t-c}^t E(s) \, \mathrm{d}s \leq \int_{t-c}^\infty E(s) \, \mathrm{d}s \leq cE(0) \exp(-(t-c)/c) \, ,$$

so that (39) is proved.

An alternative method is to introduce a modified (or perturbed) energy E_ε which is equivalent to the natural one for small values of the parameter ε as in Komornik and

Zuazua [76]. Then one shows that this modified energy satisfies a differential Gronwall inequality so that it decays exponentially at infinity. The exponential decay of the natural energy follows then at once. In this case, the modified energy is indeed a Lyapunov function for the PDE. The natural energy cannot be in general such a Lyapunov function due to the finite speed of propagation (consider initial data which have compact support compactly embedded in $\Omega\backslash\omega$).

There are also very interesting approaches using the frequency domain approach, or spectral analysis such as developed by K. Liu [87] Z. Liu and S. Zheng [88]. In the sequel, we concentrate on the integral inequality method. This method has been generalized in several directions and we present in this note some results concerning extensions to

- nonlinear feedback
- indirect or single feedback for coupled system
- memory type feedbacks

Generalizations to Nonlinear Feedbacks Assume now that the feedback term $a(x)u_t$ in (33) is replaced by a nonlinear feedback $a(x)\rho(u_t)$ where ρ is a smooth, increasing function satisfying $v\rho(v) \geq 0$ for $v \in \mathbb{R}$, linear at ∞ and with polynomial growth close to zero, that is: $\rho(v) = |v|^p$ for $|v| \leq 1$ where $p \in (1, \infty)$.

Assume moreover that ω satisfies Zuazua's multiplier geometric condition (MGC) or Liu's piecewise multiplier method (PWMGC). Then using multipliers of the space and time variables defined as $E(s)^{(p-1)/2}\, Mu(x)$ where $Mu(x)$ are multipliers of the form described in section 5.1 and integrating by parts expressions of the form

$$\int_t^T E(s)^{(p-1)/2} \times \int_\Omega \left(\partial_t^2 u - \Delta u + a(x)\rho(u_t)\right) Mu(x)\, \mathrm{d}x\, \mathrm{d}s = 0\,,$$

one can prove that the energy E of solutions satisfies the following inequality for all $0 \leq t \leq T$

$$\int_t^T E^{(p+1)/2}(s)\, \mathrm{d}t \leq cE^{(p+1)/2}(t) + c\int_t^T E^{(p-1)/2}(s) \times \left(\int_\Omega \rho(u_t)^2 + \int_\omega |u_t|^2\right) .$$

One can remark than an additional multiplicative weight in time depending on the energy has to be taken. This weight is $E^{(p-1)/2}$. Then as in the linear case, but in a more involved way, thanks to the dissipation relation

$$E'(t) = -\int_\Omega a(x) u_t \rho(u_t)\,, \tag{40}$$

one can prove that E satisfies the following nonlinear integral inequality

$$\int_t^T E^{(p+1)/2}(s)\, \mathrm{d}s \leq cE(t)\,, \quad \forall 0 \leq t \leq T\,.$$

Thanks to the fact that E is nonincreasing, a well-known result by Komornik [74] shows that E is polynomially decaying, as $t^{-2/(p-1)}$ at infinity. The above type results have been obtained by many authors under weaker form (see also [40,41,71,98,122]).

Extensions to nonlinear feedbacks without growth conditions close to zero have been studied by Lasiecka and Tataru [78], Martinez [93], W. Liu and Zuazua [89], Eller Lagnese and Nicaise [56] and Alabau–Boussouira [5]. We present the results obtained in this last reference since they provide *optimal* decay rates.

The method is as follows. Define respectively the linear and nonlinear kinetic energies

$$\begin{cases} \int_\omega |u_t|^2\, \mathrm{d}x\,, \\ \int_\Omega |a(x)\rho(u_t)|^2\, \mathrm{d}x\,, \end{cases}$$

and use a weight function in time $f(E(s))$ which is to be determined later on in an optimal way. Integrating by parts expressions of the form

$$\int_t^T f(E(s)) \int_\Omega \left(\partial_t^2 u - \Delta u + a(x)\rho(u_t)\right) Mu(x)\, \mathrm{d}x\, \mathrm{d}s = 0\,,$$

one can prove that the energy E of solutions satisfies the following inequality for all $0 \leq t \leq T$

$$\int_t^T E(s) f(E(s))\, \mathrm{d}s \leq c f(E(t)) + c\int_t^T f(E(s)) \times \left(\int_\Omega |a(x)\rho(u_t)|^2 + \int_\omega |u_t|^2\right) . \tag{41}$$

The difficulty is to determine the optimal weight under general growth conditions on the feedback close to 0, in particular for cases for which the feedback decays to 0 faster than polynomials.

Assume now that the feedback satisfies

$$g(|v|) \leq |\rho(v)| \leq Cg^{-1}(|v|)\,, \quad \forall |v| \leq 1\,, \tag{42}$$

where g is continuously differentiable on $\mathbb{R}$ strictly increasing with $g(0) = 0$ and

$$\begin{cases} g \in C^2([0, r_0])\,,\, r_0 \text{ sufficiently small }, \\ H(.) = \sqrt{.}g(\sqrt{.}) \text{ is strictly convex on } \left[0, r_0^2\right], \\ g \text{ is odd}\,. \end{cases}$$

Moreover, ρ is assumed to have a linear growth at infinity. We define the *optimal* weight function f as follows.

We first extend H to a function $\hat{H}$ define on all $\mathbb{R}$

$$\hat{H}(x) = \begin{cases} H(x) \text{ if } x \in \left[0, r_0^2\right], \\ +\infty \text{ otherwise}, \end{cases}$$

then, define a function F as follows:

$$F(y) = \begin{cases} \dfrac{\hat{H}^*(y)}{y} & \text{if } \; y \in (0, +\infty)\,, \\ 0 & \text{if } \; y = 0\,, \end{cases}$$

where $\hat{H}^*$ stands for the convex conjugate of $\hat{H}$, that is

$$\hat{H}^*(y) = \sup_{x \in \mathbb{R}}\{x\,y - \hat{H}(x)\}\,.$$

Then the *optimal* weight function f is determined in the following way

$$f(s) = F^{-1}(s/2\beta) \quad s \in \left[0, 2\beta r_0^2\right)\,,$$

where β is of the form $\max(\eta_1, \eta_2 E(0))$, η_1 and η_2 being explicit positive constants.

One can prove that the above formulas make sense, and in particular that F is invertible and smooth. More precisely, F is twice continuously differentiable strictly increasing, one-to-one function from $[0, +\infty)$ onto $[0, r_0^2)$. Note that since the feedback is supposed to be linear at infinity, if one wants to obtain results for general growth types of the feedback, one can assume convexity of H only in a neighborhood of 0.

One can prove from (41) that there exists an (explicit) $T_0 > 0$ such that for all initial data, E satisfies the following nonlinear integral inequality

$$\int_t^T E(s) f(E(s))\,\mathrm{d}s \leq T_0 E(t) \quad \forall 0 \leq t \leq T\,. \tag{43}$$

This inequality is proved thanks to convexity arguments as follows. Thanks to the convexity of $\hat{H}$, one can use Jensen's inequality and (42), so that

$$\int_{\Omega_t} |a(x)\rho(u_t)|^2\,\mathrm{d}x \leq \gamma_1(t)\hat{H}^{-1} \times \left(\frac{1}{\gamma_1(t)} \int_\Omega a(x) u_t \rho(u_t)\,\mathrm{d}x\right)$$

In a similar way, one proves that

$$\int_{\omega_t} |u_t|^2\,\mathrm{d}x \leq \gamma_2(t)\hat{H}^{-1}\left(\frac{1}{\gamma_2(t)} \int_\Omega a(x) u_t \rho(u_t)\,\mathrm{d}x\right)$$

where Ω_t and ω_t are time-dependent sets of respective Lebesgue measures $\gamma_1(t)$ and $\gamma_2(t)$ on which the velocity $u_t(t, x)$ is sufficiently small. Using the above two estimates, together with the linear growth of ρ at infinity, one proves

$$\int_t^T f(E(s))\left(\int_\Omega |a(x)\rho(u_t)|^2 + \int_\omega |u_t|^2\right) \leq \int_t^T f(E(s))\hat{H}^{-1}\left(\frac{1}{c}\int_\Omega a(x) u_t \rho(u_t)\,\mathrm{d}x\right)$$

Using then Young's inequality, together with the dissipation relation (40) in the above inequality, one obtains

$$\int_t^T f(E(s))\left(\int_\Omega |a(x)\rho(u_t)|^2 + \int_\omega |u_t|^2\right) \leq C_1 \int_t^T \hat{H}^\star\left(f(E(s)\right)\,\mathrm{d}s + C_2 E(t)\,, \tag{44}$$

where $C_i > 0$ $i = 1, 2$ is a constant independent of the initial data. Using the dissipation relation (40) in the above inequality, this gives for all $0 \leq t \leq T$

Combining this last inequality with (41) gives

$$\int_t^T E(s) f(E(s))\,\mathrm{d}s \leq \beta \int_t^T (\hat{H})^\star\left(f(E(s)\right)\,\mathrm{d}s + C_2 E(t)$$

where β is chosen of the form $\max(\eta_1, \eta_2 E(0))$, η_1 and η_2 being explicit positive constants to guarantee that the argument E of f stays in the domain of definition of f. Thus (43) is proved, thanks to the fact that the weight function has been chosen so that

$$\beta\hat{H}^\star(f(E(s)) = \frac{1}{2}E(s) f(E(s)) \quad \forall\, 0 \leq s\,.$$

Therefore E satisfies a nonlinear integral inequality with a weight function $f(E)$ which is defined in a semi-explicit way in general cases of feedback growth.

The last step is to prove that a nonincreasing and nonnegative absolutely continuous function E satisfying a nonlinear integral inequality of the form (43) is decaying at infinity, and to establish at which rate this holds. For this, one proceeds as in [5].

Let $\eta > 0$ and $T_0 > 0$ be fixed given real numbers and F be a strictly increasing function from $[0, +\infty)$ on $[0, \eta)$, with $F(0) = 0$ and $\lim_{y \to +\infty} F(y) = \eta$.

For any $r \in (0, \eta)$, we define a function K_r from $(0, r]$ on $[0, +\infty)$ by

$$K_r(\tau) = \int_\tau^r \frac{\mathrm{d}y}{yF^{-1}(y)}\,, \tag{45}$$

and a function ψ_r which is a strictly increasing function from $[\frac{1}{F^{-1}(r)}, +\infty)$ onto $[\frac{1}{F^{-1}(r)}, +\infty)$ by

$$\psi_r(z) = z + K_r(F(\frac{1}{z})) \geq z, \quad \forall z \geq \frac{1}{F^{-1}(r)}\,, \tag{46}$$

One can prove that if E is a nonincreasing, absolutely continuous function from $[0, +\infty)$ on $[0, +\infty)$, satisfying $0 < E(0) < \eta$ and the inequality

$$\int_t^T E(s)F^{-1}(E(s))\,\mathrm{d}s \leq T_0 E(S)\,, \quad \forall\, 0 \leq t \leq T\,, \tag{47}$$

then E satisfies the following estimate:

$$E(t) \leq F\left(\frac{1}{\psi_r^{-1}(\frac{t}{T_0})}\right), \quad \forall t \geq \frac{T_0}{F^{-1}(r)}\,, \tag{48}$$

where r is any real such that

$$\frac{1}{T_0}\int_0^{+\infty} E(\tau)F^{-1}(E(\tau))\,\mathrm{d}\tau \leq r \leq \eta\,.$$

Thus, one can apply the above result to E with $\eta = r_0^2$ and show that $\lim t \to +\infty E(t) = 0$, the decay rate being given by estimate (48).

If g is polynomial close to zero, one gets back that the energy $E(t)$ decays as $t^{\frac{-2}{p-1}}$ at infinity. If $g(v)$ behaves as $\exp(-1/|v|)$ close to zero, then $E(t)$ decays as $1/(\ln(t))^2$ at infinity.

The usefulness of convexity arguments has been first pointed out by Lasiecka and Tataru [78] using Jensen's inequality and then in different ways by Martinez [93] (the weight function does not depend on the energy) and W. Liu and Zuazua [89] and Eller Lagnese and Nicaise [56]. Optimal decay rates have been obtained by Alabau–Boussouira [5,6] using a weight function determined through the theory of convex conjugate functions and Young's (named also as Fenchel–Moreau's) inequality. This argument was also used by W. Liu and Zuazua [89] in a slightly different way and combined to a Lyapunov technique. Optimality of estimates in [5] is proved in one-dimensional situation and for boundary dampings applying optimality results of Vancostenoble [119] (see also Martinez and Vancostenoble [118]).

Indirect Damping for Coupled Systems

Many complex phenomena are modeled through coupled systems. In stabilizing (or controlling) energies of the vector state, one has very often access only to some components of this vector either due to physical constraints or to cost considerations. In this case, the situation is to stabilize a full system of coupled equation through a reduced number of feedbacks. This is called indirect damping. This notion has been introduced by Russell [109] in 1993.

As an example, we consider the following system:

$$\begin{cases} \partial_t^2 u - \Delta u + \partial_t u + \alpha v = 0 \\ \partial_t^2 v - \Delta v + \alpha u = 0 \end{cases}$$
$$\text{in } \Omega \times \mathbb{R}\,, \quad u = 0 = v \quad \text{on } \partial\Omega \times \mathbb{R}\,. \tag{49}$$

Here, the first equation is damped through a linear distributed feedback, while no feedback is applied to the second equation. The question is to determine if this coupled system inherits any kind of stability for nonzero values of the coupling parameter α from the stabilization of the first equation only.

In the finite dimensional case, stabilization (or control) of coupled ODE's can be analyzed thanks to a powerful rank type condition named Kalman's condition. The situation is much more involved in the case of coupled PDE's.

One can show first show that the above system fails to be exponentially stable (see also [66] for related results). More generally, one can study the stability of the system

$$\begin{cases} u'' + A_1 u + Bu' + \alpha v = 0 \\ v'' + A_2 v + \alpha u = 0 \end{cases} \tag{50}$$

in a separable Hilbert space H with norm $|\cdot|$, where A_1, A_2 and B are self-adjoint positive linear operators in H. Moreover, B is assumed to be a bounded operator. So, our analysis applies to systems with internal damping supported in the whole domain Ω such as (49); the reader is referred to [1,2] for related results concerning boundary stabilization problems (see also Beyrath [23,24] for localized indirect dampings).

In light of the above observations, system (50) fails to be exponentially stable, at least when H is infinite dimensional and A_1 has a compact resolvent as in (49). Indeed it is shown in Alabau, Cannarsa and Komornik [8] that the total energy of sufficiently smooth solutions of (50) decays polynomially at infinity whenever $|\alpha|$ is small enough but nonzero. From this result we can also deduce that any solution of (50) is strongly stable regardless of its smoothness: this fact follows by a standard density argument since the semigroup associated with (50) is a contraction semigroup.

A brief description of the key ideas of the approach developed in [2,8] is as follows. Essentially, one uses a finite iteration scheme and suitable multipliers to obtain an estimate of the form

$$\int_0^T E(u(t), v(t))\mathrm{d}t \leq c \sum_{k=0}^{j} E(u^{(k)}(0), v^{(k)}(0)) \qquad \forall\, T \geq 0\,, \quad (51)$$

where j is a positive integer and E denotes the total energy of the system

$$E(u, v) = \frac{1}{2}\left(|A_1^{1/2}u|^2 + |u'|^2\right) + \frac{1}{2}\left(|A_2^{1/2}v|^2 + |v'|^2\right) + \alpha\langle u, v\rangle\,.$$

Once (51) is proved, an abstract lemma due to Alabau [1,2] shows that $E(u(t), v(t))$ decays polynomially at ∞. This abstract lemma can be stated as follows.

Let A be the infinitesimal generator of a continuous semi-group $\exp(tA)$ on an Hilbert space $\mathcal{H}$, and $D(A)$ its domain. For U^0 in $\mathcal{H}$ we set in all the sequel $U(t) = \exp(tA)U^0$ and assume that there exists a functional E defined on $C([0, +\infty), \mathcal{H})$ such that for every U^0 in $\mathcal{H}$, $E(\exp(.A))$ is a non-increasing, locally absolutely continuous function from $[0, +\infty)$ on $[0, +\infty)$. Assume moreover that there exist an integer $k \in \mathbb{N}^\star$ and nonnegative constants c_p for $p = 0, \ldots k$ such that

$$\int_S^T E(U(t))\mathrm{d}t \leq \sum_{p=0}^{k} c_p E(U^{(p)}(S)) \qquad \forall 0 \leq S \leq T\,, \forall U^0 \in D(A^k)\,. \quad (52)$$

Then the following inequalities hold for every U^0 in $D(A^{kn})$ and all $0 \leq S \leq T$ where n is any positive integer:

$$\int_S^T E(U(\tau))\frac{(\tau - S)^{n-1}}{(n-1)!}\mathrm{d}\tau \leq c \sum_{p=0}^{kn} E(U^{(p)}(S))\,, \quad (53)$$

and

$$E(U(t)) \leq c \sum_{p=0}^{kn} E(U^{(p)}(0))t^{-n} \qquad \forall t > 0\,, \quad \forall U^0 \in D(A^{kn})\,,$$

where c is a constant which depends on n.

First (53) is proved by induction on n. For $n = 1$, it reduces to the hypothesis (52). Assume now that (53) holds for n and let U^0 be given in $D(A^{k(n+1)})$. Then we have

$$\int_S^T \int_t^T E(U(\tau))\frac{(\tau - t)^{n-1}}{(n-1)!}\mathrm{d}\tau\mathrm{d}t \leq c \sum_{p=0}^{kn} \int_S^T E(U^{(p)}(t))\mathrm{d}t \qquad \forall\, 0 \leq S \leq T\,, \forall\, U^0 \in D(A^{kn}).$$

Since U^0 is in $D(A^{k(n+1)})$ we deduce that $U^{(p)}(0) = A^p U^0$ is in $D(A^k)$ for $p \in \{0, \ldots kn\}$. Hence we can apply the assumption (52) to the initial data $U^{(p)}(0)$. This together with Fubini's Theorem applied on the left hand side of the above inequality give (53) for $n + 1$. Using the property that $E(U(t))$ is non increasing in (53) we easily obtain the last desired inequality.

Applications to wave-wave, wave-Petrowsky equations and various concrete examples hold.

The above results have been studied later on by Batkai, Engel, Prüss and Schnaubelt [18] using very interesting resolvent and spectral criteria for polynomial stability of abstract semigroups. The above abstract lemma in [2] has also been generalized using interpolation theory. One should note that this integral inequality involving higher order energies of solutions is not of differential nature, unlike Haraux's and Komornik's integral inequalities. Another approach based on decoupling techniques and for slightly different abstract systems have been introduced by Ammar Khodja Bader and Ben Abdallah [12].

Spectral conditions have also been studied by Z. Liu [88] and later on by Z. Liu and Rao [90], Loreti and Rao [92] for peculiar abstract systems and in general for coupled equations only of the *same* nature (wave-wave for instance), so that a dispersion relation for the eigenvalues of the coupled system can be derived. Also these last results are given for internal stabilization only. Because of the above limitations, Z. Liu–Rao and Loreti–Rao's results are less powerful in generality than the ones given by Alabau, Cannarsa and Komornik [8] and Alabau [2]. Moreover results through energy type estimates and integral inequalities can be generalized to include nonlinear indirect dampings as shown in [7]. On the other side spectral methods are very useful to obtain optimal decay rates provided that one can determine at which speed the eigenvalues approach the imaginary axis for high frequencies.

Memory Dampings

We consider the following model problem

$$\begin{cases} u_{tt}(t,x) - \Delta u(t,x) + \int_0^t \beta(t-s)\,\Delta u(s,x)\,\mathrm{d}s = \\ \qquad\qquad\qquad\qquad |u(t,x)|^{\gamma} u(t,x) \\ u(t,\cdot)_{|\partial\Omega} = 0 \\ (u(0,\cdot), u_t(0,\cdot)) = (u_0, u_1) \end{cases} \tag{54}$$

where $0 < \gamma \leq \frac{2}{N-2}$ holds. The second member is a source term. The damping

$$\int_0^t \beta(t-s)\Delta u(s,x)\,\mathrm{d}s$$

is of memory type.

The energy is defined by

$$\begin{aligned} E_u(t) = {} & \frac{1}{2}\|u_t(t)\|^2_{L^2(\Omega)}\,\mathrm{d}x \\ & + \frac{1}{2}\left(1 - \int_0^t \beta(s)\,\mathrm{d}s\right)\|\nabla u(t)\|^2_{L^2(\Omega)} \\ & - \frac{1}{\gamma+2}\|u(t)\|^{\gamma+2}_{L^{\gamma+2}(\Omega)} \\ & + \frac{1}{2}\int_0^t \beta(t-s)\|\nabla u(t) - \nabla u(s)\|^2_{L^2(\Omega)}\,\mathrm{d}s \end{aligned}$$

The damping term produces dissipation of the energy, that is (for strong solutions)

$$\begin{aligned} E'_u(t) = {} & -\frac{1}{2}\beta(t)\|\nabla u(t)\|^2 \\ & + \frac{1}{2}\int_0^t \beta'(t)\|\nabla u(s) - \nabla u(t)\|^2\,\mathrm{d}s \leq 0 \end{aligned}$$

One can consider more general abstract equations of the form

$$u''(t) + Au(t) - \int_0^t \beta(t-s)Au(s)\,\mathrm{d}s = \nabla F(u(t)) \qquad t \in (0,\infty) \tag{55}$$

in a Hilbert space X, where $A\colon D(A) \subset X \to X$ is an accretive self-adjoint linear operator with dense domain, and ∇F denotes the gradient of a Gâteaux differentiable functional $F\colon D(A^{1/2}) \to \mathbb{R}$. In particular, equation (54) fits into this framework as well as several other classical equations of mathematical physics such as the linear elasticity system.

We consider the following assumptions.

Assumptions (H1)

1. A is a self-adjoint linear operator on X with dense domain $D(A)$, satisfying

$$\langle Ax, x\rangle \geq M\|x\|^2 \quad \forall x \in D(A) \tag{56}$$

for some $M > 0$.

2. $\beta\colon [0,\infty) \to [0,\infty)$ is a locally absolutely continuous function such that

$$\int_0^\infty \beta(t)\mathrm{d}t < 1 \; \beta(0) > 0 \quad \beta'(t) \leq 0 \qquad \text{for a.e. } t \geq 0\,.$$

3. $F\colon D(A^{1/2}) \to \mathbb{R}$ is a functional such that
   1. F is Gâteaux differentiable at any point $x \in D(A^{1/2})$;
   2. for any $x \in D(A^{1/2})$ there exists a constant $c(x) > 0$ such that

   $$|DF(x)(y)| \leq c(x)\|y\|, \quad \text{for any } y \in D(A^{1/2}),$$

   where $DF(x)$ denotes the Gâteaux derivative of F in x; consequently, $DF(x)$ can be extended to the whole space X (and we will denote by $\nabla F(x)$ the unique vector representing $DF(x)$ in the Riesz isomorphism, that is, $\langle \nabla F(x), y\rangle = DF(x)(y)$, for any $y \in X$);
   3. for any $R > 0$ there exists a constant $C_R > 0$ such that

   $$\|\nabla F(x) - \nabla F(y)\| \leq C_R\|A^{1/2}x - A^{1/2}y\|$$

   for all $x, y \in D(A^{1/2})$ satisfying $\|A^{1/2}x\|\,,\; \|A^{1/2}y\| \leq R$.

