Article Outline

Glossary

Scanning tunneling microscope (STM) A nano-technology instrument capable of imaging the topography of conducting surfaces with atomistic resolution. It can also be used to manipulate individual atoms and molecules, and construct nano-scale structures.

Atomic force microscope (AFM) A nano-technology instrument for investigation of material surfaces on atomistic and molecular scales. It can be used to map the topography of non-conducting surfaces, by sensing the inter-atomic forces, and produce three-dimensional images of these surfaces.

Spintronics Refers to the field of spin-based electronics rather than charge-based electronics. It will lead to a new type of device that is based on the use of electron spin for transfer and storage of information.

Brillouin zone In solid state physics several Brillouin zones can be defined. The first zone is defined as the Wigner–Seitz primitive cell of the reciprocal lattice. The *n*th Brillouin zone is defined as the set of points that are reached from the origin by crossing $(n-1)$ Bragg planes.

Monte Carlo (MC) method In computational modeling, this method provides a probabilistic scheme for solving a variety of problems by employing powerful sampling techniques. In nano-science and condensed matter physics, one application of this method is for computing the minimum energy state of a nano-structure.

Stochastic dynamics (SD) method This refers to the computer simulation method wherein the Langevin equation of motion, describing the random behavior of a particle, is solved as opposed to the deterministic MD method in which Newton's equations of motion are solved.

Nano-electromechanical systems (NEMS) These are nano-technology based systems that are the smaller versions of the micro-electromechanical systems (MEMS). They are capable of measuring small displacements, sensing minute amount of substances, and performing rotary motions. NEMS can be constructed via either the top-down approach, i. e., via miniaturization of the micro-scale devices, or via the bottom-up approach, i. e., by positioning single atoms or molecules so that a complex and functional nano-system is built from below the nano-scale.

Ab initio approach This is the first-principles approach to the computation of the properties, especially the electronic-structure properties, of nano-scale systems using quantum-mechanical concepts and methods. In this method, the structure of a molecule, for instance, is obtained purely from a knowledge of its composition by solving the Schrödinger equation.

Definition of the Subject

Carbon nanotubes form the fourth allotrope of crystalline carbon after graphite, diamond, and a variety of caged-like fullerene molecules, and were discovered in the early 1990s. Their mechanical properties make them stronger than steel, and their thermal conductivity is faster than copper. They have very exotic electronic-conduction properties, namely, by changing their geometry, or introducing topological defects into their structure, their electronic conductance can change from metals to semiconductors. They can also be used to store gases and transport fluids. Furthermore, nano-scale robots, machines, and sensors can be constructed from them, and these can be used to deliver drugs to specific locations in the body, or detect individual cancer cells, or be used as molecular filters to separate minute particles from the environment. Carbon nanotubes are referred to as the fabric of nanotechnology, and will play a central role in the future development of this technology. Understanding the properties of nanotubes, via computational simulation studies, has been one of the most intensive areas of research in physical sciences during the past 20 years.

Introduction

The current scientific-technological arena is distinguished by the presence of *four* distinct and highly complex disciplines, namely:

1) information science, underlying the fields of information technology, high performance computing, and computational science,
2) molecular genetics and molecular biology, underlying the fields of genetic engineering and bio-technology,
3) neuro and cognitive sciences, and their related fields of neural- and brain-based technologies,
4) nano-science, and its related fields of nano-technology and molecular-scale engineering, making atom-by-atom manipulation of the physical, biological and smart matter possible.

These four areas are strongly correlated, and the post-modern era in science and technology will be characterized by research efforts to establish, step-by-step, a close synergy among these fields, leading to their total integration within a *unified* and holistic framework, promoting the convergence of all these seemingly separate and compartmentalized branches and paving the way for the emergence of a *convergent* technology [49]. Such a technology will produce advanced man-made machines, devices, components, and materials that carry some of the most essential characteristics of the biological and smart systems, such as self-repair, self-assembly, self-correction of internal faults, re-production, ability to establish communication, and adaptation to unfamiliar environments.

The convergence takes place at the nano-scale (1–100 nanometers) since the main building blocks of the physical, biological and smart matter, i. e., the physical and biological *nano-structures*, and the laws governing their evolution, are formed at this scale. It is, therefore, no exaggeration to state that nano-scale science and nano-scale technology [17] represent the main components of the 21st century science and technology. It is now accepted that nano-science can be defined as *the study of structures, dynamics, and properties of systems wherein one or more of spatial dimensions varies in the nanoscopic range*. At this scale, the dynamics and properties of systems are distinctly different, very often in quite unforeseen ways, from those in microscopic and macroscopic systems.

Nanoscopic structures operate on very reduced time and energy scales, and are constructed from a *countable* number of atoms and molecules. Their sizes are located between those of molecules and micro-structures, and their distinguishing feature is their high aspect, or surface-to-volume, ratio. Nano-technology represents the combination of atomic and molecular level techniques and instrumentations for constructing nano-scale devices, systems, and components from the *assemblies* of individual nano-structures. On the other hand, nano-technology is an *enabling* technology, injecting nano-structures into micro- and macro-scale, devices, materials, and systems to enhance, or radically change, their electronic, mechanical, optical and thermal properties. For instance, nano-structured materials, i. e., materials with nano-sized grains, or materials injected with nano-grains, can show very different mechanical, thermal, electronic and optical properties. For instance, it is known that nano-structured Fe, Cu and Ni have electrical resistances respectively 55%, 15% and 35% higher than the coarse-grained polycrystalline samples [38].

Nano-structures can be assembled by a precise positioning of the atoms at specified locations, using such highly sensitive devices as the scanning tunneling microscope (STM) [9], and the atomic force microscope (AFM) [8]. These devices can provide access to the detailed topography, crystal structure, and the electronic-structure maps at material surfaces and of individual nano-structures. Their use has led to the design and fabrication of devices, and materials, that manifest novel physical, chemical and biological properties.

Among the multitude of nano-structures currently used in nano-technology, carbon nano-structures occupy a central position, with wide-ranging applications in practically all the nano-technology sub-fields. Carbon is a fundamental element, crystallizing in several allotropes. In the 1970s, *diamond* and *graphite* were the only known forms of condensed carbon, and a third allotrope, the cage-like *fullerene* molecules, was discovered and synthesised in macroscopic amounts by mid 1980s. In 1990s, the fourth allotrope, the multi-walled carbon *nanotube* (MWCNT), and the single-walled carbon nanotube (SWCNT) were synthesized [20,21]. Several growth techniques, namely, the arc-discharge, the laser ablation, and recently the chemical vapor deposition method, have been developed. The appearance of nanotubes has led to the emergence of new and very active areas of research within several fields; in computational and experimental nano-science, industrial nano-technology, theoretical and experimental condensed matter physics and chemistry, materials science and engineering, bio-physics, medical nano-technology, molecular genetics, nano-biotechnology, information technology device fabrication, optics, electro-mechanical systems and electronics, carbon nanotubes are viewed as highly relevant nano-structures with extensive potential applications.

Originally, the carbon nanotubes were of *multi-walled* variety, with outer diameters in the range of 4–30 nm and lengths of up to 1 μm [21]. These consisted of seamless concentric cylindrical shells, separated by 3.4 Å. Each shell was a rolled-up version of a two-dimensional graphene sheet. The *single-walled* nanotubes were synthesized later [6,22], and consisted of single graphene sheets with a typical diameter on the order of 1.4 nm, similar to the diameter of a C_{60} molecule, and lengths usually on microscopic orders [21]. It was also found that these SWCNTs can bundle together to form a *rope*, normally patterned as a hexagonal array, with a morphology very similar to porous materials, and membranes, with nanometer spaces available both inside the nanotubes and in the interstitial channels between them that can be utilized for *storage* of adsorbed gases, and *flow* of fluids, turning them into filtering channels and molecular sieves.

Another form of SWCNTs, called single-walled carbon *nanohorn* (SWCNH), has also been synthesized [23]. This horn-shaped material has a closed structure, with a cylindrical part and a horn-tip part. Its internal space is not normally available as a storage medium, but heat-treatment within an oxygen environment promotes the appearance of windows on the its walls, allowing for gas and liquid particle transfer to the interior.

Nanotubes incorporating fullerenes, such C_{60} molecules, have also been synthesized [55], and are referred to as *peapods*. The internal space of the SWCNT is filled with a regularly-arranged formation of fullerene molecules [21]. Peapods, when heated to 1000–1200°C, transform into double-walled carbon nanotubes (DWCNTs), as the encapsulated molecules coalesce [21]. Peapods provide a good model of nano-platforms for targeted drug delivery.

As will be discussed later, an SWCNT is identified by two *chiral* indices (n, m) that determine its diameter, and depending on their values, three *different* classes of nanotube are observed. These are the $(n, 0)$, or the *zigzag*, nanotube, the (n, n), or the *armchair* nanotube, and the $(2n, n)$, or the general *chiral* nanotube. They have very different *electronic* conduction properties. The graphene sheet is a semi-metal with a zero band-gap. The electronic states of an infinitely long nanotube are continuous in its axial direction, but are quantized along its circumference. For the (n, n) armchair nanotubes, there always exist electronic states that cross the corner points of the first Brillouin zone, making these nanotubes a *metallic* material. For the (n, m) nanotubes, if $(n - m)/3 \neq$ an integer, the electronic states miss the corner points, and these nanotubes behave as semi-conductors with a band-gap that scales with the diameter d of the tube as $1/d$, and which is on the order of 0.5 eV. If $(n - m)/3 =$ an integer, however, certain electronic states are located on the corner points, and these nanotubes behave as semi-metals, but become small-band semi-conductors due to the curvature-induced rehybridization [14]. These remarkable electronic-conduction properties, that are linked with the geometry of the material, are also very partial to local deformations in the geometry. Recent exploitation of the electronic properties of carbon nanotubes includes the field of spin-electronics, or *spintronics* that utilizes the spin of the electrons to transfer and store of information.

Nanotubes have also extraordinary mechanical, thermal, mass-transport, and gas-storage properties. For example, their Young's modulus, being a measure of their stiffness, is estimated to be of the order of 1.5 to nearly 5 TPa, and their tensile strength is far higher than that of steel. They are, therefore, strong candidates as functional units in molecular-scale machinery, and highly complex nano-electromechanical systems (NEMS), and as probe *tips* in STM and AFM [56]. Their high thermal conductivity, far exceeds that of diamond. They can also act as media for the transport and storage of various types of gases and fluids.

The investigation into nanotube properties has prompted an intensive experimental and theoretical/computational research, leading to major discoveries, and the appearance of several thousand patents and publications in fields of basic sciences, engineering, and medicine. One of the most active areas has involved the use of predictive computational modeling of their mechanical, thermal and mass transport properties [44]. These computational modelings and simulations have been performed via two distinct methodologies:

1) using quantum mechanical methods, such as the density functional theory (DFT) of atoms and molecules [36] that provides an *ab initio* approach to computation of the properties of nano-scale systems composed of several *ten* to several *hundred* atoms,
2) using classical statistical mechanics methods, such as the molecular dynamics (MD), Monte Carlo (MC) and stochastic dynamics (SD) simulation methods [2] that can handle nano-scale structures composed of several *thousand* to several *billion* atoms. These simulation methods require the use of phenomenological inter-atomic potentials to model the energetics of the system. These potentials play a very crucial role, and the more accurate they are, the closer the simulation results approach the experimental data. A good deal of efforts have been focused to develop highly accurate inter-atomic potentials for different classes of materials, particularly the covalently-bonded ones. Some of these potentials are *many-body* potentials, and most of the simulations concerning carbon nanotubes have used these many-body potentials.

Research into the properties of carbon nanotubes has led to the appearance of several informative reviews, among which one can mention those by [1,5,16,40,43,45]. In addition, an impressive number of encyclopedias and handbooks [7,34,48,51] covering most sub-fields of this topic are also available.

In this review I have surveyed the field of computational modeling of the thermo-mechanical, transport and storage properties of nanotubes. In the interest of saving space, I have only described, albeit very briefly, one of the computational methods that has been extensively employed in these research studies, namely the MD simulation method. The interested reader can find a very good summary of the other methods in [43]. An extensive part of the modeling-based research into the mechanical properties has employed concepts from the field of continuum elasticity theory, using such structures such as *curved plates, shells, vibrating rods, and bent beams*. An easy-to-follow introduction to these topics can found in my book [44].

The organization of this review is as follows. In Sect. "Geometry of SWCNT, MWCNT and SWCNH", the description of the geometrical structure of the SWCNTs, MWCNTs and the SWCNHs is briefly considered. In Sect. "Simulation at Nano-Scale" the basic principles of the classical MD simulation method is presented. In Sect. "Modeling Fluid Transport and Gas Storage Properties of Nanotubes", the flow of fluids and the storage of gases in nanotubes are considered, while in Sect. "Modeling the Mechanical Properties of Nanotubes", the mechanical properties are considered. Section. "Modeling the Thermal Properties of Nanotubes" summarizes the thermal conductivity and specific heat properties of nanotubes, and Sect. "Concluding Remarks" presents an overall summary together with the future directions.

Geometry of SWCNT, MWCNT and SWCNH

The SWCNT

We can construct an SWCNT by rolling a 2D graphene sheet into a cylinder. Consider a lattice point O as the origin in a graphene sheet, as shown in Fig. 1. The 2D Bravais lattice vector of the graphene sheet $\mathbf{C}_h$, referred to as the *chiral* vector, can be used to reach any other equivalent point Z on the sheet. The vector $\mathbf{C}_h$ is constructed from the pair of unit-cell vectors $\mathbf{a}_1$ and $\mathbf{a}_1$ as

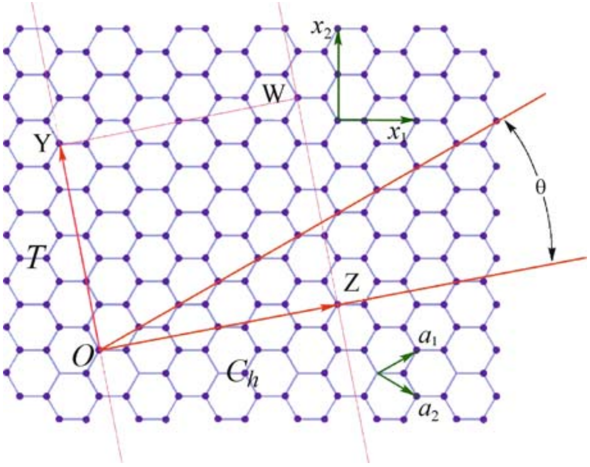
$$\mathbf{C}_h = n\mathbf{a}_1 + m\mathbf{a}_2 \,, \tag{1}$$

where m and n are a pair of integers, and

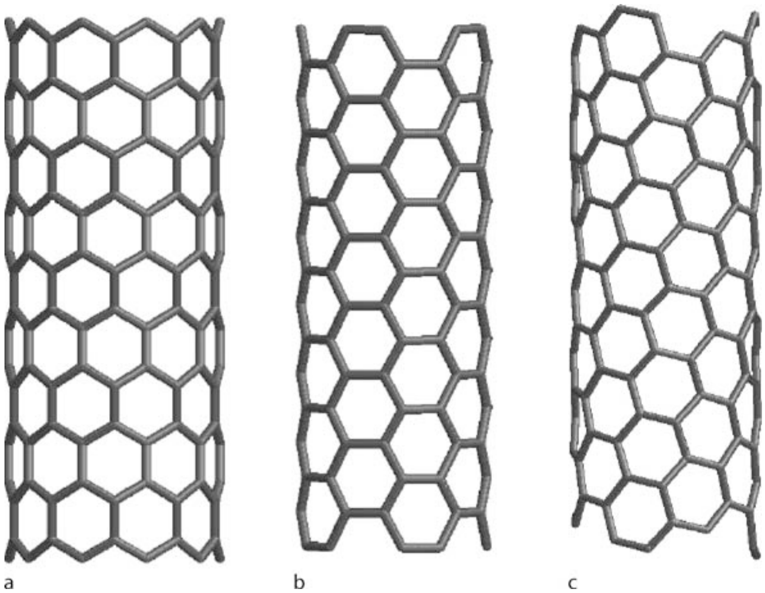
$$\mathbf{a}_1 = \left(\frac{\sqrt{3}}{2}, \frac{1}{2}\right)a \,, \quad \mathbf{a}_2 = \left(\frac{\sqrt{3}}{2}, -\frac{1}{2}\right)a \,, \tag{2}$$

where $a = 2.46$ Å is the lattice constant of graphite

$$a = \sqrt{3}a_{\text{C–C}} \,, \tag{3}$$



Carbon Nanotubes, Thermo-mechanical and Transport Properties of, Figure 1
The geometry of a two-dimensional graphene sheet, showing the relevant vectors that characterize a single-walled carbon nanotube (SWCNT). Figure based on [15]



Carbon Nanotubes, Thermo-mechanical and Transport Properties of, Figure 2
The outlines of three types of nanotube: a a (10,0) zig-zag nanotube; b a (5,5) armchair nanotube; c a (7,3) general chiral nanotube

and a_{C-C} is the carbon-carbon bond length. The angle θ that $\mathbf{C}_h$ makes with the zigzag axis of the sheet is referred to as the chiral angle, and (n, m) are called the chiral indices. If the sheet is rolled, and the point characterized by the pair of values of (n, m) coincides with the origin O, then an (n, m) nanotube is generated. The *zigzag* direction corresponds to $\theta = 0$, and when the direction of rolling is along this axis, a zigzag nanotube is formed. When $\theta = \pi/6$, the direction is called the *armchair* direction, and rolling along this direction generates an armchair nanotube. A nanotube generated for any other value $0 < \theta < \pi/6$ is referred to as a general chiral nanotube. Figure 2 shows the schematic representations of these three types of nanotube.

The circumference of the nanotube, i. e., the length of the chiral vector, is given by [15]

$$L = |\, \mathbf{C}_h \,| = a(n^2 + m^2 + nm)^{\frac{1}{2}} \,, \tag{4}$$

and, hence, the diameter is

$$d_t = \frac{L}{\pi} = \frac{(n^2 + m^2 + nm)^{\frac{1}{2}}}{\pi} a \,. \tag{5}$$

Other relationships connecting the chiral angle with the chiral indices are [15]

$$\sin\theta = \frac{\sqrt{3}m}{2(n^2 + m^2 + nm)^{\frac{1}{2}}} \,,$$

$$\cos\theta = \frac{2n + m}{2(n^2 + m^2 + nm)^{\frac{1}{2}}} \,,$$

$$\tan\theta = \frac{\sqrt{3}m}{2n + m} \,. \tag{6}$$

Hence, if $n = m$, then $\theta = \pi/6$ and the resulting nanotube is an (n, n), or an armchair, nanotube. If $m = 0$, then $\theta = 0$, and an $(n, 0)$, or a zigzag, nanotube is obtained. The nanotubes in the general chiral category are $(2n, n)$.

The rectangle bounded by the chiral vector $\mathbf{C}_h$ and the vector $\mathbf{T}$, i. e., OYWZ, where Y is the first lattice point through which the vector passes, is the unit-cell of the nanotube. This vector is written as [15]

$$\mathbf{T} = t_1\mathbf{a}_1 + t_2\mathbf{a}_2 \,, \tag{7}$$

where t_1 and t_2 are a pair of integers, related to m and n via

$$t_1 = \frac{2m + n}{d_R} \,, t_2 = -\frac{2n + m}{d_R} \,, \tag{8}$$

and d_R denotes the highest common divisor (HCD) of $(2n + m, 2m + n)$, given by

$$d_R = \begin{cases} = d & \text{if } (n - m) \text{ not a multiple of } 3d \,, \\ = 3d & \text{if } (n - m) \text{ multiple of } 3d \,, \end{cases} \tag{9}$$

where d is the HCD of (n, m). The length T of the vector $\mathbf{T}$ is given by

$$T = |\, \mathbf{T} \,| = \frac{\sqrt{3}L}{d_R} \,. \tag{10}$$

The unit-cell of the nanotube contains $2N$ atoms, where

$$N = \frac{2(n^2 + m^2 + nm)}{d_R} \,. \tag{11}$$

Carbon nanotubes can be capped at both ends [15]. This can be done by bisecting a C_{60} molecule into two hemispheres and joining these with a cylindrical nanotube of the same diameter as the molecule.

An SWCNT is a low-energy structure with a distinct topology, brought about by distorting the geometry of the 2D graphene sheet into the third dimension. The act of rolling the sheet calls for the expenditure of a modest amount of strain, or curvature, energy, which is the difference between the total energy of a carbon atom in an SWCNT and that in a graphene sheet. In nanotubes with a diameter less than 1 nm, this energy penalty is more significant since the bond angles deviate far below the ideal 120° angles in the graphene sheet.

The MWCNT

Two forms of MWCNTs have been found in experiments. These are a thermodynamically-stable system composed of nested coaxial cylinders [20], and a metastable type with a scroll structure [26]. The transition from the latter type to the nested type is attributed [26] to the presence of the dislocation-like defects in the scroll type. The inter-shell gap in an MWCNT is estimated to be ≈3.4 Å [50], very close to the inter-planar gap in the graphite crystal. Several other values of this gap, in the range 3.42 Å to 3.75 Å, have also been reported [25], with the gap increasing when the nanotube diameter decreases. The simplest type of an MWCNT is a DWCNT. To construct a DWCNT, the chiral vector of the inner SWCNT, with indices (n_1, m_1), is related to the chiral vector of the outer SWCNT, with indices (n_2, m_2). These indices are related via

$$m_2^2 + m_2 n_2 + (n_2^2 - \kappa(n_1, m_1)) = 0 \,, \tag{12}$$

where

$$\kappa(n_1, m_1) = \left[\frac{2\pi(r_{t1} + r_g)}{a}\right]^2 \,, \tag{13}$$

and r_{t1} and r_g are respectively the radius of the inner nanotube, and the inter-shell gap. Then n_2 and m_2 can be obtained by solving (12). For example, for a (9,6) inner nanotube, and $n_2 = 15$, we find $m_2 = 9.96$ which rounds to $m_2 = 10$ and, therefore, the nanotube (9,6) can be nested inside the nanotube (15,10).

The SWCNH

These objects are distinguished by their horn shape. Pure SWCNH samples are relatively easier to produce than pure SWCNT samples [33]. SWCNHs are always produced with closed tips, incorporating pentagons into their hexagonal lattices to close the ends. They consist of a tubule part, and a conical cap whose average angle is 20°, implying that the caps contain five pentagon rings and several hexagon rings. The average length of SWCNHs is 30-50 nm, and the separation between neighboring SWCNH is about 0.35 nm. The average diameter of the tubular parts is 2-3 nm, larger than the 1.4 nm diameter of a typical SWCNT. The interstitial spaces in an SWCNH assembly provide the external micropore and mesopore spaces [33,35], where pores with a width of less than 2 nm are called micropores, and those with a width between 2 and 50 nm are called mesopores. The width of the internal pores in SWCNHs is close to the critical size of 2 nm [33]. Oxidation produces windows on the walls of a closed SCWNH [35], making available 11% and 36% of the closed spaces at $T = 573$ K and 623 K respectively [32].

Simulation at Nano-Scale

The time-evolution of the energetics and dynamics of complex nano-structures and nano-processes, involving several billions of atoms, can be accurately studied via simulation methods that use concepts from classical statistical mechanics. The information gained from these simulations can be profitably used in the design of nano-scale components, nano-structured materials, and structures dominated by nano-interfaces. Furthermore, the construction of functional assemblies of nano-structures requires a deep understanding of the interaction between individual nano-structures, and this can be handled by the use of such simulation methods. We briefly consider the essential elements of one of the most popular simulation methods at the nano-scale, namely the MD simulation method.

MD Simulation Method

Classical MD simulation [2,18,46] studies the motion of individual atoms in an assembly of N atoms or molecules employing either the Newtonian, or the stochastic dynamics, when the initial spatial configuration and velocities of these atoms are given. In MD, the N-atom structure is confined to a simulation cell of volume V, and this cell is replicated in all dimensions, generating the periodic images of itself and of the N atoms. This periodic boundary condition (PBC) is necessary to compensate for the undesirable effects of the artificial surfaces associated with the finite size of the simulated system. The energetics of the system are modeled by two- or many-body inter-atomic potentials $H_I(r_{ij})$, and in the simulation the force experienced by each atom is obtained from

$$\mathbf{F}_i = -\sum_{j>i} \nabla_{\mathbf{r}_i} H_I(r_{ij}) \,, \tag{14}$$

where r_{ij} is the distance between atoms i and j. The $3N$ coupled equations of motion are integrated numerically via a variety of numerical techniques, all based on the finite-difference method. One popular integration scheme is the velocity Verlet algorithm [2], whereby the positions $\mathbf{r}_i$ and velocities $\mathbf{v}_i$ of the atoms of mass m_i are updated at each simulation time step $\mathrm{d}t$ according to

$$\begin{aligned} \mathbf{r}_i(t+\mathrm{d}t) &= \mathbf{r}_i(t) + \mathbf{v}_i(t)\mathrm{d}t + \frac{1}{2}(\mathrm{d}t)^2\frac{\mathbf{F}_i(t)}{m_i} \,, \\ \mathbf{v}_i(t+\frac{1}{2}\mathrm{d}t) &= \mathbf{v}_i(t) + \frac{1}{2}\mathrm{d}t\frac{\mathbf{F}_i(t)}{m_i} \,, \\ \mathbf{v}_i(t+\mathrm{d}t) &= \mathbf{v}_i(t+\frac{1}{2}\mathrm{d}t) + \frac{1}{2}\mathrm{d}t\frac{\mathbf{F}_i(t+\mathrm{d}t)}{m_i} \,. \end{aligned} \tag{15}$$

At each $\mathrm{d}t$, the exact *instantaneous* values of thermodynamical observables, such as the temperature and pressure

$$\begin{aligned} T_{\text{ins}} &= \frac{1}{3Nk_\text{B}} \sum_i^N \frac{|\mathbf{p}_i^2|}{m_i} \,, \\ P_{\text{ins}} &= \frac{1}{3V}\left(\sum_i^N \frac{|\mathbf{p}_i^2|}{m_i} + \sum_{i=1}^N \sum_{j>i}^N \mathbf{r}_{ij}.\mathbf{F}_{ij}\right) \,. \end{aligned} \tag{16}$$

can be computed, where $\mathbf{p}_i$ is momentum of particle i, k_B is the Boltzmann constant and $\mathbf{F}_{ij}$ is the force experienced by atom i due to atom j. These instantaneous data then allow for the computation of time-averaged values at the conclusion of the simulation.

Constant-Temperature MD: The Nosé–Hoover Method

MD simulations are generally performed on closed isothermal systems, represented in statistical mechanics by canonical ensembles wherein N, V, and the temperature T of the members are all fixed [37]. A constant-temperature MD simulation can be realized in a variety of ways [42], and a method that generates the canonical ensemble distribution in *both* the configuration and momentum parts of the phase space was proposed by Nosé [42]. Its application leads to a modification of the equations of motion (15) to the following forms [59]

$$\begin{aligned} \mathbf{r}_i(t+\mathrm{d}t) &= \mathbf{r}_i(t) + \mathbf{v}_i(t)\mathrm{d}t \\ &\quad + \frac{1}{2}\mathrm{d}t^2\left[\frac{\mathbf{F}_i(t)}{m_i} - \eta(t)\mathbf{v}_i(t)\right] \,, \\ \mathbf{v}_i(t+\frac{\mathrm{d}t}{2}) &= \mathbf{v}_i(t) + \frac{\mathrm{d}t}{2}\left[\frac{\mathbf{F}_i(t)}{m_i} - \eta(t)\mathbf{v}_i(t)\right] \,, \\ \eta(t+\frac{\mathrm{d}t}{2}) &= \eta(t) + \frac{\mathrm{d}t}{2\,Q}\left[\sum_i^N m_i\mathbf{v}_i^2(t) - gk_\text{B}\,T\right] \,, \\ \eta(t+\mathrm{d}t) &= \eta(t+\frac{\mathrm{d}t}{2}) \\ &\quad + \frac{\mathrm{d}t}{2\,Q}\left[\sum_i^N m_i\mathbf{v}_i^2(t+\frac{\mathrm{d}t}{2}) - gk_\text{B}\,T\right] \,, \\ \mathbf{v}_i(t+\mathrm{d}t) &= \frac{2}{2+\eta(t+\mathrm{d}t)\,\mathrm{d}t} \\ &\quad \cdot \left[\mathbf{v}_i(t+\frac{\mathrm{d}t}{2}) + \mathrm{d}t\frac{\mathbf{F}_i(t+\mathrm{d}t)}{2\,m_i}\right] \,. \end{aligned} \tag{17}$$

where Q is given by

$$Q = g\,k_\text{B}\,T\,\tau^2 \,, \tag{18}$$

and η is the friction coefficient of the heat bath connected to the system, τ is the relaxation time of this bath, normally of the same order of magnitude as $\mathrm{d}t$, and $g = 3(N-1)$ is the number of degrees of freedom. The parameter τ controls the speed with which the bath damps down the fluctuations in the temperature.