Assumptions (H2)

1. There exist $p \in (2,\infty]$ and $k > 0$ such that

$$\beta'(t) \leq -k\beta^{1+\frac{1}{p}}(t) \quad \text{for a.e. } t \geq 0$$

(here we have set $\frac{1}{p} = 0$ for $p = \infty$).

2. $F(0) = 0$, $\nabla F(0) = 0$, and there is a strictly increasing continuous function $\psi\colon [0,\infty) \to [0,\infty)$ such that $\psi(0) = 0$ and

$$|\langle \nabla F(x), x\rangle| \leq \psi(\|A^{1/2}x\|)\|A^{1/2}x\|^2 \quad \forall x \in D(A^{1/2})\,.$$

Under these assumptions, global existence for sufficiently small (resp. all) initial data in the energy space can be proved for nonvanishing (resp. vanishing) source terms.

It turns out that the above energy methods based on multiplier techniques combined with linear and nonlinear integral inequalities can be extended to handle memory dampings and applied to various concrete examples such as wave, linear elastodynamic and Petrowsky equations for instance. This allows to show in [10] that exponential as well as polynomial decay of the energy holds if the kernel decays respectively exponentially or polynomially at infinity.

The method is as follows. One evaluates expressions of the form

$$\int_t^T \langle u''(s) + Au(s) - \int_0^t \beta * Au(s) - \nabla F(u(s), Mu\rangle \,\mathrm{d}s$$

where the multipliers Mu are of the form $\phi(s)(c_1(\beta * u)(s) + c_2(s)u)$ with ϕ which is a differentiable, nonincreasing and nonnegative function, and c_1 being a suitable constant, whereas c_2 may be chosen dependent on β.

Integrating by parts the resulting relations and performing some involved estimates, one can prove that for all $t_0 > 0$ and all $T \geq t \geq t_0$

$$\int_t^T \phi(s)E(s)\,\mathrm{d}s \leq C\phi(0)E(t) + \int_t^T \phi(s) \times \int_0^s \beta(s-\tau)\left\|A^{1/2}u(s) - A^{1/2}u(\tau)\right\|^2 \,\mathrm{d}\tau\,\mathrm{d}s\,,$$

If $p = \infty$, that is if the kernel β decays exponentially, one can easily bound the last term of the above estimate by $cE(t)$ thanks to the dissipation relation.

If $p \in (2, \infty)$, one has to proceed differently since the term

$$\int_t^T \phi(s)\int_0^s \beta(s-\tau)\left\|A^{1/2}u(s) - A^{1/2}u(\tau)\right\|^2 \,d\tau\,\mathrm{d}s$$

cannot be directly estimated thanks to the dissipation relation. To bound this last term, one can generalize an argument of Cavalcanti and Oquendo [37] as follows. Define, for any $m \geq 1$,

$$\varphi_m(t) := \int_0^t \beta^{1-\frac{1}{m}}(t-s)\|A^{1/2}u(s) - A^{1/2}u(t)\|^2\mathrm{d}s\,, \quad t \geq 0\,. \tag{57}$$

Then, we have for any $T \geq S \geq 0$

$$\int_S^T E_u^{\frac{m}{p}}(t)\int_0^t \beta(t-s)\|A^{1/2}u(s) - A^{1/2}u(t)\|^2\mathrm{d}s\mathrm{d}t \leq CE_u^{\frac{p}{p+m}}(S)\left(\int_S^T E_u^{1+\frac{m}{p}}(t)\varphi_m(t)\mathrm{d}t\right)^{\frac{m}{p+m}} \tag{58}$$

for some constant $C > 0$. Suppose that, for some $m \geq 1$, the function φ_m defined in (57) is bounded. Then, for any $S_0 > 0$ there is a positive constant C such that

$$\int_S^\infty E_u^{1+\frac{m}{p}}(t)\mathrm{d}t \leq C\Big(E_u^{\frac{m}{p}}(0) + \|\varphi_m\|_\infty^{\frac{m}{p}}\Big)E_u(S) \quad \forall\, S \geq S_0\,. \tag{59}$$

One uses this last result first with $m = 2$ noticing that φ_2 is bounded and $\phi = E^{2/p}$. This gives a first energy decay rate as $(t+1)^{-p/2}$. This estimate shows that φ_1 is bounded. Then one applies once again the last result with $m = 1$ and $\phi = E^{1/p}$. One deduces then that E decays as $(t+1)^{-p}$ which is the *optimal* decay rate expected.

Bibliographical Comments

For an introduction to the multiplier method, we refer the interested reader to the books of J.-L. Lions [86], Komornik [74] and the references therein. The celebrated result of Bardos Lebeau and Rauch is presented in [86]. A general abstract presentation of control problems for hyperbolic and parabolic equations can be found in the book of Lasiecka and Triggiani [80,81]. Results on spectral methods and the frequency domain approach can be found in the book of Z. Liu [88]. There also exists an interesting approach developed for bounded feedback operators by Haraux and extended to the case of unbounded feedbacks by Ammari and Tucsnak [11]. In this approach, the polynomial (or exponential) stability of the damped system is proved thanks to the corresponding observability for the undamped (conservative) system. Such observability results for weakly coupled undamped systems have been obtained for instance in [3].

Many other very interesting issues have been studied in connection to semilinear wave equations, see [34,123] and the references therein, and damped wave equations with nonlinear source terms [39].

Well-posedness and asymptotic properties for PDE's with memory terms have first been studied by Dafermos [53,54] for convolution kernels with past history (convolution up to $t = -\infty$), by Prüss [103] and Prüss and Propst [102] in which the efficiency of different models of dampings are compared to experiments (see also Londen Petzeltova and Prüss [91]). Decay estimates for the energy of solutions using multiplier methods combined with Lyapunov type estimates for an equivalent energy are proved in Munoz Rivera [97], Munoz Rivera and Salvatierra [96], Cavalcanti and Oquendo [37] and Giorgi Naso and Pata [67] and many other papers.

Optimal Control

As for positional control, also for optimal control problems it is convenient to adopt the abstract formulation introduced in Sect. "Abstract Evolution Equations". Let the state space be represented by the Hilbert space H, and the state equation be given in the form (12), that is

$$\begin{cases} u'(t) = Au(t) + Bf(t) & t \in [0, T] \\ u(0) = u_0 \, . \end{cases} \tag{60}$$

Recall that A is the infinitesimal of a strongly continuous semigroup, e^{tA}, in H, B is a (bounded) linear operator from F (the control space) to H, and u_f stands for the unique (mild) solution of (60) for a given control function $f \in L^2(0, T; H)$.

A typical optimal control problem of interest for PDE's is the *Bolza problem* which consists in

$$\begin{cases} \text{minimizing the } \textit{cost functional} \\ \quad J(f) \doteq \int_0^T L(t, u_f(t), f(t))\mathrm{d}t + \ell\left(u_f(T)\right) \\ \text{over all controls} \quad f \in L^2(0, T; F) \, . \end{cases} \tag{61}$$

Here, T is a positive number, called the *horizon*, whereas L and ℓ are given functions, called the *running cost* and *final cost*, respectively. Such functions are usually assumed to be *bounded below*.

A control function $f_* \in L^2(0, T; F)$ at which the above minimum is attained is called an *optimal control* for problem (61) and the corresponding solution u_{f_*} of (60) is said to be an *optimal trajectory*. Alltogether, $\{u_{f_*}, f_*\}$ is called an *optimal (trajectory/control) pair*.

For problem (61) the following issues will be addressed in the sections below:

- *the existence* of controls minimizing functional J;
- *necessary conditions* that a candidate solution must satisfy;
- *sufficient conditions for optimality* provided by the dynamic programming method.

Other problems of particular interest to CT for PDE's are problems with an *infinite horizon* ($T = \infty$), problems with a *free horizon* T and a final *target*, and problems with constraints on both control variables and state variables. Moreover, the study of nonlinear variants of (60), including semilinear problems of the form

$$\begin{cases} u'(t) = Au(t) + h(t, u(t), f(t)) & t \in [0, T] \\ u(0) = u_0 \, , \end{cases} \tag{62}$$

is strongly motivated by applications. The discussion of all these variants, however, will not be here pursued in detail.

Traditionally, in optimal control theory, state variables are denoted by the letters $x, y, \ldots$, whereas $u, v, \ldots$ are reserved for control variables. For notational consistency, in this section $u(\cdot)$ will still denote the state of a given system and $f(\cdot)$ a control function, while ϕ will stand for a fixed element of control space F.

Existence of Optimal Controls

From the study of finite dimensional optimization it is a familiar fact that the two essential ingredients to guarantee the existence of minima are compactness and lower semicontinuity. Therefore, it is clear that, in order to obtain a solution of the optimal control problem (60)–(61), one has to make assumptions that allow to recover such properties. The typical hypotheses that are made for this purpose are the following:

- *coercivity*: there exist constants $c_0 > 0$ and $c_1 \in \mathbb{R}$ such that

$$\ell(\phi) \geq c_1 \quad \text{and} \quad L(t, u, \phi) \geq c_0\|\phi\|^2 + c_1 \qquad \forall (t, u, \phi) \in [0, T] \times H \times F \tag{63}$$

- *convexity*: for every $(t, u) \in [0, T] \times H$

$$\phi \mapsto L(t, u, \phi) \quad \text{is convex on} \quad F \, . \tag{64}$$

Under the above hypotheses, assuming lower semicontinuity of ℓ and of the map $L(t, \cdot, \phi)$, it is not hard to show that problem (60)–(61) has at least one solution. Indeed, assumption (63) allows to show that any minimizing sequence of controls $\{f_k\}$ is bounded in $L^2(0, T; H)$. So, it admits a subsequence, still denoted by $\{f_k\}$ which converges weakly in $L^2(0, T; H)$ to some function f. Then, by linearity, $u_{f_k}(t)$ converges to $u_f(t)$ for every $t \in [0, T]$. So, using assumption (64), it follows that f is a solution of (60)–(61).

The problem becomes more delicate when the Tonelli type coercivity condition (63) is relaxed, or the state equation is nonlinear as in (62). Indeed, the convergence of $u_{f_k}(t)$ is no longer ensured, in general. So, in order to recover compactness, one has to make further assumptions, such as the compactness of e^{tA}, or structural properties of L and h. For further reading, one may consult the monographs [22,85], and [79], for problems where the running and final costs are given by quadratic forms (the so-called Linear Quadratic problem), or [84] and [59] for more general optimal control problems.

Necessary Conditions

Once the existence of a solution to problem (60)–(61) has been established, the next important step is to provide conditions to detect a candidate solution, possibly showing that it is, in fact, optimal. By and large the optimality conditions of most common use are the ones known as Pontryagin's Maximum Principle named after the Russian mathematician L.S. Pontryagin who greatly contributed to the development of control theory, see [100,101].

So, suppose $\{u_*, f_*\}$, where $u_* = u_{f_*}$ is a candidate optimal pair and consider the so-called adjoint system

$$\begin{cases} -p'(t) = A^* p(t) + \partial_u L(t, u_*(t), f_*(t)) = 0 \\ \qquad\qquad\qquad\qquad\qquad\qquad t \in [0,T] \text{ a.e.} \\ p(T) = \partial \ell(u_*(T)) , \end{cases}$$

where $\partial_u L(t,u,\phi)$ and $\partial\ell(u)$ denote the Fréchet gradients of the maps $L(t,\cdot,\phi)$ and ℓ at u, respectively. Observe that the above is a backward linear Cauchy problem with terminal condition, which can obviously be reduced to a forward one by the change of variable $t \to T - t$. So, it admits a unique mild solution, labeled p_*, which is called the *adjoint state* associated with $\{u_*, f_*\}$.

Pontryagin's Maximum Principle states that, if $\{u_*, f_*\}$ is optimal, then

$$\langle p_*(t), Bf_*(t)\rangle + L(t, u_*(t), f_*(t)) = \min_{\phi\in F}\left[\langle p_*(t), B\phi\rangle + L(t, u_*(t), \phi)\right] \qquad t \in [0,T] \text{ a.e.} \tag{65}$$

The name Maximum Principle rather than Minimum Principle, as it would be more appropriate, is due to the fact that, traditionally, attention was focussed on the *maximization*—instead of minimization—of the functional in (61). Even today, in most models from economics, one is interested in maximizing payoffs, such as revenues, utility, capital and so on. In that case, (65) would still be true, with a "max" instead of a "min".

At first glance, it might be hard to understand the revelance of (65) to problem (61). To explain this, introduce the function, called the *Hamiltonian*,

$$\mathcal{H}(t,u,p) = \min_{\phi\in F}\left[\langle p, B\phi\rangle + L(t,u,\phi)\right] \qquad (t,u,p) \in [0,T]\times H \times H . \tag{66}$$

Then, Fermat's rule yields $B^* p + \partial_\phi L(t,u,\phi) = 0$ at every $\phi \in F$ at which the minimum in (66) is attained. Therefore, from (65) it follows that

$$B^* p_*(t) + \partial_\phi L(t, u_*(t), f_*(t)) = 0 \qquad t \in [0,T] \text{ a.e.} \tag{67}$$

which provides a much-easier-to-use optimality condition.

There is a vast literature on necessary conditions for optimality for distributed parameter systems. The set-up that was considered above can be generalized in several ways: one can consider nonlinear state equations as in (62), nonsmooth running and finals costs, constraints on both state and control, problems with infinite horizon or exit times. Further reading and useful references on most of these extensions can be found in the aforementioned monographs [22,79,84,85], and in [59] which is mainly concerned with time optimal control problems.

Dynamic Programming

Though useful as it may be, Pontryagin's Maximum Principle remains a necessary condition. So, without further information, it does not suffice to prove the optimality of a give trajectory/control pair. Moreover, even when the map $\phi \mapsto \partial_\phi L(t,u,\phi)$ turns out to be invertible, the best result identity (67) can provide, is a representation of $f_*(t)$ in terms of $u_*(t)$ and $p_*(t)$: not enough to determine $f_*(t)$, in general.

This is why other methods to construct optimal controls have been proposed over the years. One of the most interesting ones is the so-called *dynamic programming* method (abbreviated, DP), initiated by the work of R. Bellman [20]. Such a method will be briefly described below in the set-up of distributed parameter systems.

Fix $T > 0$, s such that $0 \le s \le T$, and consider the optimal control problem

to minimize

$$J^{s,\nu}(f) = \int_s^T L\left(t, u_f^{s,\nu}(t), f(t)\right) \mathrm{d}t + \ell\left(u_f^{s,\nu}(T)\right) \tag{68}$$

over all control functions $f \in L^2(s,T;F)$, where $u_f^{s,\nu}(t)$ is the solution of the controlled system

$$\begin{cases} u'(t) = Au(t) + Bf(t) & t \in [s,T] \\ u(s) = \nu . \end{cases} \tag{69}$$

The *value function* U associated to (68)-(69) is the real-valued function defined by

$$U(s,\nu) = \inf_{f\in L^2(s,T;F)} J^{s,\nu}(f) \quad \forall (s,\nu) \in [0,T]\times H . \tag{70}$$

A fundamental step of DP is the following result, known as Bellman's *optimality principle*.

Theorem 5 *For any* $(s, v) \in [0, T] \times H$ *and any* $f \in L^2(s, T; F)$

$$U(s,v) \leq \int_s^r L\left(t, u_f^{s,v}(t), f(t)\right) dt + U\left(r, u_f^{s,v}(r)\right) \quad \forall r \in [s,T]\,.$$

Moreover, $f^*(\cdot)$ *is optimal if and only if*

$$U(s,v) = \int_s^r L\left(t, u_f^{s,v}(t), f(t)\right) dt + U\left(r, u_f^{s,v}(r)\right) \quad \forall r \in [s,T]\,.$$

The connection between DP and optimal control is based on the properties of the value function. Indeed, applying Bellman's optimality principle, one can show that, if U is Fréchet differentiable, then

$$\begin{cases} \partial_s U(s,v) + \langle Av, \partial_v U(s,v)\rangle + \mathcal{H}(s,v,\partial_v U(s,v)) = 0 \\ \qquad\qquad (s,v) \in (0,T) \times D(A) \\ U(T,v) = \ell(v) \quad v \in H \end{cases}$$

where $\mathcal{H}$ is the Hamiltonian defined in (66). The above equation is the celebrated *Hamilton–Jacobi equation* of DP. To illustrate its connections with the original optimal control problem, a useful formal argument—that can, however, be made rigorous—is the following. Consider a sufficiently smooth solution W of the above problem and let $(s, v) \in (0, T) \times D(A)$. Then, for any trajectory/control pair $\{u, f\}$,

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} W(t,u(t)) &= \partial_s W(t,u(t)) + \langle \partial_v W(t,u(t)), Au(t) \\ &\quad + Bf(t)\rangle \\ &= \langle \partial_v W(t,u(t)), Bf(t)\rangle \\ &\quad - \mathcal{H}(t,u(t),\partial_v W(t,u(t))) \\ &\geq -L(t,u(t),f(t)) \end{aligned} \tag{71}$$

by the definition of $\mathcal{H}$. Therefore, integrating from s to T,

$$\ell(u(T)) - W(s,v) \geq -\int_s^T L(t,u(t),f(t))\mathrm{d}t,$$

whence $J^{s,v}(f) \geq W(s,v)$. Thus, taking the infimum over all $f \in L^2(s,T;F)$,

$$W(s,v) \leq U(s,v) \quad \forall (s,v) \in (0,T) \times D(A)\,. \tag{72}$$

Now, suppose there is a control function $f_* \in L^2(s,T;F)$ such that, for all $t \in [s,T]$,

$$\begin{aligned} \langle \partial_v W(t,u_*(t)), Bf_*(t)\rangle &+ L(t,u_*(t),f_*(t)) \\ &= \mathcal{H}(t,u_*(t),\partial_v W(t,u_*(t)))\,, \end{aligned} \tag{73}$$

where $u_*(\cdot) = u_{f_*}^{s,v}(\cdot)$. Then, from (71) and (73) it follows that

$$\frac{\mathrm{d}}{\mathrm{d}t} W(t,u_*(t)) = -L(t,u(t),f(t))\,,$$

whence

$$W(s,v) = J^{s,v}(f_*) \geq U(s,v)\,.$$

From the above inequality and (72) it follows that $W(s,v) = U(s,v)$ for all $(s,v) \in (0,T) \times D(A)$, hence for all $(s,v) \in (0,T) \times H$ since $D(A)$ is dense in H. So, f_* is an **optimal control**.

Note 2 The above considerations lead to the following procedure to obtain optimal an optimal trajectory:

- find a smooth solution of the Hamilton–Jacobi equation;
- for every $(t,v) \in (0,T) \times D(A)$ provide a feedback $f(t,v)$ such that

$$\begin{aligned} \langle \partial_v W(t,v), Bf(t,v)\rangle &+ L(t,v,f(t,v)) \\ &= \mathcal{H}(t,v,\partial_v W(t,v)) \end{aligned}$$

- solve the so-called *closed loop equation*

$$\begin{cases} u'(t) = Au(t) + Bf(t,u(t)) & t \in [s,T] \\ u(s) = v \end{cases}$$

Notice that not only is trajectory u optimal, but the corresponding control f is given in feedback form as well.

Linear Quadratic Optimal Control

One of the most successful applications of DP is the so-called Linear Quadratic optimal control problem. Consider problem (68)–(69) with costs L and ℓ given by

$$L(t,u,\phi) = \langle M(t)u,u\rangle + \langle N(t)\phi,\phi\rangle \quad \forall (T,u,\phi) \in [0,T] \times H \times F$$

and

$$\ell(u) = \langle Du,u\rangle \quad \forall u \in H\,,$$

where

- $M\colon [0,T] \to \mathcal{L}(H)$ is continuous, $M(t)$ is symmetric and $\langle M(t)u,u\rangle \geq 0$ for every $(t,u) \in [0,T] \times H$;
- $N\colon [0,T] \to F$ is continuous, $N(t)$ is symmetric and $\langle N(t)\phi,\phi\rangle \geq c_0|\phi|^2$ for every $(t,\phi) \in [0,T] \times F$ and some constant $c_0 > 0$;

- $D \in \mathcal{L}(H)$ is symmetric and $\langle Du, u\rangle \geq 0$ for every $u \in H$.

Then, assumptions (63) and (64) are satisfied. So, a solution to (68)–(69) does exist. Moreover, it is unique because of the strict convexity of functional $J^{s,v}$.

In order to apply DP, one computes the Hamiltonian

$$\mathcal{H}(t,u,p) = \min_{\phi \in F} \Big[\langle p, B\phi\rangle + \langle M(t)u,u\rangle + \langle N(t)\phi,\phi\rangle\Big] = \langle M(t)u,u\rangle - \frac{1}{4}\langle BN^{-1}(t)B^* p, p\rangle \,,$$

where the above minimum is attained at

$$\phi_*(t,p) = -\frac{1}{2}N^{-1}(t)B^* p \,. \tag{74}$$

Therefore, the Hamilton–Jacobi equation associated to the problem is

$$\begin{cases} \partial_s W(s,v) + \langle Av, \partial_v W(s,v)\rangle + \langle M(s)v,v\rangle \\ \quad -\frac{1}{4}\langle BN^{-1}(s)B^* \partial_v W(s,v), \partial_v W(s,v)\rangle = 0 \\ \qquad\qquad\qquad\qquad \forall (s,v) \in (0,T)\times D(A) \\ w(T,v) = \langle Dv,v\rangle \quad \forall v \in H \end{cases}$$

It is quite natural to search a solution of the above problem in the form

$$W(s,v) = \langle P(s)v,v\rangle \quad \forall (s,v) \in [0,T]\times H\,,$$

with $P\colon [0,T] \to \mathcal{L}(H)$ continuous, symmetric and such that $\langle P(t)u,u\rangle \geq 0$. Substituting into the Hamilton–Jacobi equation yields

$$\begin{cases} \langle P'(s)v,v\rangle + \langle [A^*P(s) + P(s)A]v,v\rangle + \langle M(s)v,v\rangle \\ \quad -\langle BN^{-1}(s)B^*P(s)v, P(s)v\rangle = 0 \\ \qquad\qquad\qquad\qquad \forall (s,v) \in (0,T)\times D(A) \\ \langle P(T)v,v\rangle = \langle Dv,v\rangle \quad \forall v \in H \end{cases}$$

Therefore, P must be a solution of the so-called *Riccati equation*

$$\begin{cases} P'(s) + A^*P(s) + P(s)A + M(s) \\ \quad -P(s)BN^{-1}(s)B^*P(s) = 0 \qquad \forall s \in (0,T) \\ P(T) = D \end{cases}$$

Once a solution $P(\cdot)$ of the Riccati equation is known, the procedure described in Note 2 can be applied. Indeed, recalling (74) and the fact that $\partial_v W(t,v) = 2P(t)v$, one concludes that $f(t,v) = -N^{-1}(t)B^*P(t)v$ is a feedback law. So, solving the closed loop equation

$$\begin{cases} u'(t) = [A - BN^{-1}(t)B^*P(t)]u(t) \quad t \in (s,T) \\ u(s) = v \end{cases}$$

one obtains the unique optimal trajectory of problem (68)–(69).

In sum, by DP one reduces the original Linear Quadratic optimal control problem to the problem of finding the solution of the Riccati equation, which is easier to solve than the Hamilton–Jacobi equation.