Modeling Fluid Transport and Gas Storage Properties of Nanotubes

Fluid flow and gas storage in nano-scale objects, like carbon nanotubes, is significantly different as compared with the corresponding activities in microscopic and macroscopic structures. For instance, fluid flow in a nano- scale machine is not similar to the flow in a large-scale machine, since in the latter case, there is no need to consider the atomic structure of the fluid, and it can be characterized by its viscosity, density and other bulk properties [61]. Furthermore, in large-scale objects, the so-called *no-slip* boundary condition is often invoked, according to which the fluid velocity is negligibly small at the fluid-wall interface.

Reduction in length scales immediately introduces new phenomena, such as *diffusion*, into the system. Moreover, for flow, or storage, in nano-scale objects, the dynamics of the walls, the fluid, or the gas, and their mutual interaction, must all be considered. We note that the dynamics of the walls can be strongly size-dependent.

An added difficulty is that, at nano-scale, standard classical notions such as pressure and viscosity may also not have a clear definition. For example, the surface area of a nano-scale object, such as a nanotube, may be ambiguous. Notwithstanding these difficulties, modeling fluid flow and gas storage in nanotubes has been an active area of research, with practical consequences. In this section we consider a set of studies, each highlighting one aspect of transport and storage properties of nanotubes.

Modeling Fluid Flow

Let us consider the MD simulation of the flow of fluids, composed of Ar and He particles, through an SWCNT [61]. In simulations, the fluid atoms were always dynamic, whereas for the nanotube, the first 10 and the last 10 rings were always frozen, and the rings in the middle section were treated either as static or as dynamic rings, giving rise to either a static or a dynamic nanotube. The significant result was that the dynamic nanotube slowed down the fluid particles faster than the static nanotube. It took about 42 ps for the fluid velocity to slow down to 2.5% of its initial velocity in the static nanotube, while in the dynamic nanotube this time was 15 ps. Furthermore, the motion of the nanotube perturbed the motion of the adjacent fluid atoms, causing faster randomization and promoting hard collisions with the walls that slowed down the fluid steadily until it essentially came to a stop. Similar results were also obtained for the Ar fluid, whose atoms are some 10 times heaver than He atoms. In this case, it was found, however, that the velocity damping was even more pronounced. It was also found that the higher the fluid density, the faster it slowed down.

Another MD simulation has addressed the rapid imbibition of oil (decane) in a (13,13) SWCNT, at temperature $T = 298$ K [58], modeling the SWCNT as a rigid cylinder. The computed fluid density ρ inside the nanotube showed that the nanotube first filled rapidly with the low density fluid, followed by the higher density fluid at lower speeds tending to ≈ 150 m/s for $\rho > 0.2$. Such speeds are comparable to the speed of sound in air (340 m/s). It was found that, the flow terminated at the end of the nanotube, i. e., although the nanotube was open, its end acted as a barrier to further flow. It was also found that the imbibition was much faster than predicted by the classical Washburn equation which relates the penetration length of the fluid, in a macroscopic tube, to its radius, the surface tension, the viscosity and the time.

The effect of confinement of liquid water in a nanotube on its vibrational and rotational spectra has been also been investigated via MD simulations [30] for four different-sized nanotubes (6,6), (8,8), (10,10) and (12,12). The liquid water density was an input. The significant aspect of the results was the presence of a frequency band, between 3640 and 3690 cm^{-1} , which is absent in bulk water. This was referred to as a vibration frequency, and its position shifted to smaller values when the nanotube radius increased. It was concluded that this *vibration band was purely an effect of confinement*. Adsorption line shape in the domain between 300 and 1000 cm^{-1}, that corresponds to the rotational motion of the molecules, was also obtained, and again a shift to lower frequencies was observed compared with those in the bulk. Hence, there was a direct connection between the radius of the nanotube and some of the observed frequency shifts.

Transport of water through a solvated carbon nanotube has also been modeled [19]. The central channel of the nanotube is strongly hydrophobic in character. It was, however, found that the initially empty channel rapidly filled up with water from the surrounding container, and was occupied during the entire simulation run. The water density inside the cylinder was found to exceed the bulk density. Since the water molecules interact weakly with the carbon atoms, the continuous hydration of the nanotube interior was unexpected.

Modeling Gas Storage

Gas storage can take place in single nanotubes, as well as in their bundles, where three adsorption sites are available, namely the interstitial channels between the SWCNTs, the outer surfaces of the nanotubes in the bundle, and the groove channels, i. e., the wedge-shaped spaces on the outer surface of the bundle where two SWCNTs meet [60]. Simulation results indicate that while H_2, He and Ne atoms can adsorb in the interstitial channels, other types of atoms are too large to fit into these spaces. The clarification of adsorption sites and the adsorbed amount has been the focal point of research in this area.

Hydrogen Storage The storage of atomic and molecular hydrogen has occupied a very prominent position in the field of gas adsorption in nanotubes. The adsorption of para-hydrogen in (9,9) and (18,18) SWCNTs and their bundles has been modeled at several temperatures [62]. The inter-nanotube spacing within a bundle, called the van der Waals gap, is approximately 3.2 Å, measured from the center of the nanotube walls. The gap g is defined as ($g = a - D$), where a is the lattice spacing, and D is the diameter of the nanotube. The total storage in the bundle is a sum of interior and interstitial adsorptions. The computed isotherms at $T = 77$ K show that, in the low pressure range, the (9,9) nanotube bundle gives a higher gravimetric and volumetric densities than the (18,18) nanotube bundle, since the hydrogen-nanotube interaction in the former case is stronger. At pressures above 5 and 10 atm, the situation is reversed. The volume of a (9,9) nanotube is of such a size that it can hold one layer of adsorbed molecules on the interior surface and a column of molecules in the center of the nanotube, whereas the volume of the (18,18) nanotube can accommodate three layers of hydrogen in three concentric rings and a column in the center of the nanotube.

It was found that the interstitial adsorption formed 14% of the total adsorption in the (18,18) nanotube bundle, in the (9,9) nanotube bundle this proportion was less than 1%. Increasing the temperature from $T = 77$ to 298 K lowered the adsorbed amount in both the (9,9) and the (18,18) bundles by approximately a factor of 5 at 100 atm. The computed adsorption isotherms on the external and internal surfaces of an isolated (18,18) SWCNT showed that it adsorbed slightly more than the (9,9) SWCNT at $T = 77$ K, except at the lowest pressures. A significant portion of the total adsorption took place on the external surfaces.

Quantum-mechanical based computation of adsorption of hydrogen atoms in (5,5) and (10,10) SWCNTs and in a (5,5)@(10,10) DWCNT has also been performed [27]. The results show that there were two chemisorption sites on the exterior and the interior of the nanotube, and that a form of H_2 *molecule* formed within the empty pore inside the nanotube. Furthermore, hydrogen capacity increased linearly with the diameter of the nanotube. The results for the DWCNT showed that the SWCNTs were better for higher hydrogen storage than the DWCNT.

Another study on the physisorption of *molecular* hydrogen H_2 in SWCNT bundles [64] has shown that small-diameter bundles are preferable for storage, and that the delamination of the nanotube bundle increases the gravimetric storage capacity.

In another simulation [63], the question of optimization of the gap in a bundle of SWCNTs for maximum storage of H_2 has been addressed for two bundle geometries, namely, a square bundle and a triangular bundle, each bundle composed of four nanotubes of types (9,9), (12,12), (18,18). The gap was varied to obtain the optimum separation for adsorption. The results on the gravimetric and volumetric densities, as a function of the gap, for $T = 298$ K and $P = 50$ atm showed that for $g = 3.2$ Å, i. e., the smallest gap, much of the volume and surface area in the bundles were unavailable for adsorption in both packing geometries. Increasing this gap allowed adsorption to take place on the external surface of the nanotubes. It was found that, the optimum value of g, as a function of temperature, was $g = 6$ Å at $T = 298$ K, and $g = 9$ Å at $T = 77$ K in a *triangular* bundle of the (9,9) nanotubes.

The adsorption of H_2 molecules in *charged* (9,9) SWCNTs, and their two-dimensional rhombic-shape bundles, has also been investigated [53]. The results for isolated SWCNTs showed more second layer adsorptions in the charged nanotubes, as compared with the uncharged nanotubes, and that the difference in adsorption was about 10%–20% at $T = 298$ K and 15%–30% at $T = 77$ K. Furthermore, it was noticed that the negatively charged nanotubes adsorbed more than the positively charged nanotubes at $T = 77$ K. At the higher temperature of $T = 298$ K, there was no observable difference. Volumetric densities for the adsorption in the bundles of charged and neutral nanotubes, as a function of the van der Waals gap, showed that the charged bundle had an enhanced adsorption of H_2 because of charge-multipole interactions. The results from these simulations imply that an enhancement of the hydrogen storage capacity of nanotubes can be achieved by using electric fields and gradients.

Adsorption of Other Gases The quantum ground-state energy of He atoms, as well as the isosteric specific heat of low-density He gas, adsorbed on the external groove sites in a bundle of 37 nanotubes have been computed [52]. The energy was found to be -22.7 meV, in close agreement with the experimental value, but larger than the computed energy for the He atom adsorbed in the interstitial channels, which is -27.9 meV. The data on specific heat for adsorption in the grooves were computed, and were seen to be very different from the data for adsorption in the interstitial positions.

The adsorption of Xe atoms in (10,10) SWCNTs, and their hexagonal bundle, at $T = 95$ K was modeled [54]. The results showed that the rather strong interaction between highly polarizable Xe atoms and the nanotubes led to significant adsorption even at very low pressures. The adsorption isotherms for internal and external surfaces showed a significant difference. Adsorption in the bundle of SWCNTs was also considered, and as the interstitial space was only 2.9 Å wide, for a large bundle, adsorption was expected to take place only in the interior of the nanotubes.

Adsorption of NO_2, O_2, NH_3, CO_2, H_2O gas molecules on (10,0), (17,0), (5,5) and (10,10) SWCNTs has also been obtained [66]. Different adsorption sites, such as the top of a carbon atom, the top of the center of a C-C bond, and the top of a carbon hexagon, were considered. The results showed that, in general most of the gases were weakly bound to the nanotubes, i. e., they were physisorbed. Furthermore, most of the molecules were charge donors with a small charge transfer, whereas O_2 and NO_2 were charge acceptors. The influence of adsorption on the electronic properties of SWCNTs was also investigated, and it was found that the adsorption of NH_3 and NO_2 did not significantly affect either the conduction or the valence band of a (10,0) nanotube. The density of states (DOS) of the nanotube decorated with NH_3 was very close to that of a pure nanotube. This behavior was also observed for all charge donor molecules, i. e., N_2, H_2O, CO_2 etc. The adsorption of NO_2 significantly changed the shape of DOS, implying that semi-conducting SWCNTs can be turned into p-type conductors following adsorption of NO_2 or O_2.

Another study [12] has considered the influence of lattice dilation, due to adsorption of He, Ne, H_2, D_2, Ar and CH_4 gases in the interstitial channels of the SWCNT triangular bundles, on the further uptake of these gases. The basic idea was that, lattice dilation allows small molecules to significantly enhance their binding energies in the interstitial channels without a substantial increase in the internanotube interaction energy. The results revealed that the chemical potential for H_2 was about 200 K lower than the value in the absence of dilation, i. e., there was a greater tendency for the adsorption in a dilated medium than in an undilated one. In the case of D_2, the lattice dilated less than in the case of H_2. Also the dilation in the He and Ne adsorptions was less than 0.5%. For H_2, Ar and CH_4 the consequences of dilation were significant.

Adsorption of Gases in SWCNH Assemblies Since SWCNHs are closed structures, access to their interior must first be achieved by opening potential entry points. The most common method for pore opening is heat treatment in oxygen [3], and oxidization at $T = 573$ and 623 K respectively leads to the opening of 11% and 36% of the spaces. Assemblies of SWCNHs also possess interstitial channels.

Adsorption of nitrogen, at $T = 77$ K was used to estimate the volumetric porosity of aggregates of heat-treated SWCNHs [32]. The interaction of the corn (apex) parts of the horns was not taken into account, and only the contribution of tube parts was considered. It was found that the interstitial site in the middle of three SWCNHs provided the strongest site. However, since only a one-dimensional array of N_2 molecules could be packed at this site the adsorption capacity was limited there. Strong adsorption could also occur on the sites within the SWCNHs near their walls, leading to the formation of a monolayer. A third site, of weaker type, also located in the interior of SWCNHs, was also identified. Therefore, three sites were found for adsorption.

Adsorption of N_2 in the internal pore space of *individual* SWCNHs has been addressed [35], with the interaction of the corn part of the SWCNH included. Adsorption isotherms were obtained for different diameters D of the tube part of the SWCNH, and since the SWCNHs were partially oxidized at $T = 693$ K, almost all of the pore spaces were available for adsorption. The computed isotherms showed two gradual steps around the normalized pressures of 10^{-5} and 10^{-1}, and the smaller the value of D, the shaper was the step. The average pore width w of the internal space was found to be $w = 29$ Å. Experimental images of three regions, namely the tip, the neck and the tube parts of the SWCNHs showed that the adsorption in these regions was considerably different, and that it began at the tip and then moved to the neck space, and in the tube space the molecules were adsorbed on the internal wall in multilayers.

Modeling the Mechanical Properties of Nanotubes

Modeling the mechanical properties of carbon nanotubes occupies a central position in research on nanotubes, and computational simulation in this field has employed highly sophisticated atomistic and continuum-elasticity models. These studies reveal that nanotubes have high tensile strength, large bending flexibility and high aspect ratios, properties that make them an ideal superstrong material. Research has focused on the elastic constants, Poisson's ratio and Young's modulus, and their dependence on the diameter and chirality of the nanotubes. A very interesting part of this research has used well-established continuum-based theories of curved plates, thin shells, bending beams and vibrating rods. An extensive presentation of these topics, as applied to nanotubes, can be found in [44]. These theories have been used either as independent computational tools to model the elastic properties and deformation modes of nanotubes, or in conjunction with the atomistic models to interpret the results obtained from them. *A key issue in this respect is the identification of the total energy of an atomistic system with the elastic strain energy of an equivalent continuum system.*

Some research problems pose a challenge to both types of the modeling. Large MWCNTs are a case in point, as their sizes present a challenge to MD simulations, and the continuum mechanics is most successful in the limit of a thin-shell. A very fruitful approach would be a *multiscale* modeling that couples the continuum, the atomistic and the quantum description of the nanotubes within a unified model, and until such models are developed, a pragmatic attitude would be the application of both atomistic and continuum modeling to extract as much useful information as possible.

Structural Deformations of Nanotubes

Modeling the axial compression, bending and torsion modes of a (7,7) SWCNT has been performed via both MD simulations, and the continuum elasticity theory of plates [65]. Let us consider the axial compression modeling, whereby a compression was applied to the ends of the nanotube by shifting the end atoms along the axis in small steps, and then relaxing the nanotube while keeping each end constrained. The variation of the strain with the strain energy showed a set of discontinuities that were associated with the rather exotic shape changes undergone by the nanotube. The evolution of this deformation mode within the continuum theory was examined via the expression for the deformation energy of a curved plate. Using the MD generated information as input, the curved plate parameters, i. e., its flexural rigidity and in-plane stiffness, that appear in the continuum energy expression were obtained. It was found that at a critical level of imposed strain, and employing the plate parameters, the nanotube buckled sideways, very similar to what happened in the MD simulation, and that the lowest value of the strain was close to that obtained in the MD simulation. The overall results from all the simulations showed that nanotubes could sustain extreme strains without developing any brittle or plastic transitions or dislocations, and beyond the range covered by Hooke's law, their behavior can be described by continuum-based modeling.

The mechanism whereby uniaxially strained (5,5) and (10,10) nanotubes release their stored strain energy has also been investigated [11]. The nanotube was subjected to a 10% tensile strain, and following equilibration at 1800 K, the first signs of mechanical yielding appeared. This yield was accompanied by the formation of *topological* defects, beyond a critical tension. The first defect to appear was a 90° rotation of a C–C bond about its center which transformed four hexagons into a double pentagon-heptagon (5-7-7-5) defect. This bond rotation is referred to as the Stone–Wales transformation. The energy barriers to the bond rotation that produced the defect were calculated, and it was found that for both types of nanotubes it decreased with an increase in the strain. Furthermore, the results showed that by annealing the (5,5) nanotube, subject to 10% strain, under the condition of high temperature ($T = 2500$ K), the (5-7-7-5) defect was reversible and the nanotube recovered its original hexagonal network.

In a further simulation [10], a (10,10) nanotube containing an initial (5-7-7-5) defect was strained up to 15%, and it was observed that octagonal defects and higher order rings appeared, i. e., the initial defect had acted as a nucleation center for other defects. The simulation showed that armchair nanotubes could display a ductile behavior via plastic flow of the (5-7) dislocation cores. These topological defects could change the chirality of the nanotube, and when dislocations covered a sizable distance of the nanotube wall, they left behind a nanotube whose chirality changed according to the dislocation rules, i. e., $(n, n) \rightarrow (n, n-1) \rightarrow (n, n-2) \ldots$, i. e., an armchair nanotube transformed into a zigzag geometry.

The effect of hydrogen storage on the deformation properties of (10,10) and (17,0) SWCNTs has also been investigated [67]. The SWCNTs were pre-stored with 4.17 or 8.34 wt % H_2 gas, and the maximum strain and maximum tensile force as a function of hydrogen wt %, and temperature were obtained, showing that both the maximum strain and maximum force decreased with the storage of H_2, and that the reduction at $T = 600$ K was much bigger than that at $T = 300$ K. The reductions were attributed to the competition between the C–C bonds and the C–H bonds. The effect of storage on the (17,0) nanotube did not seem to be as significant as on the (10,10) nanotube.

Elastic Properties of Nanotubes

Elastic properties of nanotubes, i. e., their elastic constants, Young's, bulk and shear moduli, have been computed [28,29] for a number of SWCNTs and MWCNTs. An inspection of the results shows that the shear and bulk moduli of SWCNTs and MWCNTs of different diameters were respectively around 0.4 TPa and 0.75 TPa, and Young's modulus for these nanotubes was around 1 TPa, comparing well with the experimental value of 1.3 TPa. Comparison of the SWCNT and MWCNT results shows that:

1) the elastic moduli change very little with the number of walls,
2) the inter-shell van der Waals interaction does not affect significantly the elastic moduli of multi-walled nanotubes,
3) there is a large anisotropy in elastic properties of both SWCNTs and MWCNTs,
4) the elastic properties are basically the same for all nanotubes with radii greater than 1 nm.

An MD simulation [41] has also computed Young's modulus and Possion's ratio ν of the SWCNTs, giving

$$\begin{aligned} &E = 1.20\,\text{TPa}\,, \quad \nu = 0.27 \text{ for a (10,10) nanotube}\,, \\ &E = 1.10\,\text{TPa}\,, \quad \nu = 0.28 \text{ for a (5,5) nanotube}\,, \end{aligned} \tag{19}$$

Another MD simulation [24], using an energy approach (EA) and a force approach (FA), has computed the axial E_z and the rotational E_θ Young's moduli of a set of (n, n) SWCNTs, for $n = 6$ to 19, and has found that E_z and E_θ had little dependence on the radius of the nanotubes in both approaches, and that both moduli were very close. The average values for different nanotubes in both approaches were

$$E_z = E_\theta = \begin{cases} 1.344 \pm 0.02 \quad \text{TPa (EA)} \,, \\ 1.238 \pm 0.01 \quad \text{TPa (FA)} \,. \end{cases} \tag{20}$$

The bulk moduli of (6,6), (10,10) and (8,4) SWCNT hexagonal bundles subject to hydrostatic pressure have also been computed [47], giving the bulk modulus of the bundle K_{bund}, and the individual nanotubes K_{tube} as

$$\begin{aligned} K_{\text{bund}} &= 37\,\text{GPa} \,, \\ K_{\text{tube}} &= 230\,\text{GPa} \,. \end{aligned} \tag{21}$$

Modeling the Thermal Properties of Nanotubes

Thermal stability of nanotubes is crucial to the safe operation of nano-scale devices. Measurements of the specific heat and thermal conductivity of microscopic *mats*, covered with compressed ropes of nanotubes have been made, providing information on the ensemble-average thermal properties of bulk-phase materials, rather than on individual nanotubes. Equilibrium and non-equilibrium types of MD simulations have also been applied. In the former case, the equilibrium time-correlation functions of the heat flux operator are computed and are used in the Green–Kubo relation to obtain the thermal conductivity. In the latter method, hot and cold reservoirs are coupled to the two ends of the nanotube, and the thermal conductivity is obtained via the average heat flux .

Thermal Conductivity of Nanotubes

In an MD simulation [4], combining both equilibrium and non-equilibrium methods, the temperature-dependence of the thermal conductivity λ of an isolated (10,10) nanotube has been computed, showing that at $T = 100$ K the nanotube displayed an unusually high value $\lambda = 37\,000$ W/m K, far exceeding that of pure diamond, i. e., $\lambda = 3320$ W/m K. Comparing the thermal conductivity of an isolated nanotube with those of an isolated graphene sheet and bulk graphite showed that the nanotube had a very similar heat transport properties as those of a hypothetical isolated graphene sheet. The results on the three carbon structures showed that below $T = 300$ K, the thermal conductivity of the graphene sheet was higher than that of the nanotube, and between $T = 300$ K and 400 K they were nearly equal. For graphite, the thermal conductivity of the basal plane also peaked near the $T = 100$ K point, and its value in the range $T = 200$ K to 400 K was always smaller than the values for other two structures.

Another MD simulation [13] investigated the dependence of λ on the nanotube length, and the presence of defects and vacancies, showing that after an initial rise in λ, up to a nanotube length of $L = 100$ Å, it converged to a fairly constant value $\lambda = 29\,800$ W/m K along the nanotube axis for L in the range 100 to 500 Å. This was similar to the value obtained by [4]. In the computations, the thickness of the nanotube was taken to be 1 Å. The results on the variation of λ with the vacancy concentration showed that it decreased smoothly from $\lambda = 14\,000$ W/m K for a concentration of 0.002 to $\lambda = 4000$ W/m K for a concentration of 0.01. Furthermore, the role of Stone–Wales (5-7-7-5) defects was examined, showing that λ decreased from $\lambda = 35000$ W/m K at concentration of 0.5 (on the 1/1000 scale) to about $\lambda = 12\,000$ W/m K for a concentration of 3. Both the rate of decrease and its absolute amount were less than the case with vacancies.

For a bundle of (10,10) nanotubes, it was found that $\lambda = 9500$ W/m K along the axis, very close to that of the in-plane bulk graphite at $\lambda = 10\,000$ W/m K, while perpendicular to the axis, $\lambda = 56$ W/m K, similar to the out-of-plane conductivity in graphite at $\lambda = 55$W/m K.

Specific Heat of Carbon Nanotubes

The low-temperature specific heats C_V of individual SWCNTs, and of their bundles composed of n SWCNTs of type (9,9), with $n = 1, 2, \ldots, 7$, and of MWCNTs have been computed [39], based on the phonon contribution to C_V. The results showed three different patterns for C_V of an individual SWCNT for $T < 100$ K, namely at very low temperatures,

$$C_V \propto T^{\frac{1}{2}} \,, \tag{22}$$

while with an increase in temperature,

$$C_V \propto T \,, \tag{23}$$

and above $T \approx 5$ K, the optical phonons began to make a contribution. Furthermore, it was found that, the $T^{\frac{1}{2}}$ behavior diminished when nanotubes were added to the bundle, and for a bundle composed of 7 nanotubes, this form of dependency on T was no longer observable and $C_V(T)$ approached the experimental value.

For MWCNTs, the specific heat of a five-walled nanotube, (5,5)@(10,10)@(15,15)@(20,20)@(25,25), was calculated, showing that by starting with the (5,5) nanotube and adding more shells to it, the $T^{\frac{1}{2}}$ part diminished and disappeared and was replaced by a linear dependence on T. If the number of shells were increased, C_V tended to that of graphite. It should be remarked that the variation of C_V with T for MWCNTs differed significantly from the experimental behavior.

Concluding Remarks

In this survey we have reviewed the modeling studies on the mechanical, thermal and transport properties of carbon nanotubes. We have seen that in modeling the fluid flow correctly, the motion of both the fluid and the walls, and their mutual coupling must be considered. In this field, the future research must address the use of such classical concepts as *viscosity* and *pressure* that are not clearly defined at nano-scales. Furthermore, flow-induced structural instability poses another important research problem.

In the storage of gases, we have seen that adsorption can take in both the internal spaces and in the interstitial channels, and that SWCNTs provided a better storage medium for hydrogen than the MWCNTs. Furthermore, the small-diameter ropes were more preferable than large-diameter ones. The future research should help clarify the question of volume storage capacity of nanotubes and the ways this capacity could be improved as the data obtained in different studies are not yet unitary. They indicate, however, that the adsorption in nanotubes is higher than in most carbonaceous materials.

In the studies of mechanical and elastic properties, both the atomistic and continuum theories have been used successfully in providing deep insights into the deformation and elastic properties of nanotubes. as well as providing quantitative estimates of the pertinent variables. Studies focusing on obtaining Young's modulus of the nanotubes have shown that the estimates obtained depended on the theoretical models or the inter-atomic potentials used. Computed values ranged from 1 TPa to 5.5 TPa for SWCNTs, and for the MWCNTs an average experimental value of about 1.8 TPa seemed to be the accepted result. Future research could employ better continuum-based models to help reduce the number of very time-consuming and costly MD simulations that are currently employed to obtain the estimates of mechanical and elastic properties.

Finally, we have seen that the thermal conductivity of the SWCNT as a function of temperature is unusually high, implying that the mean free path of phonons was quite large in nanotubes. The presence of defects and vacancies also substantially affected this conductivity. In the computation of the specific heat, the main finding concerned the significant contribution of phonons to the specific heat as compared with the electrons, and in the low temperature regime, several important scaling laws on the behavior of the specific heat have been derived. The future research could consider such problems as the computation of the thermal properties of nanotubes containing defects, or decorated with adsorbed molecules, or nano-scale devices composed of carbon nanotubes.

Article Outline

Glossary

Singularity Let $f\colon \mathbb{R}^n \to \mathbb{R}^m$ be a differentiable map defined in some open neighborhood of the point $p \in \mathbb{R}^n$ and $J_p f$ its Jacobian matrix at p, consisting of the partial derivatives of all components of f with respect to all variables. f is called singular in p if rank $J_p f < \min\{n, m\}$. If rank $J_p f = \min\{m, n\}$, then f is called regular in p. For $m = 1$ (we call the map $f\colon \mathbb{R}^n \to \mathbb{R}$ a differentiable function) the definition implies: A differentiable function $f\colon \mathbb{R}^n \to \mathbb{R}$ is singular in $p \in \mathbb{R}^n$, if grad $f(p) = 0$. The point p, where the function is singular, is called a singularity of the function. Often the name "singularity" is used for the function itself if it is singular at a point p. A point where a function is singular is also called critical point. A critical point p of a function f is called a degenerated critical point if the Hessian (a quadratic matrix containing the second order partial derivatives) is singular at p; that means its determinant is zero at p.

Diffeomorphism A diffeomorphism is a bijective differentiable map between open sets of $\mathbb{R}^n$ whose inverse is differentiable, too.

Map germ Two continuous maps $f\colon U \to \mathbb{R}^k$ and $g\colon V \to \mathbb{R}^k$, defined on neighborhoods U and V of $p \in \mathbb{R}^n$, are called equivalent as germs at p if there exists a neighborhood $W \subset U \cap V$ on which both coincide. Maps or functions, respectively, that are equivalent as germs can be considered to be equal regarding local features. The equivalence classes of this equivalence relation are called germs. The set of all germs of differentiable maps $\mathbb{R}^n \to \mathbb{R}^k$ at a point p is named $\varepsilon_p(n, k)$. If p is the origin of $\mathbb{R}^n$, one simply writes $\varepsilon(n, k)$ instead of $\varepsilon_0(n, k)$. Further, if $k = 1$, we write $\varepsilon(n)$ instead of $\varepsilon(n, 1)$ and speak of function germs (also simplified as "germs") at the origin of $\mathbb{R}^n$. $\varepsilon(n, k)$ is a vector space and $\varepsilon(n)$ is an algebra, that is, a vector space with a structure of a ring. The ring $\varepsilon(n)$ contains a unique maximal ideal $\mu(n) = \{f \in \varepsilon(n) | f(0) = 0\}$. The ideal $\mu(n)$ is generated by the germs of the coordinate functions $x_1, \ldots, x_n$. We use the form $\mu(n) = \langle x_1, \ldots, x_n \rangle \varepsilon(n)$ to emphasize, that this ideal is generated over the ring $\varepsilon(n)$. So a function germ in $\mu(n)$ is of the form $\sum_{i=1}^{n} a_i(x) \cdot x_i$, with certain function germs $a_i(x) \in \varepsilon(n)$.

r-Equivalence Two function germs $f, g \in \varepsilon(n)$ are called r-equivalent if there exists a germ of a local diffeomorphism $h\colon \mathbb{R}^n \to \mathbb{R}^n$ at the origin, such that $g = f \circ h$.