Bibliographical Comments

Different variants of the Riccati equation have been successfully studied by several authors in connection with different state equations and cost functionals, including boundary control problems and problems for other functional equations, see [22,79] and the references therein. Sometimes, the solution of the Riccati equation related to a linearized model provides feedback stabilization for nonlinear problems as in [104].

Unfortunately, the DP method is hard to implement for general optimal control problems, because of several obstructions: nonsmoothness of solutions to Hamilton–Jacobi equations, selection problems that introduce discontinuities, unboundedness of the coefficients, numerical complexity. Besides the Linear Quadratic case, the so-called Linear Convex case is the other example that can be studied by DP under fairly general conditions, see [14]. For nonlinear optimal control problems some of the above difficulties have been overcome extending the notion of viscosity solutions to infinite dimensional spaces, see [45,46,47,48,49], see also [28,29,30,31,32,33] and [112]. Nevertheless, finding additional ideas to make a generalized use of DP for distributed parameter systems possible, remains a challenging problem for the next generations.

Future Directions

In addition to all considerations spread all over this article on promising developments of recent—as well as established—research lines, a few additional topics deserve to be mentioned.

The one subject that has received the highest attention, recently, is that of numerical approximation of control problems, from the point of view of both controllability and optimal control. Here the problem is that, due to high frequency spurious numerical solutions, stable algorithms for solving initial-boundary value problems do not necessarily yield convergent algorithms for computing controls. This difficulty is closely related to the existence of concentrated numerical solutions that escape the observation mechanisms. Nevertheless, some interesting results have been obtained so far, see, e. g., [124,125].

Several interesting results for nonlinear control problems have been obtained by the *return method*, developed initially by Coron [42] for a stabilization problem. This and other techniques have then been applied to fluid models ([68,69]), the Korteweg–de Vries equation ([105,106,107]), and Schrödinger type equations ([19]), see also [43] and the references therein. It seems likely that these ideas, possibly combined with other techniques like Carleman estimates as in [70], will lead to new exiting results in the years to come.

A final comment on null controllability for *degenerate parabolic equations* is in order. Indeed, many problems that are relevant for applications are described by parabolic equation equations in divergence form

$$\partial_t u = \nabla\cdot(A(x)\nabla u) + b(x)\cdot\nabla u + c(t,x)u + f \quad \text{in} \quad Q_T\,,$$

or in the general form

$$\partial_t u = \text{Tr}\,[A(x)\nabla^2 u] + b(x)\cdot\nabla u + c(t,x)u + f \quad \text{in} \quad Q_T\,,$$

where $A(x)$ is a symmetric matrix, positive definite in Ω but possibly singular on Γ. For instance, degenerate parabolic equations arise in fluid dynamics as suitable transformations of the Prandtl equations, see, e. g., [94]. They can also be obtained as Kolmogorov equations of diffusions processes on domains that are invariant for stochastic flows, see, e. g., [52]. The latter interpretation explains why they have been applied to biological problems, such as gene frequency models for population genetics (see, e. g., the Wright–Fischer model studied in [111]).

So far, null controllability properties of degenerate parabolic equations have been fully understood only in dimension one: for some kind of degeneracy, null controllability holds true (see [36] and [9]), but, in general, one can only expect regional null controllability (see [35]). Since very little is known on null controllability for degenerate parabolic equations in higher space dimensions, it is conceivable that such a topic will provide interesting problems for future developments.

Article Outline

Glossary

Game theory Discipline that studies strategic situations.

Cooperative game Strategic situation involving coalitions, whose formation assumes the existence of binding agreements among players.

Characteristic or coalitional function The most usual way to represent a cooperative game.

Solution concept Mapping that assigns predictions to each game.

Core Solution concept that assigns the set of payoffs that cannot be improved upon by any coalition.

Shapley value Solution concept that assigns the average of marginal contributions to coalitions.

Definition of the Subject

Cooperative game theory It is one of the two counterparts of game theory. It studies the interactions among coalitions of players. Its main question is this: Given the sets of feasible payoffs for each coalition, what payoff will be awarded to each player? One can take a positive or normative approach to answering this question, and different solution concepts in the theory lean towards one or the other.

Core It is a solution concept that assigns to each cooperative game the set of payoffs that no coalition can improve upon or block. In a context in which there is unfettered coalitional interaction, the core arises as a good positive answer to the question posed in cooperative game theory. In other words, if a payoff does not belong to the core, one should not expect to see it as the prediction of the theory if there is full cooperation.

Shapley value It is a solution that prescribes a single payoff for each player, which is the average of all marginal contributions of that player to each coalition he or she is a member of. It is usually viewed as a good normative answer to the question posed in cooperative game theory. That is, those who contribute more to the groups that include them should be paid more.

Although there were some earlier contributions, the official date of birth of game theory is usually taken to be 1944, year of publication of the first edition of the *Theory* *of Games and Economic Behavior*, by John von Neumann and Oskar Morgenstern [42]. The core was first proposed by Francis Ysidro Edgeworth in 1881 [13], and later reinvented and defined in game theoretic terms in [14]. The Shapley value was proposed by Lloyd Shapley in his 1953 Ph D dissertation [37]. Both the core and the Shapley value have been applied widely, to shed light on problems in different disciplines, including economics and political science.

Introduction

Game theory is the study of games, also called strategic situations. These are decision problems with multiple decision makers, whose decisions impact one another. It is divided into two branches: non-cooperative game theory and cooperative game theory. The actors in non-cooperative game theory are individual players, who may reach agreements only if they are self-enforcing. The non-cooperative approach provides a rich language and develops useful tools to analyze games. One clear advantage of the approach is that it is able to model how specific details of the interaction among individual players may impact the final outcome. One limitation, however, is that its predictions may be highly sensitive to those details. For this reason it is worth also analyzing more abstract approaches that attempt to obtain conclusions that are independent of such details. The cooperative approach is one such attempt, and it is the subject of this article.

The actors in cooperative game theory are coalitions, that is, groups of players. For the most part, two facts, that coalitions can form and that each coalition has a feasible set of payoffs available to its members, are taken as given. Given the coalitions and their sets of feasible payoffs as primitives, the question tackled is the identification of final payoffs awarded to each player. That is, given a collection of feasible sets of payoffs, one for each coalition, can one predict or recommend a payoff (or set of payoffs) to be awarded to each player? Such predictions or recommendations are embodied in different solution concepts.

Indeed, one can take several approaches to answering the question just posed. From a positive or descriptive point of view, one may want to get a prediction of the likely outcome of the interaction among the players, and hence, the resulting payoff be understood as the natural consequence of the forces at work in the system. Alternatively, one can take a normative or prescriptive approach, set up a number of normative goals, typically embodied in axioms, and try to derive their logical implications. Although authors sometimes disagree on the classification of the different solution concepts according to these two criteria – as we shall see, the understanding of each solution concept is enhanced if one can view it from very distinct approaches –, in this article we shall exemplify the positive approach with the core and the normative approach with the Shapley value. While this may oversimplify the issues, it should be helpful to a reader new to the subject.

The rest of the article is organized as follows. Sect. "Cooperative Games" introduces the basic model of a cooperative game, and discusses its assumptions as well as the notion of solution concepts. Sect. "The Core" is devoted to the core, and Sect. "The Shapley Value" to the Shapley value. In each case, some of the main results for each of the two are described, and examples are provided. Sect. "Future Directions" discusses some directions for future research.

Cooperative Games

Representations of Games. The Characteristic Function

Let us begin by presenting the different ways to describe a game. The first two are the usual ways employed in non-cooperative game theory.

The most informative way to describe a game is called its *extensive form*. It consists of a game tree, specifying the timing of moves for each player and the information available to each of them at the time of making a move. At the end of each path of moves, a final outcome is reached and a payoff vector is specified. For each player, one can define a *strategy*, i. e., a complete contingent plan of action to play the game. That is, a strategy is a function that specifies a feasible move each time a player is called upon to make a move in the game.

One can abstract from details of the interaction (such as timing of moves and information available at each move), and focus on the concept of strategies. That is, one can list down the set of strategies available to each player, and arrive at the *strategic* or *normal form* of the game. For two players, for example, the normal form is represented in a bimatrix table. One player controls the rows, and the other the columns. Each cell of the bimatrix is occupied with an ordered pair, specifying the payoff to each player if each of them chooses the strategy corresponding to that cell.

One can further abstract from the notion of strategies, which will lead to the *characteristic function form* of representing a game. From the strategic form, one makes assumptions about the strategies used by the complement of a coalition of players to determine the feasible payoffs for the coalition (see, for example, the derivations in [7,42]). This is the representation most often used in cooperative game theory.

Thus, here are the primitives of the basic model in cooperative game theory. Let $N = \{1, \dots, n\}$ be a finite set of players. Each non-empty subset of N is called a *coalition*. The set N is referred to as the *grand coalition*. For each coalition S, we shall specify a set $V(S) \subset \mathbb{R}^{|S|}$ containing $|S|$-dimensional payoff vectors that are feasible for coalition S. This is called the characteristic function, and the pair (N, V) is called a *cooperative game*. Note how a reduced form approach is taken because one does not explain what strategic choices are behind each of the payoff vectors in $V(S)$. In addition, in this formulation, it is implicitly assumed that the actions taken by the complement coalition (those players in $N \setminus S$) cannot prevent S from achieving each of the payoff vectors in $V(S)$. There are more general models in which these sorts of externalities across coalitions are considered, but we shall ignore them in this article.

Assumptions on the Characteristic Function

Some of the most common technical assumptions made on the characteristic function are the following:

(1) For each $S \subseteq N$, $V(S)$ is closed. Denote by $\partial V(S)$ the boundary of $V(S)$. Hence, $\partial V(S) \subseteq V(S)$.

(2) For each $S \subseteq N$, $V(S)$ is comprehensive, i. e., for each $x \in V(S)$, $\{x\} - \mathbb{R}^{|S|}_{+} \subseteq V(S)$.

(3) For each $x \in \mathbb{R}^{|S|}$,

$$\partial V(S) \cap \left(\{x\} + \mathbb{R}^{|S|}_{+}\right)$$

is bounded.

(4) For each $S \subseteq N$, there exists a continuously differentiable representation of $V(S)$, i. e., a continuously differentiable function $g_S : \mathbb{R}^{|S|} \to \mathbb{R}$ such that

$$V(S) = \{x \in \mathbb{R}^{|S|} | g_S(x) \leq 0\} .$$

(5) For each $S \subseteq N$, $V(S)$ is non-leveled, i. e., for every $x \in \partial V(S)$, the gradient of g_S at x is positive in all its coordinates.

With the assumptions made, $\partial V(S)$ is its Pareto frontier, i. e., the set of vectors $x_S \in V(S)$ such that there does not exist $y_S \in V(S)$ satisfying that $y_i \geq x_i$ for all $i \in S$ with at least one strict inequality.

Other assumptions usually made relate the possibilities available to different coalitions. Among them, a very important one is *balancedness*, which we shall define next:

A collection $\mathcal{T}$ of coalitions is balanced if there exists a set of weights $w(S) \in [0, 1]$ for each $S \in \mathcal{T}$ such that for every $i \in N$, $\sum_{S \in \mathcal{T}, S \supseteq \{i\}} w(S) = 1$. One can think of these weights as the fraction of time that each player devotes to each coalition he is a member of, with a given coalition representing the same fraction of time for each player. The game (N, V) is balanced if $x_N \in V(N)$ whenever $(x_S) \in V(S)$ for every S in a balanced collection $\mathcal{T}$. That is, the grand coalition can always implement any "time-sharing arrangement" that the different subcoalitions may come up with.

The characteristic function defined so far is often referred to as a *non-transferable utility (NTU)* game. A particular case is the *transferable utility (TU)* game case, in which for each coalition $S \subseteq N$, there exists a real number $v(S)$ such that

$$V(S) = \left\{ x \in \mathbb{R}^{|S|} : \sum_{i \in S} x_i \leq v(S) \right\} .$$

Abusing notation slightly, we shall denote a TU game by (N, v). In the TU case there is an underlying nummeraire – money – that can transfer utility or payoff at a one-to-one rate from one player to any other. Technically, the theory of NTU games is far more complex: it uses convex analysis and fixed point theorems, whereas the TU theory is based on linear inequalities and combinatorics.

Solution Concepts

Given a characteristic function, i. e., a collection of sets $V(S)$, one for each S, the theory formulates its predictions on the basis of different *solution concepts*. We shall concentrate on the case in which the grand coalition forms, that is, cooperation is totally successful. Of course, solution concepts can be adapted to take care of the case in which this does not happen.

A *solution* is a mapping that assigns a set of payoff vectors in $V(N)$ to each characteristic function game (N, V). Thus, a solution in general prescribes a set, which can be empty, or a singleton (when it assigns a unique payoff vector as a function of the fundamentals of the problem). The leading set-valued cooperative solution concept is the core, while one of the most used single-valued ones is the Shapley value for TU games.

There are several criteria to evaluate the reasonableness or appeal of a cooperative solution. As outlined above, in a normative approach, one can propose axioms, abstract principles that one would like the solution to satisfy, and the next step is to pursue their logical consequences. Historically, this was the first argument to justify the Shapley value. Alternatively, one could start by defending a solution on the basis of its definition alone. In the case of the core, this will be especially natural: in a context in which players can freely get together in groups, the prediction should be payoff vectors that cannot be improved upon by any coalition. One can further enhance one's positive understanding of the solution concept by proposing games in extensive form or in normal form played non-cooperatively by players whose self-enforcing agreements lead to a given solution. This is simply to provide non-cooperative foundations or non-cooperative implementation to the cooperative solution in question, and it is an important research agenda initiated by John Nash in [25], referred to as the Nash program (see [34] for a recent survey). Today, there are interesting results of these different kinds for many solution concepts, which include axiomatic characterizations and non-cooperative foundations. Thus, one can evaluate the appeal of the axioms and the non-cooperative procedures behind each solution to defend a more normative or positive interpretation in each case.

The Core

The idea of agreements that are immune to coalitional deviations was first introduced to economic theory by Edgeworth in [13], which defined the set of coalitionally stable allocations of an economy under the name "final settlements." Edgeworth envisioned this concept as an alternative to *competitive equilibrium* [43], of central importance in economic theory, and was also the first to investigate the connections between the two concepts. Edgeworth's notion, which today we refer to as the *core*, was rediscovered and introduced to game theory in [14]. The origins of the core were not axiomatic. Rather, its simple and appealing definition appropriately describes stable outcomes in a context of unfettered coalitional interaction.

The core of the game (N, V) is the set of payoff vectors

$$C(N, V) = \{x \in V(N): \ \nexists S \subseteq N, x_S \in V(S) \setminus \partial V(S)\}\,.$$

In words, it is the set of feasible payoff vectors for the grand coalition that no coalition can upset. If such a coalition S exists, we shall say that S can improve upon or block x, and x is deemed unstable. That is, in a context where any coalition can get together, when S has a blocking move, coalition S will form and abandon the grand coalition and its payoffs x_S in order to get to a better payoff for each of the members of the coalition, a plan that is feasible for them.

Non-Emptiness

The core can prescribe the empty set in some games. A game with an empty core is to be understood as a situation of strong instability, as any payoffs proposed to the grand coalition are vulnerable to coalitional blocking.

Example Consider the following simple majority 3-player TU game, in which the votes of at least two players makes the coalition winning. That is, we represent the situation by the following characteristic function: $v(S) = 1$ for any S containing at least two members, $v(\{i\}) = 0$ for all $i \in N$. Clearly, $C(N, v) = \emptyset$. Any feasible payoff agreement proposed to the grand coalition will be blocked by at least one coalition.

An important sufficient condition for the non-emptiness of the core of NTU games is balancedness, as shown in [32]:

Theorem 1 (Scarf [32]) *Let the game (N, V) be balanced. Then $C(N, V) \neq \emptyset$.*

For the TU case, balancedness is not only sufficient, but it becomes also necessary for the non-emptiness of the core:

Theorem 2 (Bondareva [9]; Shapley [39]) *Let (N, v) be a TU game. Then, (N, v) is balanced if and only if $C(N, v) \neq \emptyset$.*

The Connections with Competitive Equilibrium

In economics, the institution of markets and the notion of prices are essential to the understanding of the allocation of goods and the distribution of wealth among individuals. For simplicity in the presentation, we shall concentrate on exchange economies, and disregard production aspects. That is, we shall assume that the goods in question have already been produced in some fixed amounts, and now they are to be allocated to individuals to satisfy their consumption needs.

An *exchange economy* is a system in which each agent i in the set N has a consumption set $Z_i \subseteq \mathbb{R}^l_+$ of commodity bundles, as well as a preference relation over Z_i and an initial endowment $\omega_i \in Z_i$ of the commodities. A feasible *allocation* of goods in the economy is a list of bundles $(z_i)_{i \in N}$ such that $z_i \in Z_i$ and $\sum_{i \in N} z_i \leq \sum_{i \in N} \omega_i$. An allocation is *competitive* if it is supported by a *competitive equilibrium*. A competitive equilibrium is a price-allocation pair $(p, (z_i)_{i \in N})$, where $p \in \mathbb{R}^l \setminus \{0\}$ is such that

- for every $i \in N$, z_i is top-ranked for agent i among all bundles z satisfying that $pz \leq p\omega_i$,
- and $\sum_{i \in N} z_i = \sum_{i \in N} \omega_i$.

In words, this is what the concept expresses. First, at the equilibrium prices, each agent demands z_i, i. e., wishes to purchase this bundle among the set of affordable bundles, the budget set. And second, these demands are such that all markets clear, i. e., total demand equals total supply.

Note how the notion of a competitive equilibrium relies on the principle of private ownership (each individual owns his or her endowment, which allows him or her to access markets and purchase things). Moreover, each agent is a price-taker in all markets. That is, no single individual can affect the market prices with his or her actions; prices are fixed parameters in each individual's consumption decision. The usual justification for the price-taking assumption is that each individual is "very small" with respect to the size of the economy, and hence, has no market power.

One difficulty with the competitive equilibrium concept is that it does not explain where prices come from. There is no single agent in the model responsible for coming up with them. Walras in [43] told the story of an auctioneer calling out prices until demand and supply coincide, but in many real-world markets there is no auctioneer. More generally, economists attribute the equilibrium prices to the workings of the forces of demand and supply, but this appears to be simply repeating the definition. So, is there a different way one can explain competitive equilibrium prices?

As it turns out, there is a very robust result that answers this question. We refer to it as the *equivalence principle* (see, e. g., [6]), by which, under certain regularity conditions, the predictions provided by different game-theoretic solution concepts, when applied to an economy with a large enough set of agents, tend to converge to the set of competitive equilibrium allocations. One of the first results in this tradition was provided by Edgeworth in 1881 for the core. Note how the core of the economy can be defined in the space of allocations, using the same definition as above. Namely, a feasible allocation is in the core if it cannot be blocked by any coalition of agents when making use of the coalition's endowments.

Edgeworth's result was generalized later by Debreu and Scarf in [11] for the case in which an exchange economy is replicated an arbitrary number of times (Anderson studies in [1] the more general case of arbitrary sequences of economies, not necessarily replicas). An informal statement of the Debreu–Scarf theorem follows:

Theorem 3 (Debreu and Scarf [11]) *Consider an exchange economy. Then,*

- *(i) The set of competitive equilibrium allocations is contained in the core.*
- *(ii) For each non-competitive core allocation of the original economy, there exists a sufficiently large replica of the economy for which the replica of the allocation is blocked.*

The first part states a very appealing property of competitive allocations, i. e., their coalitional stability. The second part, known as the core convergence theorem, states that the core "shrinks" to the set of competitive allocations as the economy grows large.

In [3], Aumann models the economy as an atomless measure space, and demonstrates the following core equivalence theorem:

Theorem 4 (Aumann [3]) *Let the economy consists of an atomless continuum of agents. Then, the core coincides with the set of competitive allocations.*

For readers who wish to pursue the topic further, [2] provides a recent survey.

Axiomatic Characterizations

The axiomatic foundations of the core were provided much later than the concept was proposed. These characterizations are all inspired by Peleg's work. They include [26,27], and [36] – the latter paper also provides an axiomatization of competitive allocations in which core convergence insights are exploited.

In all these characterizations, the key axiom is that of *consistency*, also referred to as the reduced game property. Consistency means that the outcomes prescribed by a solution should be "invariant" to the number of players in the game. More formally, let (N, V) be a game, and let σ be a solution. Let $x \in \sigma(N, V)$. Then, the solution is consistent if for every $S \subseteq N$, $x_S \in \sigma(S, V_{xS})$, where (S, V_{xS}) is the reduced game for S given payoffs x, defined as follows. The feasible set for S in this reduced game is the projection of $V(N)$ at $x_{N\setminus S}$, i. e., what remains after paying those outside of S:

$$V_{xS}(S) = \{y_S : (y_S, x_{N\setminus S}) \in V(N)\} .$$

However, the feasible set of $T \subset S$, $T \neq S$, allows T to make deals with any coalition outside of S, provided that those services are paid at the rate prescribed by $x_{N\setminus S}$:

$$V_{xS}(T) = \{y_T \in \cup_{Q \subseteq N\setminus S}(y_T, x_Q) \in V(T \cup Q)\} .$$

It can be shown that the core satisfies consistency with respect to this reduced game. Moreover, consistency is the central axiom in the characterization of the core, which, depending on the version one looks at, uses a host of other axioms; see [26,27,36].

Non-cooperative Implementation

To obtain a non-cooperative implementation of the core, the procedure must embody some feature of anonymity, since the core is usually a large set and it contains payoffs where different players are treated very differently. For instance, if the procedure always had a fixed set of moves, typically the prediction would favor the first mover, making it impossible to obtain an implementation of the entire set of payoffs.

The model in [30] builds in this anonymity by assuming that negotiations take place in continuous time, so that anyone can speak at the beginning of the game, and at any point in time, instead of having a fixed order. The player that gets to speak first makes a proposal consisting of naming a coalition that contains him and a feasible payoff for that coalition. Next, the players in that coalition get to respond. If they all accept the proposal, the coalition leaves and the game continues among the other players. Otherwise, a new proposal may come from any player in N. It is shown that, if the TU game has a non-empty core (as well as any of its subgames), a class of stationary self-enforcing predictions of this procedure coincide with the core. If a core payoff is proposed to the grand coalition, there are no incentives for individual players to reject it. Conversely, a non-core payoff cannot be sustained because any player in a blocking coalition has an incentive to make a proposal to that coalition, who will accept it (knowing that the alternative, given stationarity, would be to go back to the non-core status quo). [24] offers a discrete-time version of the mechanism: in this work, the anonymity required is imposed on the solution concept, by looking at the order-independent equilibria of the procedure.

The model in [33] sets up a market to implement the core. The anonymity of the procedure stems from the random choice of broker. The broker announces a vector $(x_1, \ldots, x_n)$, where the components add up to $v(N)$. One can interpret x_i as the price for the productive asset held by player i. Following an arbitrary order, the remaining players either accept or reject these prices. If player i accepts, he sells his asset to the broker for the price x_i and leaves the game. Those who reject get to buy from the broker, at the called out prices, the portfolio of assets of their choice if the broker still has them. If a player rejects, but does not get to buy the portfolio of assets he would like because someone else took them before, he can always leave the market with his own asset. The broker's payoff is the worth of the final portfolio of assets that he holds, plus the net monetary transfers that he has received. It is shown in [33] that the prices announced by the broker will always be his top-ranked vectors in the core. If the TU game is such that gains from cooperation increase with the size of coalitions, a beautiful theorem of Shapley in [41] is used to prove that the set of all equilibrium payoffs of this procedure will coincide with the core. Core payoffs are here understood as those price vectors where all arbitrage opportunities in the market have been wiped out. Also, procedures in [35] implement the core, but do not rely on the TU assumption, and they use a procedure in which the order of moves can be endogenously changed by players. Finally, yet another way to build anonymity in the procedure is by allowing the proposal to be made by brokers outside of the set N, as done in [28].