Unfolding An unfolding of a differentiable function germ $f \in \mu(n)$ is a germ $F \in \mu(n + r)$ with $F|\mathbb{R}^n = f$ (here | means the restriction. The number r is called an unfolding dimension of f. An unfolding F of a germ f is called universal if every other unfolding of f can be received by suitable coordinate transformations, "morphisms of unfoldings" from F, and the number of unfolding parameters of F is minimal (see "codimension").

Unfolding morphism Suppose $f \in \varepsilon(n)$ and $F\colon \mathbb{R}^n \times \mathbb{R}^k \to \mathbb{R}$ and $G\colon \mathbb{R}^n \times \mathbb{R}^r \to \mathbb{R}$ be unfoldings of f. A right-morphism from F to G, also called unfolding morphism, is a pair (Φ, α), with $\Phi \in \varepsilon(n + k, n + r)$ and $\alpha \in \mu(k)$, such that:

1. $\Phi|\mathbb{R}^n = \mathrm{id}(\mathbb{R}^n)$, that is $\Phi(x, 0) = (x, 0)$,
2. If $\Phi = (\phi, \psi)$, with $\phi \in \varepsilon(n + k, n)$, $\psi \in \varepsilon(n + k, r)$, then $\psi \in \varepsilon(k, r)$,
3. For all $(x, u) \in \mathbb{R}^n \times \mathbb{R}^k$ we get $F(x, u) = G(\Phi(x, u)) + \alpha(u)$.

Catastrophe A catastrophe is a universal unfolding of a singular function germ. The singular function germs are called organization centers of the catastrophes.

Codimension The codimension of a singularity f is given by $\operatorname{codim}(f) = \dim_{\mathbb{R}} \mu(n)/\langle \partial_x f \rangle$ (quotient space). Here $\langle \partial_x f \rangle$ is the Jacobian ideal generated by the partial derivatives of f and $\mu(n) = \{f \in \varepsilon(n) | f(0) = 0\}$. The codimension of a singularity gives of the minimal number of unfolding parameters needed for the universal unfolding of the singularity.

Potential function Let $f: \mathbb{R}^n \to \mathbb{R}^n$ be a differentiable map (that is, a differentiable vector field). If there exists a function $\varphi: \mathbb{R}^n \to \mathbb{R}$ with the property that $\operatorname{grad} \varphi = f$, then f is called a gradient vector field and φ is called a potential function of f.

Definition of the Subject

Catastrophe theory is concerned with the mathematical modeling of sudden changes – so called "catastrophes" – in the behavior of natural systems, which can appear as a consequence of continuous changes of the system parameters. While in common speech the word catastrophe has a negative connotation, in mathematics it is neutral.

You can approach catastrophe theory from the point of view of differentiable maps or from the point of view of dynamical systems, that is, differential equations. We use the first case, where the theory is developed in the mathematical language of maps and functions (maps with range $\mathbb{R}$). We are interested in those points of the domain of differentiable functions where their gradient vanishes. Such points are called the "singularities" of the differentiable functions.

Assume that a system's behavior can be described by a potential function (see Sect. "Glossary"). Then the singularities of this function characterize the equilibrium points of the system under consideration. Catastrophe theory tries to describe the behavior of systems by local properties of corresponding potentials. We are interested in local phenomena and want to find out the qualitative behavior of the system independent of its size.

An important step is the classification of catastrophe potentials that occur in different situations. Can we find any common properties and unifying categories for these catastrophe potentials? It seems that it might be impossible to establish any reasonable criteria out of the many different natural processes and their possible catastrophes. One of the merits of catastrophe theory is the mathematical classification of simple catastrophes where the model does not depend on too many parameters.

Classification is only one of the mathematical aspects of catastrophe theory. Another is stability. The stable states of natural systems are the ones that we can observe over a longer period of time. But the stable states of a system, which can be described by potential functions and their singularities, can become unstable if the potentials are changed by perturbations. So stability problems in nature lead to mathematical questions concerning the stability of the potential functions.

Many mathematical questions arise in catastrophe theory, but there are also other kinds of interesting problems, for example, historical themes, didactical questions and even social or political ones. How did catastrophe theory come up? How can we teach catastrophe theory to the students at our universities? How can we make it understandable to non-mathematicians? What can people learn from this kind of mathematics? What are its consequences or insights for our lives?

Let us first have a short look at mathematical history. When students begin to study a new mathematical field, it is always helpful to learn about its origin in order to get a good historical background and to get an overview of the dependencies of inner-mathematical themes. Catastrophe theory can be thought of as a link between classical analysis, dynamical systems, differential topology (including singularity theory), modern bifurcation theory and the theory of complex systems. It was founded by the French mathematician René Thom (1923–2002) in the sixties of the last century. The name 'catastrophe theory' is used for a combination of singularity theory and its applications. In the year 1972 Thom's famous book "Stabilité structurelle et morphogénèse" appeared. Thom's predecessors include Marston Morse, who developed his theory of the singularities of differentiable functions (Morse theory) in the thirties, Hassler Whitney, who extended this theory in the fifties to singularities of differentiable maps of the plane into the plane, and John Mather (1960), who introduced algebra, especially the theory of ideals of differentiable functions, into singularity theory. Successors to Thom include Christopher Zeeman (applications of catastrophe theory to physical systems), Martin Golubitsky (bifurcation theory), John Guckenheimer (caustics and bifurcation theory), David Schaeffer (shock waves) and Gordon Wassermann (stability of unfoldings). From the point of view of dynamical systems, the forerunners of Thom are Jules Henry Poincaré (1854–1912) who looked at stability problems of dynamical systems, especially the problems of celestial mechanics, Andrei Nikolaevic **K**olmogorov, Vladimir I. **A**rnold and Jürgen **M**oser (KAM), who influenced catastrophe theory with their works on stability problems (KAM-theorem).

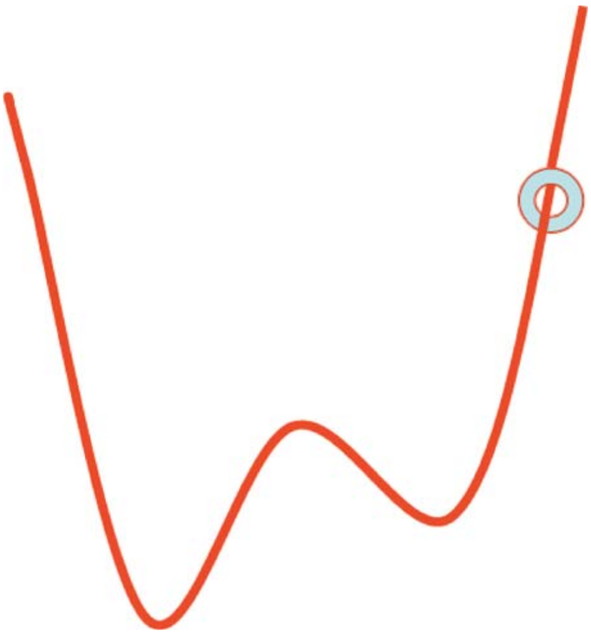
From the didactical point of view, there are two main positions for courses in catastrophe theory at university level: Trying to teach the theory as a perfect axiomatic system consisting of exact definitions, theorems and proofs or trying to teach mathematics as it can be developed from historical or from natural problems (see [9]). In my opinion the latter approach has a more lasting effect, so there is a need to think about simple examples that lead to the fundamental ideas of catastrophe theory. These examples may serve to develop the theory in a way that starts with intuitive ideas and goes forward with increasing mathematical precision.

When students are becoming acquainted with catastrophe theory, a useful learning tool is the insight that continuous changes in influencing system parameters can lead to catastrophes in the system behavior. This phenomenon occurs in many systems. Think of the climate on planet earth, think of conflicts between people or states. Thus, they learn that catastrophe theory is not only a job for mathematical specialists, but also a matter of importance for leading politicians and persons responsible for guiding the economy.

Introduction

Since catastrophe theory is concerned with differentiable functions and their singularities, it is a good idea to start with the following simple experiment: Take a piece of wire, about half a meter in length, and form it as a 'curve' as shown in Fig. 1. Take a ring or screw-nut and thread the wire through it so that the object can move along the wire easily.

The wire represents the model of the graph of a potential function, which determines the reactions of a system by its gradient. This means the ring's horizontal position represents the actual value of a system parameter x that characterizes the state of the system, for example, x might be its position, rotation angle, temperature, and so on. This parameter x is also called the state parameter. The form of the function graph determines the behavior of the system, which tries to find a state corresponding to a minimum of the function (a zero of the gradient of f) or to stay in such a 'stable' position. (Move the ring to any position by hand and then let it move freely.) Maxima of the potential function are equilibrium points too, but they are not stable. A small disturbance makes the system leave such an equilibrium. But if the ring is in a local minimum, you may disturb its position by slightly removing it from that position. If this disturbance is not too big, the system will return to its original position at the minimum of the function when allowed to move freely. The minimum is a stable point of the function, in the sense that small disturbances of the system are corrected by the system's behavior, which tries to return to the stable point. Observe that you may disturb the system by changing its position by hand (the position of the ring) or by changing the form of the potential function (the form of the wire). If the form of the potential function is changed, this corresponds to the change of one or more parameters in the defining equation for the potential. These parameters are called external parameters. They are usually influenced by the experimenter. If the form of the potential (wire) is changed appropriately (for example, if you pull upward at one side of the wire), the ring can leave the first disappearing minimum and fall into the second stable position. This is the way catastrophes happen: changes of parameters influence the potentials and thus may cause the system to suddenly leave a stable position.



Catastrophe Theory, Figure 1
Ring on the wire

Some typical questions of catastrophe theory are:

- How can one find a potential function that describes the system under consideration and its catastrophic jumps?
- What does this potential look like locally? How can we describe the changes in the potential's parameters?
- Can we classify the potentials into simple categories?
- What insights can such a classification give us?

Now we want to consider two simple examples of systems where such sudden changes become observable. They are easy to describe and lead to the simplest forms of catastrophes which Thom listed in the late nineteen-sixties. The first is a simple physical model of an eccentric cylinder on an inclined plane. The second example is a model for the formation of a traffic jam.

Example 1: The Eccentric Cylinder on the Inclined Plane

We perform some experiments with a cylinder or a wide wheel on an inclined plane whose center of gravity is eccentric with respect to its axes (Fig. 2).

You can build such a cylinder from wood or metal by taking two disks of about 10 cm in radius. Connect them with some sticks of about 5 cm in length. The eccentric center of gravity is generated by fixing a heavy piece of metal between the two discs at some distance from the axes of rotation. Draw some lines on the disks, where you can read or estimate the angle of rotation. (Hint: It could be interesting for students to experimentally determine the center of gravity of the construction.)

If mass and radius are fixed, there are two parameters which determine the system: The position of the cylinder can be specified by the angle x against a zero level (that is, against the horizontal plane; Fig. 4). This angle is the "inner" variable of the system, which means that it is the "answer" of the cylinder to the experimenter's changes of the inclination u of the plane, which is the "outer" parameter. In this example you should determine experimentally the equilibrium positions of the cylinder, that is, the angle of rotation where the cylinder stays at rest on the inclined plane (after releasing it cautiously and after letting the system level off a short time). We are interested in the stable positions, that is, the positions where the cylinder returns after slight disturbances (slightly nudging it or slightly changing the inclination of the plane) without rolling down the whole plane. The search for the equilibrium position x varies with the inclination angle u. You can make a table and a graphic showing the dependence of x and u.

The next step is to find an analytical approach. Refer to Fig. 3: Point P is the supporting point of the cylinder on the plane. Point A marks the starting position of the center of gravity. When the wheel moves and the distance between M and A is big enough, this center can come into two equilibrium positions S_1 and S_2, which lie vertically over P.

Now, what does the potential function look like? The variables are:

***R*:** radius of the discs,

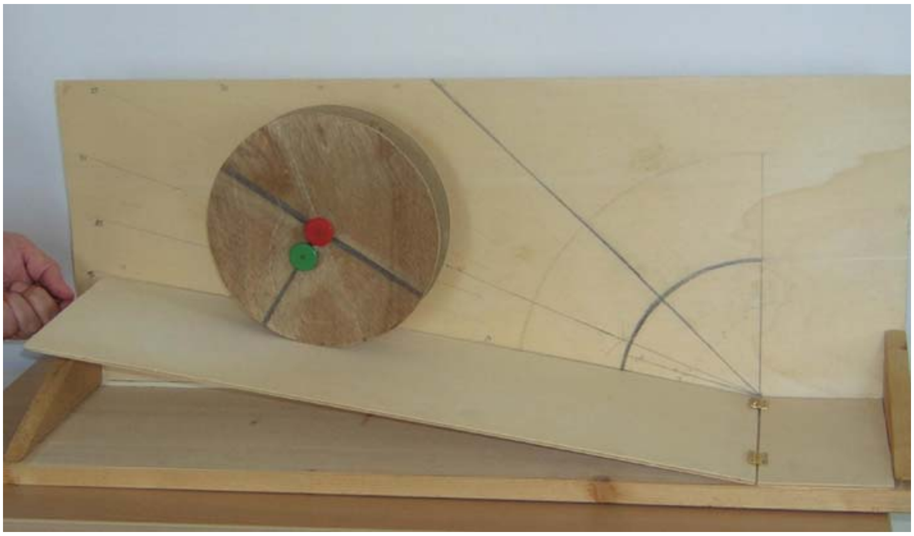
***u*:** angle of the inclined plane against the horizontal plane measured in radians,

***x*:** angle of rotation of the cylinder measured against the horizontal plane in radians,

***r*:** distance between the center of gravity S of the cylinder from the axes marked by point M,

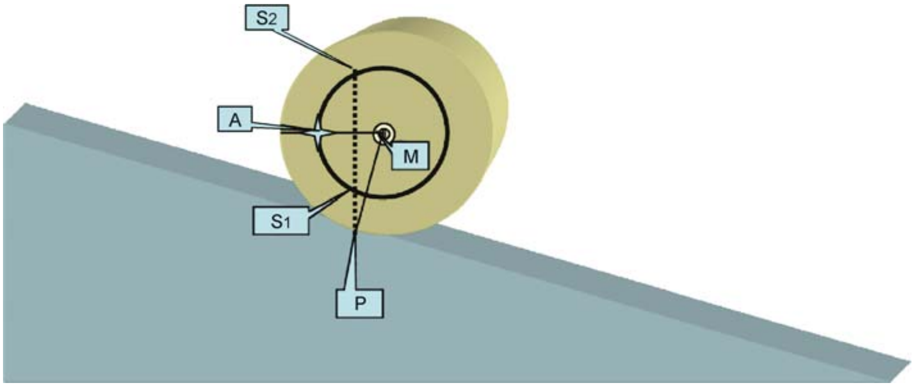
x_0 (resp. u_0): angles where the cylinder suddenly starts to roll down the plane.

Refer to Fig. 4. If the wheel is rolled upward by hand from the lower position on the right to the upper position, the center of gravity moves upward with the whole wheel, or

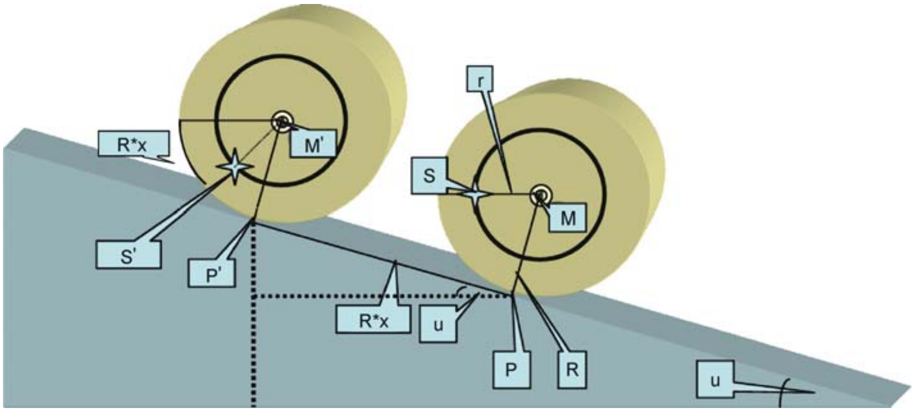


Catastrophe Theory, Figure 2

The eccentric cylinder on the inclined plane. The inclination of the plane can be adjusted by hand. The position of the disc center and the center of gravity are marked by colored buttons



Catastrophe Theory, Figure 3
Two equilibrium positions (S_1 and S_2) are possible with this configuration. If the point A lies "too close" to M, there is no equilibrium position possible at all when releasing the wheel, since the center of gravity can never lie vertically over P



Catastrophe Theory, Figure 4
The movement of S is a composite of the movement of the cylinder represented by the movement of point M and the rotation movement with angle *x*

as the midpoint M or the point P. But point S also moves downward by rotation of the wheel with an amount of $r \cdot \sin(x)$.

The height gained is

$$h = R \cdot x \cdot \sin(u) - r \cdot \sin(x) . \qquad (1)$$

From physics one knows the formula for the potential energy E_{pot} of a point mass. It is the product $m \cdot g \cdot h$, where $m =$ mass, $g =$ gravitational constant, $h =$ height, where the height is to be expressed by the parameters x and u and the given data of the cylinder.

To a fixed angle u_1 of the plane, by formula (1), there corresponds the following potential function:

$$f(x) = E_{\text{pot}} = m \cdot g \cdot h = m \cdot g \cdot (R \cdot x \cdot \sin(u_1) - r \cdot \sin(x)) .$$

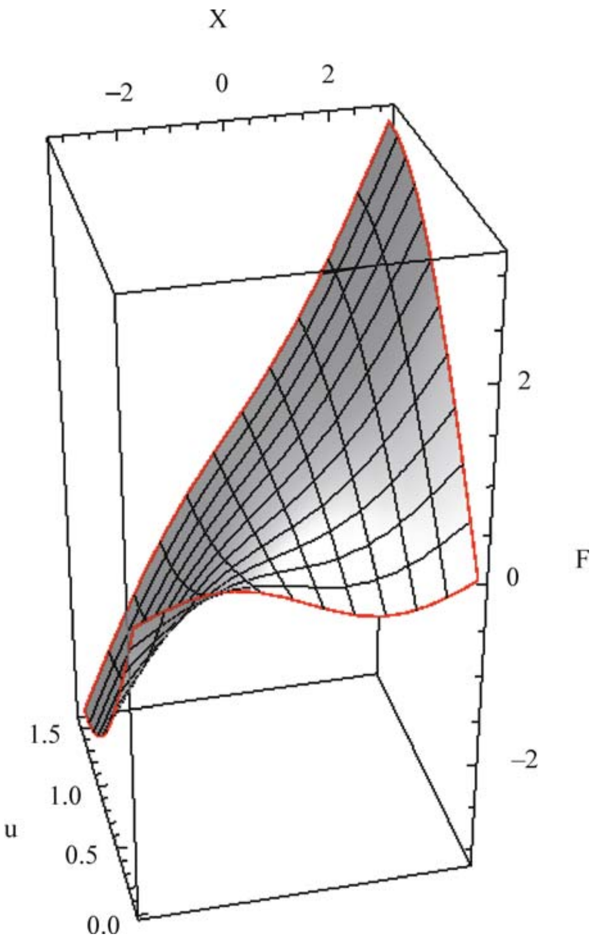
If the inclination of the plane is variable, the angle u of inclination serves as an outer parameter and we obtain a whole family of potential functions as a function F in two variables x and u:

$$F(x,u) = F_u(x) = m \cdot g \cdot (R \cdot x \cdot \sin(u) - r \cdot \sin(x)) .$$

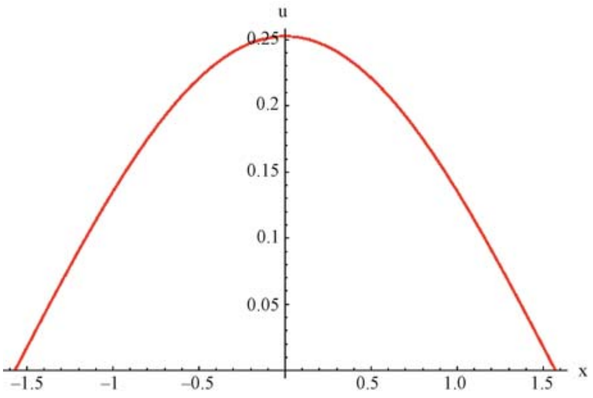
Thus, the behavior of the eccentric cylinder is described by a family of potential functions. The extrema of the single potentials characterize the equilibria of the system. The saddle point characterizes the place where the cylinder suddenly begins to roll down due to the slightest disturbance, that is, where the catastrophe begins (see Fig. 5).

Example. The data are $m = 1\,\text{kg}$, $g = 10\,\text{m/sec}^2$, $R = 0.1\,\text{m}$, $r = 0.025\,\text{m}$.

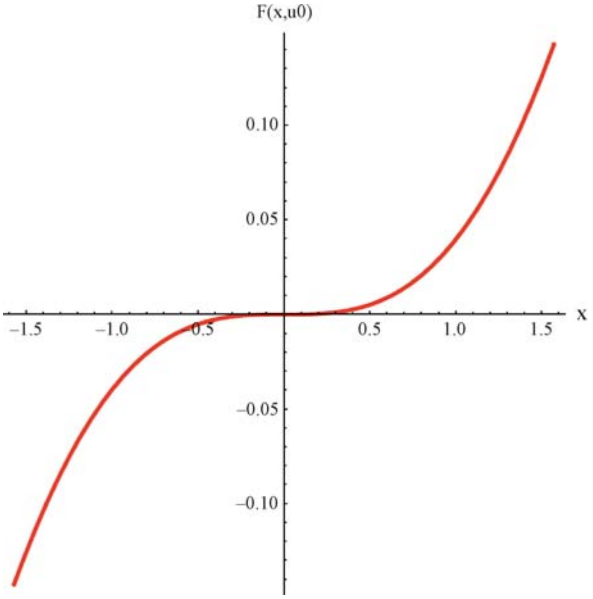
For constant angle of inclination u, each of the functions $f(x) = F(x, u = \text{const})$ is a section of the function F.



Catastrophe Theory, Figure 5
Graph of $F(x, u)$ for a concrete cylinder



Catastrophe Theory, Figure 6
Curve in x–u-space, for which $F(x, u)$ has local extrema



Catastrophe Theory, Figure 7
Graph of the section $F(x, u_0)$

To determine the minima of each of the section graphs, we calculate the zeros of the partial derivative of F with respect to the inner variable x. In our particular example above, the result is $\partial_x F = -0.25\cos(x) + \sin(u)$. The solution for $\partial_x F = 0$ is $u = \arcsin(0.25\cos(x))$ (see Fig. 6).

Calculating the point in x–u-space at which both partial derivatives $\partial_x F$ and $\partial_{xx} F$ vanish (saddle point of the section) and using only positive values of angle u gives the point $(x_0, u_0) = (0, 0.25268)$. In general: $x_0 = 0$ and $u_0 = \arcsin(r/R)$. In our example this means the catastrophe begins at an inclination angle of $u_0 = 0.25268$ (about 14.5 degrees). At that angle, sections of F with $u > u_0$ do not possess any minimum where the system could stably rest. Making u bigger than u_0 means that the cylinder must leave its stable position and suddenly roll down the plane. The point u_0 in the u-parameter space is called catastrophe point.

What is the shape of the section of F at u_0? Since in our example

$$f(x) = F(x, u_0) = 0.25x - 0.25\sin(x) ,$$

the graph appears as shown in Fig. 7.

The point $x = 0$ is a degenerated critical point of $f(x)$, since $f'(x) = f''(x) = 0$. If we expand f into its Taylor polynomial $t(x)$ around that point we get

$$t(x) = 0.0416667x^3 - 0.00208333x^5 + 0.0000496032x^7 \\ -6.88933 \times 10^{-7}x^9 + O[x]^{11} .$$

Catastrophe theory tries to simplify the Taylor polynomials of the potentials locally about their degenerated critical points. This simplification is done by coordinate transformations, which do not change the structure of the singularities. These transformations are called diffeomorphisms (see Sect. "Glossary"). A map $h\colon U \to V$, with U and V open in $\mathbb{R}^n$, is a local diffeomorphism if the Jacobian determinant $\det(J_p h) \neq 0$ at all points p in U. Two functions f and g, both defined in some neighborhood of the origin of $\mathbb{R}^n$, are called r-equivalent if there exists a local diffeomorphism $h\colon U \to V$ at the origin, such that $g = f \circ h$.

The Taylor polynomial $t(x)$ in our example starts with a term of 3rd order in x. Thus, there exists a diffeomorphism (a non-singular coordinate transformation), such that in the new coordinates t is of the form x^3. To see this, we write $t(x) = x^3 \cdot a(x)$, with $a(0) \neq 0$. We define $h(x) = x \cdot a(x)^{1/3}$. Note that the map h is a local diffeomorphism near the origin since $h'(0) = a(0)^{1/3} \neq 0$. (Hint: Modern computer algebra systems, such as Mathematica, are able to expand expressions like $a(x)^{1/3}$ and calculate the derivative of h easily for the concrete example.)

Thus for the eccentric cylinder the intersection of the graph of the potential $F(x, u)$ with the plane $u = u_0$ is the graph of a function, whose Taylor series at its critical point $x = 0$ is $t = x^3 \circ h$, in other words: t is r-equivalent to x^3.

Before we continue with this example and its relation to catastrophe theory, let us introduce another example which leads to a potential of the form x^4. Then we will have two examples which lead to the two simplest catastrophes in René Thom's famous list of the seven elementary catastrophes.

Example 2: The Formation of Traffic Jam

In the first example we constructed a family F of potential functions directly from the geometric properties of the model of the eccentric cylinder. We then found its critical points by calculating the derivatives of F. In this second example the method is slightly different. We start with a partial differential equation which occurs in traffic flow modeling. The solution surface of the initial value problem will be regarded as the surface of zeros of the derivative of a potential family. From this, we then calculate the family of potential functions. Finally, we will see that the Taylor series of a special member of this family, the one which belongs to its degenerated critical point, is equivalent to x^4.

Note: When modeling a traffic jam we use the names of variables that are common in literature about this subject. Later we will rename the variables into the ones commonly used in catastrophe theory.

Let $u(x, t)$ be the (continuous) density of the traffic at a street point x at time t and let $a(u)$ be the derivative of the traffic flow $f(u)$. The mathematical modeling of simple traffic problems leads to the well known traffic flow equation:

$$\frac{\partial u(x,t)}{\partial t} + a(u)\frac{\partial u(x,t)}{\partial x} = 0\,.$$

We must solve the Cauchy problem for this quasilinear partial differential equation of first order with given initial density $u_0 = u(x, 0)$ by the method of characteristics. The solution is constant along the (base) characteristics, which are straight lines in xt-plane with slope $a(u_0(y))$ against the t-axes, if y is a point on the x-axes, where the characteristic starts at $t = 0$. For simplicity we write "a" instead of $a(u_0(y))$. Thus the solution of the initial value problem is $u(x, t) = u_0(x - a \cdot t)$ and the characteristic surface $S = \{(x, t, u) | u - u_0(x - a \cdot t) = 0\}$ is a surface in xtu-space. Under certain circumstances S may not lie uniquely above the xt-plane but may be folded as is shown in Fig. 8. There is another curve to be seen on the surface: The border curve of the fold. Its projection onto the xt-plane is a curve with a cusp, specifying the position and the beginning time of the traffic jam.

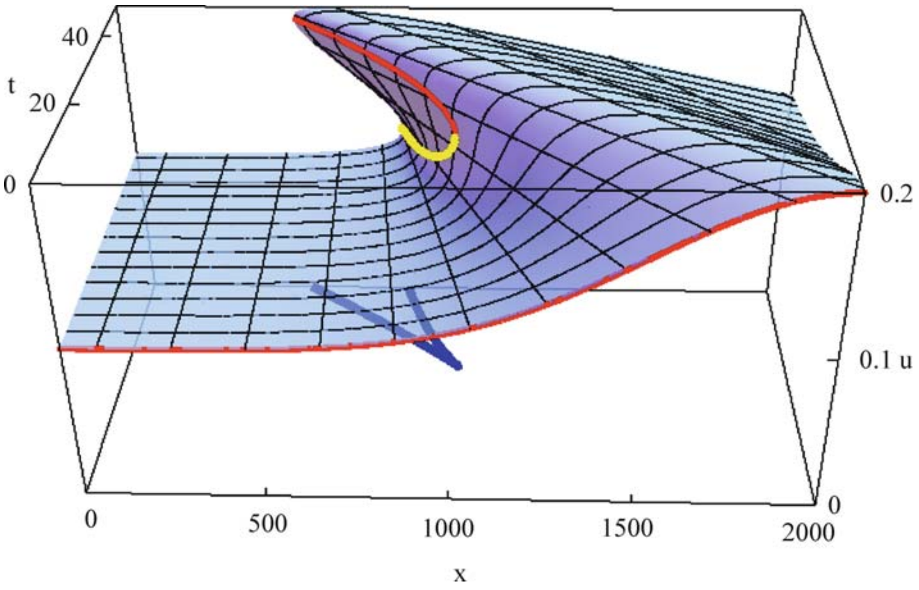
The equations used in the example, in addition to the traffic flow equation, can be deduced in traffic jam modeling from a simple parabolic model for a flow-density relation (see [5]). The constants in the following equations result from considerations of maximal possible density and an assumed maximal allowed velocity on the street. In our example a model of a road of 2 km in length and maximal traffic velocity of 100 km/h is chosen. Maximal traffic density is $u_{\max} = 0.2$. The equations are $f(u) = 27.78u - 138.89u^2$ and $u(x, 0) = u_0(x) = 0.1 + 0.1 \cdot \operatorname{Exp}(-((x - 2000)/700)^2)$. The latter was constructed to simulate a slight increase of the initial density u_0 along the street at time $t = 0$. The graph of u_0 can be seen as the front border of the surface.

To determine the cusp curve shown in Fig. 8, consider the following parameterization Φ of the surface S and the projection map $\pi\colon S \to \mathbb{R}^2$:

$$\begin{aligned}\Phi\colon \mathbb{R} \times \mathbb{R}_{\geq 0} &\to S \subset \mathbb{R}^3 \\ (x, t) &\mapsto (x + a(u_0(x)) \cdot t, t, u_0(x))\,.\end{aligned}$$

The Jacobian matrix of $\pi \circ \Phi$ is

$$\begin{aligned}J(\pi \circ \Phi)(x,t) &= \begin{pmatrix} \dfrac{\partial(\pi\circ\Phi)_1}{\partial x} & \dfrac{\partial(\pi\circ\Phi)_1}{\partial t} \\ \dfrac{\partial(\pi\circ\Phi)_2}{\partial x} & \dfrac{\partial(\pi\circ\Phi)_2}{\partial t} \end{pmatrix} \\ &= \begin{pmatrix} 1 + a(u_0(x))' \cdot t & a(u_0(x)) \\ 0 & 1 \end{pmatrix}.\end{aligned}$$



Catastrophe Theory, Figure 8
Characteristic surface *S*, initial density, fold curve and cusp curve

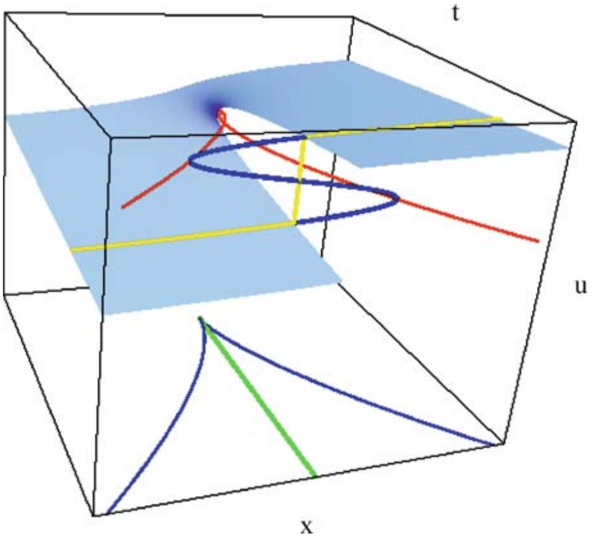
It is singular (that is, its determinate vanishes) if $1 + (a(u_0(x)))' \cdot t = 0$. From this we find the curve $c\colon \mathbb{R} \to \mathbb{R}^2$

$$c(x) = \left(x, -\frac{1}{a'(u_0(x)) \cdot u_0'(x)}\right)$$

which is the pre-image of the cusp curve and the cusp curve in the Fig. 8 is the image of c under $\pi \circ \Phi$.

Whether the surface folds or not depends on both the initial density u_0 and the properties of the flow function $f(u)$. If such folding happens, it would mean that the density would have three values at a given point in xt-space, which is a physical impossibility. Thus, in this case, no continuous solution of the flow equation can exist in the whole plane. "Within" the cusp curve, which is the boundary for the region where the folding happens, there exists a curve with its origin in the cusp point. Along this curve the surface must be "cut" so that a discontinuous solution occurs. The curve within the cusp region is called a shock curve and it is characterized by physical conditions (jump condition, entropy condition). The density makes a jump along the shock.

The cusp, together with the form of the folding of the surface, may give an association to catastrophe theory. One has to find a family of potential functions for this model, that is, functions $F_{(x,t)}(u)$, whose negative gradient, that is, its derivative by u (the inner parameter), describes the characteristic surface S by its zeroes. The family of potentials is given by



Catastrophe Theory, Figure 9
The solution surface is "cut" along the shock curve, running within the cusp region in the *xt*-plane

$$F(x,t,u) = -t\cdot\left(u \cdot a(u) - \int a(u)\mathrm{d}u\right) - \int_0^{x-a(u)\cdot t} u_0(x)\mathrm{d}x$$

(see [6]). Since

$$-\mathrm{grad}F_{x,t}(u) = -\frac{\partial F}{\partial u} = 0 \Leftrightarrow u - u_0(x - a(u) \cdot t) = 0$$

the connection of F and S is evident. One can show that a member f of the family F, the function $f(u) = F(\xi, \tau, u)$, is locally in a traffic jam formation point (ξ, τ) of the form $f(u) = u^4$ (after Taylor expansion and after suitable coordinate transformations, similar to the first example).

The complicated function terms of f and F thus can be replaced in qualitative investigations by simple polynomials. From the theorems of catastrophe theory, more properties of the models under investigation can be discovered.

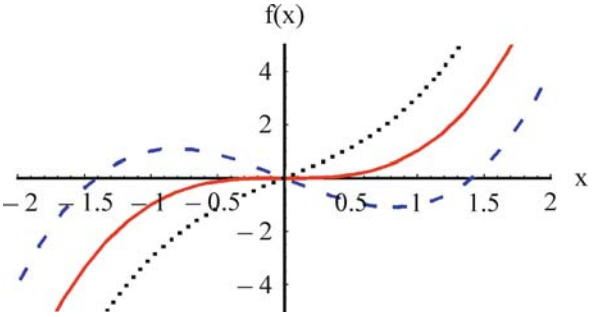
Now we want to use the customary notation of catastrophe theory. We shall rename the variables: u is the inner variables, which in catastrophe theory usually is x, and x, t (the outer parameters) get the names u and v respectively. Thus $F = F(x, u, v)$ is a potential family with one inner variable (the state variable x) and two outer variables (the control variables u and v).

Unfoldings

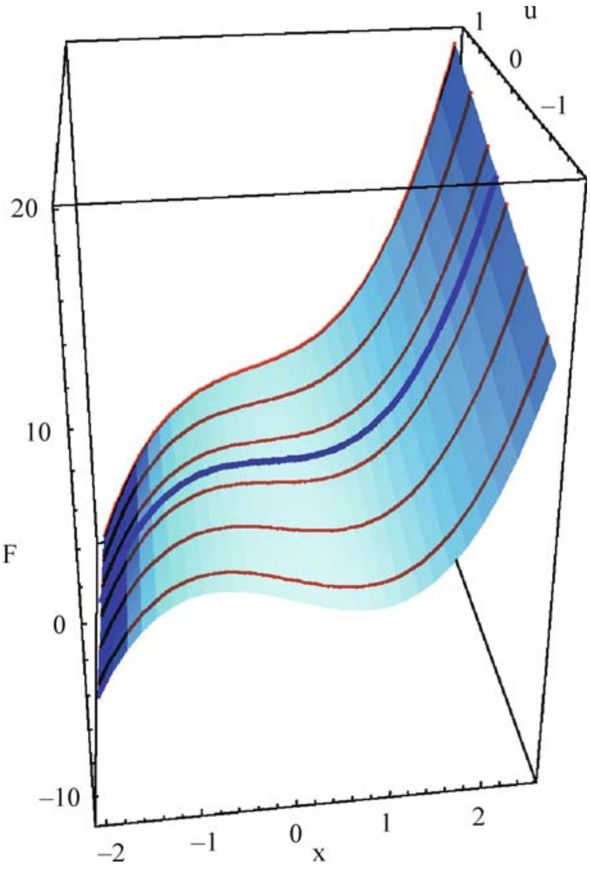
In the first examples above we found a family $F(x, u)$ of potential functions for the eccentric cylinder. For u fixed we found single members of that family. The member which belonged to the degenerated critical point of F, that is, to the point (x, u) where $\partial_x F = \partial_{xx} F = 0$, turned out to be equivalent to x^3. In the second example the corresponding member is equivalent to x^4 (after renaming the variables). These two singularities are members of potential families which also can be transformed into simple forms.

In order to learn how such families, in general, arise from a single function germ, let us look at the singularity $f(x) = x^3$. If we add to it a linear "disturbance" $u \cdot x$, where the factor (parameter) u may assume different values, we qualitatively have one of the function graphs in Fig. 10.

The solid curve in Fig. 10 represents the graph of $f(x) = x^3$. The dashed curve is the graph of $g(x) = x^3 - u \cdot x$; $u > 0$. The dotted line is $h(x) = x^3 + u \cdot x$; $u > 0$.



Catastrophe Theory, Figure 10
Perturbations of x^3

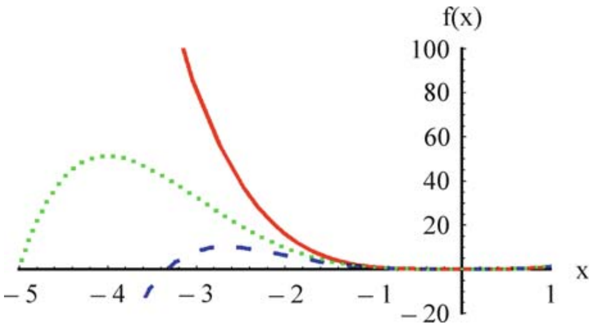


Catastrophe Theory, Figure 11
The function $f(x) = x^3$ embedded in a function family

Please note: While for positive parameter values, the disturbed function has no singularity, in the case of negative u-values a relative maximum and a relative minimum exist. The origin is a singular point only for $u = 0$, that is, for the undisturbed function f.

We can think of $f(x) = x^3$ as a member of a function family, which contains disturbances with linear terms.

The function $f(x) = x^3$ changes the type of singularity with the addition of an appropriate small disturbing function, as we have seen. Therefore f is called "structurally unstable". But we have also learned that $f(x) = x^3$ can be seen as a member of a whole family of functions $F(x, u) = x^3 + u \cdot x$, because $F(x, 0) = f(x)$. This family is stable in the sense that all kinds of singularities of the perturbed function are included by its members. This family is only one of the many possibilities to "unfold" the function germ $f(x) = x^3$ by adding disturbing terms. For example $F(x, u, v) = x^3 + u \cdot x^2 + v \cdot x$ would be another such unfolding (see Sect. "Glossary") of f. But this unfolding has more parameters than the minimum



Catastrophe Theory, Figure 12
The function *f*(*x*) = x4 + *u* · x5, *u* = 0 (*solid*), *u* = 0.2 (*dotted*) and *u* = 0.3 (*dashed*)

needed. The example of a traffic jam leads to an unfolding of $f(x) = x^4$ which is $F(x, u, v) = x^4 + u \cdot x^2 + v \cdot x$.

How can we find unfoldings, which contain all possible disturbances (all types of singularities), that is, which are stable and moreover have a minimum number of parameters?

Examine the singularity x^4 (Fig. 12). It has a degenerated minimum at the origin. We disturb this function by a neighboring polynomial of higher degree, for example, by $u \cdot x^5$, where the parameter u with small values (here and in what follows "small" means small in amount), ensures that the perturbed function is "near" enough to x^4.

For $f(x) = x^4 + u \cdot x^5$, we find that the equation $f'(x) = 0$ has the solutions $x_1 = x_2 = x_3 = 0$, $x_4 = -4/(5u)$. To the threefold zero of the derivative, that is, the threefold degenerated minimum, another extremum is added which is arbitrarily far away from the origin for values of u that are small enough in amount due to the term $-4/(5u)$. This is so, because the term $-4/(5u)$ increases as u decreases. (This is shown in Fig. 12 with $u = 0$, $u = 0.2$ and $u = 0.3$). The type of the singularity at the origin thus is not influenced by neighboring polynomials of the form $u \cdot x^5$.

If we perturb the polynomial x^4 by a neighboring polynomial of lower degree, for example, $u \cdot x^3$, then for small amounts of u a new minimum is generated arbitrarily close to the existing singularity at the origin.

If disturbed by a linear term, the singularity at the origin can even be eliminated. The only real solution of $h'(x) = 0$, where $h(x) = x^4 + ux$, is $x = -(u/4)^{(1/3)}$.

Note: Only for $u = 0$, that is, for a vanishing disturbance, is h singular at the origin. For each $u \neq 0$ the linear disturbance ensures that no singularity at the origin occurs.

The function $f(x) = x^4$ is structurally unstable. To find a stable unfolding for the singularity $f(x) = x^4$, we must add terms of lower order. But we need not take into account all terms $x^4 + u \cdot x^3 + v \cdot x^2 + w \cdot x + k$, since the absolute term plays no role in the computation of singular points, and each polynomial of degree 4 can be written by a suitable change of coordinates without a cubic term. Similarly, a polynomial of third degree after a coordinate transformation can always be written without a quadratic term. The "Tschirnhaus-transformation": $x \mapsto x - a_1/n$, if a_1 is the coefficient of x^{n-1} in a polynomial $p(x) = x^n + a_1 x^{n-1} + \ldots + a_{n-1}x + a_n$ of degree n, leads to a polynomial $q(x) = x^n + b_1 x^{n-2} + \ldots + b_{n-2}x + b_{n-1}$ without a term of degree $n - 1$. Indeed, the expression $F(x, u, v) = x^4 + u \cdot x^2 + v \cdot x$ is, as we shall see later, the "universal" unfolding of x^4. Here an unfolding F of a germ f is called universal, if every other unfolding of f can be received by suitable coordinate transformations "morphism of unfoldings" from F, and the number of unfolding parameters of F is minimal.

The minimal number of unfolding parameters needed for the universal unfolding F of the singularity f is called the codimension of f. It can be computed as follows:

$$\operatorname{codim}(f) = \dim_{\mathbb{R}} \mu(n)/\langle \partial_x f \rangle \,.$$

Here $\langle \partial_x f \rangle$ is the Jacobian ideal generated by the partial derivatives of f and $\mu(n) = \{f \in \varepsilon(n) | f(0) = 0\}$. $\varepsilon(n)$ is the vector space of function germs at the origin of $\mathbb{R}^n$. The quotient $\mu(n)/\langle \partial_x f \rangle$ is the factor space.

What is the idea behind that factor space? Remember, that the mathematical description of a plane (a two dimensional object) in space (3 dimensional) needs only one equation, while the description of a line (1 dimensional) in space needs two equations. The number of equations that are needed for the description of these geometrical objects is determined by the difference between the dimensions of the surrounding space and the object in it. This number is called the codimension of the object. Thus the codimension of the plane in space is 1 and the codimension of the line in space is 2. From linear algebra it is known that the codimension of a subspace W of a finite dimensional vector space V can be computed as $\operatorname{codim} W = \dim V - \dim W$. It gives the number of linear independent vectors that are needed to complement a basis of W to get a basis of the whole space V. Another well known possibility for the definition is $\operatorname{codim} W = \dim V/W$. This works even for infinite dimensional vector spaces and agrees in finite dimensional cases with the previous definition. In our example $V = \mu(n)$ and W should be the set O of all functions germs, which are r-equivalent to f (O is the orbit of f under the action of the group of local diffeomorphisms preserving the origin of $\mathbb{R}^n$). But this is an infinite dimensional manifold, not a vector space. Instead, we can use its tangent space $T_f O$ in the point f, since spaces tangent to manifolds are vector spaces with the same dimension as the manifold itself and this tangent space is contained in the space tangent to $\mu(n)$ in an obvious way. It turns out, that the tangent space $T_f O$ is $\langle \partial_x f \rangle$. The space tangent to $\mu(n)$ agrees with $\mu(n)$, since it is a vector space. The details for the computations together with some examples can be found in the excellent article by M. Golubitsky (1978).

The Seven Elementary Catastrophes

Elementary catastrophe theory works with families (unfoldings) of potential functions

$$F\colon \mathbb{R}^n \times \mathbb{R}^k \to \mathbb{R} \quad (\text{with } k \leq 4)$$
$$(x, u) \mapsto F(x, u) \, .$$

$\mathbb{R}^n$ is called the state space, $\mathbb{R}^k$ is called the parameter space or control space. Accordingly $x = (x_1, \ldots, x_n)$ is called a state variable or endogenous variable and $u = (u_1, \ldots, u_k)$ is called a control variable (exogenous variable, parameter).

We are interested in the singularities of F with respect to x and the dependence of F with respect to the control variables u. We regard F as the unfolding of a function germ f and want to classify F.

In analogy to the r-equivalence of function germs, we call two unfoldings F and G of the same function germ r-equivalent as unfoldings if there exists an unfolding-morphism (see Sect. "Glossary") from F to G. An unfolding F of f is called versal (or stable), if each other unfolding of f is right-equivalent as unfolding to F, that is, if there exists a right-morphism between the unfoldings. A versal unfolding with minimal unfolding dimensions is called universal unfolding of f.

Thus we have the following theorem (all proofs of the theorems cited in this article can be found in [1,2] or [12].)

Theorem 1 (Theorem on the existence of a universal unfolding) *A singularity f has a universal unfolding iff codim$(f) = k < \infty$.*

Examples (see also the following theorem with its examples):

$$\text{If } \; f(x) = x^3 \quad \text{it follows}$$
$$F(x, u, v) = x^3 + ux^2 + vx \quad \text{is versal,}$$
$$F(x, u) = x^3 + ux \quad \text{is universal,}$$
$$F(x, u) = x^3 + ux^2 \quad \text{is not versal .}$$

The following theorem states how one can find a universal unfolding of a function germ:

Theorem 2 (Theorem on the normal form of universal unfoldings) *Let $f \in \mu(n)$ be a singularity with codim$(f) = k < \infty$. Let $u = (u_1, \ldots, u_k)$ be the parameters of the unfolding. Let $b_i(x)$, $i = 1, \ldots, k$, be the elements of $\mu(n)$, whose cosets modulo $\langle \partial_x f \rangle$ generate the vector space $\mu(n)/\langle \partial_x f \rangle$. Then*

$$F(x, u) = f(x) + \sum_{i=1}^{k} u_i b_i(x)$$

is a universal unfolding of f.

Examples:

1. Consider $f(x) = x^4$. Here $n = 1$ and $\mu(n) = \mu(1) = \langle x \rangle$. The derivative of f is $4x^3$, so $\langle \partial_x f \rangle = \langle x^3 \rangle$ and we get $\langle x \rangle / \langle x^3 \rangle = \langle x, x^2 \rangle$. Thus $F(x, u_1, u_2) = x^4 + u_1 x^2 + u_2 x$ is the universal unfolding of f.
2. Consider $f(x, y) = x^3 + y^3$. Here $n = 2$ and $\mu(n) = \mu(2) = \langle x, y \rangle$. The partial derivatives of f with respect to x and y are $3x^2$ and $3y^2$, thus $\langle \partial_x f \rangle = \langle x^2, y^2 \rangle$ and we get $\langle x, y \rangle / \langle x^2, y^2 \rangle = \langle x, xy, y \rangle$. Therefore $F(x, y, u_1, u_2, u_3) = x^3 + y^3 + u_1 \cdot x \cdot y + u_2 \cdot x + u_3 \cdot y$ is the universal unfolding of f.

Hint: There exists a useful method for the calculation of the quotient space which you will find in the literature as "Siersma's trick" (see for example [7]).

We now present René Thom's famous list of the seven elementary catastrophes.

Classification Theorem (Thom' s List)

Up to addition of a non degenerated quadratic form in other variables and up to multiplication by ±1 a singularity f of codimension k $(1 \leq k \leq 4)$ is right-equivalent to one of the following seven:

f	codim f	universal unfolding	name
x^3	1	$x^3 + ux$	fold
x^4	2	$x^4 + ux^2 + vx$	cusp
x^5	3	$x^5 + ux^3 + vx^2 + wx$	swallowtail
$x^3 + y^3$	3	$x^3 + y^3 + uxy + vx + wy$	hyperbolic umbilic
$x^3 - xy^2$	3	$x^3 - xy^2 + u(x^2 + y^2) + vx + wy$	elliptic umbilic
x^6	4	$x^6 + ux^4 + vx^3 + wx^2 + tx$	butterfly
$x^2y + y^4$	4	$x^2y + y^4 + ux^2 + vy^2 + wx + ty$	parabolic umbilic

In a few words: The seven elementary catastrophes are the seven universal unfoldings of singular function germs of codimension k $(1 \leq k \leq 4)$. The singularities itself are called organization centers of the catastrophes.

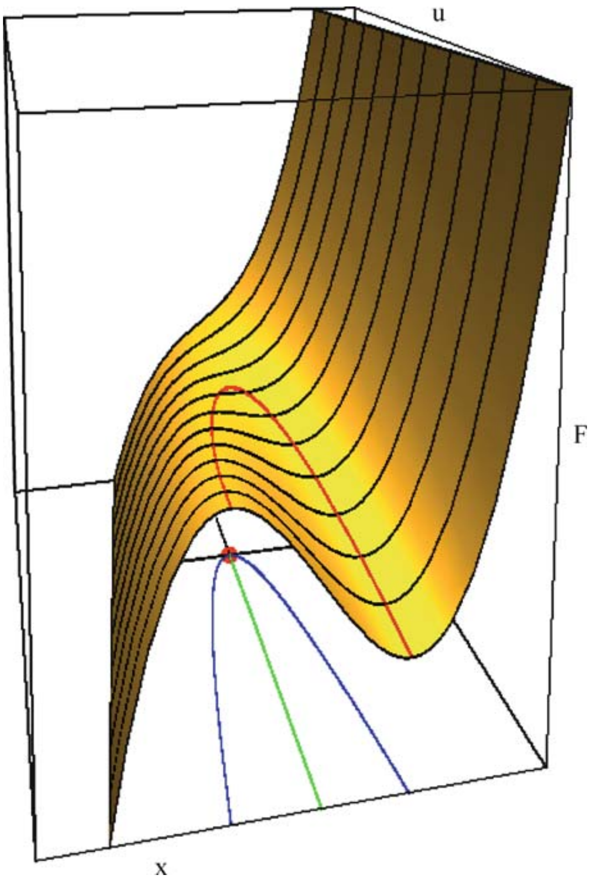
We will take a closer look at the geometry of the simplest of the seven elementary catastrophes: the fold and the cusp. The other examples are discussed in [9].

The Geometry of the Fold and the Cusp

The fold catastrophe is the first in Thom's list of the seven elementary catastrophes. It is the universal unfolding of the singularity $f(x) = x^3$ which is described by the equation $F(x, u) = x^3 + u \cdot x$. We are interested in the set of singular points of F relative to x, that is, for those points where the first partial derivative with respect to x (the system variable) vanishes. This gives the parabola $u = -3x^2$. Inserting this into F gives a space curve.

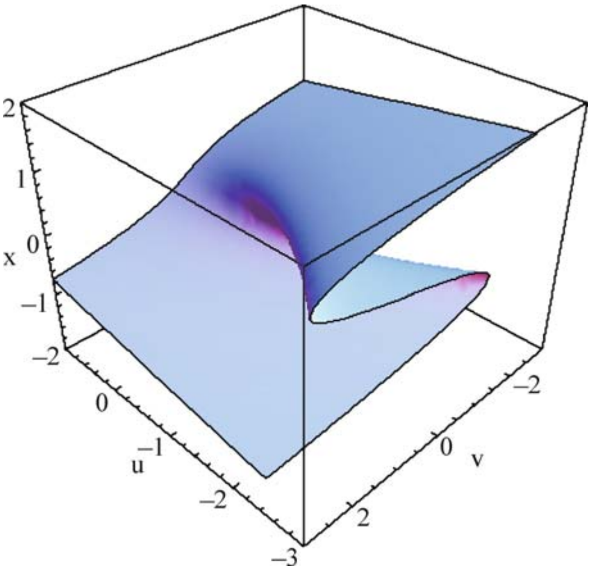
Figure 13 shows the graph of $F(x, u)$. The curve on the surface joins the extrema of F and the projection curve represents their x, u values. There is only one degenerated critical point of F (at the vertex of the Parabola), that is, a critical point where the second derivative by x also vanishes. The two branches of the parabola in the xu-plane give the positions of the maxima and the minima of F, respectively. At the points belonging to a minimum, the system is stable, while in a maximum it is unstable. Projecting x–u space, and with it the parabola, onto parameter space (u-axis), one gets a straight line shown within the interior of the parabola, which represents negative parameter values of u. There, the system has a stable minimum (and an unstable maximum, not observable in nature). For parameter values $u > 0$ the system has no stability points at all. Interpreting the parameter u as time, and "walking along" the u-axis, the point $u = 0$ is the beginning or the end of a stable system behavior. Here the system shows catastrophic behavior. According to the interpretation of the external parameter as time or space, the morphology of the fold is a "beginning," an "end" or a "border", where something new occurs.

What can we say about the fold catastrophe and the modeling of our first example, the eccentric cylinder? We have found that the potential related to the catastrophe point of the eccentric cylinder is equivalent to x^3, and $F(x, u) = x^3 + ux$ is the universal unfolding. This is independent of the size of our 'machine'. The behavior of the machine should be qualitatively the same as that of other machines which are described by the fold catastrophe as a mechanism. We can expect that the begin (or end) of a catastrophe depends on the value of a single outer parameter. Stable states are possible (for $u < 0$ in the standard fold. In the untransformed potential function of our model of the eccentric cylinder, this value is $u = 0.25268$) corresponding to the local minima of $F(., u)$. This means that it is possible for the cylinder to stay at rest on the inclined plane. There are unstable equilibria (local maxima of $F(., u)$ and the saddle point, too). The cylinder can be turned such that the center of gravity lies in the upper position over the supporting point (see Fig. 3). But a tiny disturbance will make the system leave this equilibrium.



Catastrophe Theory, Figure 13
Graph of $F(x, u) = x^3 + u \cdot x$

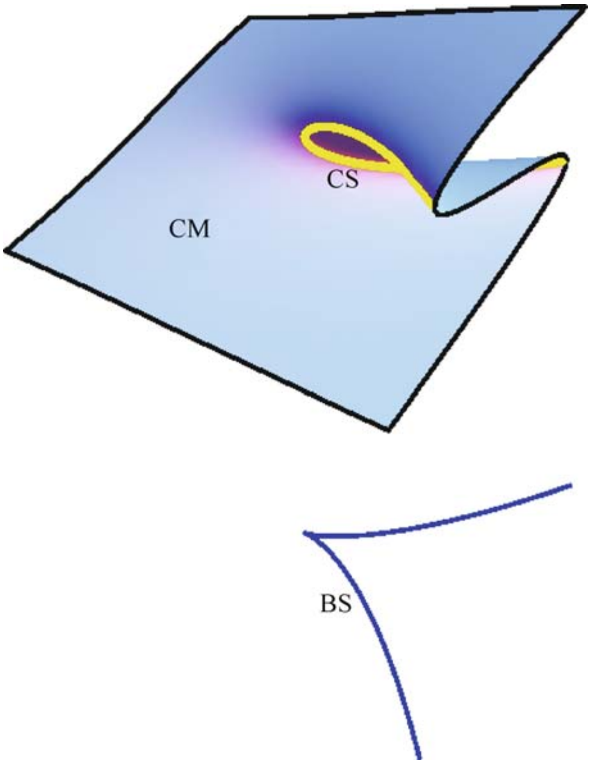
Let us now turn to the cusp catastrophe. The cusp catastrophe is the universal unfolding of the function germ $f(x) = x^4$. Its equation is $F(x, u, v) = x^4 + u \cdot x^2 + v \cdot x$. In our second example (traffic jam), the function f is equivalent to the organization center of the cusp catastrophe, the second in René Thom's famous list of the seven elementary catastrophes. So the potential family is equivalent to the universal unfolding $F(x, u, v) = x^4 + u \cdot x^2 + v \cdot x$ of the function x^4. We cannot draw such a function in three variables in three-space, but we can try to draw sections giving u or v certain constant values. We want to look at its catastrophe surface S, that is, the set of those points in (x, u, v)-



Catastrophe Theory, Figure 14
The catastrophe manifold of the cusp catastrophe

space, where the partial derivative of F with respect to the system variable x is zero. It is a surface in three-space called catastrophe manifold, stability surface or equilibrium surface, since the surface S describes the equilibrium points of the system.