An Application

Consider majority games within a parliament. Suppose there are 100 seats, and decisions are made by simple majority so that 51 votes are required to pass a piece of legislation.

In the first specification, suppose there is a very large party – player 1 –, who has 90 seats. There are five small parties, with 2 seats each. Given the simple majority rules, this problem can be represented by the following TU characteristic function: $v(S) = 1$ if S contains player 1, and $v(S) = 0$ otherwise. The interpretation is that each winning coalition can get the entire surplus – pass the desired proposal. Here, a coalition is winning if and only if player 1 is in it. For this problem, the core is a singleton: the entire unit of surplus is allocated to player 1, who has all the power. Any split of the unit surplus of the grand coalition ($v(N) = 1$) that gives some positive fraction of surplus to any of the small parties can be blocked by the coalition of player 1 alone.

Consider now a second problem, in which player 1, who continues to be the large party, has 35 seats, and each of the other five parties has 13 seats. Now, the characteristic function is as follows: $v(S) = 1$ if and only if S either contains player 1 and two small parties, or it contains four of the small parties; $v(S) = 0$ otherwise. It is easy to see that now the core is empty: any split of the unit surplus will be blocked by at least one coalition. For example, the entire unit going to player 1 is blocked by the coalition of all five small parties, which can award 0.2 to each of them. But this arrangement, in which each small party gets 0.2 and player 1 nothing, is blocked as well, because player 1 can bribe two of the small parties (say, players 2 and 3) and promise them 1/3 each, keeping the other third for itself, and so on. The emptiness of the core is a way to describe the fragility of any agreement, due to the inherent instability of this coalition formation game.

The Shapley Value

Now consider a transferable utility or TU game in characteristic function form. The number $v(S)$ is referred to as the worth of S, and it expresses S's initial position (e. g., the maximum total amount of surplus in nummeraire – money, or power – that S initially has at its disposal.

Axiomatics

Shapley in [37] is interested in solving in a fair and unique way the problem of distribution of surplus among the players, when taking into account the worth of each coalition. To do this, he restricts attention to single-valued solutions and resorts to the axiomatic method. He proposes the following axioms on a single-valued solution:

(i) Efficiency: The payoffs must add up to $v(N)$, which means that all the grand coalition surplus is allocated.
(ii) Symmetry: If two players are substitutes because they contribute the same to each coalition, the solution should treat them equally.
(iii) Additivity: The solution to the sum of two TU games must be the sum of what it awards to each of the two games.
(iv) Dummy player: If a player contributes nothing to every coalition, the solution should pay him nothing.

(To be precise, the name of the first axiom should be different. In an economic sense, the statement does imply efficiency in superadditive games, i. e., when for every pair of disjoint coalitions S and T, $v(S) + v(T) \leq v(S \cup T)$. In the absence of superadditivity, though, forming the grand coalition is not necessarily efficient, because a higher aggregate payoff can be obtained from a different coalition structure.)

The surprising result in [37] is this:

Theorem 5 (Shapley [37]) *There is a unique single-valued solution to TU games satisfying efficiency, symmetry, additivity and dummy. It is what today we call the Shapley value, the function that assigns to each player i the payoff*

$$Sh_i(N,v) = \sum_{S, i \in S} \frac{(|S|-1)!(|N|-|S|)!}{|N|!}[v(S) - v(S \setminus \{i\})] .$$

That is, the Shapley value awards to each player the average of his marginal contributions to each coalition. In taking this average, all orders of the players are considered to be equally likely. Let us assume, also without loss of generality, that $v(\{i\}) = 0$ for each player i.

What is especially surprising in Shapley's result is that nothing in the axioms (with the possible exception of the dummy axiom) hints at the idea of marginal contributions, so marginality in general is the outcome of all the axioms, including additivity or linearity. Among the axioms utilized by Shapley, additivity is the one with a lower normative content: it is simply a mathematical property to justify simplicity in the computation of the solution. Young in [45] provides a beautiful counterpart to Shapley's theorem. He drops additivity (as well as the dummy player axiom), and instead, uses an axiom of marginality. Marginality means that the solution should pay the same to a pleyar in two games if his or her marginal contributions to coalitions is the same in both games. Marginality is an idea with a strong tradition in economic theory. Young's result is "dual" to Shapley's, in the sense that marginality is assumed and additivity derived as the result:

Theorem 6 (Young [45]) *There exists a unique single-valued solution to TU games satisfying efficiency, symmetry and marginality. It is the Shapley value.*

Apart from these two, [19] provides further axiomatizations of the Shapley value using the idea of potential and the concept of consistency, as described in the previous section.

There is no single way to extend the Shapley value to the class of NTU games. There are three main extensions that have been proposed: the Shapley λ-transfer value [40], the Harsanyi value [16], and the Maschler–Owen consistent value [23]. They were axiomatized in [5,10,17], respectively.

The Connections with Competitive Equilibrium

As was the case for the core, there is a value equivalence theorem. The result holds for the TU domain (see [4,8,38]). It can be shown that the Shapley value payoffs can be supported by competitive prices. Furthermore, in large enough economies, the set of competitive payoffs "shrinks" to approximate the Shapley value. However, the result cannot be easily extended to the NTU domain. While it holds for the λ-transfer value, it need not obtain for the other extensions. For further details, the interested reader is referred to [18] and the references therein.

Non-cooperative Implementation

Reference [15] was the first to propose a procedure that provided some non-cooperative foundations of the Shapley value. Later, other authors have provided alternative procedures and techniques to the same end, including [20,21,29,44].

We shall concentrate on the description of the procedure proposed by Hart and Mas-Colell in [20]. Generalizing an idea found in [22], which studies the case of $\delta = 0$ – see below –, Hart and Mas-Colell propose the following non-cooperative procedure. With equal probability, each player $i \in N$ is chosen to publicly make a feasible proposal to the others: $(x_1, \ldots, x_n)$ is such that the sum of its components cannot exceed $v(N)$. The other players get to respond to it in sequence, following a prespecified order. If all accept, the proposal is implemented; otherwise, a random device is triggered. With probability $0 \leq \delta < 1$, the same game continues being played among the same n players (and thus, a new proposer will be chosen again at random among them), but with probability $1 - \delta$, the proposer leaves the game. He is paid 0 and his resources are removed, so that in the next period, proposals to the remaining $n - 1$ players cannot add up to more than $v(N \setminus \{i\})$. A new proposer is chosen at random among the set $N \setminus \{i\}$, and so on.

As shown in [20], there exists a unique stationary self-enforcing prediction of this procedure, and it actually coincides with the Shapley value payoffs for any value of δ. (Stationarity means that strategies cannot be history dependent). As $\delta \to 1$, the Shapley value payoffs are also obtained not only in expectation, but with independence of who is the proposer. One way to understand this result, as done in [20], is to check that the rules of the procedure and stationary behavior in it are in agreement with Shapley's axioms. That is, the equilibrium relies on immediate acceptances of proposals, stationary strategies treat substitute players similarly, the equations describing the equilibrium have an additive structure, and dummy players will have to receive 0 because no resources are destroyed if they are asked to leave. It is also worth stressing the important role in the procedure of players' marginal contributions to coalitions: following a rejection, a proposer incurs the risk of being thrown out and the others of losing his resources, which seem to suggest a "price" for them.

In [21], the authors study the conditions under which stationarity can be removed to obtain the result. Also, [29] uses a variant of the Hart and Mas-Colell procedure, by replacing the random choice of proposers with a bidding stage, in which players bid to obtain the right to make proposals.

An Application

Consider again the class of majority problems in a parliament consisting of 100 seats. As we shall see, the Shapley value is a good way to understand the power that each party has in the legislature.

Let us begin by considering again the problem in which player 1 has 90 seats, while each of the five small parties has 2 seats. It is easy to see that the Shapley value, like the core in this case, awards the entire unit of surplus to player 1: effectively, each of the small parties is a dummy player, and hence, the Shapley value awards zero to each of them.

Consider a second problem, in which player 1 is a big party with 35 seats, and there are 5 small parties, with 13 seats each. The Shapley value awards 1/3 to the large party, and, by symmetry, 2/15 to each of the small parties. To see this, we need to see when the marginal contributions of player 1 to any coalition are positive. Recall that there are 6! possible orders of players. Note how, if player 1 arrives first or second in the room in which the coalition is forming, his marginal contribution is zero: the coalition was losing before he arrived and continues to be a losing coalition after his arrival. Similarly, his marginal contribution is also zero if he arrives fifth or sixth to the coalition; indeed, in this case, before he arrives the coalition is already winning, so he adds nothing to it. Thus, only when he arrives third or fourth, which happens a third of the times, does he change the nature of the coalition, from losing to winning. This explains his Shapley value share of 1/3. In this game, the Shapley value payoffs roughly correspond to the proportion of seats that each party has.

Next, consider a third problem in which there are two large parties, while the other four parties are very small. For example, let each of the large parties have 48 seats (say, players 1 and 2), while each of the four small parties has only one seat. Now, the Shapley value payoffs are 0.3 to each of the two large parties, and 0.1 to each of the small ones. To see this, note that the marginal contribution of a small party is only positive when he comes fourth in line, and out of the preceding three parties in the coalition, exactly one of them is a large party, i. e., 72 orders out of the 5! orders in which he is fourth. That is, $(72/5!) \times (1/6) = 1/10$. In this case, the competition between the large parties for the votes of the small parties increases the power of the latter quite significantly, with respect to the proportion of seats that each of them holds.

Finally, consider a fourth problem with two large parties (players 1 and 2) with 46 seats each, one mid-size party (player 3) with 5 seats, and three small parties, each with one seat. First, note that each of the three small parties has become a dummy player: no winning coalition where he belongs becomes losing if he leaves the coalition, and so players 4, 5 and 6 are paid zero by the Shapley value. Now, note that, despite the substantial difference of seats between each large party and the mid-size party, each of them is identical in terms of marginal contributions to a winning coalition. Indeed, for $i = 1, 2, 3$, player i's marginal contribution to a coalition is positive only if he arrives second or third or fourth or fifth (and out of the preceding players in the coalition, exactly one is one of the non-dummy players). Note how the Shapley value captures nicely the changes in the allocation of power due to each different political scenario. In this case, the fierce competition between the large parties for the votes of player 3, the swinging party to form a majority, explains the equal share of power among the three.

Future Directions

This article has been a first approach to cooperative game theory, and has emphasized two of its most important solution concepts. The literature on these topics is vast, and the interested reader is encouraged to consult the general references listed below. For the future, one should expect to see progress of the theory into areas that have been less explored, including games with asymmetric information and games with coalitional externalities. In both cases, the characteristic function model must be enriched to take care of the added complexities.

Relevant to this encyclopedia are issues of complexity. The complexity of cooperative solution concepts has been studied (see, for instance, [12]). In terms of computational complexity, the Shapley value seems to be easy to compute, while the core is harder, although some classes of games have been identified in which this task is also simple.

Finally, one should insist on the importance of novel and fruitful applications of the theory to shed new light on concrete problems. In the case of the core, for example, the insights of core stability in matching markets have been successfully applied by Alvin Roth and his collaborators to the design of matching markets in the "real world" (e. g., the job market for medical interns and hospitals, the allocation of organs from doners to patients, and so on) – see [31].

Characteristic function form game
A characteristic function form game consists of a set of players and a characteristic function that gives each group of players, called a coalition, a value or a set of payoff vectors that they can gain by themselves. It is a typical representation of cooperative games. For characteristic function form games, several solution concepts are defined such as von Neumann – Morgenstern stable set, core, bargaining set, kernel, nucleolus, and Shapley value.

Abstract game An abstract game consists of a set of outcomes and a binary relation, called domination, on the outcomes. Von Neumann and Morgenstern presented this game form for general applications of stable sets.

Strategic form game A strategic form game consists of a player set, each player's strategy set, and each player's payoff function. It is usually used to represent non-cooperative games.

Imputation An imputation is a payoff vector in a characteristic function form game that satisfies group rationality and individual rationality. The former means that the players divide the amount that the grand coalition of all players can gain, and the latter says that each player is assigned at least the amount that he/she can gain by him/herself.

Domination Domination is a binary relation defined on the set of imputations, outcomes, or strategy combinations, depending on the form of a given game. In characteristic function form games, an imputation is said to dominate another imputation if there is a coalition of players such that they can realize their payoffs in the former by themselves, and make each of them better off than in the latter. Domination given a priori in abstract games can be also interpreted in the same way. In strategic form games, domination is defined on the basis of commonly beneficial changes of strategies by coalitions.

Internal stability A set of imputations (outcomes, strategy combinations) satisfies internal stability if there is no domination between any two imputations in the set.

External stability A set of imputations (outcomes, strategy combinations) satisfies external stability if any imputation outside the set is dominated by some imputation inside the set.

von Neumann–Morgenstern stable set A set of imputations (outcomes, strategy combinations) is a von Neumann–Morgenstern stable set if it satisfies both internal and external stability.

Farsighted stable set A farsighted stable set is a more sophisticated stable set concept mainly defined for strategic form games. Given two strategy combinations x and y, we say that x indirectly dominates y if there exist a sequence of coalitions $S^1, \dots, S^p$ and a sequence of strategy combinations $y = x^0, x^1, \dots, x^p = x$ such that each coalition S^j can induce strategy combination x^j by a joint move from x^{j-1}, and all members of S^j end up with better payoffs at $x^p = x$ compared to the payoffs at x^{j-1}. A farsighted stable set is a set of strategy combinations that is stable both internally and externally with respect to the indirect domination. A farsighted stable can be defined in abstract games and characteristic function form games.

Definition of the Subject

The von Neumann–Morgenstern stable set for solution (hereafter stable set) is the first solution concept in cooperative game theory defined by J. von Neumann and O. Morgenstern. Though it was defined cooperative games in characteristic function form, von Neumann and Morgenstern gave a more general definition of a stable set in abstract games. Later, J. Greenberg and M. Chwe cleared a way to apply the stable set concept to the analysis of non-cooperative games in strategic and extensive forms. Though general existence of stable sets in characteristic function form games was denied by a 10-person game presented by W.F. Lucas, stable sets exist in many important games. In voting games, for example, stable sets exist, and they indicate what coalitions can be formed in detail. The core, on the other hand, can be empty in voting games, though it is one of the best known solution concept in cooperative game theory. The analysis of stable sets is not necessarily straightforward, since it can reveal a variety of possibilities. However, stable sets give us deep insights into players' behavior in economic, political and social situations such as coalition formation among players.

Introduction

For studies of economic or social situations where players can take cooperative behavior, the stable set was defined by von Neumann and Morgenstern [31] as a solution concept for characteristic function form cooperative games. They also defined the stable set in abstract games so that one can apply the concept to more general games including non-cooperative situations. Greenberg [9] and Chwe [3] cleared a way to apply the stable set concept to the analysis of non-cooperative games in strategic and extensive forms.

The stable set is a set of outcomes satisfying two stability conditions: internal and external stability. The internal stability means that between any two outcomes in the set, there is no group of players such that all of its members prefer one to the other and they can realize the preferred outcome. The external stability means that for any outcome outside the set, there is a group of players such that all of its members have a commonly preferred outcome in the set and they can realize it. Though general existence was denied by Lucas [18] and Lucas and Rabie [21], the stable set has revealed many interesting behavior of players in economic, political, and social systems.

Von Neumann and Morgenstern (also Greenberg) assumed only a single move by a group of players. Harsanyi [13] first pointed out that stable sets in characteristic function form games may fail to cover "farsighted" behavior of players. Harsanyi's work inspired Chwe's [3] contribution to the formal study of foresight in social environments.

Chwe paid attention to a possible chain of moves such that a move of a group of players will bring about a new move of another group of players, which will further cause a third group of players to move, and so on. Then the group of players moving first should take into account a sequence of moves that may follow, and evaluate their profits obtained at the end. By incorporating such a sequence of moves, Chwe [3] defined a more sophisticated stable set, which we call a farsighted stable set in what follows. Recent work by Suzuki and Muto [51,52] showed that the farsighted stable set provides more reasonable outcomes than the original (myopic) stable set in important classes of strategic form games.

The rest of the chapter is organized as follows. Section "Stable Sets in Abstract Games" presents the definition of a stable set in abstract games. Section "Stable Set and Core" shows basic relations between the two solution concepts of stable set and core. Section "Stable Sets in Characteristic Function form Games" gives the definition of a stable set in characteristic function form games. Section "Applications of Stable Sets in Abstract and Characteristic Function Form Games" first discusses general properties of stable sets in characteristic function form games, and then presents applications of stable sets in abstract and characteristic function games to political and economic systems. Section "Stable Sets and Farsighted Stable Sets in Strategic Form Games" gives the definitions of a stable set and a farsighted stable set in strategic form games. Section "Applications of Farsighted Stable Sets in Strategic Form Games" discusses properties of farsighted stable sets and their applications to social and economic situations. Section "Future Directions" ends the chapter with remarks. Section "Bibliography" offers a list of references.

Stable Sets in Abstract Games

An *abstract game* is a pair $(W, \succ)$ of a set of outcomes W and an irreflexive binary relation $\succ$ on W, where irreflexivity means that $x \succ x$ holds for no element $x \in W$. The relation $\succ$ is interpreted as follows: if $x \succ y$ holds, then there must exist a set of players such that they can induce x from y by themselves and all of them are better off in x.

A subset K of W is called a *stable set* of abstract game $(W, \succ)$ if the following two conditions are satisfied:

1. Internal stability: For any two elements $x, y \in K$, $x \succ y$ never holds.
2. External stability: For any element $z \notin K$, there must exist $x \in K$ such that $x \succ z$.

We explain more in detail what the external and internal stability conditions imply in the definition of a stable set. Suppose players have common understanding that each outcome inside a stable set is "stable" and that each outcome outside the set is "unstable". Here the "stability" means that no group of players has an incentive to deviate from it, and the "instability" means that there is at least one group of players that has an incentive to deviate from it. Then the internal and external stability conditions guarantee that the common understanding is never disproved, and thus continues to prevail.

In fact, suppose the set is both internally and externally stable, and pick any outcome in the set. Then by internal stability, no group of players can be better off by deviating from it and inducing an outcome inside the set. Thus no group of players reaches an agreement to deviate, which makes each outcome inside the set remain stable. Deviating players may be better off by inducing an outcome outside the set; but outcomes outside the set are commonly considered to be unstable. Thus deviating players can never expect that such an outcome will continue. Next pick any outcome outside the set. Then by external stability, there exists at least one group of players who can become better off by deviating from it and inducing an outcome inside the set. The induced outcome is considered to be stable since it is in the set. Hence the group of players will deviate. Hence each outcome outside the set remains unstable.

Stable Set and Core

Another solution concept that is widely known is a core. For a given abstract game $G = (W, \succ)$, a subset C of W is called the *core* of G if $C = \{x \in W |$ there is no $y \in W$ with $y \succ x\}$. From the definition, the core satisfies internal stability. Thus the core C of G is contained in any stable set of G if the latter exists. To see this, suppose that $C \not\subset K$ for a stable set K, and C is non-empty, i. e., $C \neq \emptyset$. (If $C = \emptyset$, then clearly $C \subset K$.) Pick any element $x \in C \backslash K$. Since $x \notin K$, by external stability there exists $y \in K$ with $y \succ x$, which contradicts $x \in C$.

When the core of a game satisfies external stability, it has very strong stability. It is called the *stable core*. The stable core is the unique stable set of the game.

Stable Sets in Characteristic Function form Games

An n-person *game in characteristic function form* with transferable utility is a pair (N, v) of a player set $N = \{1, 2, \ldots, n\}$ and a characteristic function v on the set 2^N of all subsets of N such that $v(\emptyset) = 0$. Each subset of N is called a *coalition*. The game (N, v) is often called a TU-game. A characteristic function form game without transferable utility is called an NTU-game: its characteristic function gives each coalition a set of payoff vectors to players. For NTU-games and their stable sets, refer to Aumann and Peleg [1] and Peleg [35]. In this section, hereafter, we deal with only TU characteristic function form games, and refer to them simply as characteristic function form games.

Let (N, v) be a characteristic function form game. The characteristic function v assigns a real number $v(S)$ to each coalition $S \subseteq N$. The value $v(S)$ indicates the worth that coalition S can achieve by itself.

An n-dimensional vector $x = (x_1, x_2, \ldots, x_n)$ is called a payoff vector. A payoff vector x is called an *imputation* if the following two conditions are satisfied:

1. Group rationality: $\sum_{i=1}^{n} x_i = v(N)$,
2. Individual rationality: $x_i \geq v(\{i\})$ for each $i \in N$.

The first condition says that all players cooperate and share the worth $v(N)$ that they can produce. The second condition says that each player must receive at least the amount that he/she can gain by him/herself. Let A be the set of all imputations.

Let x, y be any imputations and S be any coalition. We say that x *dominates* y *via* S and write this as $x \operatorname{dom}_S y$ if the following two conditions are satisfied:

1. Coalitional rationality: $x_i > y_i$ for each $i \in S$,
2. Effectivity: $\sum_{i \in S} x_i \leq v(S)$.

The first condition says that every member of coalition S strictly prefers x to y. The second condition says that coalition S can guarantee the payoff x_i for each member $i \in S$ by themselves. We say that x *dominates* y (denoted by $x \operatorname{dom} y$) if there exists at least one coalition S such that $x \operatorname{dom}_S y$.

It should be noted that a pair (A, dom) is an abstract game defined in Sect. "Stable Sets in Abstract Games". It is easily seen that "dom" is an irreflexive binary relation on A. A stable set and the core of game (N, v) are defined to be a stable set and the core of the associated abstract game (A, dom), respectively.

Since von Neumann and Morgenstern defined the stable set, its general existence had been one of the most important problems in game theory. The problem was eventually solved in a negative way. Lucas [18] found the following 10-person characteristic function form game in which no stable set exists.

A game with no stable set: Consider the following 10-person game:

$$\begin{aligned}
N &= \{1, 2, \ldots, 10\}\,, \\
v(N) &= 5\,, \quad v(\{1,3,5,7,9\}) = 4\,, \\
v(\{3,5,7,9\}) &= v(\{1,5,7,9\}) = v(\{1,3,7,9\}) = 3\,, \\
v(\{1,2\}) &= v(\{3,4\}) = v(\{5,6\}) = v(\{7,8\}) \\
&= v(\{9,10\}) = 1\,, \\
v(\{3,5,7\}) &= v(\{1,5,7\}) = v(\{1,3,7\}) = v(\{3,5,9\}) \\
&= v(\{1,5,9\}) = v(\{1,3,9\}) = 2\,, \\
v(\{1,4,7,9\}) &= v(\{3,6,7,9\}) = v(\{5,2,7,9\}) = 2 \text{ and} \\
v(S) &= 0 \text{ for all other } S \subset N\,.
\end{aligned}$$

Though this game has no stable set, it has a nonempty core. A game with no stable set and an empty core was also found by Lucas and Rabie [21].

We remark on a class of games in which a stable core exists. As mentioned before, if a stable set exists, it always contains the core, which is of course true also in characteristic function form games. Furthermore, in characteristic function form games, there is an interesting class, called convex games, in which the core satisfies external stability. That is, the core is a stable core. A characteristic function form game (N, v) is a *convex game* if for any $S, T \subseteq N$ with $S \subset T$ and for any $i \notin T$, $v(S \cup \{i\}) - v(S) \leq v(T \cup \{i\}) - v(T)$, i. e., the bigger coalition a player joins, the larger the player's contribution becomes. In convex games, the core is large and satisfies external stability. For the details, refer to Shapley [45].

Though general existence is denied, the stable set provides us with very useful insights into many economic, political, and social issues. In the following, we will present some stable set analyzes applied to those issues.

Applications of Stable Sets in Abstract and Characteristic Function Form Games

Symmetric Voting Games

This section deals with applications of stable sets to voting situations. Let us start with a simple example.

Example 1 Suppose there is a committee consisting of three players 1, 2 and 3. Each player has one vote. Decisions are done according to a simple majority rule. That is, to pass a bill, at least two votes are necessary.

Before analyzing players' behavior, we first formulate the situation as a characteristic function form game. Let the player set be $N = \{1, 2, 3\}$. Since a coalition of a simple majority of players can pass any bill, we give value 1 to such coalitions. Other coalitions can pass no bill. We thus give them value 0. Hence the characteristic function is given by

$$v(S) = \begin{cases} 1 & \text{if } |S| \geq 2\,, \\ 0 & \text{if } |S| \leq 1\,, \end{cases}$$

where $|S|$ denotes the number of players in coalition S. The set of imputations is given by

$$A = \{x = (x_1, x_2, x_3) | x_1 + x_2 + x_3 = 1, x_1, x_2, x_3 \geq 0\}\,.$$

One stable set of this game is given by the set K consisting of three imputations, $(1/2, 1/2, 0), (1/2, 0, 1/2), (0, 1/2, 1/2)$. A brief proof is the following. Since each of the three imputations has only two numbers 1/2 and 0, internal stability is trivial. To show external stability, take any imputation $x = (x_1, x_2, x_3)$ from outside K. Suppose first $x_1 < 1/2$. Since $x \notin K$, at least one of x_2 and x_3 is less than 1/2. We assume $x_2 < 1/2$. Then $(1/2, 1/2, 0)$ dominates x via coalition $\{1, 2\}$. Next suppose $x_1 = 1/2$. Since $x \notin K, 0 < x_2, x_3 < 1/2$. Thus $(0, 1/2, 1/2)$ dominates x via coalition $\{2, 3\}$. Finally suppose $x_1 > 1/2$. Then $x_2, x_3 < 1/2$, and thus $(0, 1/2, 1/2)$ dominates x via coalition $\{2, 3\}$. Thus the proof of external stability is complete. This three-point stable set indicates that a two-person coalition is formed, and that players in the coalition share equally the outcome obtained by passing a bill.

This game has another three types of stable sets. First, any set $K_c^1 = \{x \in A | x_1 = c\}$ with $0 \leq c < 1/2$ is a stable set. The internal stability of each K_c^1 is trivial. To show external stability, take any imputation $x = (x_1, x_2, x_3) \notin K_c^1$. Suppose $x_1 > c$. Define by $y_1 = c, y_2 = x_2 + (x_1 - c)/2, y_3 = x_3 + (x_1 - c)/2$. Then $y \in K_c^1$ and $y \operatorname{dom}_{\{2,3\}} x$. Next suppose $x_1 < c$. Notice that at least one of x_2 and x_3 is less than $1-c$ since $c < 1/2$. Suppose without loss of generality $x_2 < 1 - c$. Since $c < 1/2$, we have $(c, 1-c, 0) \in K_c^1$ and $(c, 1-c, 0) \operatorname{dom}_{\{1,2\}} x$. Thus external stability holds. This stable set indicates that player 1 gets a fixed amount c and players 2 and 3 negotiate for how to allocate the rest $1 - c$. Similarly, any sets $K_c^2 = \{x \in A | x_2 = c\}$ and $K_c^3 = \{x \in A | x_3 = c\}$ with $0 \leq c < 1/2$ are stable sets.

The three-person game of Example 1 has no other stable set. See von Neumann and Morgenstern [31]. The former stable set is called a *symmetric* (or *objective*) stable set, while the latter types are called *discriminatory* stable sets.

As a generalization of the above result, symmetric stable sets are found in general n-person simple majority voting games. An n-person characteristic function form game (N, v) with $N = \{1, 2, \ldots, n\}$ is called a *simple majority voting game* if

$$v(S) = \begin{cases} 1 & \text{if } |S| > n/2\,, \\ 0 & \text{if } |S| \leq n/2\,. \end{cases}$$

A coalition S with $v(S) = 1$, i. e., with $|S| > n/2$, is called a *winning* coalition. A winning coalition including no smaller winning coalitions is called a *minimal winning* coalition. In simple majority voting games, a minimal winning coalition means a coalition of $(n + 1)/2$ players if n is odd, or $(n + 2)/2$ players if n is even. The following theorem holds. See Bott [2] for the proof.

Theorem 1 *Let (N, v) be a simple majority voting game. Then the following hold.*

(1) If n is odd, then the set

$$K = \langle \underbrace{2/(n+1), \ldots, 2/(n+1)}_{\frac{n+1}{2}}, \underbrace{0, \ldots, 0}_{\frac{n-1}{2}} \rangle$$

is a stable set where the symbol $\langle x \rangle$ denotes the set of all imputations obtained from x through permutations of its components.

(2) If n is even, the set

$$K = \langle \{x \in A |\, \underbrace{x_1 = \ldots = x_{n/2}}_{\frac{n}{2}} \geq \underbrace{x_{(n/2)+1} = \ldots = x_n}_{\frac{n}{2}}\} \rangle$$

is a stable set, where

$$A = \left\{ x = (x_1, \ldots, x_n) \,\middle|\, \sum_{i=1}^{n} x_i = 1, x_1, \ldots, x_n \geq 0 \right\}$$

and $\langle Y \rangle = \bigcup_{x \in Y} \langle x \rangle\,.$

It should be noted from (1) of Theorem 1 that when the number of players is odd, a minimal winning coalition is formed. The members of the coalition share equally the total profit. On the other hand, when the number of players is even, (2) of Theorem 1 shows that every player may gain a positive profit. This implies that the grand coalition of all players is formed. In negotiating for how to share the profit, two coalitions, each with $n/2$ players, are formed and profits are shared equally within each coalition. Since at least $n/2 + 1$ players are necessary to win when n is even, an $n/2$-player coalition is the smallest coalition that can prevent its complement from winning. Such a coalition is called a *minimal blocking* coalition. When n is odd, an $(n + 1)/2$-player minimal winning coalition is also a minimal blocking coalition.

General Voting Games

In this section, we present properties of stable sets and cores in general (not necessarily symmetric) voting games. A characteristic function from game (N, v) is called a *simple game* if $v(S) = 1$ or 0 for each nonempty coalition $S \subseteq N$. A coalition S with $v(S) = 1$ (resp. $v(S) = 0$) is a winning coalition (resp. losing coalition). A simple game is called a *voting game* if it satisfies (1) $v(N) = 1$, (2) if $S \subseteq T$, then $v(S) \leq v(T)$, and (3) if S is winning, then $N - S$ is losing. The first condition implies that the grand coalition N is always winning. The second condition says that a superset of a winning coalition is also winning. The third condition says that there are no two disjoint winning coalitions. It is easily shown that the simple majority voting game studied in the previous section satisfies these conditions. A player has a veto if he/she belongs to every winning coalition. As for cores of voting games, the following theorem holds.

Theorem 2 *Let (N, v) be a voting game. Then the core of (N, v) is nonempty if and only if there exists a player with veto.*

Thus the core is not a useful tool for analyzing voting situations with no veto player. In simple majority voting games, no player has a veto, and thus the core is empty. The following theorem shows that stable sets always exist.

Theorem 3 *Let (N, v) be a voting game. Let S be a minimal winning coalition and define a set K by*

$$K = \left\{ x \in A \middle| \sum_{i \in S} x_i = 1, x_i = 0 \forall i \notin S \right\} .$$

Then K is a stable set.

Thus in voting games, a minimal winning coalition is always formed, and they gain all the profit. For the proofs of these theorems, see Owen [34]. Further results on stable sets in voting games are found in Bott [2], Griesmer [12], Heijmanns [16], Lucas et al. [20], Muto [26,28], Owen [32], Rosenmüller [36], Shapley [43,44].

Production Market Games

Let us start with a simple example.

Example 2 There are four players, each having one unit of a raw material. Two units of the raw material are necessary for producing one unit of an indivisible commodity. One unit of the commodity is sold at p dollars.

The situation is formulated as the following characteristic function form game. The player set is $N = \{1, 2, 3, 4\}$. Since two units of the raw material are necessary to produce one unit of the commodity, the characteristic function v is given by

$$v(S) = 2p \text{ if } |S| = 4 , \quad v(S) = p \text{ if } |S| = 3, 2 , \quad v(S) = 0 \text{ if } |S| = 1, 0 .$$

The set of imputations is

$$A = \{x = (x_1, x_2, x_3, x_4) | x_1 + x_2 + x_3 + x_4 = 2p, \quad x_1, x_2, x_3, x_4 \geq 0\} .$$

The following set K is one of the stable sets of the game:

$$K = \langle \{x = (x_1, x_2, x_3, x_4) \in A | x_1 = x_2 = x_3 \geq x_4\} \rangle .$$

To show internal stability, take two imputations $x = (x_1, x_2, x_3, x_4)$ with $x_1 = x_2 = x_3 \geq x_4$ and $y = (y_1, y_2, y_3, y_4)$ in K. Suppose x dominates y. Since $x_1 = x_2 = x_3 \geq p/2 \geq x_4$, the domination must hold via coalition $\{i, 4\}$ with $i = 1, 2, 3$. Then we have a contradiction $2p = \sum_{i=1}^4 x_i > \sum_{i=1}^4 y_i = 2p$, since $y \in K$ implies that the largest three elements of y are equal. To show external stability, take $z = (z_1, z_2, z_3, z_4) \notin K$. Suppose $z_1 \geq z_2 \geq z_3 \geq z_4$. Then $z_1 > z_3$. Define $y = (y_1, y_2, y_3, y_4)$ by

$$y_i = \begin{cases} z_3 + \dfrac{z_1 + z_2 - 2z_3}{4} & \text{for } i = 1, 2, 3 , \\ z_4 + \dfrac{z_1 + z_2 - 2z_3}{4} & \text{for } i = 4 . \end{cases}$$

Then $y \in K$ and $y \operatorname{dom}_{\{3,4\}} z$, since $y_3 > z_3$, $y_4 > z_4$ and $y_3 + y_4 \leq p = v(\{3, 4\})$.

This stable set shows that in negotiating for how to share the profit of $2p$ dollars, three players form a coalition and share equally the gain obtained through collaboration. At least two players are necessary to produce the commodity. Thus a three-player coalition is the smallest coalition that can prevent its complement from producing the commodity, i. e., a minimal blocking coalition. We would claim that in the market a minimal blocking coalition is formed and that profits are shared equally within the coalition.

An extension of the model was given by Hart [14] and Muto [27]. Hart considered the following production market with n players, each holding one unit of a raw material. To produce one unit of an indivisible commodity, k units of raw materials are necessary. The associated production market game is defined by the player set $N = \{1, 2, \ldots, n\}$ and the characteristic function v given by

$$v(S) = \begin{cases} 0 & \text{if } 0 \leq |S| < k , \\ p & \text{if } k \leq |S| < 2k , \\ \vdots & \\ jp & \text{if } jk \leq |S| < (j+1)k , \\ \vdots & \\ hp & \text{if } hk \leq |S| < n , \end{cases} ,$$

where $n = hk + r$ and h, r are integers such that $h \geq 1$ and $0 \leq r \leq k - 1$. When $h = 1$,

$$v(S) = \begin{cases} 0 & \text{if } |S| < k , \\ p & \text{if } |S| \geq k . \end{cases}$$

The following theorem holds.

Theorem 4 *Suppose $h = 1$. Let $t = n - k + 1$ and $n = tu + w$ where u, w are integers such that $u \geq 1$ and $0 \leq w \leq t - 1$. Then the following set K is a stable set.*

$$\begin{aligned} K = \langle \{x = (x_1, \ldots, x_n) \in A | \\ x_1 = \ldots = x_t \geq x_{t+1} = \ldots = x_{2t} \\ \geq \ldots \geq x_{tu+1} = \ldots = x_n = 0 \rangle , \end{aligned}$$

where

$$A = \left\{ x = (x_1, \ldots, x_n) \middle| \sum_{i=1}^n x_i = p, x_1, \ldots, x_n \geq 0 \right\}$$

is the set of imputations.

The theorem shows that in negotiating for how to share the profit, minimal blocking coalitions, i. e., coalitions of

$n-k+1$ players, are formed and within each coalition, profits are shared equally. Players failing to form a coalition gain nothing. When $h \geq 2$, the following theorem holds.

Theorem 5 *Suppose $h \geq 2$. Let*

$$K = \left\langle \left\{ x = (x_1, \ldots, x_n) \in A \right| \right. \\ \left. \left. x_1 = \cdots = x_{n-k+1} \geq \frac{p}{k} \geq x_{n-k+2} = \cdots = x_n \right\} \right\rangle ,$$

where

$$A = \left\{ x = (x_1, \ldots, x_n) \middle| \sum_{i=1}^{n} x_i = hp, x_1, \ldots, x_n \geq 0 \right\} .$$

Then K is a stable set if and only if

$$n \geq (h+1)(k-1) .$$

Therefore if n is large or k is small, then a minimal blocking coalition is formed and the rest of the players also form a coalition. Within each coalition, profits are shared equally.

The next example deals with the case in which more than one raw materials are necessary to produce a commodity.

Example 3 Two types of raw materials P and Q are needed, one unit each, to produce one unit of an indivisible commodity, which is sold at p dollars. Player 1 holds one unit of raw material p, and each of players 2 and 3 holds one unit of raw material Q.

This situation is formulated as the following characteristic function form game. The player set is $N = \{1, 2, 3\}$. Since one unit of raw materials P and Q are necessary to produce the commodity, the characteristic function ν is given by

$$\nu(N) = p , \\ \nu(\{1,2\}) = \nu(\{1,3\}) = p , \quad \nu(\{2,3\}) = 0 , \\ \nu(\{1\}) = \nu(\{2\}) = \nu(\{3\}) = 0 , \quad \nu(\emptyset) = 0 .$$

The set of imputations is

$$A = \{x = (x_1, x_2, x_3) | x_1 + x_2 + x_3 = p, \ x_1, x_2, x_3 \geq 0\} .$$

The following set K is one of the stable sets in this game:

$$K = \{x = (x_1, x_2, x_3) \in A | x_2 = x_3\} .$$

To show internal stability, take two imputations $x = (x_1, x_2, x_3)$ and $y = (y_1, y_2, y_3)$ in K and suppose x dominates y. Then the domination must hold via coalitions $\{1,2\}, \{1,3\}$ since values of other coalitions (except $\{1,2,3\}$) are 0. If $x \operatorname{dom}_{\{1,2\}} y$, then $x_1 > y_1$ and $x_2 > y_2$ hold. Thus we have a contradiction $p = \sum_{i=1}^{3} x_i > \sum_{i=1}^{3} y_i = p$. The domination via $\{1,3\}$ leads to the same contradiction. To show external stability, take any imputation $z = (z_1, z_2, z_3) \notin K$. Then $z_2 \neq z_3$. Without loss of generality, let $z_2 < z_3$. Define $y = (y_1, y_2, y_3)$ by

$$y_i = \begin{cases} z_1 + \dfrac{z_3 - z_2}{3} & \text{for } i = 1 , \\ z_2 + \dfrac{z_3 - z_2}{3} & \text{for } i = 2 , \\ z_2 + \dfrac{z_3 - z_2}{3} & \text{for } i = 3 . \end{cases}$$

Then $y \in K$ and $y \operatorname{dom}_{\{1,2\}} z$, since $y_1 > z_1, y_2 > z_2$ and $y_1 + y_2 < \nu(\{1,2\})$. This stable set shows that in negotiating for how to share the profit p dollars, players 2 and 3 form a coalition against player 1 and share equally the gain obtained through collaboration.

There exist other stable sets in which players 2 and 3 collaborate but they do not share equally the profit. More precisely, the following set

$$K = \{x = (x_1, x_2, x_3) \in A | \\ x_2 \text{ and } x_3 \text{ move towards the same direction}\}$$

is a stable set, where "move towards the same direction" means that if x_2 increases then x_3 increases, and if x_2 decreases then x_3 decreases.

A generalization of the results above is given by the following theorem due to Shapley [42]. Shapley's original theorem is more complicated and holds in more general markets.

Theorem 6 *Suppose there are m players, $1, \ldots, m$, each holding one unit of raw material P, and n players, $m+1, \ldots, m+n$, each holding one unit of raw material Q. To produce one unit of an indivisible commodity, one unit of each of raw materials Pand Q is necessary. One unit of commodity is sold at p dollars. In this market, the following set K is a stable set.*

$$K = \{x = (x_1, x_2, \ldots, x_{m+n}) \in A | \\ x_1 = \cdots = x_m, x_{m+1} = \cdots = x_{m+n}\} .$$

where

$$A = \left\{ x = (x_1, \ldots, x_m, x_{m+1}, \ldots, x_{m+n}) \right| \\ \left. \sum_{i=1}^{m+n} x_i = p \times \min(m,n), \ x_1, \ldots, x_{m+n} \geq 0 \right\} ,$$

is the set of imputations of this game.

This theorem shows that players holding the same raw material form a coalition and share equally the profit gained through collaboration.

For further results on stable sets in production market games, refer to Hart [14], Muto [27], Owen [34]. Refer also to Lucas [19], Owen [33], Shapley [41], for further general studies on stable sets.

Assignment Games

The following two sections deal with markets in which indivisible commodities are traded between sellers and buyers, or bartered among agents. The first market is the assignment market originally introduced by Shapley and Shubik [47].

An assignment market consists of a set of $n(\geq 1)$ buyers $B = \{1, \dots, n\}$ and a set of n sellers $F = \{1', \dots, n'\}$. Each seller $k' \in F$ is endowed with one indivisible commodity to sell, which is called object k'. Thus F also denotes the set of n objects in the market. The objects are differentiated. Each buyer $i \in B$ wants to buy at most one of the objects, and places a nonnegative monetary valuation $u_{ik'}(\geq 0)$ for each object $k' \in F$. The matrix $U = (u_{ik'})_{(i,k') \in B \times F}$ is called the valuation matrix. The sellers place no valuation for any objects. An *assignment market* is denoted by $M(B, F, U)$. We remark that an assignment market with $|B| \neq |F|$ can be transformed into the market with $|B| = |F|$ by adding dummy buyers resp. sellers, and zero rows resp. columns correspondingly to valuation matrix U.

For each coalition $S \subseteq B \cup F$ with $S \cap B \neq \emptyset$ and $S \cap F \neq \emptyset$, we define assignment problem $P(S)$ as follows:

$$\begin{aligned} P(S)\colon \overline{m}(S) = \max_x & \sum_{(i,k') \in (S\cap B) \times (S \cap F)} u_{ik'} x_{ik'} \\ s.t. \sum_{k' \in S \cap F} x_{ik'} &\leq 1 \quad \text{for all } \ i \in S \cap B\,, \\ \sum_{i \in S \cap B} x_{ik'} &\leq 1 \quad \text{for all } \ k' \in S \cap F\,, \\ x_{ik'} &\geq 0 \quad \text{for all } \ (i, k') \in (S \cap B) \times (S \cap F)\,. \end{aligned}$$

Assignment problem $P(S)$ has at least one optimal integer solution (see Simonnard [49]), which gives an optimal matching between sellers and buyers in S that yields the highest possible surplus in S. Without loss of generality, we assume that the rows and columns of valuation matrix U are arranged so that the diagonal assignment x^* with $x^*_{ii'} = 1, i = 1, \dots, n$, is one of the optimal solutions to $P(B \cup F)$.

For a given assignment market $M(B, F, U)$, we define the associated *assignment game* G to be the characteristic function form game $(B \cup F, v)$. The player set of G is $B \cup F$. The characteristic function v is defined as follows: $v(S) = \overline{m}(S)$ for each $S \subseteq F \cup B$ with $S \cap B \neq \emptyset$ and $S \cap F \neq \emptyset$. For coalitions only of sellers or buyers, they cannot produce surplus from trade. Thus $v(S) = 0$ for each S with $S \subseteq B$, $S \subseteq F$, or $S = \emptyset$. The imputation set of G is

$$A = \left\{(w, p) \in \Re^B_+ \times \Re^F_+ \,\middle|\, \sum_{i \in B} w_i + \sum_{k' \in F} p_{k'} = v(B \cup F)\right\}.$$

Shapley and Shubik [47] proved that for any assignment game G, the core C is given by the set of optimal solutions to the dual problem of assignment problem $P(B \cup F)$, i. e.,

$$\begin{aligned} C = \{(w, p) \in A | w_i + p_{k'} \geq u_{ik'} = v(\{i, k'\}) \\ \text{for each } \ (i, k') \in B \times F\}\,, \end{aligned}$$

and thus the core is nonempty. They also showed that sellers' core payoff vector p gives market prices of the respective objects at which the demand and supply equilibrates for each object.

The general existence of stable sets in assignment games is still unsolved. However, as mentioned in Sect. "Stable Set and Core", if a game has the stable core, i. e., the core with external stability, then it is the unique stable set of the game. Thus we consider when an assignment game has the stable core.

Given an assignment market $M(B, F, U)$, we say that valuation matrix U satisfies the *dominant diagonal* condition if all of its diagonal entries are row and column maximums, i. e.,

$$\begin{aligned} u_{ii'} &= \max\{u_{ik'} | k' \in F\} \\ &= \max\{u_{ji'} | j \in B\} \quad \text{for each } \ i = 1, \dots, n\,. \end{aligned}$$

The dominant diagonal condition implies that each buyer i can yield the maximum surplus by purchasing the object of seller i'. Thus the players do not have to compete for partners. They come to be more concerned with the bargaining with his/her best matched partner. Then it is proved that valuation matrix U satisfies the dominant diagonal condition if and only if the core of G includes the imputations $(\underline{w}, \overline{p})$ and $(\overline{w}, \underline{p})$, where $\underline{w}_i = 0, \overline{p}_{i'} = u_{ii'}, \overline{w}_i = u_{ii'}$, and $\underline{p}_{i'} = 0$ for each $i \in N$. Furthermore, the following theorem holds.

Theorem 7 *Let $M(B, F, U)$ be any assignment market with $|B| = |F|$. The associated assignment game G has the stable core if and only if valuation matrix U satisfies the dominant diagonal condition.*

It is also proved that an assignment game G is convex if and only if valuation matrix U satisfies that $u_{ik'} = 0$ for each $(i, k') \in B \times F$ with $i \neq k$. This implies that the core has the von Neumann–Morgenstern stability in a larger class of assignment games including convex assignment games. For more details, refer to Solymosi and Raghavan [50].

House Barter Games

In this section, we consider a market in which only indivisible commodities are bartered. This market was originally considered by Shapley and Scarf [46].