If S is not folded over a point in u, v-space there is exactly one minimum of the potential F. If it is folded in three sheets, there are two minima (corresponding to the upper and lower sheet of the fold) and a maximum (corresponding to the middle sheet). Stable states of the system belong to the stable minima, that is, to the upper and lower sheets of the folded surface. Other points in three-space that do not lie on the surface S correspond to the states of the system that are not equilibrium. The system does not rest there. Catastrophes do occur when the system jumps suddenly from one stable state to another stable state, that is, from one sheet to the other. There are two principal possibilities, called "conventions", where this jump can happen. The "perfect delay convention" says that jumps happen at the border of the folded surface. The "Maxwell convention" says that jumps can happen along a curve in uv-space (a "shock-curve") which lays inside the cusp area. This curve consists of those points (u, v) in parameter space, where $F(., u, v)$ has two critical points with the same critical value. In our traffic jam model a shock curve is a curve in xt-space that we can interpret dynamically as the movement of the jam formation front along the street (see Fig. 9). The same figure shows what we call the morphology of the cusp: according to the convention, the



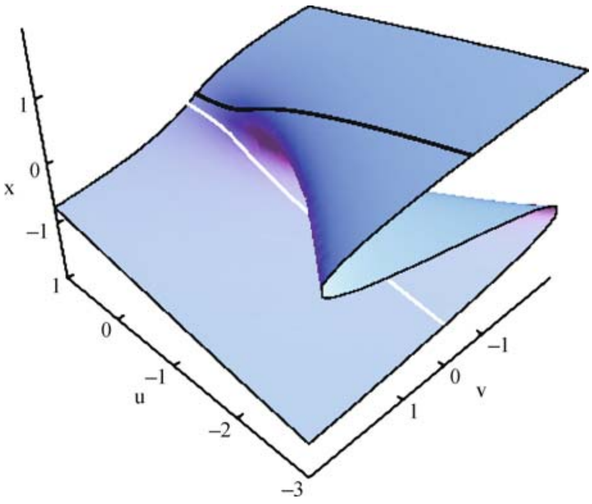
Catastrophe Theory, Figure 15
The catastrophe manifold (CM), catastrophe set (CS) and bifurcation set (BS) of the cusp catastrophe

catastrophe manifold with its fold or its cut can be interpreted as a fault or slip (as in geology) or a separation (if one of the parameter represents time). In our traffic jam model, there is a "line" (actually a region) of separation (shock wave) between the regions of high and low traffic density.

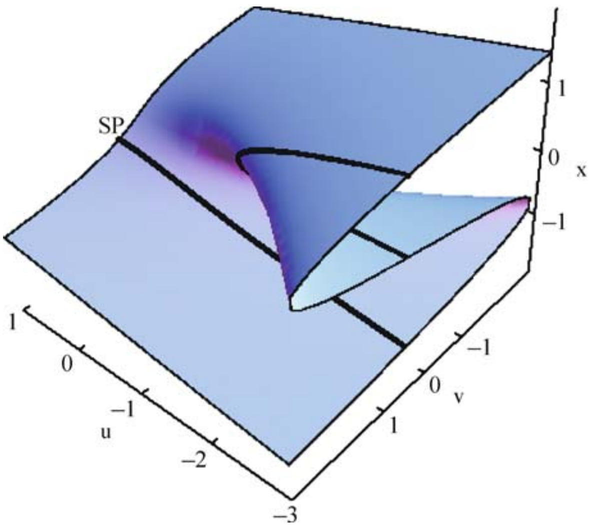
Besides the catastrophe manifold (catastrophe surface) there are two other essential terms: catastrophe set and bifurcation set (see Fig. 15). The catastrophe set can be viewed as the curve which goes along the border of the fold on the catastrophe manifold. It is the set of degenerated critical points and is described mathematically as the set $\{(x, u, v) | \partial_x F = \partial_x^2 F = 0\}$. Its projection into the uv-parameter space is the cusp curve, which is called the bifurcation set of the cusp catastrophe.

The cusp catastrophe has some special properties which we discuss now with the aid of some graphics. If the system under investigation shows one or more of these properties, the experimenter should try to find a possible cusp potential that accompanies the process.

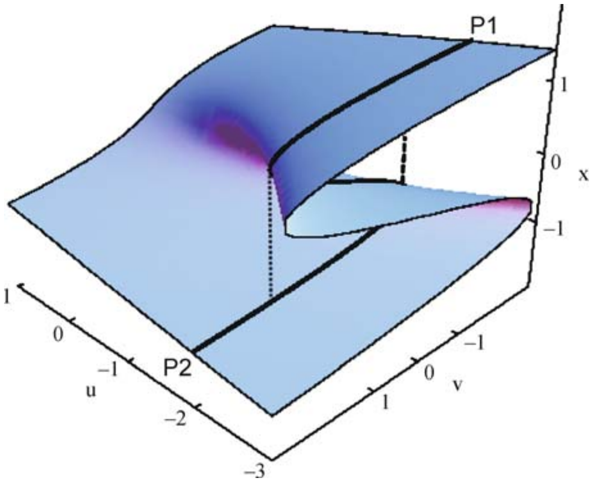
The first property is called divergence. This property can be shown by the two curves (black and white) on the



Catastrophe Theory, Figure 16
The divergence property of the cusp catastrophe



Catastrophe Theory, Figure 18
The bifurcation property of the cusp catastrophe



Catastrophe Theory, Figure 17
The hysteresis property of the cusp catastrophe

catastrophe manifold which describes the system's equilibrium points. Both curves initially start at nearby positions on the surface, that is, they start at nearby stable system states. But the development of the system can proceed quite differently. One of the curves runs on the upper sheet of the surface while the other curve runs on the lower sheet. The system's stability positions are different and thus its behavior is different.

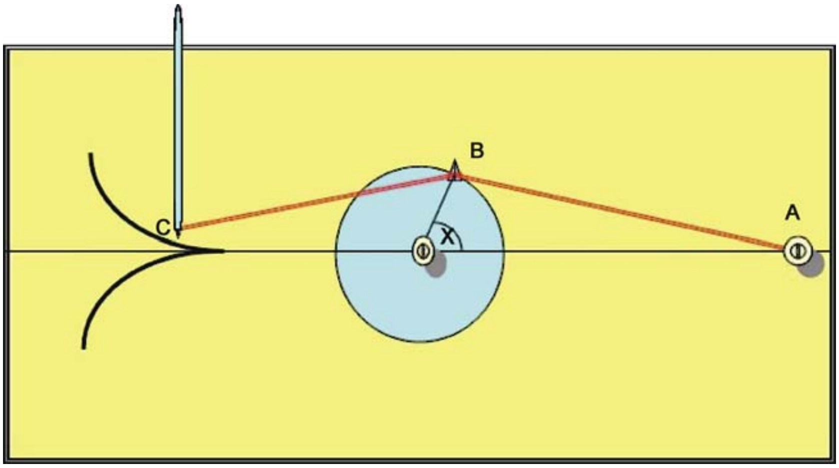
The next property is called hysteresis. If the system development is running along the path shown in Fig. 17 from P1 to P2 or vice versa, the jumps in the system behavior, that is, the sudden changes of internal system variables, occur at different parameter constellations, depending on the direction the path takes, from the upper to the lower sheet or vice versa. Jumps upward or downward happen at the border of the fold along the dotted lines. The name of this property of the cusp comes from the characteristic hysteresis curve in physics, occurring for example at the investigation of the magnetic properties of iron.

Figure 18 shows the bifurcation property of the cusp catastrophe: the number of equilibrium states of the system splits from one to three along the path beginning at the starting point (SP) and running from positive to negative u values as shown. If the upper and the lower sheet of the fold correspond to the local minima of F and the middle sheet corresponds to the local maxima, then along the path shown, one stable state splits into two stable states and one unstable state.

Further Applications

Many applications of catastrophe theory are attributable to Christopher Zeeman. For example, his catastrophe machine, the "Zeeman wheel," is often found in literature. This simple model consists of a wheel mounted flat against a board and able to turn freely. Two elastics are attached at one point (Fig. 19, point B) close to the periphery of the wheel. One elastic is fixed with its second end on the board (point A). The other elastic can be moved with its free end in the plane (point C).

Moving the free end smoothly, the wheel changes its angle of rotation smoothly almost everywhere. But at certain positions of C, which can be marked with a pencil, the wheel suddenly changes this angle dramatically. Join-



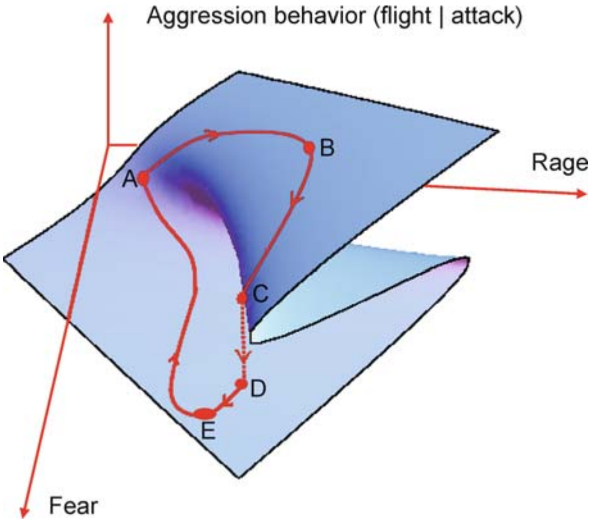
Catastrophe Theory, Figure 19
The Zeeman wheel

ing the marked points where these jumps occur, you will find a cusp curve in the plane. In order to describe this behavior, the two coordinates of the position of point C serve as control parameters in the catastrophe model. The potential function for this model results from Hook's law and simple geometric considerations. Expanding the potential near its degenerated critical point into its Taylor series, and transforming the series with diffeomorphisms similar to the examples we have already calculated, this model leads to the cusp catastrophe. Details can be found in the book of Poston and Stewart [7] or Saunders (1986).

Another example of an application of catastrophe theory is similar to the traffic jam model we used here. Catastrophe theory can describe the formation of shockwaves in hydrodynamics. Again the cusp catastrophe describes this phenomenon. The mathematical frame is given in the works of Lax [6], Golubitsky and Schaeffer[3] and Guckenheimer [4].

In geometrical optics light rays are investigated which are reflected on smooth surfaces. Caustics are the envelopes of the light rays. They are the bright patterns of intensive light, which can be seen, for example, on a cup of coffee when bright sunlight is reflected on the border of the cup. Catastrophe theory can be applied to light caustics, because the light rays obey a variational principle. According to Fermat's principle, light rays travel along geodesics and the role of the potential functions in catastrophe theory is played by geodesic distance functions. Caustics are their bifurcation sets. The calculations are given for example in the work of Sinha [11].

A purely speculative example, given by Zeeman, is an aggression model for dogs. Suppose that fear and rage of a dog can be measured in some way from aspects of its body language (its attitude, ears, tail, mouth, etc.). Fear and rage are two conflicting parameters, so that a catastrophe in the dog's behavior can happen. Look at Fig. 20.



Catastrophe Theory, Figure 20
A dog's aggression behavior depending on its rage and fear

The vertical axis shows the dog's aggression potential, the other axes show its fear and rage. Out of the many different ways the dog can behave, we choose one example. Suppose we start at point A on the catastrophe manifold (behavioral surface). Maybe the dog is dozing in the sun without any thought of aggression. The dog's aggression behavior is neutral (point A). Another dog is coming closer and our dog, now awakened, is becoming more and more angry by this breach of his territory. Moving along the path on the behavior surface, the dog is on a trajectory to attack his opponent. But it suddenly notices that the enemy is very big (point B). So its fear is growing, its rage diminishes. At point C the catastrophe happens: Attack suddenly changes to flight (point D). This flight continues until the dog notices that the enemy does not follow (point E). Fear and rage both get smaller until the dog becomes calm again.

The example can be modified a little bit to apply to conflicts between two states. The conflicting factors can be the costs and the expected gain of wars, and so on.

Among the variety of possible examples, those worthy of mention include investigations of the stability of ships, the gravitational collapse of stars, the buckling beam (Euler beam), the breaking of ocean waves, and the development of cells in biology. The latter two problems are examples for the occurrence of higher catastrophes, for example the hyperbolic umbilic (see Thom's List of the seven elementary catastrophes).

Future Directions

When catastrophe theory came up in the nineteen-sixties, much enthusiasm spread among mathematicians and other scientists about the new tool that was expected to explain many of the catastrophes in natural systems. It seemed to be the key for the explanation of discontinuous phenomena in all sciences. Since many applications were purely qualitative and speculative, a decade later this enthusiasm ebbed away and some scientists took this theory for dead. But it is far from that. Many publications in our day show that it is still alive. The theory has gradually become a 'number producing' theory, so that it is no longer perceived as purely qualitative. It seems that it will be applied the sciences increasingly, producing numerical results. Thom's original ideas concerning mathematical biology seem to have given the basis for the trends in modern biology. This is probably the most promising field of application for catastrophe theory. New attempts are also made, for example, in the realm of decision theory or in statistics, where catastrophe surfaces may help to clarify statistical data.

From the point of view of teaching and learning mathematics, it seems that catastrophe theory is becoming and increasingly popular part of analysis courses at our universities. Thus, students of mathematics meet the basic ideas of catastrophe theory within their first two years of undergraduate studies. Perhaps in the near future its basic principles will be taught not only to the mathematical specialists but to students of other natural sciences, as well.

Article Outline

Glossary

Dynamical system is a set of components the properties of which (e. g. their quantity, activity level etc.) change in time because the components interact among themselves and are also influenced by external forces.

Network node is a constituent component of the network, in biological networks most often identified with a molecular species.

Interaction is a connection between network nodes; in biological networks an interaction means that two nodes chemically react, regulate each other, or effectively influence each other's activities. Interactions are mostly pairwise, but can be higher-order as well; they can be directed or undirected, and are usually characterized by an interaction strength.

Network is a system of interacting nodes. A network can be represented mathematically as a graph, where vertices denote the nodes and edges denote the interactions. Biological networks often are understood to be dynamical systems as well, because the activities of network nodes evolve in time due to the graph of interactions.

Network state is the vector of activities of all nodes that fully characterizes the network at any point in time; since a biological network is a dynamical system, this state generally changes through time according to a set of dynamical equations.

Biological function refers to the role that a specific network plays in the life of the organism; the network can be viewed as existing to perform a task that enables the cell to survive and reproduce, such as the detection or transduction of a specific chemical signal.

Pathway is a subset of nodes and interactions in a network along which information or energy and matter flow in a directed fashion; pathways can be coupled through interactions or unwanted cross-talk.

Curse of dimensionality is the rapid increase of complexity encountered when analyzing or experimentally observing network states, as more and more network nodes are added. If there are N network nodes each of which only has two states (for example *on* and *off*), the number of states that the network can be in grows as 2^N.

Design principle is an (assumed) constraint on the network architecture, stating that a biological network, in addition to performing a certain function, implements that function in a particular way, usually to maximize or minimize some further objective measure, for instance robustness, information transmission, or designability.

Definition of the Subject

In cell biology, networks are systems of interacting molecules that implement cellular functions, such as the regulation of gene expression, metabolism or intracellular signaling. While on a molecular level a biological network is a mesh of chemical reactions between, for example, enzymes and their substrates, or DNA-binding proteins and the genes that they regulate, the collective effect of these reactions can often be thought of as the enabling and regulating the flow of matter and energy (in metabolic networks), or of information (in signaling and transcriptional regulatory networks). The field is concerned primarily with the description and properties of such flows and with their emergence from network constituent parts – the molecules and their physical interactions. An important focus is also the question of how network function and operating principles can be inferred despite the limited experimental access to network states and building blocks.

Introduction

Biological network has come to mean a system of interacting molecules that jointly perform cellular tasks such as the regulation of gene expression, information transmission, or metabolism [28]. Specific instances of biological networks include, for example, the DNA and DNA binding proteins comprising the transcriptional regulatory network; signaling proteins and small molecules comprising various signaling networks; or enzymes and metabolites comprising the metabolic network. Two important assumptions shape our current understanding of such systems: first, that the biological networks have been under selective evolutionary pressure to perform specific cellular functions in a way that furthers the overall reproductive success of the individual; and second, that these functions often are not implemented on a microscopic level by single molecules, but are rather a collective property of the whole interaction network. The question of how complex behavior emerges in a network of (simple) nodes under a functional constraint is thus central [144].

To start off with a concrete example, consider chemotaxis in the bacterium *Escherichia coli* [16,40], one of the paradigmatic examples of signal transduction. This system is dedicated to steering the bacteria towards areas high in nutrient substances and away from repellents. Chemoeffector molecules in the solution outside the bacterium bind to receptor molecules on the cell surface, and the resulting structural changes in the receptors are relayed in turn by the activities of the intracellular signaling proteins to generate a control signal for molecular motors that drive the bacterial flagella. The chemotactic network consists of about 10 nodes (here, signaling proteins), and the interactions between the nodes are the chemical reactions of methylation or phosphorylation. Notable features of this system include its extreme sensitivity, down to the limits set by counting individual molecules as they arrive at the cell surface [17], and the maintenance of this sensitivity across a huge dynamic range, through an adaptation mechanism that provides nearly perfect compensation of background concentrations [27]. More recently it has been appreciated that aspects of this functionality, such as perfect adaptation, are also robust against large variations in the concentrations of the network components [6].

Abstractly, different kinds of signaling proteins, such those in chemotaxis, can be thought of as the building blocks of a network, with their biochemical interactions forming the wiring diagram of the system, much like the components and wiring diagram of, for instance, a radio receiver. In principle, these wiring diagrams are hugely complex; for a network composed of N species, there are $\sim C_k^N$ possible connections among any set of k components, and typically we don't have direct experimental guidance about the numbers associated with each 'wire.' One approach is to view this as giant fitting problem: once we draw a network, there is a direct translation of this graph into dynamical equations, with many parameters, and we should test the predictions of these dynamics against whatever data are available to best determine the underlying parameters. Another approach is to ask whether this large collection of parameters is special in any way other than that it happens to fit the data – are there principles that allow us to predict how these systems *should* work? In the context of chemotaxis, we might imagine that network parameters have been selected to optimize the average progress of bacteria up the chemical gradients of nutrients, or to maximize the robustness of certain functions against extreme parameter variations. These ideas of design principles clearly are not limited to bacterial chemotaxis.

An important aspect of biological networks is that the same components (or components that have an easily identifiable evolutionary relationship) can be (re)used in different modules or used for the same function in a different way across species, as discussed for example by Rao et al. [118] for the case of bacterial chemotaxis. Furthermore, because evolutionary selection depends on function and not directly on microscopic details, different wiring diagrams or even changes in components themselves can result in the same performance; evolutionary process can gradually change the structure of the network as long as its function is preserved; as an example see the discussion of transcriptional regulation in yeast by Tanay et al. [148]. On the other hand, one can also expect that signal processing problems like gain control, noise reduction, ensuring (bi)stability etc, have appeared and were solved repeatedly, perhaps even in similar ways across various cellular functions, and we might be able to detect the traces of their commonality in the network structure, as for example in the discussion of local connectivity in bacterial transcriptional regulation by Shen–Orr et al. [136]. Thus there are reasons to believe that in addition to design principles at the network level, there might also be local organizing principles, similar to common wiring motifs in electronic circuitry, yet still independent of the identity of the molecules that implement these principles.

Biological networks have been approached at many different levels, often by investigators from different disciplines. The basic wiring diagram of a network – the fact that a kinase phosphorylates these particular proteins, and not all others, or that a transcription factor binds to the promoter regions of particular genes – is determined by classical biochemical and structural concepts such as binding specificity. At the opposite extreme, trying to understand the collective behavior of the network as a whole suggests approaches from statistical physics, often looking at simplified models that leave out many molecular details. Analyses that start with design principles are yet a different approach, more in the 'top–down' spirit of statistical physics but leaving perhaps more room for details to emerge as the analysis is refined. Eventually, all of these different views need to converge: networks really are built out of molecules, their functions emerge as collective behaviors, and these functions must really be functions of use to the organism. At the moment, however, we seldom know enough to bridge the different levels of description, so the different approaches are pursued more or less independently, and we follow this convention here. We will start with the molecular building blocks, then look at models for networks as a whole, and finally consider design principles. We hope that this sequence doesn't leave the impression that we actually know how to build up from molecules to function!

Before exploring our subject in more detail, we take a moment to consider its boundaries. Our assignment from the editors was to focus on phenomena at the level of molecular and cellular biology. A very different approach attempts to create a 'science of networks' that searches for common properties in biological, social, economic and computer networks [104]. Even within the biological world, there is a significant divide between work on networks in cell biology and networks in the brain. As far as we can see this division is an artifact of history, since there are many issues which cut across these different fields. Thus, some of the most beautiful work on signaling comes from photoreceptors, where the combination of optical inputs and electrical outputs allowed, already in the 1970s, for experiments with a degree of quantitative analysis that even today is hard to match in systems which take chemical inputs and give outputs that modulate the expression levels of genes [14,121]. Similarly, problems of noise in the control of gene expression have parallels in the long history of work on noise in ion channels, as we have discussed elsewhere [156], and the problems of robustness have also been extensively explored in the network of interactions among the multiple species of ion channels in the membrane [51,88]. Finally, the ideas of collective behavior are much better developed in the context of neural networks than in cellular networks, and it is an open question how much can be learned by studying these different systems in the same language [151].

Biological Networks and Their Building Blocks

Genetic Regulatory Networks

Cells constantly adjust their levels of gene expression. One central mechanism in this regulatory process involves the control of transcription by proteins known as transcription factors (TFs), which locate and bind short DNA sequences in the regulated genes' promoter or enhancer regions. A given transcription factor can regulate either a few or a sizable proportion of the genes in a genome, and a single gene may be regulated by more than one transcription factor; different transcription factors can also regulate each other [166].

In the simplest case of a gene regulated by a single TF, the gene might be expressed whenever the factor – in this case called an activator – is bound to the cognate sequence in the promoter (which corresponds to the situation when the TF concentration in the nucleus is high), whereas the binding of a repressor would shut a normally active gene down. The outlines of these basic control principles were established long ago, well before the individual transcription factors could be isolated, in elegant experiments on the *lactose* operon of *Escherichia coli* [69] and even simpler model systems such as phage λ [115]. To a great extent the lessons learned from these experiments have provided the framework for understanding transcriptional control more generally, in prokaryotes [114], eukaryotes [75], and even during the development of complex multicellular organisms [8].

The advent of high throughput techniques for probing gene regulation has extended our reach beyond single genes. In particular, microarrays [30] and the related data analysis tools, such as clustering [36], have enabled researchers to find sets of genes, or *modules*, that are *coexpressed*, i. e. up- or down-regulated in a correlated fashion when the organism is exposed to different external conditions, and are thus probably regulated by the same set of transcription factors. Chromatin immunoprecipitation (ChIP) assays have made it possible to directly screen for short segments of DNA that known TFs bind; using microarray technology it is then possible to locate the intergenic regions which these segments belong to, and hence find the regulated genes, as has recently been done for the *Saccharomyces cerevisiae* DNA-TF interaction map [86].

These high throughput experimental approaches, combined with traditional molecular biology and complemented by sequence analysis and related mathematical tools [139], provide a large scale, topological view of the transcriptional regulatory network of a particular organism, where each link between two nodes (genes) in the regulatory graph implies either activation or repression [5]. While useful for describing causal interactions and trying to predict responses to mutations and external perturbations [89], this picture does not explain how the network operates on a physical level: it lacks dynamics and specifies neither the strengths of the interactions nor how all the links converging onto a given node jointly exercise control over it. To address these issues, representative wild-type or simple synthetic regulatory elements and networks consisting of a few nodes have been studied extensively to construct quantitative models of the network building blocks.

For instance, combinatorial regulation of a gene by several transcription factors that bind and interact on the promoter has been considered by Buchler et al. [31] as an example of (binary) biological computation and synthetic networks implementing such computations have been created [56,170]. Building on classical work describing allosteric proteins such as hemoglobin, thermodynamic models have been used with success to account for combinatorial interactions on the operator of the λ phage [2]. More recently Bintu et al. [24,25] have reviewed the equilibrium statistical mechanics of such interactions, Setty et al. [134] have experimentally and systematically mapped out the response surface of the *lac* promoter to combinations of its two regulatory inputs, cAMP and IPTG, and Kuhlman et al. [85] have finally provided a consistent picture of the known experimental results and the thermodynamic model for the combinatorial regulation of the lactose operon. There have also been some successes in eukaryotic regulation, where Schroeder et al. [132] used thermodynamically motivated models to detect clusters of binding sites that regulate the gap genes in morphogenesis of the fruit fly.

Gene regulation is a dynamical process composed of a number of steps, for example the binding of TF to DNA, recruitment of transcription machinery and the production of the messenger RNA, post-transcriptional regulation, splicing and transport of mRNA, translation, maturation and possible localization of proteins. While the extensive palette of such microscopic interactions represents a formidable theoretical and experimental challenge for each detailed study, on a network level it primarily induces three effects. First, each node – usually understood as the amount of gene product – in a graph of regulatory interactions is really not a single dynamical variable, but has a nontrivial internal state representing the configuration on the associated promoter, concentration of the corresponding messenger RNA etc.; the relation of these quantities to the concentration of the output protein is not necessarily straightforward, as emphasized in recent work comparing mRNA and protein levels in yeast [46]. Second, collapsing multiple chemical species onto a single node makes it difficult to include non-transcriptional regulation of gene expression in the same framework. Third, the response of the target gene to changes in the concentrations of its regulators will be delayed and extended in time, as in the example explored by Rosenfeld and Alon [123].

Perhaps the clearest testimonies to the importance of dynamics in addition to network topology are provided by systems that involve regulatory loops, in which the output of a network feeds back on one of the inputs as an activator or repressor. McAdams and Shapiro [99] have argued that the time delays in genetic regulatory elements are essential for the proper functioning of the phage λ switch, while Elowitz and Leibler [38] have created a synthetic circuit made up of three mutually repressing genes (the "repressilator"), that exhibits spontaneous oscillations. Circadian clocks are examples of naturally occurring genetic oscillators [171].

In short, much is known about the skeleton of genetic regulatory interactions for model organisms, and physical models exist for several well studied (mostly prokaryotic) regulatory elements. While homology allows us to bridge the gap between model organisms and their relatives, it is less clear how and at which level of detail the knowledge about regulatory elements must be combined into a network to explain and predict its function.

Protein–Protein Interaction Networks

After having been produced, proteins often assemble into complexes through direct contact interactions, and these complexes are functionally active units participating in signal propagation and other pathways. Proteins also interact through less persistent encounters, as when a protein kinase meets its substrate. It is tempting to define a link in the network of protein–protein interactions by such physical associations, and this is the basis of several experimental methods which aim at a genome-wide survey of these interactions. Although starting out being relatively unreliable (with false positive rates of up to 50%), high throughput techniques like the yeast two hybrid assay [68,161] or mass spectrometry [45,61] are providing data of increasing quality about protein–protein interactions, or the “interactome” [84]. While more reliable methods are being developed [5] and new organisms are being analyzed in this way [49,91,125], the existing interaction data from high throughput experiments and curated databases has already been extensively studied.

Interpretation of the interactions in the protein network is tricky, however, due to the fact that different experimental approaches have various biases – for example, mass spectrometry is biased towards detecting interactions between proteins of high abundance, while two hybrid methods seem to be unbiased in this regard; on the other hand, all methods show some degree of bias towards different cellular localizations and evolutionary novelty of the proteins. Assessing such biases, however, currently depends not on direct calibration of the methods themselves but on comparison of the results with manually curated databases, although the databases surely have their own biases [70]. It is reassuring that the intersection of various experimental results shows significantly improved agreement with the databases, but this comes at the cost of a substantial drop in coverage of the proteome [100].

In contrast to the case of transcriptional regulation, the relationship between two interacting proteins is symmetric: if protein A binds to protein B, B also binds to A, so that the network is described by an undirected graph. Most of the studies have been focused on binary interactions that yeast two hybrid and derived approaches can probe, although spectrometry can detect multiprotein complexes as well. Estimates of number of links in these networks vary widely, even in the yeast *Saccharomyces cerevisiae*: Krogan et al. [84] directly measure around 7100 interactions (between 2700 proteins), while Tucker et al. [158] estimate the total to be around 13 000–17 000, and von Mering et al. [100] would put the lower estimate at about 30 000. Apart from the experimental biases that can influence such estimates and have been discussed already, it is important to realize that each experiment can only detect interactions between proteins that are expressed under the chosen external conditions (e. g. the nutrient medium); moreover, interactions can vary from being transient to permanent, to which various measurement methods respond differently. It will thus become increasingly important to qualify each interaction in a graph by specifying how it depends on context in which the interaction takes place.

Proteins ultimately carry out most of the cellular processes such as transcriptional regulation, signal propagation and metabolism, and these processes can be modeled by their respective network and dynamical system abstractions. In contrast, the interactome is not a dynamical system itself, but instead captures specific reactions (like protein complex assembly) and structural and/or functional relations that are present in all of the above processes. In this respect it has an important practical role of annotating currently unknown proteins through ‘guilt by association,’ by tying them into complexes and processes with a previously known function.