The market we consider has $n(\geq 2)$ players, each endowed with one indivisible commodity, e. g., a house. Let $N = \{1, \ldots, n\}$ be the set of players. The n indivisible commodities are differentiated. The commodity initially owned by player i is called *house i*. Thus N also denotes the set of houses in the market. We assume that each player wants to own exactly one house, and no player disposes any house. Each player i has a complete, reflexive, and transitive preference relation R_i on N. Here, $jR_i h$ denotes that player i prefers house j at least as well as house h. Let $jP_i h$ denote that player i strictly prefers j to h, and $jI_i h$ denote that player i is indifferent between j and h. Defining players' preferences this way, we assume that each player strictly prefers owning a house to owning no house. The bundle $R = (R_i)_{i \in N}$ of players' preference relations is called a *preference profile*.

There is no divisible good such as money in the market. The players only exchange their houses to make a mutually beneficial trade. Thus an *allocation* of the market is defined to be a bijection x from N onto N, where $x(i)$ denotes the house assigned to player i in x. An allocation can be regarded as a permutation of N. An allocation x is also indicated by the vector $x = (x_1, \ldots, x_n)$ with $x_i = x(i)$ for each $i \in N$. Let A be the set of allocations. The market above is referred to as house barter market $M(N, R)$, or briefly market M.

Let x, y be any allocations of market M. For each coalition $S \subseteq N$, let $x(S)$ be the set of houses assigned to the members of S in x, i. e.,

$$x(S) = \{j \in N | j = x(i) \quad \text{for some} \quad i \in S\} .$$

We say that x *weakly dominates* y (denoted by x wdom y) if there exists a coalition S satisfying the following conditions:

1. $x(i)R_i y(i)$ for each $i \in S$ with P_i holding for at least one $i \in S$,
2. $x(S) = S$.

The second condition is the effectivity condition, which requires that each player i in S can obtain house $x(i)$ by exchanging their own endowments. We say that x *strongly dominates* y (denoted by x sdom y) if $x(i)P_i y(i)$ for *each* $i \in S$, and $x(S) = S$. We use the notations x wdom$_S$ y and x sdom$_S$ y to indicate the associated coalition S.

An allocation x is said to be *individually rational* if $x(i)R_i i$ for each player $i \in N$. An allocation x is *Pareto efficient* if there exists no allocation $y \in A$ with y wdom$_N$ x. If there is no $y \in A$ with y sdom$_N$ x, then x is *weakly Pareto efficient*. The three sets of individually rational, Pareto efficient, and weakly Pareto efficient allocations are denoted by IR, PA, and WPA, respectively.

We define cores and stable sets of market M by cores and stable sets of the associated *house barter games* (A, wdom) and (A, sdom), which are the abstract games with the outcome sets given by the allocation set A, and the binary relations on A given by the weak and strong dominations, respectively.

A nonempty subset of A is referred to as a *wdom stable set* of market M if it is a stable set of abstract game (A, wdom). A nonempty subset of A is referred to as a *sdom stable set stable set* of market M if it is a stable set of abstract game (A, sdom). The wdom and sdom stable sets are the stable sets defined by the weak and strong dominations, respectively. A subset of A, which may be empty, is called the *strict core* of market M if it is the core of abstract game (A, wdom). The *core* of market M is the core of abstract game (A, sdom). The strict core and the core of market M are the cores defined by the weak and strong dominations, respectively.

From the definitions above, a wdom stable set is a subset of PA, and an sdom stable set is a subset of WPA. However, both wdom and sdom stable sets may not be subsets of IR. The strict core is a subset of $PA \cap IR$. The core is a subset of $WPA \cap IR$.

Shapley and Scarf [46] proved that the core is nonempty for any house barter market $M(N, R)$. However, since external stability is not imposed on the core, the core does not necessarily coincide with an sdom stable set. In fact, the following example shows that there is a house barter market with no sdom stable set.

Example 4 Let M_1 be the market with the player set $N = \{1, 2, 3\}$ and the following preference profile:

1) $2 \; P_1 \; 3 \; P_1 \; 1$,
2) $3 \; P_2 \; 1 \; P_2 \; 2$,
3) $1 \; P_3 \; 2 \; P_3 \; 3$,

Market M_1 has six allocations: $x^1 = (2, 3, 1)$, $x^2 = (2, 1, 3)$, $x^3 = (1, 3, 2)$, $x^4 = (3, 2, 1)$, $x^5 = (3, 1, 2)$, $x^6 =$

$(1, 2, 3)$. From the preference profile, x^1 is clearly a core allocation. Allocation x^1 strongly dominates x^5 and x^6. Let $X = \{x^2, x^3, x^4\}$. We note that x^1 does not strongly dominate any $x^k \in X$. Here, suppose market M_1 has an sdom stable set K. Then the external stability of K implies $x^1 \in K$ and $K \cap X \neq \emptyset$. Note that $x^2 \text{ sdom}_{\{1,2\}}\, x^4$, $x^4 \text{ sdom}_{\{1,3\}}\, x^3$, and $x^3 \text{ sdom}_{\{2,3\}}\, x^2$. This together with the internal stability of K implies that K can contain only one allocation $x^k \in X$. However, the allocation x^k strongly dominates only one allocation in $X \backslash \{x^k\}$. This means that K does not have external stability, which is a contradiction. Thus, there exists no sdom stable set in market M_1.

Market M_1 however has a nice feature: the singleton $\{x^1\}$ is the strict core, and x^1 weakly dominates all the other allocations $x^2, \ldots, x^6$. In addition, every player shows only strict preferences. Noticing these facts, Roth and Postlewaite [38] proved that for any house barter market $M(N, R)$, if each player has a strict preference relation, then the strict core is a singleton, and it is the unique wdom stable set, i. e., the wdom stable core. Wako [54] proved that this property is extended as follows:

Theorem 8 *For any house barter market $M(N, R)$, if the strict core SC is nonempty, then it is the unique wdom stable set. Furthermore, for any $x, y \in SC$, $x(i) I_i y(i)$ for each $i \in N$.*

Even if some players do not have strict preference relations, the strict core is characterized as the wdom stable core as far as it is nonempty. The wdom stable core SC of market M has nice properties. First, each allocation $x \in SC$ is individually rational, Pareto efficient, and not weakly dominated by any other allocations since x is a strict core allocation. Secondly, any allocation outside SC is weakly dominated by some allocation in SC, since SC is a wdom stable set. Thirdly, even if SC contains different allocations, we may choose any one of them, since they are indifferent for each player.

However, the strict core can be empty when indifferences are allowed in preference relations. Shapley and Scarf [46] already discussed this point by the following example.

Example 5 Let M_2 be the market with the player set $N = \{1, 2, 3\}$ and the following preference profile:

1) $2 \; P_1 \; 3 \; I_1 \; 1$,
2) $1 \; I_2 \; 3 \; P_2 \; 2$,
3) $2 \; P_3 \; 1 \; I_3 \; 3$,

It can be verified that the strict core of M_2 is empty, and that the sets $V^1 = \{(2, 3, 1), (2, 1, 3)\}$ and $V^2 = \{(1, 3, 2), (3, 1, 2)\}$ are both wdom stable sets of M_2. Thus Theorem 8 does not carry over to the cases with the strict core being empty.

Quint and Wako [40] then gave a necessary and sufficient condition for the strict core to be nonempty. For each player $i \in N$ and each nonempty coalition$S \subseteq N$, let $B_i(S)$ be the set of player i's most-preferred house in S, i. e., $B_i(S) = \{h \in S | h R_i j \text{ for each } j \in S\}$. We call a partition $T = \{T_1, \ldots, T_m\}$ of N a *partition by minimal self-mapped sets (PMSS)* if each $T_k \in T$ satisfies the following conditions:

$$T_k = \bigcup_{i \in T_k} B_i\big(N \backslash \cup_{l=1}^{k-1} T_l\big) \text{ and there}$$
$$\text{is no } \; S \subset T_k \; \text{ with } \; S = \bigcup_{i \in S} B_i\big(N \backslash \cup_{l=1}^{k-1} T_l\big) \,.$$

There exists at least one PMSS for any market M. When there are more than one PMSSs, each PMSS consists of the same sets with only the order of some sets being different. We say that group $T_k \in T$ is a lower (resp. higher) group of $T_l \in T$ if $k > l$ (resp. $k < l$). The fact that $T = \{T_1, \ldots, T_m\}$ is a PMSS means that for each player i of any given group $T_k \in T$, the houses most preferred by i among the endowments of groups T_k and lower are all owned in his/her group T_k. The following theorem holds.

Theorem 9 *Let $T = \{T_1, \ldots, T_m\}$ be a PMSS of a given house barter market $M(N, R)$. Then the strict core is nonempty if and only if there exists an allocation $x \in A$ such that*

$$x(T_k) = T_k \;\; \text{and} \;\; x(i) \in B_i\big(N \backslash \cup_{l=1}^{k-1} T_l\big)$$
$$\text{for each } \; i \in T_k \; \text{ and each } \; T_k \in T \,.$$

The necessary and sufficient condition above requires that in any group $T_k \in T$, each player $i \in T_k$ can obtain his/her most-preferred houses (among those owned in groups T_k and lower) through a feasible exchange within his/her own group T_k. We refer to this condition as *segmentability*. Suppose a house barter market has segmentability, and that some players in a group T_k of PMSS T have more preferable houses in higher groups. However, such houses can be exchanged within the higher groups in a mutually beneficial way, and by the definition of a PMSS, no player in the higher groups has an incentive to trade with lower groups. In this sense, the market is segmented into distinct groups. It follows from Theorems 8 and 9 that in house barter markets, segmentability is necessary and sufficient for the existence of the wdom stable core. Quint and Wako [40] gave a polynomial-time algorithm to examine segmentability of a given house barter market. The following example shows a house barter market with segmentability.

Example 6 Let M_3 be the market with the player set $N = \{1, 2, 3, 4, 5, 6\}$ and the following preference profile:

$$\begin{array}{ll}
1) & 2\ P_1\ 3\ P_1\ 5\ P_1\ 4\ P_1\ 1\ P_1\ 6\,, \\
2) & 1\ I_2\ 3\ P_2\ 4\ P_2\ 6\ P_2\ 5\ P_2\ 2\,, \\
3) & 1\ P_3\ 2\ P_3\ 3\ P_3\ 4\ P_3\ 5\ P_3\ 6\,, \\
4) & 2\ P_4\ 5\ P_4\ 6\ P_4\ 3\ P_4\ 4\ P_4\ 1\,, \\
5) & 1\ I_5\ 4\ P_5\ 5\ P_5\ 3\ P_5\ 6\ P_5\ 2\,, \\
6) & 3\ P_6\ 6\ P_6\ 1\ P_6\ 2\ P_6\ 4\ P_6\ 5\,.
\end{array}$$

Although market M_3 has two PMSSs, $T = \{T_1 = \{1, 2, 3\}, T_2 = \{4, 5\}, T_3 = \{6\}\}$ and $T' = \{T'_1 = \{1, 2, 3\}, T'_2 = \{6\}, T'_3 = \{4, 5\}\}$, the differences are only the order of the groups. The wdom stable core of M_3 is the set $K = \{(2, 3, 1, 5, 4, 6)\}$.

The house barter market was also discussed by Moulin [25] from a wide perspective of cooperative microeconomics and game theory. Ehlers [5] initiated a study on stable sets of two-sided matching games, which were originally studied by Gale and Shapley [8]. For a comprehensive study on two-sided matching games, refer to Roth and Sotomayor [39].

Stable Sets and Farsighted Stable Sets in Strategic Form Games

We first defined a stable set in an abstract game in Sect. "Stable Sets in Abstract Games". This means that we can also define a stable set of a strategic form game. In this section we introduce a more sophisticated stable set concept: a *farsighted stable set* of a strategic form game.

Let $G = (N, \{X_i\}_{i \in N}, \{u_i\}_{i \in N})$ be an *n-person strategic form game*, where $N = \{1, 2, \ldots, n\}$ is the set of players, X_i is the set of *strategies* of player i, and u_i is player i's *payoff function*, $u_i\colon X = X_1 \times X_2 \times \cdots \times X_n \to \Re$ (the set of real numbers).

For any two strategy combinations $x = (x_1, \ldots, x_n)$, $y = (y_1, \ldots, y_n) \in X$, we say that x *is induced from* y *via coalition* $S \subseteq N$ if $y_i = x_i$ for each $i \in N \backslash S$, that is, the combination x is reached from y by moves only of players in S. It is easily seen from the definition that if x is induced from y via coalition S, y is induced from x via coalition S. Thus we write this inducement relation as $x \leftrightarrow_S y$. We say that x *indirectly dominates* y (denoted by $x \succ y$) if there exist a sequence of strategy combinations $y = x^0, x^1, \ldots, x^{p-1}, x^p = x$ and a sequence of coalitions $S^1, \ldots, S^p$ such that for each $j = 1, \ldots, p$, $x^{j-1} \leftrightarrow_{S^j} x^j$ and $u_i(x) > u_i(x^{j-1})$ for each $i \in S^j$. We sometimes say that x *indirectly dominates* y *starting with* S^1 (denoted by $x \succ_{S^1} y$) to specify the set of players which deviates first from y.

We hereupon remark that in the definition of indirect domination we implicitly assume that joint moves by groups of players are neither once-and-for-all nor binding, i. e., some players in a deviating group may later make another move with players within or even outside the group. It should be noted that the indirect domination defined above is borrowed from Chwe [3]. Though Harsanyi [13] first proposed the notion of indirect domination, his definition was given in characteristic function form games.

When $p = 1$ in the definition of indirect domination, we simply say that x *directly dominates* y, which is denoted by $x \succ^d y$. When we want to specify a deviating coalition, we say that x directly dominates y via coalition S, which is denoted by $x \succ^d_S y$. This direct domination in strategic form games was defined by Greenberg [9].

Let pairs $(X, \succ)$ and $(X, \succ^d)$ be the abstract games associated with game G. A *farsighted stable set* of G is defined to be a stable set of abstract game $(X, \succ)$ with indirect domination. A stable set of abstract game $(X, \succ^d)$ with direct domination is simply called a *stable set* of G .

Applications of Farsighted Stable Sets in Strategic Form Games

Existence of farsighted stable sets in strategic form games remains unsolved. Nevertheless, it has turned out through applications that farsighted stable sets give much sharper insights into players' behavior in economic, political, and social situations than (myopic) stable sets with direct dominations. In what follows, we show the analyses of farsighted stable sets in the prisoner's dilemma and two types of duopoly market games in strategic form.

Prisoner's Dilemma

To make discussion as clear as possible, we will focus on the following particular version of the prisoner' s dilemma shown below. Similar results hold in general prisoner' s dilemma games.

Prisoner's Dilemma:

		Player 2	
		Cooperate	Defect
Player 1	Cooperate	4, 4	0, 5
	Defect	5, 0	1, 1

$$\begin{tikzcd}
\text{(Cooperate, Cooperate)} \arrow[r, "2"] \arrow[d, "1"'] & \text{(Cooperate, Defect)} \arrow[d, "1"'] \\
\text{(Defect, Cooperate)} \arrow[r, "2"] & \text{(Defect, Defect)} \arrow[ul, "12"']
\end{tikzcd}$$

Cooperative Games (Von Neumann–Morgenstern Stable Sets), Figure 1

Here → denotes a direct domination. For example, "(Cooperate, Cooperate)$\xrightarrow{2}$(Cooperate,Defect) means (Cooperate, Defect) $\succ^d_{\{2\}}$ (Cooperate,Cooperate). "(Cooperate, Cooperate) $\overset{12}{\leftarrow}$ (Defect, Defect)" means (Cooperate, Cooperate) $\succ^d_{\{1,2\}}$ (Defect, Defect)

We first present a farsighted stable set derived when two players use only pure strategies. In this case, the set of strategy combinations is $X = \{$(Cooperate, Cooperate), (Cooperate, Defect), (Defect, Cooperate), (Defect, Defect)$\}$, where in each combination, the former (resp. the latter) is player 1's (resp. 2's) strategy.

The direct domination relation of this game is summarized as in Fig. 1.

From Fig. 1, no stable set (with direct domination) exists in the prisoner's dilemma. However, since (Cooperate, Cooperate) $\succ$ (Cooperate, Defect), (Defect,Cooperate) and there is no other indirect domination, the singleton $\{$(Cooperate, Cooperate)$\}$ is the unique farsighted stable set with respect to $\succ$. Hence if the two players are farsighted and make a joint but not binding move, the farsighted stable set succeeds in showing that cooperation of the players results in the unique stable outcome.

We now study stable outcomes in the mixed extension of the prisoner's dilemma, i. e., the prisoner's dilemma with mixed strategies played. Let $X_1 = X_2 = [0, 1]$ be the sets of mixed strategies of players 1 and 2, respectively, and let $t_1 \in X_1$ (resp. $t_2 \in X_2$) denote the probability that player 1 (resp. 2) plays "Cooperate". It is easily seen that the minimax payoffs to players 1 and 2 are both 1 in this game. We call a strategy combination that gives both players at least (resp. more than) their minimax payoffs, an *individually rational* (resp. a *strictly individually rational*) strategy combination. We then have the following theorem.

Theorem 10 *Let*

$$T = \{(t_1, t_2) | 1/4 < t_1 \le 1\ , t_2 = 1\} \cup \\ \{(t_1, t_2) | t_1 = 1, 1/4 < t_2 \le 1\}\ ,$$

and define the singleton $K^1(t_1, t_2) = \{(t_1, t_2)\}$ for each $(t_1, t_2) \in T$. Let $K^2 = \{(0, 0), (1, 1/4)\}$ and $K^3 = \{(0, 0), (1/4, 1)\}$. Then the sets K^2, K^3, and any $K^1(t_1, t_2)$ with $(t_1, t_2) \in T$ are farsighted stable sets of the mixed extension of the prisoner's dilemma. There are no other types of farsighted stable sets in the mixed extension of the prisoner's dilemma.

This theorem shows that if the two players are farsighted and make a joint but not binding move in the prisoner's dilemma, then essentially a single Pareto efficient and strictly individually rational strategy combination results as a stable outcome. i. e., $K^1(t_1, t_2)$. We, however, have two exceptional cases K^2, K^3 that (Defect, Defect) could be stable together with one Pareto efficient point at which one player gains the same payoff as in (Defect, Defect).

n-Person Prisoner's Dilemma

We consider an n-person prisoner's dilemma. Let $N = \{1, \dots, n\}$ be the player set. Each player i has two strategies: C (Cooperate) and D (Defect). Let $X_i = \{C, D\}$ for each $i \in N$. Hereafter we refer to a strategy combination as a *state*. The set of states is $X = \prod_{i \in N} X_i$. For each coalition $S \subset N$, let $X_S = \prod_{i \in S} X_i$ and $X_{-S} = \prod_{i \in S^c} X_i$, where S^c denotes the complement of S with respect to N. Let x_s and x_{-s} denote generic elements of X_S and X_{-S}, respectively. Player i's payoff depends not only on his/her strategy but also on the number of other cooperators. Player i's payoff function $u_i : X \to \Re$ is given by $u_i(x) = f_i(x_i, h)$, where $x \in X, x_i \in X_i$ (player i's choice in x), and h is the number of players other than i playing C. We call the strategic form game thus defined an *n-person prisoner's dilemma game*.

For simplifying discussion, we assume that all players are homogeneous and each player has an identical payoff function. That is, f_i's are identical, and simply written as f unless any confusion arises. We assume the following properties on the function f

Assumption 1

(1) $f(D, h) > f(C, h)$ for all $h = 0, 1, \dots, n - 1$
(2) $f(C, n - 1) > f(D, 0)$
(3) $f(C, h)$ and $f(D, h)$ are strictly increasing in h.

Property (1) means that every player prefers playing D to playing C regardless of which strategies other players play. Property (2) means that if all players play C, then each of them gains a payoff higher than the one in $(D, \dots, D)$.

Property (3) means that if the number of cooperators increases, every player becomes better off regardless of which strategy he/she plays.

It holds from Property (1) that $(D, \dots, D)$ is the unique Nash equilibrium of the game. Here for $x, y \in X$, we say that *y is Pareto superior to x* if $u_i(y) \geq u_i(x)$ for all $i \in N$ and $u_i(y) > u_i(x)$ for some $i \in N$. The state $x \in X$ is said to be *Pareto efficient* if there is no $y \in X$ that is Pareto superior to x. By Property (2), $(C, \dots, C)$ is Pareto superior to $(D, \dots, D)$. Together with Property (3), $(C, \dots, C)$ is Pareto efficient.

Given a state x, we say that x is *individually rational* if for all $i \in N, u_i(x) \geq \min_{y_{-i} \in X_{-i}} \max_{y_i \in X_i} u_i(y)$. If a strict inequality holds, we say that x is *strictly individually rational*. It holds from (1), (3) of Assumption 8.1 that $\min_{y_{-i} \in X_{-i}} \max_{y_i \in X_i} u_i(y) = f(D, 0)$.

The following theorem shows that any state that is strictly individually rational and Pareto efficient is itself a singleton farsighted stable set. That is, any strictly individually rational and Pareto efficient outcome is stable if the players are farsighted. Refer to Suzuki and Muto [51,52] for the details.

Theorem 11 *For n-person prisoner's dilemma game, if x is a strictly individually rational and Pareto efficient state, then $\{x\}$ is a farsighted stable set.*

Duopoly Market Games

We consider two types of duopoly: Cournot quantity-setting duopoly and Bertrand price-setting duopoly. For simplifying discussion, we will consider a simple duopoly model in which firms' cost functions and a market demand function are both linear. Similar results, however, hold in more general duopoly models.

There are two firms 1,2, each producing a homogeneous good with the same marginal cost $c > 0$. No fixed cost is assumed.

(1) **Cournot duopoly:** Firms' strategic variables are their production levels. Let x_1 and x_2 be production levels of firms 1 and 2, respectively. The market price $p(x_1, x_2)$ for x_1 and x_2 is given by

$$p(x_1, x_2) = \max(a - (x_1 + x_2), 0) ,$$

where $a > c$. We restrict the domain of production of both firms to $0 \leq x_i \leq a - c$, $i = 1, 2$. This is reasonable since a firm would not overproduce to make a nonpositive profit. When x_1 and x_2 are produced, firm i's profit is given by

$$\pi_i(x_1, x_2) = (p(x_1, x_2) - c)x_i .$$

Thus Cournot duopoly is formulated as the following strategic form game

$$G^C = (N, \{X_i\}_{i=1,2} , \{\pi_i\}_{i=1,2}) ,$$

where the player set is $N = \{1, 2\}$, each player's strategy set is a closed interval between 0 and $a - c$, i. e., $X_1 = X_2 = [0, a - c]$, and their payoff functions are π_i, $i = 1, 2$. Let $X = X_1 \times X_2$. The joint profit of two firms is maximized when $x_1 + x_2 = (a - c)/2$.

(2) **Bertrand duopoly:** Firms' strategic variables are their price levels. Let

$$D(p) = \max(a - p, 0)$$

be the market demand at price p. Then the total profit at p is

$$\prod(p) = (p - c)D(p) .$$

We restrict the domain of price level p of both firms to $c \leq p \leq a$. This assumption is also reasonable since a firm would avoid a negative profit. The total profit $\prod(p)$ is maximized at $p = (a + c)/2$, which is called a *monopoly price*.

Let p_1 and p_2 be prices of firms 1 and 2, respectively. We assume that if firms' prices are equal, then they share equally the total profit, otherwise all sales go to the lower pricing firm of the two. Thus firm i's profit is given by

$$\rho_i(p_i, p_j) = \begin{cases} \prod(p_i) & \text{if } p_i < p_j \\ \prod(p_i)/2 & \text{if } p_i = p_j \\ 0 & \text{if } p_i > p_j \end{cases}$$
$$\text{for } i, j = 1, 2, i \neq j .$$

Hence Bertrand duopoly is formulated as the strategic form game

$$G^B = \left(N, \{Y_i\}_{i=1,2}, \{\rho_i\}_{i=1,2}\right) ,$$

where $N = \{1, 2\}$, $Y_1 = Y_2 = [c, a]$, and $\rho_i (i = 1, 2)$ is i's payoff function. Let $Y = Y_1 \times Y_2$.

It is well-known that a Nash equilibrium is uniquely determined in either market: $x_1 = x_2 = (a - c)/3$ in the Cournot market, and $p_1 = p_2 = c$ in the Bertrand market.

The following theorem holds for the farsighted stable sets in Cournot duopoly.

Theorem 12 *Let $(x_1, x_2) \in X$ be any strategy pair with $x_1 + x_2 = (a - c)/2$. Then the singleton $\{(x_1, x_2)\}$ is a farsighted stable set. Furthermore, every farsighted stable set is of the form $\{(x_1, x_2)\}$ with $x_1 + x_2 = (a - c)/2$ and $x_1, x_2 \geq 0$.*

As mentioned before, any strategy pair (x_1, x_2) with $x_1 + x_2 = (a - c)/2$ and $x_1, x_2 \geq 0$ maximizes two firms' joint profit. This suggests that the von Neumann–Morgenstern stability together with firms' farsighted behavior produce joint profit maximization even if firms' collaboration is not binding.

As for Bertrand duopoly, we have the following theorem, which claims that the monopoly price pair is itself a farsighted stable set, and no other farsighted stable set exists. Therefore the von Neumann–Morgenstern stability together with firms' farsighted behavior attain efficiency (from the standpoint of firms) also in Bertrand duopoly. Refer to Suzuki and Muto [53] for the details.

Theorem 13 *Let $p = (p_1, p_2)$ be the pair of monopoly prices, i. e., $p_1 = p_2 = (a + c)/2$. Then the singleton $\{p\}$ is the unique farsighted stable set.*

For studies of stable sets with direct domination in duopoly market games, refer to Muto and Okada [29,30]. Properties of stable sets and Harsanyi's original farsighted stable sets in pure exchange economies are investigated by Greenberg et al. [10]. For further studies on stable sets and farsighted stable sets in strategic form games, refer to Kaneko [17], Mariotti [24], Xue [55,56], Diamantoudi and Xue [4].

Future Directions

In this paper, we have reviewed applications of von Neumann–Morgenstern stable sets in abstract games, characteristic function form games, and strategic form games to economic, political and social systems.

Stable sets give us insights into coalition formation among players in the systems in question. Farsighted stable sets, especially applied to some economic systems, show that players' farsighted behavior leads to Pareto efficient outcomes even though their collaboration is not binding. The stable set analysis is also applicable to games with infinitely many players. Those analyses show us new approaches to large economic and social systems with infinitely many players. For the details, refer to Hart [15], Einy et al. [7], Einy and Shitovitz [6], Greenberg et al. [11], Shitovitz and Weber [48], and Rosenmüller and Shitovitz [37]. There is also a study on the linkage between common knowledge of Bayesian rationality and achievement of stable sets in generalized abstract games. Refer to Luo [22,23] for the details.

Analyses of social systems by applying the concepts of farsighted stable sets as well as stable sets must further advance theoretical studies on games in which players inherently take both cooperative and non-cooperative behavior. Those studies will in turn have impacts on developments of economics, politics, sociology, and many applied social sciences.

Article Outline

Glossary

Autonomous information system An autonomous information system is an information system existing as an independent entity.

Intelligent query answering Intelligent query answering is an enhancement of query-answering into a sort of intelligent system (capable or being adapted or molded). Such systems should be able to interpret incorrectly posed questions and compose an answer not necessarily reflecting precisely what is directly referred to by the question, but rather reflecting what the intermediary understands to be the intention linked with the question.

Knowledge base Knowledge base is a collection of rules defined as expressions written in predicate calculus. These rules have a form of associations between conjuncts of values of attributes.

Ontology Ontology is an explicit formal specification of how to represent objects, concepts and other entities that are assumed to exist in some area of interest and relationships holding among them. Systems that share the same ontology are able to communicate about the domain of discourse without necessarily operating on a globally shared theory. A system commits to ontology if its observable actions are consistent with the definitions in the ontology.

Semantics The meaning of expressions written in some language as opposed to their syntax which describes how symbols may be combined independently of their meaning.

Definition of the Subject

One way to make a Query Answering System (QAS) intelligent is to assume the hierarchical structure of their attributes. Such systems have been investigated by Cuppens and Demolombe [3], Gal and Minker [4], and Gaasterland et al. [6], and they are called cooperative. Queries submitted to them are built, in a classical way, from values of attributes describing objects in an information system S and from two-argument functors "and", "or". Instead of "or", we use the symbol "+". Instead of "and", we use the symbol "*". Let us assume that QAS is associated with an information system S. Now, if query q submitted to QAS fails, then any attribute value listed in q can be generalized and the number of objects supporting q in S may increase. In cooperative systems, these generalizations are controlled either by users [4], or by methods based on knowledge discovery [12]. Conceptually, a similar approach has been proposed by Lin [11]. He defines a neighborhood of an attribute value which we can interpret as its generalization (or its parent in the corresponding hierarchical attribute structure). When query fails, then the query answering system is trying to replace values in a query by new values from their corresponding neighborhoods. QAS for S can also collaborate and exchange knowledge with other information systems. In all such cases, it is called intelligent. In papers [14,15] the query answering strategy was based on a guided process of knowledge (rules) extraction and knowledge exchange among systems. Knowledge extracted from information systems collaborating with S was used to construct new attributes in S and/or impute null or hidden values of attributes in S. This way we do not only enlarge the set of queries which QAS can successfully answer but also increase the overall number of retrieved objects and their confidence. Some attributes in S can be distinguished. We usually call them decision attributes. Their values represent concepts which can be defined in terms of the remaining attributes in S, called classification attributes. Query languages for such information systems are built only from values of decision attributes and from two-argument functors "+", "*" [16]. The semantics of queries is defined in terms of semantics of values of classification attributes. Precision and recall of QAS is strictly dependent on the support and confidence of the classifiers used to define queries.

Introduction

Responses by QAS to submitted queries do not always contain the information desired and although they may be logically correct, can sometimes be misleading. Research in the area of intelligent query answering rectifies these problems. The classical approach is based on a cooperative method called relaxation for expanding an information system and related to it queries [3,4]. The relaxation method expands the scope of a query by relaxing the constraints implicit in the query. This allows QAS to return answers related to the original query as well as the literal answers which may be of interest to the user.

This paper concentrates on multi-hierarchical decision systems which are defined as information systems with several hierarchical distinguished attributes called decision attributes. Their values are used to build queries. We give the theoretical framework for modeling such systems and its corresponding query languages. Standard interpretation and the classifier-based interpretation of queries are introduced and used to model the quality (precision, recall) of QAS.

Multi-hierarchical Decision System

In this section we introduce the notion of a multi-hierarchical decision system S and the query language built from atomic expressions containing only values of the decision attributes in S. Classifier-based semantics and the standard semantics of queries in S are proposed. The set of objects X in S is defined as the interpretation domain for both semantics. Standard semantics identifies all objects in X which should be retrieved by a query. Classifier-based semantics gives weighted sets of objects which are retrieved by queries. The notion of precision and recall of QAS in the proposed setting is introduced. We use only rule-based classifiers to define the classifier-based semantics. By improving the confidence and support of the classifiers we improve the precision and recall of QAS.

Definition 1 By a multi-hierarchical decision system we mean a triple $S = (X, A \cup D, V)$, where X is a nonempty, finite set of objects, $D = \{d[i] : 1 \le i \le k\}$ is a set of hierarchical decision attributes, A is a nonempty finite set of classification attributes, and $V = \bigcup\{V_a : a \in A \cup D\}$ is a set of their values.

We assume that: V_a, V_b are disjoint for any $a, b \in A \cup D$, such that $a \neq b$, $a : X \to V_a$ is a partial function for every $a \in A \cup D$.

Definition 2 By a set of decision queries (d-queries) for S we mean a least set T_D such that:

- $0, 1 \in T_D$,
- if $w \in \bigcup\{V_a : a \in D\}$, then $w, \sim w \in T_D$,
- if $t_1, t_2 \in T_D$, then $(t_1 + t_2), (t_1 * t_2) \in T_D$.

Definition 3 Decision query t is called simple if $t = t_1 * t_2 * \ldots * t_n$ and

$$(\forall j \in \{1, 2, \ldots, n\}) \left[\left(t_j \in \bigcup\{V_a : a \in D\}\right) \vee \left(t_j = \sim w \wedge w \in \bigcup\{V_a : a \in D\}\right)\right] .$$

Definition 4 By a set of classification terms (c-terms) for S we mean a least set T_C such that:

- $0, 1 \in T_C$,
- if $w \in \bigcup\{V_a : a \in A\}$, then $w, \sim w \in T_C$,
- $t_1, t_2 \in T_C$, then $(t_1 + t_2), (t_1 * t_2) \in T_C$.

Definition 5 Classification term t is called simple if $t = t_1 * t_2 * \ldots * t_n$ and

$$(\forall j \in \{1, 2, \ldots, n\}) \left[\left(t_j \in \bigcup\{V_a : a \in A\}\right) \vee \left(t_j = \sim w \wedge w \in \bigcup\{V_a : a \in A\}\right)\right] .$$

Definition 6 By a classification rule we mean any expression of the form $[t_1 \to t_2]$, where t_1 is a simple classification term and t_2 is a simple decision query.

Definition 7 Semantics M_S of c-terms in $S = (X, A \cup D, V)$ is defined in a standard way as follows:

- $M_S(0) = 0$, $M_S(1) = X$,
- $M_S(w) = \{x \in X : w = a(x)\}$ for any $w \in V_a$, $a \in A$,
- $M_S(\sim w) = \{x \in X : (\exists v \in V_a)[v = a(x) \,\&\, v \neq w]\}$ for any $w \in V_a$, $a \in A$,
- if t_1, t_2 are terms, then

$$M_S(t_1 + t_2) = M_S(t_1) \cup M_S(t_2) ,$$
$$M_S(t_1 * t_2) = M_S(t_1) \cap M_S(t_2) .$$

Now, we introduce the notation used for values of decision attributes. Assume that the term $d[i]$ also denotes the first granularity level of a hierarchical decision attribute $d[i]$. The set $\{d[i,1], d[i,2], d[i,3], \ldots\}$ represents the values of attribute $d[i]$ at its second granularity level. The set $\{d[i,1,1], d[i,1,2], \ldots, d[i,1,n_i]\}$ represents the values of attribute d at its third granularity level, right below the node $d[i,1]$. We assume here that the value $d[i,1]$ can be refined to any value from $\{d[i,1,1], d[i,1,2], \ldots, d[i,1,n_i]\}$, if necessary. Similarly, the set $\{d[i,3,1,3,1], d[i,3,1,3,2], d[i,3,1,3,3], d[i,3,1,3,4]\}$ represents the values of attribute d at its fourth granularity level which are finer than the value $d[i,3,1,3]$.

Now, let us assume that a rule-based classifier is used to extract rules describing simple decision queries in S. We denote that classifier by **RC**. The definition of semantics N_S of c-terms is **RC** independent whereas the definition of semantics M_S of d-queries is **RC** dependent.

Definition 8 Classifier-based semantics M_S of d-queries in $S = (X, A \cup D, V)$ is defined as follows:

If t is a simple d-query in S and $\{r_j = [t_j \to t] : j \in J_t\}$ is a set of all rules defining t which are extracted from S by classifier **RC**, then $M_S(t) = \{(x, p_x) : (\exists j \in J_t)(x \in M_S(t_j)[p_x = \Sigma\{\text{conf}(j) \cdot \text{sup}(j) : x \in M_S(t_j) \,\&\, j \in J_t\}/\Sigma\{\text{sup}(j) : x \in M_S(t_j) \,\&\, j \in J_t\}]$, where conf($j$), sup($j$) denote the confidence and the support of the rule $[t_j \to t]$, correspondingly.

Definition 9 Attribute value $d[j_1, j_2, \ldots, j_n]$ in $S = (X, A \cup D, V)$ is dependent on $d[i_1, i_2, \ldots, i_k]$ in S, if one of the following conditions hold:

1) $n \le k \,\&\, (\forall m \le n)\,[i_m = j_m]$,
2) $n > k \,\&\, (\forall m \le k)\,[i_m = j_m]$.

Otherwise, $d[j_1, j_2, \ldots, j_n]$ is called independent from $d[i_1, i_2, \ldots, i_k]$ in S.

Example 1 The attribute value $d[\mathbf{2}, \mathbf{3}, \mathbf{1}, \mathbf{2}]$ is dependent on the attribute value $d[\mathbf{2}, \mathbf{3}, \mathbf{1}, \mathbf{2}, 5, 3]$. Also, $d[\mathbf{2}, \mathbf{3}, \mathbf{1}, \mathbf{2}, \mathbf{5}, \mathbf{3}, 2, 4]$ is dependent on $d[\mathbf{2}, \mathbf{3}, \mathbf{1}, \mathbf{2}, \mathbf{5}, \mathbf{3}]$.

Definition 10 Let $S = \left(X, A \cup \{d[1], d[2], \ldots, d[k]\}, V\right)$, $w \in V_{d[i]}$, and $IV_{d[i]}$ be the set of all attribute values in $V_{d[i]}$ which are independent from w.

Standard semantics N_S of d-queries in S is defined as follows:

- $N_S(0) = 0$, $N_S(1) = X$,
- if $w \in V_{d[i]}$, then $N_S(w) = \{x \in X: d[i](x) = w\}$, for any $1 \leq i \leq k$
- if $w \in V_{d[i]}$, then $N_S(\sim w) = \{x \in X: (\exists v \in IV_{d[i]}) [d[i](x) = v]\}$, for any $1 \leq i \leq k$
- if t_1, t_2 are terms, then

$$N_S(t_1 + t_2) = N_S(t_1) \cup N_S(t_2)\,,$$
$$N_S(t_1 * t_2) = N_S(t_1) \cap N_S(t_2)\,.$$

Definition 11 Let $S = (X, A \cup D, V)$, t is a d-query in S, $N_S(t)$ is its meaning under standard semantics, and $M_S(t)$ is its meaning under classifier-based semantics. Assume that $N_S(t) = X_1 \cup Y_1$, where $X_1 = \{x_i, i \in I_1\}$, $Y_1 = \{y_i, i \in I_2\}$. Assume also that $M_S(t) = \{(x_i, p_i): i \in I_1\} \cup \{(z_i, q_i): i \in I_3\}$ and $\{y_i, i \in I_2\} \cap \{z_i, i \in I_3\} = \emptyset$.

By precision of a classifier-based semantics M_S on a d-query t, we mean

$$\text{Prec}(M_S, t) = [\Sigma\{p_i: i \in I_1\} + \Sigma\{(1 - q_i): i \in I_3\}] / [\text{card}(I_1) + \text{card}(I_3)]\,.$$

By recall of a classifier-based semantics M_S on a d-query t, we mean

$$\text{Rec}(M_S, t) = [\Sigma\{p_i: i \in I_1\}]/[\text{card}(I_1) + \text{card}(I_2)]\,.$$

Example 2 Assume that $N_S(t) = \{x_1, x_2, x_3, x_4\}$, $M_S(t) = \{(x_1, p_1), (x_2, p_2), (x_5, p_5), (x_6, p_6)\}$. Then:

$$\text{Prec}(M_S, t) = [p_1 + p_2 + (1 - p_5) + (1 - p_6)]/4\,,$$
$$\text{Rec}(M_S, t) = [p_1 + p_2]/4\,.$$

Cooperative Query Answering

There are cases when classical Query Answering Systems fail to return any answer to a d-query q but still a satisfactory answer can be found. For instance, let us assume that in a multi-hierarchical decision system $S = (X, A \cup D, V)$, where $D = \{d[1], d[2], \ldots, d[k]\}$, there is no single object whose description matches the query q. Assuming that a distance measure between objects in S is defined, then by generalizing q, we may identify objects in S whose descriptions are closest to the description of q. This problem is similar to the problem when the granularity of an attribute value used in a query q is finer than the granularity of the corresponding attribute used in S. By replacing such attribute values in q by more general values used in S, we may retrieve objects from S which satisfy q.

Definition 12 The distance δ_S between two attribute values $d[j_1, j_2, \ldots j_n], d[i_1, i_2, \ldots, i_m]$ in $S = (X, A \cup D, V)$, where $j_1 = i_1$, $p \geq 1$, is defined as follows:

1) if $[j_1, j_2, \ldots, j_p] = [i_1, i_2, \ldots, i_p]$ and $j_{p+1} \neq i_{p+1}$, then $\delta_S\left[d[j_1, j_2, \ldots, j_n], d[i_1, i_2, \ldots, i_m]\right] = 1/2^{p-1}$
2) if $n \leq m$ and $[j_1, j_2, \ldots, j_n] = [i_1, i_2, \ldots, i_n]$, then $\delta_S\left[d[j_1, j_2, \ldots, j_n], d[i_1, i_2, \ldots, i_m]\right] = 1/2^n$

The second condition, in the above definition, represents the average case between the best and the worth case.

Example 3 Following the above definition of the distance measure, we get:

1. $\delta_S\left[d[2, 3, 2, 4], d[2, 3, 2, 5, 1]\right] = 1/4$
2. $\delta_S\left[d[2, 3, 2, 4], d[2, 3, 2]\right] = 1/8$

Let us assume that $q = q(a[3, 1, 3, 2], b[1], c[2])$ is a d-query submitted to S. The notation $q(a[3, 1, 3, 2], b[1], c[2])$ means that q is built from $a[3, 1, 3, 2], b[1], c[2]$ which are the atomic attribute values in S. Additionally, we assume that attribute a is not only hierarchical but also it is ordered. It basically means that the difference between the values $a[3, 1, 3, 2]$ and $a[3, 1, 3, 3]$ is smaller than between the values $a[3, 1, 3, 2]$ and $a[3, 1, 3, 4]$. Also, the difference between any two elements in $\{a[3, 1, 3, 1], a[3, 1, 3, 2], a[3, 1, 3, 3], a[3, 1, 3, 4]\}$ is smaller than between $a[3, 1, 3]$ and $a[3, 1, 2]$.

Now, we outline a possible strategy which QAS can follow to solve q. Clearly, the best solution for answering q is to identify objects in S which precisely match the d-query submitted by the user. If it fails, we try to identify objects which match d-query $q(a[3, 1, 3], b[1], c[2])$. If we succeed, then we try d-queries $q(a[3, 1, 3, 1], b[1], c[2])$ and $q(a[3, 1, 3, 3], b[1], c[2])$. If we fail, then we should succeed with $q(a[3, 1, 3, 4], b[1], c[2])$. If we fail with $q(a[3, 1, 3], b[1], c[2])$, then we try $q(a[3, 1], b[1], c[2])$ and so on.

Cooperative Multi-hierarchical Query Answering Systems, Table 1
Multi-hierarchical decision system *S*

X	e	f	g	…	…	a	b	c	d
x_1	$e[1$	$f[1]$	…	…	…	$a[1]$	$b[2]$	$c[1,1]$	$d[3]$
x_2	$e[2]$	$f[1]$	…	…	…	$a[1,1]$	$b[2,1]$	$c[1,1,1]$	$d[3,1,2]$
x_3	$e[2]$	$f[1]$	…	…	…	$a[1,1,1]$	$b[2,2,1]$	$c[2,2]$	$d[1]$
x_4	$e[1]$	$f[2]$	…	…	…	$a[2]$	$b[2,2]$	$c[1,1]$	$d[1,1]$

To present this cooperative strategy in a more precise way, we use an example and start with a very simple dataset. Namely, we assume that S has four decision attributes which belong to the set $\{a, b, c, d\}$. System S contains only four objects listed in Table 1.

Now, we assume that d-query $q = a[1,2] * b[2] * c[1,1] * d[3,1,1]$ is submitted to the multi-hierarchical decision system S (see Table 1). Clearly, q fails in S.

Jointly with q, also a threshold value for a minimum support can be supplied as a part of a d-query. This threshold gives the minimal number of objects that need to be returned as an answer to q. When QAS fails to answer q, the nearest objects satisfying q have to be identified.

The algorithm for finding these objects is based on the following steps:

If QAS fails to identify a sufficient number of objects satisfying q in S, then the generalization process starts. We can generalize either attribute a or d. Since the value $d[3,1,2]$ has a lower granularity level than $a[1,1]$, then we generalize $d[3,1,2]$ getting a new query $q_1 = a[1,2] * b[2] * c[1,1] * d[3,1]$. But q_1 still fails in S. Now, we generalize $a[1,1]$ getting a new query $q_2 = a[1] * b[2] * c[1,1] * d[3,1]$. Objects x_1, x_2 are the only objects in S which support q_2.

If the user is only interested in one object satisfying the query q, then we need to identify which object in $\{x_1, x_2\}$ has a distance closer to q.

Clearly,

$$\begin{aligned}\delta_S[q, x_1] &= \delta_S\big[[a[1,2], b[2], c[1,1], d[3,1,1]],\\ &\qquad [a[1], b[2], c[1,1], d[3]]\big]\\ &= 1/4 + 0 + 0 + 1/4 = 1/2\,,\\ \delta_S[q, x_2] &= \delta_S\big[[a[1,2], b[2], c[1,1], d[3,1,1]],\\ &\qquad [a[1,1], b[2,1], c[1,1,1], d[3,1,2]]\big]\\ &= 1/4 + 1/4 + 1/8 + 1/8 = 3/4\,,\end{aligned}$$

which means x_1 is the winning object.

Note that the cooperative strategy only identifies objects satisfying d-queries and it identifies objects to be returned by QAS to the user. The confidence assigned to these objects depends on the classifier **RC**.

Future Directions

We have introduced the notion of system-based semantics and user-based semantics of queries. User-based semantics are associated with the indexing of objects by a user which is time consuming and unrealistic for very large sets of data. System-based semantics are associated with automatic indexing of objects in X which strictly depends on the support and confidence of classifiers and depends on the precision and recall of a query answering system. The quality of classifiers can be improved by a proper enlargement of the set X and the set of features describing them which differentiate the real-life objects from the same semantic domain as X in a better way. An example, for instance, is given in [16]. The quality of a query answering system can be improved by its cooperativeness. Both precision and recall of QAS is increased if no-answer queries are replaced by generalized queries which are answered by QAS on a higher granularity level than the initial level of queries submitted by users. Assuming that the system is distributed, the quality of QAS for multi-hierarchical decision system S can also be improved through collaboration among sites [14,15].

The key concept of intelligent QAS based on collaboration among sites is to generate global knowledge through knowledge sharing. Each site develops knowledge independently which is used jointly to produce global knowledge. Assume that two sites S_1 and S_2 accept the same ontology of their attributes and share their knowledge in order to solve a user query successfully. Also, assume that one of the attributes at site S_1 is confidential. The confidential data in S_1 can be hidden by replacing them with null values. However, users at S_1 may treat them as missing data and reconstruct them with the knowledge extracted from S_2 [10]. The vulnerability illustrated in this example shows that a security-aware data management is an essential component for any intelligent QAS to ensure data confidentiality.