Metabolic Networks

Metabolic networks organize our knowledge about anabolic and catabolic reactions between the enzymes, their substrates and co-factors (such as ATP), by reducing the set of reactions to a graph representation where two substrates are joined by a link if they participate in the same reaction. For model organisms like the bacterium *Escherichia coli* the metabolic networks have been studied in depth and are publicly available [77,78], and an increasing number of analyzed genomes offers sufficient sampling power to make statistical statements about the network properties across different domains of life [72].

Several important features distinguish metabolic from protein–protein interaction and transcriptional regulation networks. First, for well studied systems the coverage of metabolic reactions is high, at least for the central routes of energy metabolism and small molecule synthesis; notice that this is a property of our knowledge, not a property of the networks (!). Second, cellular concentrations of metabolites usually are much higher than those of transcription factors, making the stochasticity in reactions due to small molecular counts irrelevant. Third, knowledge of the stoichiometry of reactions allows one to directly write down a system of first order differential equations for the metabolite fluxes [60], which in steady state reduces to a set of linear constraints on the space of solutions. These chemical constraints go beyond topology and can yield strong and testable predictions; for example, Ibarra et al. [66] have shown how computationally maximizing the growth rate of *Escherichia coli* within the space of allowed solutions given by flux balance constraints can correctly predict measurable relationships between oxygen and substrate uptake, and that bacteria can be evolved towards the predicted optimality for growth conditions in which the response was initially suboptimal.

Signaling Networks

Signaling networks consist of receptor and signaling proteins that integrate, transmit and route information by means of chemical transformations of the network constituents. One class of such transformations, for example, are post–translational modifications, where targets are phosphorylated, methylated, acetylated, … on specific residues, with a resulting change in their enzymatic (and thus signaling) activity. Alternatively, proteins might form stable complexes or dissociate from them, again introducing states of differential activity. The ability of cells to modify or tag proteins (possibly on several residues) can increase considerably the cell's capacity to encode its state and transmit information, assuming that the signaling proteins are highly specific not only for the identity but also the modification state of their targets; for a review see [110].

Despite the seeming overlap between the domains of protein–protein network and signaling networks, the focus of the analysis is substantially different. The interactome is simply a set of possible protein–protein interactions and thus a topological (or connectivity) map; in contrast, signaling networks aim to capture signal transduction and therefore need to establish a causal map, in which the nature of the protein–protein interaction, its direction and timescale, and its quantitative effect on the activity of the target protein matter. As an example, see the discussion by Kolch et al. [83] on the role of protein–protein interactions in MAPK signaling cascade.

Experiments on some signaling systems, such as the *Escherichia coli* chemotactic module, have generated enough experimental data to require detailed models in the form of dynamical equations. Molecular processes in a signaling cascade extend over different time scales, from milliseconds required for kinase and phosphatase reactions and protein conformational changes, to minutes or more required for gene expression control, cell movement and receptor trafficking; this fact, along with the (often essential) spatial effects such as the localization of signaling machinery and diffusion of chemical messengers, can considerably complicate analyses and simulations.

Signaling networks are often factored into pathways that have specific inputs, such as the ligands of the G protein coupled receptors on the cell surface, and specific outputs, as with pathways that couple to the transcriptional regulation apparatus or to changes in the intracellular concentration of messengers such as calcium or cyclic nucleotides. Nodes in signaling networks can participate in several pathways simultaneously, thus enabling signal integration or potentially inducing damaging "crosstalk" between pathways; how junctions and nodes process signals is an area of active research [74].

The components of signaling networks have long been the focus of biochemical research, and genetic methods allow experiments to assess the impact of knocking out or over-expressing particular components. In addition, several experimental approaches are being designed specifically for elucidating signaling networks. Ab-chips localize various signaling proteins on chips reminiscent of DNA microarrays, and stain them with appropriate fluorescent antibodies [105]. Multicolor flow cytometry is performed on cells immuno-stained for signaling protein modifications and hundreds of single cell simultaneous measurements of the modification state of pathway nodes are collected [113]. Indirect inference of signaling pathways is also possible from genomic or proteomic data.

One well studied signal transduction system is the mitogen activated protein kinase (MAPK) cascade that controls, among other functions, cell proliferation and differentiation [32]. Because this system is present in all eukaryotes and its structural components are used in multiple pathways, it has been chosen as a paradigm for the study of specificity and crosstalk. Similarly, the TOR system, identified initially in yeast, is responsible for integrating the information on nutrient availability, growth factors and energy status of the cell and correspondingly regulating the cell growth [95]. Another interesting example of signal integration and both intra- and inter-cellular communication is observed in the quorum sensing circuit of the bacterium *Vibrio harveyi*, where different kinds of species- and genus-specific signaling molecules are detected by their cognate receptors on the cell surface, and the information is fed into a common *Lux* phosphorelay pathway which ultimately regulates the quorum sensing genes [165].

Models of Biological Networks

Topological Models

The structural features of a network are captured by its connectivity graph, where interactions (reactions, structural relations) are depicted as the links between the interacting nodes (genes, proteins, metabolites). Information about connectivity clearly cannot and does not describe the network behavior, but it might influence and constrain it in revealing ways, similar to effect that the topology of the lattice has on the statistical mechanics of systems living on it.

Theorists have studied extensively the properties of regular networks and random graphs starting with Erdös and Rényi in 1960s. The first ones are characterized by high symmetry inherent in a square, triangular, or all-to-all (mean field) lattice; the random graphs were without such regularity, constructed simply by distributing K links at random between N nodes. The simple one–point statistical characterization that distinguishes random from regular networks looks at the node degree, that is the probability $P(k)$ that any node has k incoming and/or outgoing links. For random graphs this distribution is Poisson, meaning that most of the nodes have degrees very close to the mean, $\langle k \rangle = \sum_k k\, P(k)$, although there are fluctuations; for regular lattices every node has the same connectivity to its neighbors.

The first analyses of the early reconstructions of large metabolic networks revealed a surprising "scale free" node degree distribution, that is $P(k) \sim k^{-\gamma}$, with γ between 2 and 3 for most networks. For the physics community, which had seen the impact of such scale invariance on our understanding of phase transitions, these observations were extremely suggestive. It should be emphasized that for many problems in areas as diverse as quantum field theory, statistical mechanics and dynamical systems, such scaling relations are much more than curiosities. Power laws relating various experimentally observable quantities are exact (at least in some limit), and the exponents (here, γ) really contain everything one might want to know about the nature of order in the system. Further, some of the first thoughts on scaling emerged from phenomenological analyses of real data. Thus, the large body of work on scaling ideas in theoretical physics set the stage for people to be excited by the experimental observation of power laws in much more complex systems, although it is not clear to us whether the implied promise of connection to a deeper theoretical structure has been fulfilled. For divergent views on these matters see Barabási et al. [10] and Keller et al. [81].

The most immediate practical consequence of a scale free degree distribution is that – relative to expectations based on random graphs – there will be an over-representation of nodes with very large numbers of links, as with pyruvate or co-enzyme A in metabolic networks [72,163]. These are sometimes called hubs, although another consequence of a scale free distribution is that there is no 'critical degree of connection' that distinguishes hubs from nonhubs. In the protein–protein interaction network of *Saccharomyces cerevisiae*, nodes with higher degree are more likely to represent essential proteins [73], suggesting that node degree does have some biological meaning. On the theoretical side, removal of a sizable fraction of nodes from a scale free network will neither increase the network diameter much, nor partition the network into equally sized parts [3], and it is tempting to think that this robustness is also biologically significant. The scale free property has been observed in many non-biological contexts, such as the topology of social interactions, World Wide Web links, electrical power grid connectivity ... [144]. A number of models have been proposed for how such scaling might arise, and some of these ideas, such as growth by preferential attachment, have a vaguely biological flavor [11,12]. Finding the properties of networks that actually discriminate among different mechanisms of evolution or growth turns out to be surprisingly subtle [173].

Two other revealing measures are regularly computed for biological networks. The mean path length, $\langle l \rangle$, is the shortest path between a pair of nodes, averaged over all pairs in the graph, and measures the network's overall 'navigability.' Intuitively, short path lengths correspond to, for example, efficient or fast flow of information and energy in signaling or metabolic networks, quick spread of diseases in a social network and so on. The clustering coefficient of a node i is defined as $C_i = 2n_i/k_i(k_i - 1)$, where n_i is the number of links connecting the k_i neighbors of node i to each other; equivalently, C_i is the ratio between the number of triangles passing through two neighbors of i and node i itself, divided by the maximum possible number of such triangles. Random networks have low path lengths and low clustering coefficients, whereas regular lattices have long path lengths and are locally clustered. Watts and Strogatz [167] have constructed an intermediate regime of "small world" networks, where the regular lattice has been perturbed by a small number of random links connecting distant parts of the network together. These networks, although not necessarily scale free, have short path lengths and high clustering coefficients, a property that was subsequently observed in metabolic and other biological networks as well [163].

A high clustering coefficient suggests the existence of densely connected groups of nodes within a network, which seems contradictory to the idea of scale invariance, in which there is no inherent group or cluster size; Ravasz et al. [120] addressed this problem by introducing hierarchical networks and providing a simple construction for synthetic hierarchical networks exhibiting both scale free and clustering behaviors. Although there is no unique scale for the clusters, clusters will appear at any scale one chooses to look at, and this is revealed by the scaling of clustering coefficient $C(k)$ with the node degree k, $C(k) \sim k^{-1}$, on both synthetic as well as natural metabolic networks of organisms from different domains of life [120]. Another interesting property of some biological networks is an anti-correlation of node degree of connected nodes [96], which we can think of as a 'dissociative' structure; in contrast, for example, with the associative character of social networks, where well connected people usually know one another.

As we look more finely at the structure of the graph representing a network, there is of course a much greater variety of things to look at. For example, Spirin and Mirny [142] have focused on high clustering coefficients as a starting point and devised algorithms to search for modules, or densely connected subgraphs within the yeast protein–protein interaction network. Although the problem has combinatorial complexity in general, the authors found about 50 modules (of 5–10 proteins in size, some of which were unknown at the time) that come in two types: the first represents dynamic functional units (e. g. signaling cascades), and the second protein complexes. A similar conclusion was reached by Han et al. [57], after having analyzed the interactome in combination with the temporal gene expression profiles and protein localization data; the authors argue that nodes of high degree can sit either at the centers of modules, which are simultaneously expressed ("party hubs"), or they can be involved in various pathways and modules at different times ("date hubs"). The former kind is at a lower level of organization, whereas the latter tie the network into one large connected component.

Focusing on even a smaller scale, Shen-Orr et al. [136] have explored motifs, or patterns of connectivity of small sets of nodes that are over-represented in a given network compared to the randomized networks of the same degree distribution $P(k)$. In the transcriptional network of the bacterium *E. coli*, three such motifs were found: feed forward loops (in which gene X regulates Y that regulates Z, but X directly regulates Z as well), single input modules (where gene X regulates a large number of other genes in the same way and usually auto-regulates itself), and dense overlapping regulons (layers of overlapping interactions between genes and a group of transcription factors, much denser than in randomized networks). The motif approach has been extended to combined network of transcriptional regulation and protein–protein interactions [169] in yeast, as well as to other systems [101].

At the risk of being overly pessimistic, we should conclude this section with a note of caution. It would be attractive to think that a decade of work on network topology has resulted in a coherent picture, perhaps of the following form: on the smallest scale, the nodes of biological networks are assembled into motifs, these in turn are linked into modules, and this continues in a hierarchical fashion until the entire network is scale free. As we will discuss again in the context of design principles, the notion of such discrete substructure – motifs and modules – is intuitively appealing, and some discussions suggest that it is essential either for the function or the evolution of networks. On the other hand, the evidence for such structure usually is gathered with reference to some null model (e. g., a random network with the same $P(k)$), so we don't even have an absolute definition of these structures, much less a measure of their sufficiency as a characterization of the whole system; for attempts at an absolute definition of modularity see Ziv et al. [174] and Hofman and Wiggins [62]. Similarly, while it is appealing to think about scale free networks, the evidence for scaling almost always is confined to less than two decades, and in practice scaling often is not exact. It is then not clear whether the idealization of scale invariance captures the essential structure in these systems.

Boolean Networks

A straightforward extension of the topological picture that also permits the study of network dynamics assumes that the entities at the nodes – for example, genes or signaling proteins – are either 'on' or 'off' at each moment of time, so that for node i the state at time t is $\sigma_i(t) \in \{0, 1\}$. Time is usually discretized, and an additional prescription is needed to implement the evolution of the system: $\sigma_i(t+1) = f_i(\{\sigma_\mu(t)\})$, where f_i is a function that specifies how the states of the nodes μ that are the inputs to node i in the interaction graph combine to determine the next state at node i. For instance, f_A might be a Boolean function for gene A, which needs to have its activator gene B present and repressor gene C absent, so that $\sigma_A(t+1) = \sigma_B(t) \wedge \bar{\sigma}_C(t)$. Alternatively, f might be a function that sums the inputs at state t with some weights, and then sets $\sigma_i = 1(0)$ if the result is above (below) a threshold, as in classical models of neural networks.

Boolean networks are amenable both to analytical treatment and to efficient simulation. Early on, Kauffman [80] considered the family of random boolean networks. In these models, each node is connected at random to K other nodes on average, and it computes a random Boolean function of its inputs in which a fraction ρ of the 2^K possible input combinations leads to $\sigma_i(t+1) = 1$. In the limit that the network is large, the dynamics are either regular (settling into a stable fixed cycle) or chaotic, and these two phases are separated by a separatrix $2\rho(1-\rho)K = 1$ in the phase space (ρ, K).

Aldana and Cluzel [4] have shown that for connectivities of $K \sim 20$ that could reasonably be expected in e. g. transcriptional regulatory networks, the chaotic regime dominates the phase space. They point out, however, that if the network is scale free, there is no 'typical' K as the distribution $P(k) \sim k^{-\gamma}$ does not have a well-defined mean for $\gamma \leq 3$ and the phase transition criterion must be restated. It turns out, surprisingly, that regular behavior is possible for values of γ between 2 and 2.5, observed in most biological networks, and this is exactly the region where the separatrix lies. Scale free architecture, at least for Boolean networks, seems to prevent chaos.

Several groups have used Boolean models to look at specific biological systems. Thomas [150] has established a theoretical framework in which current states of the genes (as well as the states in the immediate past) and the environmental inputs are represented by Boolean variables that evolve through the application of Boolean functions. This work has been continued by, for example, Sanchez and Thieffry [128] who analyzed the gap-gene system of the fruit fly *Drosophila* by building a Boolean network that generates the correct levels of gene expression for 4 gap genes in response to input levels of 3 maternal morphogens with spatially varying profiles stretched along the anterior-posterior axis of the fly embryo. Interestingly, to reproduce the observed results and correctly predict the known *Drosophila* segmentation mutants, the authors had to introduce generalized Boolean variables that can take more than two states, and have identified the smallest necessary number of such states for each gene.

In a similar spirit, Li et al. [91] studied the skeleton of the budding yeast cell cycle, composed of 11 nodes, and a thresholding update rule. They found that the topology of this small network generates a robust sequence of transitions corresponding to known progression through yeast cell-cycle phases G1 (growth), S (DNA duplication), G2 (pause) and M (division), triggered by a known 'cell-size checkpoint.' This progression is robust, in the sense that the correct trajectory is the biggest dynamical attractor of the system, with respect to various choices of update rules and parameters, small changes in network topology, and choice of triggering checkpoints.

The usefulness of Boolean networks stems from the relative ease of implementation and simple parametrization of network topology and dynamics, making them suitable for studying medium or large networks. In addition to simplifying the states at the nodes to two (or more) discrete levels, which is an assumption that has not been clearly explored, one should be cautious that the discrete and usually synchronous dynamics in time can induce unwanted artifacts.

Probabilistic Models

Suppose one is able to observe simultaneously the activity levels of several proteins comprising a signaling network, or the expression levels of a set of genes belonging to the same regulatory module. Because they are part of a functional whole, the activity levels of the components will be correlated. Naively, one could build a network model by simply computing pairwise correlation coefficients between pairs of nodes, and postulating an interaction, and therefore a link, between the two nodes whenever their correlation is above some threshold. However, in a test case where A → B → C (gene A induces B which induces C), one expects to see high positive correlation among all three elements, even though there is no (physical) interaction between A and C. Correlation therefore is not equal to interaction or causation. Constructing a network from the correlations in this naive way also does not lead to a generative model that would predict the probabilities for observing different states of the network as a whole. Another approach is clearly needed; see Markowetz and Spang [94] for a review.

In the simple case where the activity of a protein/gene i can either be 'on' ($\sigma_i = 1$) or 'off' ($\sigma_i = 0$), the state of a network with N nodes will be characterized by a binary word of N bits, and because of interaction between nodes, not all these words will be equally likely. For example, if node A represses node B, then combinations such as $1_A 0_B \ldots$ or $0_A 1_B \ldots$ will be more likely than $1_A 1_B \ldots$. In the case of deterministic Boolean networks, having node A be 'on' would imply that node B is 'off' with certainty, but in probabilistic models it only means that there is a positive *bias* for node B to be 'off,' quantified by the probability that node B is 'off' given that the state of node A is known. Having this additional probabilistic degree of freedom is advantageous, both because the network itself might be noisy, and because the experiment can induce errors in the signal readout, making the inference of deterministic rules from observed binary patterns an ill-posed problem.

Once we agree to make a probabilistic model, the goal is to find the distribution over all network states, which we can also think of as the joint distribution of all the N variable that live on the nodes of the network, $P(\sigma_1, \ldots, \sigma_N | C)$, perhaps conditioned on some fixed set of environmental or experimental factors C. The activities of the nodes, σ_i, can be binary, can take on a discrete set of states, or be continuous, depending on our prior knowledge about the system and experimental and numerical constraints. Even for a modest N, experiments of realistic scale will not be enough to directly estimate the probability distribution, since even with binary variable the number of possible states, and hence the number of parameters required to specify the general probability distribution, grows as $\sim 2^N$. Progress thus depends in an essential way on simplifying assumptions.

Returning to the three gene example A → B → C, we realize that C depends on A only through B, or in other words, C is *conditionally independent* of A and hence no interaction should be assigned between nodes A and C. Thus, the joint distribution of three variables can be factorized,

$$P(\sigma_\mathrm{A}, \sigma_\mathrm{B}, \sigma_\mathrm{C}) = P(\sigma_\mathrm{C} | \sigma_\mathrm{B}) P(\sigma_\mathrm{B} | \sigma_\mathrm{A}) P(\sigma_\mathrm{A}) .$$

One might hope that, even in a large network, these sorts of conditional independence relations could be used to simplify our model of the probability distribution. In general this doesn't work, because of feedback loops which, in our simple example, would include the possibility that C affects the state of A, either directly or through some more circuitous path. Nonetheless one can try to make an approximation in which loops either are neglected or (more sensibly) taken into account in some sort of average way; in statistical mechanics, this approximation goes back at least to the work of Bethe [19].

In the computer science and bioinformatics literature, the exploitation of Bethe-like approximations has come to be known as 'Bayesian network modeling' [43]. In practice what this approach does is to search among possible network topologies, excluding loops, and then for fixed topology one uses the conditional probability relationships to factorize the probability distribution and fit the tables of conditional probabilities at each node that will best reproduce some set of data. Networks with more links have more parameters, so one must introduce a trade-off between the quality of the fit to the data and this increasing complexity. In this framework there is thus an explicit simplification based on conditional independence, and an implicit simplification based on a preference for models with fewer links or sparse connectivity.

The best known application of this approach to a biological network is the analysis of the MAPK signaling pathway in T cells from the human immune system [127]. The data for this analysis comes from experiments in which the phosophorylated states of 11 proteins in the pathway are sampled simultaneously by immunostaining [113], with hundreds of cells sampled for each set of external conditions. By combining experiments from multiple conditions, the Bayesian network analysis was able to find a network of interactions among the 11 proteins that has high overlap with those known to occur experimentally.

A very different approach to simplification of probabilistic models is based on the maximum entropy principle [71]. In this approach one views a set of experiments as providing an estimate of some set of correlations, for example the $\sim N^2$ correlations among all pairs of elements in the network. One then tries to construct a probability distribution which matches these correlations but otherwise has as little structure – as much entropy – as possible. We recall that the Boltzmann distribution for systems in thermal equilibrium can be derived as the distribution which has maximum entropy consistent with a given average energy, and maximum entropy modeling generalizes this to take account of other average properties. In fact one can construct a hierarchy of maximum entropy distributions which are consistent with higher and higher orders of correlation [130]. Maximum entropy models for binary variables that are consistent with pairwise correlations are exactly the Ising models of statistical physics, which opens a wealth of analytic tools and intuition about collective behavior in these systems.

In the context of biological networks (broadly construed), recent work has shown that maximum entropy models consistent with pairwise correlations are surprisingly successful at describing the patterns of activity among populations of neurons in the vertebrate retina as it responds to natural movies [131,153]. Similar results are obtained for very different retinas under different conditions [137], and these successes have touched a flurry of interest in the analysis of neural populations more generally. The connection to the Ising model has a special resonance in the context of neural networks, where the collective behavior of the Ising model has been used for some time as a prototype for thinking about the dynamics of computation and memory storage [64]; in the maximum entropy approach the Ising model emerges directly as the least structured model consistent with the experimentally measured patterns of correlation among pairs of cells. A particularly striking result of this analysis is that the Ising models which emerge seem to be poised near a critical point [153]. Returning to cell biology, the maximum entropy approach has also been used to analyze patterns of gene expression in yeast [90] as well as to revisit the MAPK cascade [151].

Dynamical Systems

If the information about a biological system is detailed enough to encompass all relevant interacting molecules along with the associated reactions and estimated reaction rates, and the molecular noise is expected to play a negligible role, it is possible to describe the system with rate equations of chemical kinetics. An obvious benefit is the immediate availability of mathematical tools, such as steady state and stability analyses, insight provided by nonlinear dynamics and chaos theory, well developed numerical algorithms for integration in time and convenient visualization with phase portraits or bifurcation diagrams. Moreover, analytical approximations can be often exploited productively when warranted by some prior knowledge, for example, in separately treating 'fast' and 'slow' reactions. In practice, however, reaction rates and other important parameters are often unknown or known only up to order-of-magnitude estimations; in this case the problem usually reduces to the identification of phase space regions where the behavior of the system is qualitatively the same, for example, regions where the system exhibits limit-cycle oscillations, bistability, convergence into a single steady state etc.; see Tyson et al. [159] for a review. Despite the difficulties, deterministic chemical kinetic models have been very powerful tools in analyzing specific network motifs or regulatory elements, as in the protein signaling circuits that achieve perfect adaptation, homeostasis, switching and so on, described by Tyson et al. [160], and more generally in the analysis of transcriptional regulatory networks as reviewed by Hasty et al. [59].

In the world of bacteria, some of the first detailed computer simulations of the chemotaxis module of *Escherichia coli* were undertaken by Bray et al. [29]. The signaling cascade from the Tar receptor at the cell surface to the modifications in the phosphorylation state of the molecular motor were captured by Michaelis–Menten kinetic reactions (and equilibrium binding conditions for the receptor), and the system of equations was numerically integrated in time. While slow adaptation kinetics was not studied in this first effort, the model nevertheless qualitatively reproduces about 80 percent of examined chemotactic protein deletion and overexpression mutants, although the extreme sensitivity of the system remained unexplained.

In eukaryotes, Novak and Tyson [107] have, for instance, constructed an extensive model of cell cycle control in fission yeast. Despite its complexity (~ 10 proteins and ~ 30 rate constants), Novak and colleagues have provided an interpretation of the system in terms of three interlocking modules that regulate the transitions from G1 (growth) into S (DNA synthesis) phase, from G2 into M (division) phase, and the exit from mitosis, respectively. The modules are coupled through cdc2/cdc13 protein complex and the system is driven by the interaction with the cell size signal (proportional to the number of ribosomes per nucleus). At small size, the control circuit can only support one stable attractor, which is the state with low cdc2 activity corresponding to G1 phase. As the cell grows, new stable state appears and the system makes an irreversible transition into S/G2 at a bifurcation point, and, at an even larger size, the mitotic module becomes unstable and executes limit cycles in cdc2-cdc13 activity until the M phase is completed and the cell returns to its initial size. The basic idea is that the cell, driven by the the size readout, progresses through robust cell states created by bistability in the three modules comprising the cell cycle control – in this way, once it commits to a transition from G2 state into M, small fluctuations will not flip it back into G2. The mathematical model has in this case successfully predicted the behaviors of a number of cell cycle mutants and recapitulated experimental observations collected during 1970s and 1980s by Nurse and collaborators [108].

The circadian clock is a naturally occurring transcriptional module that is particularly amenable to dynamical systems modeling. Leloup and Goldbeter [87] have created a mathematical model of a mammalian clock (with ~ 20 rate equations) that exhibits autonomous sustained oscillations over a sizable range of parameter values, and reproduces the entrainment of the oscillations to the light–dark cycles through light-induced gene expression. The basic mechanism that enables the cyclic behavior is negative feedback transcriptional control, although the actual circuit contains at least two coupled oscillators. Studying circadian clock in mammals, the fruit fly *Drosophila* or *Neurospora* is attractive because of the possibility of connecting a sizable catalog of physiological disorders in circadian rhythms to malfunctions in the clock circuit and direct experimentation with light-dark stimuli [171]. Recent experiments indicate that at least in cyanobacteria the circadian clock can be reconstituted from a surprisingly small set of biochemical reactions, without transcription or translation [102,157], and this opens possibilities for even simpler and highly predictive dynamical models [126].

Dynamical modeling has in addition been applied to many smaller systems. For example, the construction of a synthetic toggle switch [44], and the 'repressilator' – oscillating network of three mutually repressing genes [38] – are examples where mathematical analysis has stimulated the design of synthetic circuits. A successful reaction-diffusion model of how localization and complex formation of Min proteins can lead to spatial limit cycle oscillations (used by *Escherichia coli* to find its division site) was constructed by Huang et al. [65]. It remains a challenge, nevertheless, to navigate in the space of parameters as it becomes ever larger for bigger networks, to correctly account for localization and count various forms of protein modifications, especially when the signaling networks also couple to transcriptional regulation, and to find a proper balance between models that capture all known reactions and interactions and phenomenological models that include coarse-grained variables.

Stochastic Dynamics

Stochastic dynamics is in principle the most detailed level of system description. Here, the (integer) count of every molecular species is tracked and reactions are drawn at random with appropriate probabilities per unit time (proportional to their respective reaction rates) and executed to update the current tally of molecular counts. An algorithm implementing this prescription, called the stochastic simulation algorithm or SSA, was devised by Gillespie [47]; see Gillespie [48] for a review of SSA and a discussion of related methods. Although slow, this approach for simulating chemical reactions can be made exact. In general, when all molecules are present in large numbers and continuous, well-mixed concentrations are good approximations, the (deterministic) rate dynamics equations and stochastic simulation give the same results; however, when molecular counts are low and, consequently, the stochasticity in reaction timing and ordering becomes important, the rate dynamics breaks down and SSA needs to be used. In biological networks and specifically in transcriptional regulation, a gene and its promoter region are only present in one (or perhaps a few) copies, while transcription factors that regulate it can also be at nanomolar concentrations (i. e. from a few to a few hundred molecules per nucleus), making stochastic effects possibly very important [97,98].

One of the pioneering studies of the role of noise in a biological system was a simulation of the phage λ lysis-lysogeny switch by Arkin et al. [7]. The life cycle of the phage is determined by the concentrations of two transcription factors, *cI* (lambda repressor) and *cro*, that compete for binding to the same operator on the DNA. If *cI* is prevalent, the phage DNA is integrated into the host's genome and no phage genes except for *cI* are expressed (the lysogenic state); if *cro* is dominant, the phage is in lytic state, using cell's DNA replication machinery to produce more phages and ultimately lyse the host cell [115]. The switch is bistable and the fate of the phage depends on the temporal and random pattern of gene expression of two mutually antagonistic transcription factors, although the balance can be shifted by subjecting the host cell to stress and thus flipping the toggle into lytic phase. The stochastic simulation correctly reproduces the experimentally observed fraction of lysogenic phages as a function of multiplicity-of-infection. An extension of SSA to spatially extended models is possible.

Although the simulations are exact, they are computationally intensive and do not offer any analytical insight into the behavior of the solutions. As a result, various theoretical techniques have been developed for studying the effects of stochasticity in biological networks. These are often operating in a regime where the deterministic chemical kinetics is a good approximation, and noise (i. e. fluctuation of concentrations around the mean) is added into the system of differential equations as a perturbation; these Langevin methods have been useful for the study of noise propagation in regulatory networks [76,111,149]. The analysis of stochastic dynamics is especially interesting in the context of design principles which consider the reliability of network function, to which we return below.

Network Properties and Operating Principles

Modularity

Biological networks are said to be modular, although the term has several related but nevertheless distinct meanings. Their common denominator is the idea that there exist a partitioning of the network nodes into groups, or modules, that are largely independent of each other and perform separate or autonomous functions. Independence can be achieved through spatial isolation of the module's processes or by chemical specificity of its components. The ability to extract the module from the cell and reconstitute it in vitro, or transplant it to another type of cell is a powerful argument for the existence of modularity [58]. In the absence of such strong and laborious experimental verifications, however, measures of modularity that depend on a particular network model are frequently used.