Article Outline

Glossary

Coordination dynamics Coordination Dynamics, defined broadly as the science of coordination, describes, explains and predicts how patterns of coordination form, adapt, persist and change in living things. In coordination dynamics the parts communicate via mutual information exchange and information is meaningful and specific to the forms coordination takes. Coordination dynamics embraces both spontaneous self-organizing tendencies and the need to guide or direct them in specific ways in a single conceptual framework. Life, brain, mind and behavior are hypothesized to be linked by virtue of sharing a common underlying coordination dynamics.

Synergies Synergies (*aka* coordinative structures) are functional groupings of structural elements (e. g. neurons, muscles, joints) that are temporarily constrained to act as a single coherent unit. They arise in many contexts on many levels of biological organization, from the genetic to the social. Synergies are the key to understanding biological coordination and as such are the significant units of coordination dynamics. The synergy hypothesis is an hypothesis about how Nature handles biological complexity.

Self-organization The 'self' in the word self-organization refers to the ability of an open system that exchanges matter, energy and information with the environment, to organize itself. Spontaneous patterns arise solely as a result of the dynamics of the system with no specific ordering influence imposed from the outside and no homunculus-like agent inside. Nonequilibrium phase transitions are the hallmark of self-organization in living things.

Collective variables Collective variables (*aka order parameters* in physics or *coordination variables* in coordination dynamics) are relational quantities that are created by the cooperation among the individual parts of a system. Yet they, in turn, govern the behavior of the individual parts. This is sometimes referred to as *circular* or *reciprocal causality*. In coordination dynamics, the identification of coordination variables depends on the level of description. What is "macro" at one level may be "meso" or "micro" at another.

Control parameters Control parameters refer to naturally occurring environmental conditions or intrinsic, endogenous factors that move the system through its repertoire of patterns and cause them to change. Experimentally, you only know for certain you have identified a control parameter if, when varied, it causes the system's behavior to change qualitatively or discontinuously, i. e., to change its functional state.

Metastability Metastability arises due to broken symmetry in the coordination dynamics where the unstable and stable fixed points (phase- and frequency-locked states) have disappeared due to tangent or saddle-node bifurcations leaving behind only remnants of the fixed points. Metastability is the simultaneous realization of two competing tendencies: the tendency of the components to couple together and the tendency of the components to express their intrinsic independent behavior. Metastability has been hailed as a new principle of organization in complex living systems, including the brain, reconciling apparent contraries such as individual and collective, part and whole, competition and cooperation, integration and segregation, and so forth.

Definition of the Subject

> *Even before man speculated about the nature and sources of his own experiences, he was probably curious about the agencies by which animal motion was affected. Life and motion are almost synonymous terms.* Franklin Fearing [48]

In his preface to the *Principia*, Isaac Newton speculated that not just the motions of the planets, the Moon and the tides could be explained by the forces of attraction and repulsion, but all other natural phenomena as well. Despite the hubris, "self-motion", Newton recognized, "was beyond our understanding" [64]. Three and a half centuries later, the problem remains: the goal-directed coordinated movements of animals are not mere mechanical consequences of the laws of physics, at least as we know them. Despite the many remarkable applications of physics to biology and entire fields devoted to them (e. g. biomechanics, biophysics, nanophysics, etc.) and despite the successes of modern molecular biology, the great unresolved problem of biology remains: *how complex living things are coordinated in space and time*. To recognize that coordination is often purposeful and goal-directed does not at all mean a return to vitalism. But it does pose the scientific challenge of extending physics to understand coordination in living things. Coordination dynamics is a response to this challenge: it is a conceptual framework and research program that deals fundamentally with *animate* (and animated) self-organizing dynamical systems (see also [181,182]). That is, it deals with animate organisms anchored to and engaged in their surrounding worlds. Table 1 compares some of the features of classical mechanics and coordination dynamics. The Table is not intended to be inclusive or to convey the idea that there have been no candidate "paradigms" between classical mechanics and coordination dynamics. For present purposes, "the complex systems" paradigm may represent the most recent break from or extension of classical mechanics. In the complex systems paradigm, self-organization would replace organization, open systems would replace closed systems, change, disorder and process would replace stasis, order and equilibrium, etc. [163]. Coordination dynamics goes a step further. In coordination dynamics it is not organization versus self-organization, order versus disorder, closed versus open systems, reductionism versus emergentism, etc., but rather both aspects that are necessary for an exhaustive account of phenomena and a deeper understanding of coordination in living things. Hence, rather than view these features in opposition, they are better viewed as complementary [100,104,110].

Coordination represents one of the most striking, most taken for granted, yet least understood features of all living things. Imagine a living system whose component parts and processes, on any level of description one choose to examine, did not interact with each other or with their surrounds. Such a collective "cell," "organ," "organism" or "society" would possess neither structure nor function. Coordination can be seen almost everywhere we look, whether in the regulatory interactions among genes that affect how an organism develops and how some diseases like cancer occur, the tumbling and twisting of the bacterial flagellum, the coordinated responses of organisms to constantly varying environmental stimuli, the coordination among nerve cells that produce basic forms of locomotion in vertebrates and invertebrates, the coordination among cell assemblies of the brain that underlies our

Coordination Dynamics, Table 1
Some complementary features of classical mechanics and coordination dynamics

Classical Mechanics	Coordination Dynamics
machines; organized	"organisms "; self-organized
inanimate	animate
motion	coordination (function); animation
matter	materially instantiated; organization
forces	information (semantic) and information exchange; couplings
fundamental dimensions (M, L, T)	collective or coordination variables
space, time	spatiotemporal
linear; smooth dynamics	essentially nonlinear; bifurcations; multi- and metastable
deterministic	fluctuations/variability play key role
decomposable;	"emergent "; synergistic;
motion of whole = sum of motion of the parts	motion of whole > sum of motion of the parts
homogeneous parts, elements, components	heterogeneous units and connectivity
micro versus macro level distinction	level independent strategy; 'one level down '
fixed laws	extensible laws; regularities
context-free	context-dependent
machine/artifactual perspective on order	organic/natural perspective on order

awareness, ability to think, remember, decide and act, the miraculous coordination between the lungs, larynx, lips and tongue that belies a child's first word, the learned coordination among fingers and brain that allows the skilled pianist to play a concerto, the congruence of motion and emotion in dance, drama and everyday life, the coordination between people – like rowers in a racing eight – working together to achieve a common goal. Everything is coordinated.

What do we mean by the word coordination? Coordination is not only spatial and temporal order. Rather, it refers to different kinds and degrees of *functional* order among interacting parts and processes in space and time. Newtonian mechanics may define limits on how biological systems are coordinated, but it says nothing about their functional organization, per se. *How are complex living things coordinated in space and time? What is the nature of the basic interactions that give rise to patterns of coordinated behavior? Why do they take the form they do*? These questions lie at the heart of understanding coordination. Given the ubiquity of coordinated behavior in living things, one might have expected its lawful basis to have been uncovered many years ago. However, it is only in the last 25 years or so, and under quite peculiar circumstances, that basic laws for a quantitative description of coordination have been found.

Introduction

A centipede was happy quite,
Until a frog in fun said:
"Pray tell which leg comes after which?"
This raised her mind to such a pitch,
She lay distracted in the ditch,
Considering how to run. Anon

Coordination Dynamics – the science of coordination – refers to the concepts, methods and tools used to describe, explain and predict how patterns of coordination form, adapt, persist, and change in living things. It is about identifying coordinated patterns in the behavior of living things and expressing how these patterns evolve and change in terms of dynamical laws or rules. The dynamics here refers to equations of motion for key *coordination variables* or *order parameters* [73] that characterize coordinated patterns of behavior on multiple levels of description. As the name implies, the dynamics deals with coordination, not (or not only) with matter in motion: *coordination dynamics* (see Table 1). Through an intimate relationship between theory, experiment, analysis and modeling, Coordination Dynamics seeks to identify the laws, principles and mechanisms underlying coordinated behavior within and between different levels of organization, explicitly addressing the connection between levels. Thus, a goal of Coordination Dynamics is to identify the nature of the functional and context-dependent coordination *within* a part of a system (e. g., the firing of cells in the heart or neurons in a part of the brain), *between* different parts of a system (e. g., parts of the brain, parts of the body, members of an audience) and *between* different kinds of system (e. g., stimuli and responses, organisms and environments, humans and robots, etc.). In coordination dynamics, the coupling between things is realized by many mechanisms, but is fundamentally informational in nature. That is, Coordination dynamics deals specifically with *meaningfully* coupled, self-organizing systems: the parts communicate via mutual information exchange and information is meaningful and specific to the forms coordination takes. As a source of biological order and pattern, self-organization has received much less attention than the teleonomic, directed nature of living things captured by terms like "program", "blueprint", "template" and so forth. Instead of treating them as opposing theories, Coordination Dynamics unites the spontaneous, self-organizing nature of coordination and the obviously directed, agent-like properties characteristic of animate nature into a single framework [100,104,110]. It does this by studying how functionally meaningful information arises from spontaneous self-organizing processes and how it in turn modifies, guides and directs them.

Coordination Dynamics is both multi- and interdisciplinary, engaging relevant aspects and subfields of psychology, philosophy, biology, neuroscience, computer science, engineering, mathematics and physics. For Coordination Dynamics, a complete understanding of coordination phenomena on *any* given level of description requires: i) specifying the individual coordinating elements and their properties; ii) identifying key parameters, boundary and task conditions that constrain coordination; and (iii) showing how interactions among coordinating elements produce or generate patterns of coordination. By demonstrating in specific cases how the nonlinear coupling among the parts produces coordinated behavior Coordination Dynamics demystifies the popular term "emergence". Even more subtly, a certain régime of Coordination Dynamics called *metastability* resolves the longstanding dichotomy between the whole and the parts by explicitly showing how the individual parts of the system may retain a certain degree of autonomy while still coordinating as a whole. To the extent that they transcend the particular mechanisms through which coordination is realized, the principles of Coordination Dynamics may be said to be "universal" and hence have the potential to describe and explain coordinated behavior in a number of fields ([75]; see also ► Movement Coordination and ► Social Coordination, from the Perspective of Coordination Dynamics). In the case of movement coordination, for example, Coordination Dynamics provides the basic laws for a quantitative description of phenomena that are observed when humans interact in a certain way with themselves, with other humans and with their environment [59,100].

History of Coordination Dynamics: Synergy and Rhythmic Order

Coordination Dynamics arose as a response to the fundamental problem of control and coordination in complex, biological systems: the problem of degrees of freedom. Consider an ordinary movement of the human body. The body itself consists of over 790 muscles and 100 joints that have co-evolved in a complex environment with a nervous system that contains $\sim 10^{12}$ neurons and neuronal connections. On the sensory side, billions of receptor elements embedded in skin, joints and muscles inform the mover about his movement. Clearly, any ordinary human activity requires the cooperation among very many structurally diverse elements – a miracle that we take for granted (e. g. [164]). How does nature compress the very high dimensional state space of such a complex system into something lower dimensional and controllable? An attractive hypothesis proposed by the Russian physiologist Bernstein (1896–1966 [17]) is that in complex living systems, the individual elements are not controlled directly but are rather organized into collectives called *synergies*. Synergies are functional groupings of structural elements (e. g. neurons, muscles, joints) that are temporarily constrained to act as a single coherent unit. Just as new states of matter form under certain conditions when a group of atoms behaves as a single particle (e. g., the Bose–Einstein condensate) so a new state of biological *function* emerges when large ensembles of different elements form a synergy. The synergy hypothesis is therefore an hypothesis about how Nature handles biological complexity. Synergies may appear in many contexts on many levels of biological organization, from the genetic to the social. Depending on context, synergies can accomplish different functions using some of the same anatomical components (e. g., those used for speaking and chewing) and the same function using different components (e. g. writing one's name with a pen attached to the big toe). Once assembled, the degrees of freedom composing a synergy take care of themselves in a relatively autonomous organization. The assembling and disassembling of synergies may be said to be "soft" demanding little energy: synergies are ready to become something else at an instant. They are the "atoms", the significant units of biological function [105,107].

The hallmark of a synergy is that the individual elements adjust to mutual fluctuations and to fluctuations in the external force field (and more generally, the synergy's environment) in order to sustain integrity of function. As a consequence, natural variations (which from the scientist's view may be seen as "errors") that occur in the individual elements of the synergy are compensated by adjustments ("covariations") in other members of the synergy in such a way as to maintain a given function stable. Retaining stability is, for a synergy, the retaining of functional integrity [105,204]. Stability, therefore, plays a key role in coordination dynamics, where the great challenge is to discover what the stability is of. Since the key variables of coordination are not known a priori in living things, they must be identified through empirical research. This, as we shall see, follows a particular strategy.

In the late 1970s and early 80s technological developments and sophisticated computer methods for analyzing complex, multidegree of freedom movements enabled stringent experimental tests of the synergy hypothesis to be carried out [112,120]. Invariably, the experiments, which ranged from postural control to speech production and complex finger and limb movements ([105,107,136,201,204] for reviews), showed: a) that a perturbation to any part of the putative synergy is rapidly compensated for by remotely linked elements in such a way as to preserve system function; b) that the same elements are used in different functions in different ways; c) that different elements may accomplish the same function; and d) that the adjustments observed could in all cases be said to be meaningful, task- and context-specific. All this evidence for the existence of synergies attests to the tremendous redundancy or degeneracy of biological systems [46].

All scientific journeys begin with a single step. The identification of synergies as significant structural–functional units of biological coordination was an important one for the development of Coordination Dynamics. Synergies simplify control by reducing the number of variables that must be independently specified: as constraints, they make control and coordination of complex, multivariable systems possible. But understanding goes far beyond identification. How are synergies formed? What principles govern their assembly? And how does one synergy change spontaneously to another as internal or external conditions change? How can distinct synergies co-exist among the same set of components? And how are individual components of the synergy engaged and disengaged as circumstances change?

Insights into these questions come from the work of a largely unheralded genius called Erich von Holst [215], a behavioral physiologist who spent his life studying coordination in a wide variety of creatures – from worms to man. Von Holst's research will not give us answers to all the questions about synergies but it will provide key insights into the essence of coordination and a stepping stone to finding the underlying principles. Using an experimental model system that allowed him to measure an elementary synergy – the to and fro motions of the fins of the swimming dogfish *Labrus* under carefully controlled water flow conditions – von Holst identified at least three basic types of coordination: *absolute* coordination, in which component parts are locked together in time (like the synchronized flashing of fireflies, a couple making love or phase synchrony between parts of the brain); partial or *relative* coordination, in which the component parts 'lock in' only transiently and then break apart as circumstances change (like a little boy walking hand in hand with his father on the beach; dad must slow down and/or son add a step so that they can stay together); and no coordination at all, in which the component parts behave quite independently (as occurs in the locomotion of millipedes and centipedes when the same little boy chops off their middle legs, or perhaps after persistent, long term practice in playing the piano or the violin). Various blends, mixes and transitions between these coordinated behaviors were also observed – always matching the exigencies of the internal and external environment.

Why might some kind of common principle exist for such diverse phenomena? The reason is that the same basic coordination phenomena seem to cut across a wide range of levels, creatures and functions. Among those observed are: patterns of coordination remain stable in time despite continuous, and often unexpected perturbations; the ease with which component parts and processes are flexibly engaged and disengaged as functional demands or environmental conditions change; the existence of multiple coordination patterns – so-called multifunctionality – that effectively satisfy the same set of circumstances; the selection of particular coordination patterns that are exquisitely tailored to suit the current needs of the organism; adaptation of coordination to changing internal and external contingencies; smooth and abrupt transitions from one coordinated pattern to another; transitions from partially to fully coordinated patterns and vice-versa; persistence of a coordinated pattern even when conditions that led to the establishment of the pattern have changed (a kind of memory), and so forth. Such phenomena appear so commonly and so consistently as to suggest the existence of an underlying lawfulness or regularity that transcends the differences between systems. Nature, as the saying goes, operates with ancient themes. Or maybe nature just is what it is.

Conceptual Foundations of Coordination Dynamics: Self-organizing Dynamical Systems

Given we accept the empirical facts about synergies and rhythmic order in the nervous system and the movements of living things, what concepts, methods and tools do we use to understand them? Were synergies simply rigid mechanical entities built by an engineer or an intelligent designer, control theory with its programs, reference levels, comparators, feedforward and feedback error correcting mechanisms and so forth, might have seemed an obvious place to look for explanatory tools. A program instructs the parts of a system what to do and when to do it. Feedback may then be used to correct errors in the outcome. But now what? The system receives an error signal: How does it know which of its many parts to correct? In a complex system composed of very many components it may take a very long time to come up with a solution, a problem computer scientists refer to as an NP-complete problem, where NP means "non-deterministic polynomial time complete". Biology with its degeneracy and redundancy has no such problem. "Error" signals from one part of a synergy are rapidly compensated by other members. So if anything, the *machine perspective* on order and regulation (Table 1) seems to compound the problem rather than solve it.

Coordination Dynamics takes its inspiration from *a natural, organic perspective*, i. e., how nature handles complexity (Table 1). It is well-known that pattern formation in open, nonequilibrium physical and chemical systems such as fluids, lasers and chemical reactions can emerge spontaneously. These patterns arise solely as a result of the dynamics of the system with no specific ordering influence imposed from the outside environment and no homunculus-like agent inside. Such "self-organized" pattern formation is a cooperative phenomenon that results from the interaction of large numbers of interacting subsystems [73,152]. It should be stressed here that there is no "self" inside the system responsible for prescribing or coding the emergent pattern. The 'self' in self-organization comes from the fact that given the ability to exchange matter, energy and information with the environment, the system organizes itself. That the organism is an open system is one of two essential criteria for life postulated by Francis Crick in *Of Molecules and Men* [33], yet it has received much less attention in biology than Crick's other criterion, the need for organisms to reproduce and pass on 'copies' of themselves to their descendants. Here already we see a dichotomy between a complex system's natural ordering tendencies and the need (at least in living systems) to guide that order in specific ways. Coordination dynamics (Table 1) reconciles this dichotomy by viewing these two fundamental aspects as complementary ([100,104,110]).

In his general theory of nonequilibrium phase transitions called "synergetics" Haken [73] showed that close to critical points where a so-called *control parameter* crosses a threshold, very complex, high-dimensional systems can be completely described by a much lower dimensional dynamics specified in terms of only a few collective variables or *order parameters*. What do these terms mean? *Control Parameters* refer to naturally occurring environmental conditions or intrinsic, endogenous factors that on first blush appear analogous to what an experimental scientist might call an independent variable. But the concept is entirely different, and the implications for experimental design far reaching [96]. The role of control parameters is to move the system through its repertoire of patterns and cause them to change. In fact, you only know for certain you have identified a control parameter if, when varied, it causes the system's behavior to change qualitatively or discontinuously, i. e., to change state. In a dynamical system, when a parameter changes smoothly, the attractor in general also changes smoothly. Sizeable changes in the input have little or no effect on the resulting output. However, when the control parameter passes through a critical point or threshold in an intrinsically nonlinear dynamical system an abrupt change in the attractor can occur. This sensitive dependence on parameters is called a *bifurcation* in mathematics, or a *nonequilibrium phase transition* in physical theories of pattern formation [73]. Indeed, control parameters are often referred to in mathematics as *bifurcation parameters*. Qualitative change does not mean that quantification is impossible. To the contrary, qualitative change is at the heart of pattern formation and, provided care is taken to evaluate system timescales (e. g., how quickly the control parameter is changed relative to the typical time of the system to react to perturbations; see [121]) quantitative predictions ensue that can be tested experimentally (see Sect. "The Theoretical Modeling Strategy of Coordination Dynamics: Symmetry and Bifurcations").

Collective variables are relational quantities that are created by the cooperation among the individual parts of a system. Yet they, in turn, govern the behavior of the individual parts. This is sometimes referred to as *circular* or *reciprocal causality*. In self-organizing systems the stranglehold of linear causality is broken. At best, simple cause-effect relations are the exception, not the rule. Depending on where the system lives in the space of its parameters, many causes can produce the same effect or the same cause can have multiple effects. One can intuit why the concept of collective or coordination variable is central to a science of coordination. The reason is that interactions in such systems are so complicated that understanding may only be possible in terms of system-specific collective or coordination variables. The latter are not necessarily "macroscopic quantities". In coordination dynamics, the identification of coordination variables depends on the level of description. What is "macro" at one level may be "meso" or "micro" at another. This strategy of folding together all aspects within the dynamics of collective or coordination variables embraces the full complexity of living things on a given level of description without proliferating arbitrary divisions (for a nice discussion see [203]).

In nonequilibrium systems, the enormous compression of degrees of freedom near critical points arises because events occur on different timescales: the faster individual elements in the system become "enslaved" to the slower, "emergent" collective variables [73]. Alternatively, one may conceive of a hierarchy of timescales for various processes involved in coordination. On a given level of the hierarchy are coordination variables subject to constraints (e. g., of the task) that act as boundary conditions on the coordination dynamics. At the next level down are component processes and events that typically operate on faster timescales. Notice for the 'tripartite scheme' of Coordination Dynamics (see pp. 66–67 in [100]) the key is to choose a level of description and understand the relation between adjacent levels, not reduce to some "fundamental" lower level (Table 1). In coordination dynamics, no level is any more or less fundamental than any other. A complete description of a phenomenon always requires three adjacent tiers: The boundary conditions and control parameters that establish the context for particular coordination phenomena to occur; the collective level and its dynamics; the component level and its dynamics including the nonlinear coupling between components.

Dynamic instability is the generic mechanism underlying self-organized pattern formation and change in all (open) systems coupled to their internal or external environments [153]. Near instability the individual elements, in order to accommodate to current conditions, must order themselves in new or different ways. The patterns that emerge at nonequilibrium phase transitions may be defined as attractive states of the collective variable dynamics. That is, the collective variable may converge in time to a certain limit set or attractor solution, a nonequilibrium steady state. Attractors can be *fixed points*, in which all initial conditions converge to some stable rest state. Attractors can also be *periodic*, exhibiting preferred rhythms or orbits on which the system settles regardless of where it starts. Or, there can be so-called *strange* attractors; strange because they exhibit *deterministic chaos*, a type of irregular behavior resembling random noise, yet often containing pockets of quite ordered behavior. Stable fixed point, limit cycle and chaotic solutions as well as a wide variety of other transient and irregular behaviors are possible in the *same* system, depending on the values of control parameters (and their time dependence). Moreover, fluctuations are always present, constantly testing whether a given pattern is stable. Fluctuations are not just noise; rather, by probing the stability of existing states they allow the system to discover new, more adaptive patterns that suit the prevailing circumstances (boundary conditions, control parameters; Table 1).

How might these conceptual tools aid our understanding of biological coordination? On first blush, it might seem a gigantic leap from the physics and mathematics of pattern formation in nonequilibrium systems to the problem of coordination in living things. Yet in science, analogy often plays a major role in bringing about conceptual breakthroughs. Although initially the analogy may seem far-fetched, great science often starts with a vague idea which, when followed by crucial experiments and mathematical theory renders the vague idea exact. A key aspect to appreciate is that cooperative phenomena in physical systems are typically independent of the particular molecular machinery or material substrate that instantiates them. This is because the elementary components are the same, i. e. homogeneous. On the other hand, in living, evolved things the component elements are often quite different. Thus any theory of coordination of living things will have to take into account the heterogeneity of its component elements. Perhaps as a consequence of inherent heterogeneity (and no doubt the advancement of technology) the tendency in biology is to focus more and more on specific processes at ever smaller and smaller scales. As a result, building huge data bases may sometimes appear to take precedence over finding scientific laws [55].

Finding Dynamical Laws of Coordination