In topological networks, the focus is on the module's independence: nodes within a module are densely connected to each other, while inter-modular links are sparse [57,120,142] and the tendency to cluster is measured by high clustering coefficients. As a caveat to this view note that despite their sparseness the inter-module links could represent strong dynamical couplings. Modular architecture has been studied in Boolean networks by Kashtan and Alon [79], who have shown that modularity can evolve by mutation and selection in a time-varying fitness landscape where changeable goals decompose into a set of fixed subproblems. In the example studied they computationally evolve networks implementing several Boolean formulae and observe the appearance of a module – a circuit of logical gates implementing a particular Boolean operator (like XOR) in a reusable way. This work makes clear that modularity in networks is plausibly connected to modularity in the kinds of problems that these networks were selected to solve, but we really know relatively little about the formal structure of these problems.

There are also ways of inferring a form of modularity directly without assuming any particular network model. Clustering tools partition genes into co-expressed groups, or clusters, that are often identified with particular modules [36,133,140]. Ihmels et al. [67] have noted that each node can belong to more than one module depending on the biological state of the cell, or the context, and have correspondingly reexamined the clustering problem. Elemento et al. [37] have recently presented a general information theoretic approach to inferring regulatory modules and the associated transcription factor binding sites from various kinds of high-throughput data. While clustering methods have been widely applied in the exploration of gene expression, it should be emphasized that merely finding clusters does not by itself provide evidence for modularity. As noted above, the whole discussion would be much more satisfying if we had independent definitions of modularity and, we might add, clearly stated alternative hypotheses about the structure and dynamics of these networks.

Focusing on the functional aspect of the module, we often observe that the majority of the components of a system (for instance, a set of promoter sites or a set of genes regulating motility in bacteria) are conserved together across species. These observations support the hypothesis that the conserved components are part of a very tightly coupled sub-network which we might identify as a module. Bioinformatic tools can then use the combined sequence and expression data to give predictions about modules, as reviewed by Siggia et al. [139]. Purely phylogenetic approaches that infer module components based on inter-species comparisons have also been productive and can extract candidate modules based only on phylogenetic footprinting, that is, studying the presence or absence of homologous genes across organisms and correlating their presence with hand annotated phenotypic traits [141].

Robustness

Robustness refers to a property of the biological network such that some aspect of its function is not sensitive to perturbations of network parameters, environmental variables (e. g. temperature), or initial state; see de Visser et al. [162] for a review of robustness from an evolutionary perspective and Goulian [53] for mechanisms of robustness in bacterial circuits. Robustness encompasses two very different ideas. One idea has to do with a general principle about the nature of explanation in the quantitative sciences: qualitatively striking facts should not depend on the fine tuning of parameters, because such a scenario just shifts the problem to understanding why the parameters are tuned as they are. The second idea is more intrinsic to the function of the system, and entails the hypothesis that cells cannot rely on precisely reproducible parameters or conditions and must nonetheless function reliably and reproducibly.

Robustness has been studied extensively in the chemotactic system of the bacterium *Escherichia coli*. The systematic bias to swim towards chemoattractants and away from repellents can only be sustained if the bacterium is sensitive to the spatial gradients of the concentration and not to its absolute levels. This discriminative ability is ensured by the mechanism of perfect adaptation, with which the proportion of bacterial straight runs and tumbles (random changes in direction) always returns to the same value in the absence of gradients [27]. Naively, however, the ability to adapt perfectly seems to be sensitive to the amounts of intracellular signaling proteins, which can be tuned only approximately by means of transcriptional regulation. Barkai and Leibler [13] argued that there is integral feedback control in the chemotactic circuit which makes it robust against changes in these parameters, and Alon et al. [6] showed experimentally that precision of adaptation truly stays robust, while other properties of the systems (such as the time to adapt and the steady state) show marked variations with intracellular signaling protein concentrations.

One seemingly clear example of robust biological function is embryonic development. We know that the spatial structure of the fully developed organism follows a 'blueprint' laid out early in development as a spatial pattern of gene expression levels. von Dassow et al. [34] studied one part of this process in the fruit fly *Drosophila*, the 'segment polarity network' that generates striped patterns of expression. They considered a dynamical system based on the wiring diagram of interactions among a small group of genes and signaling molecules, with ~ 50 associated constants parametrizing production and degradation rates, saturation response and diffusion, and searched the parameter space for solutions that reproduce the known striped patterns. They found that, with their initial guess at network topology, such solutions do not exist, but adding a particular link – biologically motivated though unconfirmed at the time – allowed them to find solutions by random sampling of parameter space. Although they presented no rigorous measure for the volume of parameter space in which correct solutions exist, it seems that a wide variety of parameter choices and initial conditions indeed produce striped expression patterns, and this was taken to be a signature of robustness.

Robustness in dynamical models is the ability of the biological network to sustain its trajectory through state space despite parameter or state perturbations. In circadian clocks the oscillations have to be robust against both molecular noise inherent in transcriptional regulation, examined in stochastic simulations by Gonze et al. [52], as well as variation in rate parameters [143]; in the latter work the authors introduce integral robustness measures along the trajectory in state space and argue that the clock network architecture tends to concentrate the fragility to perturbations into parameters that are global to the cell (maximum overall translation and protein degradation rates) while increasing the robustness to processes specific to the circadian oscillator. As was mentioned earlier, robustness to state perturbations was demonstrated by Li et al. [91] in the threshold binary network model of the yeast cell cycle, and examined in scale-free random Boolean networks by Aldana and Cluzel [4].

As with modularity, robustness has been somewhat resistant to rigorous definitions. Importantly, robustness has always been used as a relational concept: function X is robust to variations in Y. An alternative to robustness is for the organism to exert precise control over Y, perhaps even using X as a feedback signal. This seems to be how neurons stabilize a functional mix of different ion channels [93], following the original theoretical suggestion of LeMasson et al. [88]. Pattern formation during embryonic development in *Drosophila* begins with spatial gradients of transcription factors, such as Bicoid, which are established by maternal gene expression, and it has been assumed that variations in these expression levels are inevitable, requiring some robust readout mechanism. Recent measurements of Bicoid in live embryos, however, demonstrate that the absolute concentrations are actually reproducible from embryo to embryo with $\sim 10\%$ precision [54]. While there remain many open questions, these results suggest that organisms may be able to exert surprisingly exact control over critical parameters, rather than having compensation schemes for initially sloppy mechanisms. The example of ion channels alerts us to the possibility that cells may even 'know' which combinations of parameters are critical, so that variations in a multidimensional parameter space are large, but confined to a low dimensional manifold.

Noise

A dynamical system with constant reaction rates, starting repeatedly from the same initial condition in a stable environment, always follows a deterministic time evolution. When the concentrations of the reacting species are low enough, however, the description in terms of time (and possibly space) dependent concentration breaks down, and the stochasticity in reactions, driven by random encounters between individual molecules, becomes important: on repeated trials from the same initial conditions, the system will trace out different trajectories in the state space. As has been pointed out in the section on stochastic dynamics, biological networks in this regime need to be simulated with the Gillespie algorithm [47], or analyzed within approximate schemes that treat noise as perturbation of deterministic dynamics. Recent experimental developments have made it possible to observe this noise directly, spurring new research in the field. Noise in biological networks fundamentally limits the organism's ability to sense, process and respond to environmental and internal signals, suggesting that analysis of noise is a crucial component in any attempt to understand the design of these networks. This line of reasoning is well developed in the context of neural function [20], and we draw attention in particular to work on the ability of the visual system to count single photons, which depends upon the precision of the G-protein mediated signaling cascade in photo receptors; see, for example, [117].

Because transcriptional regulation inherently deals with molecules, such as DNA and transcription factors, that are present at low copy numbers, most noise studies were carried out on transcriptional regulatory elements. The availability of fluorescent proteins and their fusions to wild type proteins have been the crucial tools, enabling researchers to image the cells expressing these probes in a controllable manner, and track their number in time and across the population of cells. Elowitz et al. [39] pioneered the idea of observing the output of two identical regulatory elements driving the expression of two fluorescent proteins of different colors, regulated by a common input in a single *Escherichia coli* cell. In this 'two-color experiment,' the correlated fluctuations in both colors must be due to the *extrinsic* fluctuations in the common factors that influence the production of both proteins, such as overall RNA polymerase or transcription factor levels; on the other hand, the remaining, uncorrelated fluctuation is due to the *intrinsic* stochasticity in the transcription of the gene and translation of the messenger RNA into the fluorescent protein from each of the two promoters [147]. Ozbudak et al. [109] have studied the contributions of stochasticity in transcription and translation to the total noise in gene expression in prokaryotes, while Pedraza and van Oudenaarden [112] and Hooshangi et al. [63] have looked at the propagation of noise from transcription factors to their targets in synthetic multi-gene cascades. Rosenfeld et al. [124] have used the statistics of binomial partitioning of proteins during the division of *Escherichia coli* to convert their fluorescence measurements into the corresponding absolute protein concentrations, and also were able to observe the dynamics of these fluctuations, characterizing the correlation times of both intrinsic and extrinsic noise.

Theoretical work has primarily been concerned with disentangling and quantifying the contributions of different steps in transcriptional regulation and gene expression to the total noise in the regulated gene [111,146,149], often by looking for signatures of various noise sources in the behavior of the measured noise as a function of the mean expression level of a gene. For many of the examples studied in prokaryotes, noise seemed to be primarily attributable to the production of proteins in bursts from single messenger RNA molecules, and to pulsatile and random activation of genes and therefore bursty translation into mRNA [50]. In yeast [26,119] and in mammalian cells [116] such stochastic synthesis of mRNA was modeled and observed as well. Simple scaling of noise with the mean was observed in ∼40 yeast proteins under different conditions by Bar-Even et al. [9] and interpreted as originating in variability in mRNA copy numbers or gene activation.

Bialek and Setayeshgar [22] have demonstrated theoretically that at low concentrations of transcriptional regulator, there should be a lower bound on the noise set by the basic physics of diffusion of transcription factor molecules to the DNA binding sites. This limit is independent of (possibly complex, and usually unknown) molecular details of the binding process; as an example, cooperativity enhances the 'sensitivity' to small changes in concentration, but doesn't lower the physical limit to noise performance [23]. This randomness in diffusive flux of factors to their 'detectors' on the DNA must ultimately limit the precision and reliability of transcriptional regulation, much like the randomness in diffusion of chemoattractants to the detectors on the surface of *Escherichia coli* limits its chemotactic performance [17]. Interestingly, one dimensional diffusion of transcription factors along the DNA can have a big impact on the speed with which TFs find their targets, but the change in noise performance that one might expect to accompany these kinetic changes is largely compensated by the extended correlation structure of one dimensional diffusion [152]. Recent measurements of the regulation of the *hunchback* gene by Bicoid during early fruit fly development by Gregor et al. [54] have provided evidence for the dominant role of such input noise, which coexists with previously studied output noise in production of mRNA and protein [156]. These results raise the possibility that initial decisions in embryonic development are made with a precision limited by fundamental physical principles.

Dynamics, Attractors, Stability and Large Fluctuations

The behavior of a dynamical system as the time tends to infinity, in response to a particular input, is interesting regardless of the nature of the network model. Both discrete and continuous, or deterministic and noisy, systems can settle into a number of fixed points, exhibit limit-cycle oscillations, or execute chaotic dynamics. In biological networks it is important to ask whether these qualitatively different outcomes correspond to distinct phenotypes or behaviors. If so, then a specific stable gene expression profile in a network of developmental genes, for example, encodes that cell's developmental fate, as the amount of lambda repressor encodes the state of lysis vs lysogeny switch in the phage. The history of the system that led to the establishment of a specific steady state would not matter as long as the system persisted in the same attractor: the dynamics could be regarded as a 'computation' leading to the final result, the identity of the attractor, with the activities of genes in this steady state in turn driving the downstream pathways and other modules; see Kauffman [80] for genetic networks and Hopfield [64] for similar ideas in neural networks for associative memory. Alternatively, such partitioning into transient dynamics and 'meaningful' steady states might not be possible: the system must be analyzed as a whole while it moves in state space, and parts of it do not separately and sequentially settle into their attractors.

It seems, for example, that qualitative behavior of the cell cycle can be understood by progression through well-defined states or checkpoints: after transients die away, the cell cycle proteins are in a 'consistent' state that regulates division or growth related activities, so long as the conditions do not warrant a new transition into the next state [33,103]. In the fruit fly *Drosophila* development it has been suggested that combined processes of diffusion and degradation first establish steady-state spatial profiles of maternal morphogens along the major axis of the embryo, after which this stable 'coordinate system' is read out by gap and other downstream genes to generate the body segments. Recent measurements by Gregor et al. [55] have shown that there is a rich dynamics in the Bicoid morphogens concentration, prompting Bergmann et al. [18] to hypothesize that perhaps downstream genes read out and respond to morphogens even before the steady state has been reached. On another note, an interesting excitable motif, called the "feedback resistor," has been found in HIV Tat system – instead of having a bistable switch like the λ phage, HIV (which lacks negative feedback capability) implements a circuit with a single stable 'off' lysogenic state, that is perturbed in a pulse of trans activation when the virus attacks. The pulse probably triggers a threshold-crossing process that drives downstream events, and subsequently decays away; the feedback resistor is thus again an example of a dynamic, as opposed to the steady-state, readout [168]. Excitable dynamics are of course at the heart of the action potential in neurons, which results from the coupled dynamics of ion channel proteins, and related dynamical ideas are now emerging other cellular networks [145].

If attractors of the dynamical system correspond to distinct biological states of the organism, it is important to examine their stability against noise-induced spontaneous flipping. Bistable elements are akin to the 'flip-flop' switches in computer chips – they form the basis of cellular (epigenetic) memory. While this mechanism for remembering the past is not unique – for example, a very slow, but not bistable, dynamics will also retain 'memory' of the initial condition through protein levels that persist on a generation time scale [138], it has the potential to be the most stable mechanism. The naturally occurring bistable switch of the λ phage was studied using stochastic simulation by Arkin et al. [7], and a synthetic toggle switch was constructed in *Escherichia coli* by Gardner et al. [44]. Theoretical studies of systems where large fluctuations are important are generally difficult and restricted to simple regulatory elements, but Bialek [21] has shown that a bistable switch can be created with as few as tens of molecules yet remain stable for years. A full understanding of such stochastic switching brings in powerful methods from statistical physics and field theory [122,129,164], ultimately with the hope of connecting to quantitative experiments [1].

Optimization Principles

If the function of a pathway or a network module can be quantified by a scalar measure, it is possible to explore the space of networks that perform the given function optimally. An example already given was that of maximizing the growth rate of the bacterium *Escherichia coli*, subject to the constraints imposed by the known metabolic reactions of the cell; the resulting optimal joint usage of oxygen and food could be compared to the experiments [66]. If enough constraints exist for the problem to be well posed, and there is sufficient reason to believe that evolution drove the organism towards optimal behavior, optimization principles allow us to both tune the otherwise unknown parameters to achieve the maximum, and also to compare the wild type and optimal performances.

Dekel and Alon [35] have performed the cost/benefit analysis of expressing *lac* operon in bacteria. On one hand *lac* genes allow *Escherichia coli* to digest lactose, but on the other there is the incurred metabolic cost to the cell for expressing them. That the cost is not negligible to the bacterium is demonstrated best by the fact that it shuts off the operon if no lactose is present in the environment. The cost terms are measured by inducing the *lac* operon with changeable amount of IPTG that provides no energy in return; the benefit is measured by fully inducing *lac* with IPTG and supplying variable amounts of lactose; both cost and benefit are in turn expressed as the change in the growth rate compared to the wild-type grown at fixed conditions. Optimal levels of *lac* expression were then predicted as a function of lactose concentration and bacteria were evolved for several hundred generations to verify that evolved organisms lie close to the predicted optimum.

Zaslaver et al. [172] have considered a cascade of amino-acid biosynthesis reactions in *Escherichia coli*, catalyzed by their corresponding enzymes. They have then optimized the parameters of the model that describes the regulation of enzyme gene expression, such that the total metabolic cost for enzyme production was balanced against the benefit of achieving a desired metabolic flux through the biosynthesis pathway. The resulting optimal on-times and promoter activities for the enzymes were compared to the measured activities of amino-acid biosynthesis promoters exposed to different amino-acids in the medium. The authors conclude that the bacterium implements a 'just-in-time' transcription program, with enzymes catalyzing initial steps in the pathway being produced from strong and low-latency promoters.

In signal transduction networks the definition of an objective function to be maximized is somewhat more tricky. The ability of the cell to sense its environment and make decisions, for instance about which genes to up- or down-regulate, is limited by several factors: scarcity of signals coming from the environment, perhaps because of the limited time that can be dedicated to data collection; noise inherent in the signaling network that degrades the quality of the detected signal; (sub-)optimality of the decision strategy; and noise in the effector systems at the output. A first idea would be to postulate that networks are designed to lower the noise, and intuitively the ubiquity of mechanisms such as negative feedback [15,53] is consistent with such an objective. There are various definitions for noise, however, which in addition are generally a function of the input, raising serious issues about how to formulate a principled optimization criterion.

When we think about energy flow in biological systems, there is no doubt that our thinking must at least be consistent with thermodynamics. More strongly, thermodynamics provides us with notions of efficiency that place the performance of biological systems on an absolute scale, and in many cases this performance really is quite impressive. In contrast, most discussions of information in biological systems leave "information" as a colloquial term, making no reference to the formal apparatus of information theory as developed by Shannon and others more than fifty years ago [135]. Although many aspects of information theory that are especially important for modern technology (e. g., sophisticated error-correcting codes) have no obvious connection to biology, there is something at the core of information theory that is vital: Shannon proved that if we want to quantify the intuitive concept that "x provides information about y," then there is only one way to do this that is guaranteed to work under all conditions and to obey simple intuitive criteria such as the additivity of independent information. This unique measure of "information" is Shannon's mutual information. Further, there are theorems in information theory which, in parallel to results in thermodynamics, provide us with limits to what is possible and with notions of efficiency.

There is a long history of using information theoretic ideas to analyze the flow of information in the nervous system, including the idea that aspects of the brain's coding strategies might be chosen to optimize the efficiency of coding, and these theoretical ideas have led directly to interesting experiments. The use of information to think about cellular signaling and its possible optimization is more recent [154,175]. An important aspect of optimizing information flow is that the input/output relations of signaling devices must be matched to the distribution of inputs, and recent measurements on the control of *hunchback* by Bicoid in the early fruit fly embryo [54] seem remarkably consistent with the (parameter free) predictions from these matching relations [155].

In the context of neuroscience there is a long tradition of forcing the complex dynamics of signal processing into a setting where the subject needs to decide between a small set of alternatives; in this limit there is a well developed theory of optimal Bayesian decision making, which uses prior knowledge of the possible signals to help overcome noise intrinsic to the signaling system; Libby et al. [92] have recently applied this approach to the *lac* operon in *Escherichia coli*. The regulatory element is viewed as an inference module that has to 'decide,' by choosing its induction level, if the environmental lactose concentration is high or low. If the bacterium detects a momentarily high sugar concentration, it has to discriminate between two situations: either the environment really is at low overall concentration but there has been a large fluctuation; or the environment has switched to a high concentration mode. The authors examine how plausible regulatory element architectures (e. g. activator vs repressor, cooperative binding etc.) yield different discrimination performance. Intrinsic noise in the *lac* system can additionally complicate such decision making, but can be included into the theoretical Bayesian framework.

The question of whether biological systems are optimal in any precise mathematical sense is likely to remain controversial for some time. Currently opinions are stronger than the data, with some investigators using 'optimized' rather loosely and others convinced that what we see today is only a historical accident, not organizable around such lofty principles. We emphasize, however, that attempts to formulate optimization principles require us to articulate clearly what we mean by "function" in each context, and this is an important exercise. Exploration of optimization principles also exposes new questions, such as the nature of the distribution of inputs to signaling systems, that one might not have thought to ask otherwise. Many of these questions remain as challenges for a new generation of experiments.

Evolvability and Designability

Kirschner and Gerhart [82] define *evolvability* as an organism's capacity to generate heritable phenotypic variation. This capacity may have two components: first, to reduce the lethality of mutations, and second, to reduce the number of mutations needed to produce phenotypically novel traits. The systematic study of evolvability is hard because the genotype-to-phenotype map is highly nontrivial, but there have been some qualitative observations relevant to biological networks. Emergence of *weak linkage* of processes, such as the co-dependence of transcription factors and their DNA binding sites in metazoan transcriptional regulation, is one example. Metazoan regulation seems to depend on combinatorial control by many transcription factors with weak DNA-binding specificities and the corresponding binding sites (called cis-regulatory modules) can be dispersed and extended on the DNA. This is in stark contrast to the strong linkage between the factors and the DNA in prokaryotic regulation or in metabolism, energy transfer or macromolecular assembly, where steric and complementarity requirements for interacting molecules are high. In protein signaling networks, strongly conserved but flexible proteins, like calmodulin, can bind weakly to many other proteins, with small mutations in their sequence probably affecting such binding and making the establishment of new regulatory links possible and perhaps easy.

Some of the most detailed attempts to follow the evolution of network function have been by Francois and coworkers [41,42]. In their initial work they showed how simple functional circuits, performing logical operations or implementing bistable or oscillatory behavior, can be reliably created by a mutational process with selection by an appropriate fitness function. More recently they have considered fitness functions which favor spatial structure in patterns of gene expression, and shown how the networks that emerge from dynamics in this fitness landscape recapitulate the outlines of the segmentation networks known to be operating during embryonic development.

Instead of asking if there *exists* a network of nodes such that they perform a given computation, and if it can be found by mutation and selection as in the examples above, one can ask how many network topologies perform a given computation. In other words, one is asking whether there is only one (fine tuned?) or many topologies or solutions to a given problem. The question of how many network topologies, proxies for different genotypes, produce the same dynamics, a proxy for phenotype, is a question of designability, a concept originally proposed to study the properties of amino-acid sequences comprising functional proteins, but applicable also to biological regulatory networks [106]. The authors examine three- and four-node binary networks with threshold updating rule and show that all networks with the shared phenotype have a common 'core' set of connections, but can differ in the variable part, similar to protein folding where the essential set of residues is necessary for the fold, with numerous variations in the nonessential part.

Future Directions

The study of biological networks is at an early stage, both on the theoretical as well as on the experimental side. Although high-throughput experiments are generating large data sets, these can suffer from serious biases, lack of temporal or spatial detail, and limited access to the component parts of the interacting system. On a theoretical front, general analytical insights that would link dynamics with network topology are few, although for specific systems with known topology computer simulation can be of great assistance. There can be confusion about which aspects of the dynamical model have biological significance and interpretation, and which aspects are just 'temporary variables' and the 'envelope' of the proverbial back-of-the-envelope calculations that cells use to perform their biological computations on; which parts of the trajectory are functionally constrained and which ones could fluctuate considerably with no ill-effects; how much noise is tolerable in the nodes of the network and what is its correlation structure; or how the unobserved, or 'hidden,' nodes (or their modification/activity states) influence the network dynamics.

Despite these caveats, cellular networks have some advantages over biological systems of comparable complexity, such as neural networks. Due to technological developments, we are considerably closer to the complete census of the interacting molecules in a cell than we are generally to the picture of connectivity of the neural tissue. Components of the regulatory networks are simpler than neurons, which are capable of a range of complicated behaviors on different timescales. Modules and pathways often comprise smaller number of interacting elements than in neural networks, making it possible to design small but interesting synthetic circuits. Last but not least, sequence and homology can provide strong insights or be powerful tools for network inference in their own right.

Those of us who come from the traditionally quantitative sciences, such as physics, were raised with experiments in which crucial elements are isolated and controlled. In biological systems, attempts at such isolation may break the regulatory mechanisms that are essential for normal operation of the system, leaving us with a system which is in fact more variable and less controlled than we would have if we faced the full complexity of the organism. It is only recently that we have seen the development of experimental techniques that allow fully quantitative, real time measurements of the molecular events inside individual cells, and the theoretical framework into which such measurements will be fit still is being constructed. The range of theoretical approaches being explored is diverse, and it behooves us to search for those approaches which have the chance to organize our understanding of many different systems rather than being satisfied with models of particular systems. Again, there is a balance between the search for generality and the need to connect with experiments on specific networks. We have tried to give some examples of all these developments, hopefully conveying the correct combination of enthusiasm and skepticism.

Cellular Automata as Models of Parallel Computation

THOMAS WORSCH
Lehrstuhl Informatik für Ingenieure
und Naturwissenschaftler, Universität Karlsruhe,
Karlsruhe, Germany

Article Outline

Glossary

Cellular automaton The classical fine-grained parallel model introduced by John von Neumann.

Hyperbolic cellular automaton A cellular automaton resulting from a tessellation of the hyperbolic plane.

Parallel Turing machine A generalization of Turing's classical model where several control units work cooperatively on the same tape (or set of tapes).

Time complexity Number of steps needed for computing a result. Usually a function $t\colon \mathbb{N}_+ \to \mathbb{N}_+$, $t(n)$ being the maximum ("worst case") for any input of size n.

Space complexity Number of cells needed for computing a result. Usually a function $s\colon \mathbb{N}_+ \to \mathbb{N}_+$, $s(n)$ being the maximum for any input of size n.

State change complexity Number of proper state changes of cells during a computation. Usually a function $sc\colon \mathbb{N}_+ \to \mathbb{N}_+$, $sc(n)$ being the maximum for any input of size n.

Processor complexity Maximum number of control units of a parallel Turing machine which are simultaneously active during a computation. Usually a function $sc\colon \mathbb{N}_+ \to \mathbb{N}_+$, $sc(n)$ being the maximum for any input of size n.

$\mathbb{N}_+$ The set $\{1, 2, 3, \dots\}$ of positive natural numbers.

$\mathbb{Z}$ The set $\{\dots, -3, -2, -1, 0, 1, 2, 3, \dots\}$ of integers.

Q^G The set of all (total) functions from a set G to a set Q.

Definition of the Subject

This article will explore the properties of cellular automata (CA) as a parallel model.

The Main Theme

We will first look at the standard model of CA and compare it with Turing machines as the standard sequential model, mainly from a computational complexity point of view. From there we will proceed in two directions: by removing computational power and by adding computational power in different ways in order to gain insight into the importance of some ingredients of the definition of CA.

What Is Left Out

There are topics which we will not cover although they would have fit under the title.

One such topic is *parallel algorithms* for CA. There are algorithmic problems which make sense only for parallel models. Probably the most famous for CA is the so-called *Firing Squad Synchronization Problem*. This is the topic of Umeo's article (▶ Firing Squad Synchronization Problem in Cellular Automata), which can also be found in this encyclopedia.

Another such topic in this area is the Leader election problem. For CA it has received increased attention in recent years. See the paper by Stratmann and Worsch [29] and the references therein for more details.

And we do want to mention the most exciting (in our opinion) CA algorithm: Tougne has designed a CA which, starting from a single point, after t steps has generated the discretized circle of radius t, for all t; see [5] for this gem.

There are also models which generalize standard CA by making the cells more powerful. Kutrib has introduced *push-down cellular automata* [14]. As the name indicates, in this model each cell does not have a finite memory but can make use of a potentially unbounded stack of symbols.

The area of nondeterministic CA is also not covered here. For results concerning formal language recognition with these devices refer to ▶ Cellular Automata and Language Theory.

All these topics are, unfortunately, beyond the scope of this article.

Structure of the Paper

The core of this article consists of four sections:

Introduction: The main point is the standard definition of Euclidean deterministic synchronous cellular automata. Furthermore, some general aspects of parallel models and typical questions and problems are discussed.

Time and space complexity: After defining the standard computational complexity measures, we compare CA with different resource bounds. The comparison of CA with the Turing Machine (TM) gives basic insights into their computational power.

Measuring and controlling activities: There are two approaches to measure the "amount of parallelism" in CA. One is an additional complexity measured directly for CA, the other via the definition of so-called parallel Turing machines. Both are discussed.

Communication: Here we have a look at "variants" of CA with communication structures other than the one-dimensional line. We sketch the proofs that some of these variants are in the second machine class.

Introduction

In this section we will first formalize the classical model of cellular automata, basically introduced by von Neumann [21]. Afterwards we will recap some general facts about parallel models.

Definition of Cellular Automata

There are several equivalent formalizations of CA and of course one chooses the one most appropriate for the topics to be investigated. Our point of view will be that each CA consists of a regular arrangement of basic processing elements working in parallel while exchanging data.

Below, for each of the words *regular*, *basic*, *processing*, *parallel* and *exchanging*, we first give the standard definition for clarification. Then we briefly point out possible alternatives which will be discussed in more detail in later sections.

Underlying Grid A Cellular Automaton (CA) consists of a set G of cells, where each cell has at least one *neighbor* with which it can exchange data. Informally speaking one usually assumes a "regular" arrangement of cells and, in particular, identically shaped neighborhoods.

For a *d-dimensional CA*, $d \in \mathbb{N}_+$, one can think of $G = \mathbb{Z}^d$. Neighbors are specified by a finite set N of coordinate differences called the *neighborhood*. The cell $i \in G$ has as its neighbors the cells $i + n$ for all $n \in N$. Usually one assumes that $0 \in N$. (Here we write 0 for a vector of d zeros.)

As long as one is not specifically interested in the precise role N is playing, one may assume some standard neighborhood: The *von Neumann neighborhood* of radius r is $N^{(r)} = \{(k_1, \ldots, k_d) \mid \sum_j |k_j| \leq r\}$ and the *Moore neighborhood* of radius r is $M^{(r)} = \{(k_1, \ldots, k_d) \mid \max_j |k_j| \leq r\}$.

The choices of G and N determine the structure of what in a real parallel computer would be called the "communication network". We will usually consider the case $G = \mathbb{Z}^d$ and assume that the neighborhood is $N = N^{(1)}$.

Discussion The structure of connections between cells is sometimes defined using the concept of *Cayley graphs*. Refer to the article by Ceccherini–Silberstein (▶ Cellular Automata and Groups), also in this encyclopedia, for details.

Another approach is via regular tessellations. For example the 2-dimensional Euclidean space can be tiled with copies of a square. These can be considered as cells, and cells sharing an edge are neighbors. Similarly one can tile, e. g., the *hyperbolic plane* with copies of a regular k-gon. This will be considered to some extent in Sect. "Communication in CA". A more thorough exposition can be found in the article by Margenstern (▶ Cellular Automata in Hyperbolic Spaces) also in this encyclopedia.

CA resulting, for example, from tessellations of the 2-dimensional Euclidean plane with triangles or hexagons are considered in the article by Bays (▶ Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations) also in this encyclopedia.

Global and Local Configurations The basic processing capabilities of each cell are those of a finite automaton. The set of possible states of each cell, denoted by Q, is finite. As inputs to be processed each cell gets the states of all the cells in its neighborhood.

We will write Q^G for the set of all functions from G to Q. Thus each $c \in Q^G$ describes a possible global state of the whole CA. We will call these c *(global) configurations*.

On the other hand, functions $\ell\colon N \to Q$ are called *local configurations*. We say that in a configuration c cell i *observes* the local configuration $c_{i+N}\colon N \to Q$ where $c_{i+N}(n) = c(i+n)$. A cell gets its currently observed local configuration as input. It remains to be defined how they are processed.

Dynamics The dynamics of a CA are defined by specifying the local dynamics of a single cell and how cells "operate in parallel" (if at all). In the first sections we will consider the classical case:

- A *local transition function* is a function $f\colon Q^N \to Q$ prescribing for each local configuration $\ell \in Q^N$ the next state $f(\ell)$ of a cell which currently observes ℓ in its neighborhood. In particular, this means that we are considering *deterministic* behavior of cells.
- Furthermore, we will first concentrate on CA where all cells are working *synchronously*: The possible transitions from one configuration to the next one in one global step of the CA can be described by a function $F\colon Q^G \to Q^G$ requiring that *all* cells make one state transition: $\forall i \in G\colon F(c)(i) = f(c_{i+N})$.

For alternative definitions of the dynamic behavior of CA see Sect. "Measuring and Controlling the Activities".

Discussion Basically, the above definition of CA is the standard one going back to von Neumann [21]; he used $G = \mathbb{Z}^2$ and $N = \{(-1,0),(1,0),(0,-1),(0,1)\}$ for his construction. But for all of the aspects just defined there are other possibilities, some of which will be discussed in later sections.

Finite Computations on CA

In this article we are interested in using CA as devices for computing, given some finite input, in a finite number of steps a finite output.

Inputs As the prototypical examples of problems to be solved by CA and other models we will consider the recognition of formal languages. This has the advantages that the inputs have a simple structure and, more importantly, the output is only one bit (accept or reject) and can be formalized easily.

A detailed discussion of CA as formal language recognizers can be found in the article by Kutrib (▶ Cellular Automata and Language Theory).

The *input alphabet* will be denoted by A. We assume that $A \subset Q$. In addition there has to be a special state $q \in Q$ which is called a *quiescent state* because it has the property that for the quiescent local configuration $\ell_q\colon N \to Q\colon n \mapsto q$ the local transition function must specify $f(\ell_q) = q$.

In the literature two input modes are usually considered.

- Parallel input mode: For an input $w = x_1 \cdots x_n \in A^n$ the initial configuration c_w is defined as

$$c_w(i) = \begin{cases} x_j & \text{iff } i = (j, 0, \ldots, 0) \\ q & \text{otherwise .} \end{cases}$$

- Sequential input mode: In this case, all cells are in state q in the initial configuration. But cell $(0, \ldots, 0)$ is a designated *input cell* and acts differently from the others. It works according to a function $g\colon Q^N \times (A {\sim} \cup \{q\})$. During the first n steps the input cell gets input symbol x_j in step j; after the last input symbol it always gets q. CA using this type of input are often called *iterative arrays (IA)*.

Unless otherwise noted we will always assume parallel input mode.

Conceptually the difference between the two input modes has the same consequences as for TM. If input is provided sequentially it is meaningful to have a look at computations which "use" less than n cells (see the definition of space complexity later on).

Technically, some results occur only for the parallel input mode but not for the sequential one, or vice versa. This is the case, for example, when one looks at devices with small time bounds like n or $n + \sqrt{n}$ steps. But as soon as one considers more generally $\Theta(n)$ or more steps and a space complexity of at least $\Theta(n)$, both CA and IA can simulate each other in linear time:

- An IA can first read the complete input word, storing it in successive cells, and then start simulating a CA, and
- A CA can shift the whole word to the cell holding the first input symbol and have it act as the designated input cell of an IA.

Outputs Concerning output, one usually defines that a CA has finished its work whenever it has reached a *stable configuration* c, i. e., $F(c) = c$. In such a case we will also say that the CA *halts* (although formally one can continue to apply F). An input word $w \in A^+$ is *accepted*, iff the cell $(1, 0, \ldots, 0)$ which got the first input symbol, is in an *accepting* state from a designated finite subset $F_+ \subset Q$ of states. We write $L(C)$ for the set of all words $w \in A^+$ which are accepted by a CA C.

For the sake of simplicity we will assume that all deterministic machines under consideration halt for all inputs. E. g., the CA as defined above always reaches a stable configuration.

The sequence of all configurations from the initial one for some input w to the stable one is called the *computation* for input w.

Discussion For 1-dimensional CA the definition of parallel input is the obvious one. For higher-dimensional CA, say $G = \mathbb{Z}^2$, one could also think of more compact forms of input for one-dimensional words, e. g., inscribing the input symbols row by row into a square with side length $\lceil\sqrt{n}\rceil$. But this requires extra care. Depending on the formal language to be accepted, the special way in which the symbols are input might provide additional information which is useful for the language recognition task at hand.

Since a CA performs work on an infinite number of bits in each step, it would also be possible to consider inputs and outputs of infinite length, e. g., as representations of all real numbers in the interval $[0, \dots, 1]$. There is much less literature about this aspect; see for example chapter 11 of [8].

It is not too surprising that this area is also related to the view of CA as dynamical systems (instead of computers); see the contributions by Formenti (▶ Chaotic Behavior of Cellular Automata) and Kůrka (▶ Topological Dynamics of Cellular Automata).

Example: Recognition of Palindromes As an example that will also be useful later, consider the formal language L_{pal} of palindromes of odd length:

$$L_{\text{pal}} = \{vxv^R \mid v \in A^* \wedge x \in A\} \, .$$

(Here v^R is the mirror image of v.) For example, if A contains all Latin letters `saippuakauppias` belongs to L_{pal} (the Finnish word for a soap dealer).

It is known that each $\mathbb{T}$ − TM with only one tape and only one head on it (see Subsect. "Turing Machines" for a quick introduction) needs time $\Omega(n^2)$ for the recognition of at least some inputs of length n belonging to L_{pal} [10].

We will sketch a CA recognizing L_{pal} in time $\Theta(n)$. As the set of states for a single cell we use $Q = A \cup \{\sqcup\} \cup Q_l \times Q_r \times Q_v \times Q_{lr}$, basically subdividing each cell in 4 "registers", each containing a "substate". The substates from $Q_l = \{\texttt{<a}, \texttt{<b}, \sqcup\}$ and $Q_r = \{\texttt{a>}, \texttt{b>}, \sqcup\}$ are used to shift input symbols to the left and to the right respectively. In the third register a substate from $Q_v = \{+, -\}$ indicates the results of comparisons. In the fourth register substates from $Q_{lr} = \{\texttt{>}, \texttt{<}, \texttt{<+>}, \texttt{<->}, \sqcup\}$ are used to realize "signals" > and < which identify the middle cell and distribute the relevant overall comparison result to all cells.

As accepting states one chooses those, whose last component is <+>: $F_+ = Q_l \times Q_r \times Q_v \times \{\texttt{<+>}\}$.

There is a total of $3 + 3 \cdot 3 \cdot 2 \cdot 5 = 93$ states and for a complete definition of the local transition function one would have to specify $f(x, y, z)$ for $93^3 = 804357$ triples of states. We will not do that, but we will sketch some important parts. In the first step the registers are initialized. For all $x, y, z \in A$:

$\ell(-1)$	$\ell(0)$	$\ell(1)$	$f(\ell)$
$\sqcup$	y	z	$(\texttt{<}y, y\texttt{>}, +, \texttt{>})$
x	y	z	$(\texttt{<}y, y\texttt{>}, +, \sqcup)$
x	y	$\sqcup$	$(\texttt{<}y, y\texttt{>}, +, \texttt{<})$
$\sqcup$	y	$\sqcup$	$(\texttt{<}y, y\texttt{>}, +, \texttt{<+>})$

In all later steps, if

$$\ell(-1) = \boxed{\begin{array}{r} < x_l \\ x_r > \\ v_l \\ d_l \end{array}} \qquad \ell(0) = \boxed{\begin{array}{r} < y_l \\ y_r > \\ v_m \\ d_m \end{array}} \qquad \ell(1) = \boxed{\begin{array}{r} < z_l \\ z_r > \\ v_r \\ d_r \end{array}}$$

then

$$f(\ell) = \boxed{\begin{array}{r} < z_l \\ x_r > \\ v'_m \\ d'_m \end{array}}$$

Here, of course, the new value of the third register is computed as

$$v'_m = \begin{cases} + & \text{if } v_m = + \wedge z_l = x_r \\ - & \text{otherwise} \, . \end{cases}$$

We do not describe the computation of d'_m in detail. Figure 1 shows the computation for the input `babbbab`, which is a palindrome. Horizontal double lines separate configurations at subsequent time steps. Registers in state $\sqcup$ are simply left empty.

As can be seen there is a triangle in the space time diagram consisting of the n input cells at time $t = 0$ and shrinking at both ends by one cell in each subsequent step where "a lot of activity" can happen due to the shifting of the input symbols in both directions.

Clearly a two-head TM can also recognize L_{pal} in linear time, by first moving one head to the last symbol and then synchronously shifting both heads towards each other comparing the symbols read.

Informally speaking in this case the ability of multihead TM to transport a small amount of information over

...		b	a	b	b	b	a	b		...

Cellular Automata as Models of Parallel Computation, Figure 1
Recognition of a palindrome; the last configuration is stable and the cell which initially stored the first input symbol is in an accepting state

a long distance in one step can be "compensated" by CA by shifting a large amount of information over a short distance. We will see in Theorem 3 that this observation can be generalized.

Complexity Measures: Time and Space For one-dimensional CA it is straightforward to define their time and space complexity. We will consider only worst-case complexity. Remember that we assume that all CA halt for all inputs (reach a stable configuration).

For $w \in A^+$ let $\text{time}'(w)$ denote the smallest number τ of steps such that the CA reaches a stable configuration after τ steps when started from the initial configuration for input w. Then

$$\text{time}\colon \mathbb{N}_+ \to \mathbb{N}_+ : n \mapsto \max\{\text{time}'(w) \mid w \in A^n\}$$

is called the *time complexity* of the CA.

Similarly, let $\text{space}'(w)$ denote the total number of cells which are not quiescent in at least one configuration occurring during the computation for input w. Then

$$\text{space}\colon \mathbb{N}_+ \to \mathbb{N}_+ : n \mapsto \max\{\text{space}'(w) \mid w \in A^n\}$$

is called the *space complexity* of the CA. If we want to mention a specific CA C, we indicate it as an index, e. g., time_C.

If s and t are functions $\mathbb{N}_+ \to \mathbb{N}_+$, we write $\text{CA} - \text{Spc}(s) - \text{Time}(t)$ for the set of formal languages which can be accepted by some CA C with $\text{space}_C \leq s$ and $\text{time}_C \leq t$, and analogously $\text{CA} - \text{Spc}(s)$ and $\text{CA} - \text{Time}(t)$ if only one complexity measure is bounded. Thus we only look at upper bounds. For a whole set of functions $\mathcal{T}$, we will use the abbreviation

$$\text{CA} - \text{Time}(\mathcal{T}) = \bigcup_{t \in \mathcal{T}} \text{CA} - \text{Time}(f)\,.$$

Typical examples will be $\mathcal{T} = \text{O}(n)$ or $\mathcal{T} = \text{Pol}(n)$, where in general $\text{Pol}(f) = \bigcup_{k \in \mathbb{N}_+} \text{O}(f^k)$.

Resource bounded complexity classes for other computational models will be noted similarly. If we want to make the dimension of the CA explicit, we write $\mathbb{Z}^d - \text{CA} - \ldots$; if the prefix $\mathbb{Z}^d$ is missing, $d = 1$ is to be assumed.

Throughout this article n will always denote the length of input words. Thus a time complexity of $\text{Pol}(n)$ simply means polynomial time, and similarly for space, so that $\text{TM} - \text{Time}(\text{Pol}(n)) = \mathbf{P}$ and $\text{TM} - \text{Spc}(\text{Pol}(n)) = \mathbf{PSPACE}$.

Discussion For higher-dimensional CA the definition of space complexity requires more consideration. One possibility is to count the number of cells used during the computation. A different, but sometimes more convenient approach is to count the number of cells in the smallest hyper-rectangle comprising all used cells.

Turing Machines

For reference, and because we will consider a parallel variant, we set forth some definitions of Turing machines.

In general we allow Turing machines with k work tapes and h heads on each of them. Each square carries a symbol from the *tape alphabet* B which includes the blank symbol $\square$. The control unit (CU) is a finite automaton with *set of states* S. The possible actions of a deterministic TM are described by a function $f\colon S \times B^{kh} \to S \times B^{kh} \times D^{kh}$, where $D = \{-1, 0, +1\}$ is used for indicating the direction of movement of a head.

If the machine reaches a situation in which $f(s, b_1, \ldots, b_{kh}) = (s, b_1, \ldots, b_{kh}, 0, \ldots, 0)$ for the current state s and the currently scanned symbols $b_1, \ldots, b_{kh}$, we say that it halts.

Initially a word w of length n over the input alphabet $A \subset B$ is written on the first tape on squares $1, \ldots, n$, all other tape squares are empty, i. e., carry the $\square$. An input is *accepted* if the CU halts in an accepting state from a designated subset $F_+ \subset S$. $L(T)$ denotes the formal language of all words accepted by a TM T.

We write $k\mathbb{T}h - \mathrm{TM} - \mathrm{SPC}(s) - \mathrm{TIME}(t)$ for the class of all formal languages which can be recognized by TM T with k work tapes and h heads on each of them which have a space complexity $\mathrm{space}_T \leq s$ and $\mathrm{time}_T \leq t$. If k and/or h is missing, 1 is assumed instead. If the whole prefix $k\mathbb{T}h$ is missing, $\mathbb{T}$ is assumed. If arbitrary k and h are allowed, we write $*\mathbb{T}*$.

Sequential Versus Parallel Models

Today quite a number of different computational models are known which intuitively look as if they are parallel. Several years ago van Emde Boas [6] observed that many of these models have one property in common. The problems that can be solved in polynomial *time* on such a model $\mathcal{P}$, coincide with the problems that can be solved in polynomial *space* on Turing machines:

$$\mathcal{P} - \mathrm{TIME}(\mathrm{Pol}(n)) = \mathrm{TM} - \mathrm{SPC}(\mathrm{Pol}(n)) = \mathbf{PSPACE} .$$

Here we have chosen $\mathcal{P}$ as an abbreviation for "parallel" model. Models $\mathcal{P}$ satisfying this equality are by definition the members of the so-called *second machine class*.

On the other hand, the *first machine class* is formed by all models S satisfying the relation

$$S - \mathrm{SPC}(s) - \mathrm{TIME}(t) = \mathrm{TM} - \mathrm{SPC}(\Theta(s)) - \mathrm{TIME}(\mathrm{Pol}(t))$$

at least for some reasonable functions s and t. We deliberately avoid making this more precise. In general there is consensus on which models are in the these machine classes.

We do want to point out that the naming of the two machine classes does *not* mean that they are different or even disjoint. This is not known. For example, if $\mathbf{P} = \mathbf{PSPACE}$, it might be that the classes coincide. Furthermore there are models, e. g., Savitch's NLPRAM [25], which might be in neither machine class.

Another observation is that in order to possibly classify a machine model it obviously has to have something like "time complexity" and/or "space complexity". This may sound trivial, but we will see in Subsect. "Parallel Turing Machines" that, for example, for so-called parallel Turing machines with several work tapes it is in fact not.

Time and Space Complexity

Comparison of Resource Bounded One-Dimensional CA

It is clear that time and space complexity for CA are Blum measures [2] and hence infinite hierarchies of complexity classes exist. It follows from the more general Theorem 9 for parallel Turing machines that the following holds:

Theorem 1 *Let s and t be two functions such that s is fully CA space constructable in time t and t is CA computable in space s and time t. Then:*

$$\bigcup_{\gamma \notin \mathrm{O}(1)} \mathrm{CA} - \mathrm{SPC}(\Theta(s/\gamma)) - \mathrm{TIME}(\Theta(t/\gamma)) \subsetneqq \mathrm{CA} - \mathrm{SPC}(\mathrm{O}(s)) - \mathrm{TIME}(\mathrm{O}(t))$$

$$\mathrm{CA} - \mathrm{SPC}(o(s)) - \mathrm{TIME}(o(t)) \subsetneqq \mathrm{CA} - \mathrm{SPC}(\mathrm{O}(s)) - \mathrm{TIME}(\mathrm{O}(t))$$

$$\mathrm{CA} - \mathrm{TIME}(o(t)) \subsetneqq \mathrm{CA} - \mathrm{TIME}(\mathrm{O}(t)) .$$

The second and third inclusion are simple corollaries of the first one. We do not go into the details of the definition of CA constructibility, but note that for hierarchy results for TM one sometimes needs analogous additional conditions. For details, interested readers are referred to [3,12,17].

We not that for CA the situation is better than for deterministic TM: there one needs $f(n)\log f(n) \in o(g(n))$ in order to prove $\mathrm{TM} - \mathrm{TIME}(f) \subsetneqq \mathrm{TM} - \mathrm{TIME}(g)$.

Open Problem 2 For the proper inclusions in Theorem 1 the construction used in [34] really needs to increase the space used in order to get the time hierarchy. It is an open problem whether there also exists a time hierarchy if the space complexity is *fixed*, e. g., as $s(n) = n$. It is even an open problem to prove or disprove that the inclusion

$$\mathrm{CA} - \mathrm{SPC}(n) - \mathrm{TIME}(n) \subseteq \mathrm{CA} - \mathrm{SPC}(n) - \mathrm{TIME}(2^{\mathrm{O}(n)}) .$$

is proper or not. We will come back to this topic in Subsect. "Parallel Turing Machines" on parallel Turing machines.

Comparison with Turing Machines

It is well-known that a TM with one tape and one head on that tape can be simulated by a one-dimensional CA. See for example the paper by Smith [27]. But even multi-tape TM can be simulated by a one-dimensional CA without any significant loss of time.

Theorem 3 *For all space bounds $s(n) \geq n$ and all time bounds $t(n) \geq n$ the following holds for one-dimensional CA and TM with an arbitrary number of heads on its tapes:*

$$* \mathbb{T} * - \mathrm{TM} - \mathrm{SPC}(s) - \mathrm{TIME}(t) \subseteq \mathrm{CA} - \mathrm{SPC}(s) - \mathrm{TIME}(\mathrm{O}(t)) .$$

Sketch of the Simulation We first describe a simulation for $1\mathbb{T}1 - \mathrm{TM}$.

In this case the actions of the TM are of the form $s, b \to s', b', d$ where $s, s' \in S$ are old and new state, $b, b' \in B$ old and new tape symbol and $d \in \{-1, 0, +1\}$ the direction of *head* movement.

The simulating CA uses three substates in each cell, one for a TM state, one for a tape symbol, and an additional one for shifting tape symbols: $Q = Q_S \times Q_T \times Q_M$. We use $Q_S = S \cup \{\text{␣}\}$ and a substate of ␣ means, that the cell does not store a state. Similarly $Q_T = B \cup \{ < \circ, \circ > \}$ and a substate of $< \circ$ or $\circ >$ means that there is no symbol stored but a "hole" to be filled with an adjacent symbol. Substates from $Q_S = B \times \{ <, > \}$, like $< b$ and $b >$, are used for shifting symbols from one cell to the adjacent one to the left or right.

Instead of moving the state one cell to the right or left whenever the TM moves its head, the tape contents as stored in the CA are shifted in the opposite direction. Assume for example that the TM performs the following actions:

- s0,d $\to$ s1, d$'$, +1
- s1,e $\to$ s2, e$'$, −1
- s2,d$'$ $\to$ s3, d$''$, −1
- s3,c $\to$ s4, c$'$, +1

Figure 2 shows how shifting the tape in direction d can be achieved by sending the current symbol in that direction and sending a "hole" $\circ$ in the opposite direction $-d$. It should be clear that the required state changes of each cell depend only on information available *in its neighborhood*.

A consequence of this approach to incrementally shift the tape contents is that it takes an arbitrary large number of steps until all symbols have been shifted. On the other hand, after only *two* steps the cell simulating the TM control unit has information about the next symbol visited and can simulate the next TM step and initialize the next tape shift.

Clearly the same approach can be used if one wants to simulate a TM with several tapes, each having one head. For each additional tape the CA would use two additional registers analogously to the middle and bottom row used in Fig. 2 for one tape. Stoß [28] has proved that $k\mathbb{T}\,h - \text{TM}$ (h heads on each tape) can be simulated by $(kh)\mathbb{T} - \text{TM}$ (only one head on each tape) in linear time. Hence there is nothing left to prove.

Discussion As one can see in Fig. 2, in every second step one signal is sent to the left and one to the right. Thus, if the TM moves its head a lot and if the tape segment which has to be shifted is already long, many signals are traveling simultaneously.

Cellular Automata as Models of Parallel Computation, Figure 2
Shifting tape contents step by step

In other words, the CA transports "a large amount of information over a short distance in one step". Theorem 3 says that this ability is at least as powerful as the ability of multi-head TM to transport "a small amount of information over a long distance in one step".

Open Problem 4 The question remains whether some kind of converse also holds and in Theorem 3 an $=$ sign would be correct instead of the $\subseteq$, or whether CA are more powerful, i. e., a $\subsetneq$ sign would be correct. This is not known.

The best simulation of CA by TM that is known is the obvious one: states of neighboring cells are stored on adjacent tape squares. For the simulation of one CA step the TM basically makes one sweep across the complete tape segment containing the states of all non-quiescent cells updating them one after the other. As a consequence one gets

Theorem 5 *For all space bounds $s(n) \geq n$ and all time bounds $t(n) \geq n$ holds:*

$$\begin{aligned} \text{CA} - \textsc{Spc}(s) - \textsc{Time}(t) &\subseteq \text{TM} - \textsc{Spc}(s) - \textsc{Time}(\mathrm{O}(s \cdot t)) \\ &\subseteq \text{TM} - \textsc{Spc}(s) - \textsc{Time}\left(\mathrm{O}\left(t^2\right)\right) . \end{aligned}$$

The construction proving the first inclusion needs only a one-head TM, and no possibility is known to take advantage of more heads. The second inclusion follows from the observation that in order to use an initially blank tape square, a TM must move one of its heads there, which requires time. Thus $s \in \mathrm{O}(t)$.

Taking Theorems 3 and 5 together, one immediately gets

Corollary 6 *Cellular automata are in the first machine class.*

And it is not known that CA are in the second machine class. In this regard they are "more like" sequential models. The reason for this is the fact, the number of active processing units only grows polynomially with the number of steps in a computation. In Sect. "Communication in CA" variations of the standard CA model will be considered, where this is different.

Measuring and Controlling the Activities

Parallel Turing Machines

One possible way to make a parallel model from Turing machines is to allow several control units (CU), but with all of them working on the same tape (or tapes). This model can be traced back at least to a paper by Hemmerling [9] who called it *Systems of Turing automata*. A few years later Wiedermann [32] coined the term *Parallel Turing machine* (PTM).

We consider only the case where there is only one tape and each of the control units has only one head on that tape. As for sequential TM, we usually drop the prefix $1\mathbb{T}1$ for PTM, too. Readers interested in the case of PTM with multi-head CUs are referred to [33].

PTM with One-Head Control Units The specification of a PTM includes a tape alphabet B with a blank Cybil $\square$ and a set S of possible states for each CU. A PTM starts with one CU on the first input symbol as a sequential $1\mathbb{T}1-\text{TM}$. During the computation the number of control units may increase and decrease, but all CUs always work cooperatively on one common tape.

The idea is to have the CUs act independently unless they are "close" to each other, retaining the idea of only local interactions, as in CA.

A *configuration* of a PTM is a pair $c = (p, b)$. The mapping $b\colon \mathbb{Z} \to B$ describes the contents of the tape. Let 2^S denote the power set of S. The mapping $p\colon \mathbb{Z} \to 2^S$ describes for each tape square i the set of states of the finite automata currently visiting it. In particular, this formalization means that it is not possible to distinguish two automata on the same square and in the same state: the idea is that because of that they will always behave identically and hence need not be distinguished.

The mode of operation of a PTM is determined by the *transition function* $f\colon 2^Q \times B \to 2^{Q\times D} \times B$ where D is the set $\{-1, 0, 1\}$ of possible movements of a control unit. In order to compute the successor configuration $c' = (p', b')$ of a configuration $c = (p, b)$, f is simultaneously computed for all tape positions $i \in \mathbb{Z}$. The arguments used are the set of states of the finite automata currently visiting square i and its tape symbol. Let $(M'_i, b'_i) = f(p(i), b(i))$. Then the new symbol on square i in configuration c' is $b'(i) = b'_i$. The set of finite automata on square i is replaced by a new set of finite automata (defined by $M'_i \subseteq Q \times D$) each of which changes the tape square according to the indicated direction of movement. Therefore $p'(i) = \{q \mid (q, 1) \in M'_{i-1} \vee (q, 0) \in M'_i \vee (q, -1) \in M'_{i+1}\}$. Thus f induces a global transition function F mapping global configurations to global configurations.

In order to make the model useful (and to come up to some intuitive expectations) it is required, that CUs cannot arise "out of nothing" and that the symbol on a tape square can change only if it is visited by at least one CU. In other words we require that $\forall\, b \in B\colon\ f(\emptyset, b) = (\emptyset, b)$.

Observe that the number of finite automata on the tape may change during a computation. Automata may vanish, for example if $f(\{s\}, b) = (\emptyset, b)$ and new automata may be generated, for example if $f(\{s\}, b) = (\{(q, 1), (q', 0)\}, b)$.

For the recognition of formal languages we define the *initial configuration* c_w for an input word $w \in A^+$ as the one in which w is written on the otherwise blank tape on squares $1, 2, \dots, |w|$, and in which there exists exactly one finite automaton in an initial state q_0 on square 1.

A configuration (p, b) of aPTM is called *accepting* iff it is stable (i. e. $F((p, b)) = (p, b)$) and $p(1) \subseteq F_+$. The *language $L(P)$ recognized by a* PTM P is the set of input words, for which it reaches an accepting configuration.

Complexity Measures for PTM Time complexity of a PTM can be defined in the obvious way.

For space complexity, one counts the total number of tape squares which are used in at least one configuration. Here we call a tape square i *unused* in a configuration $c = (p, b)$ if $p(i) = \emptyset$ and $b(i) = \square$; otherwise it is used.

What makes PTM interesting is the definition of its *processor complexity*. Let $\text{proc}'(w)$ denote the maximum number of CU which exist simultaneously in a configuration occurring during the computation for input w and define $\text{proc}\colon \mathbb{N}_+ \to \mathbb{N}_+\colon n \mapsto \max\{\text{proc}'(w) \mid w \in A^n\}$. For complexity classes we use the notation $\text{PTM}-\textsc{Spc}(s)-\textsc{Time}(t)-\textsc{Proc}(p)$ etc.

The processor complexity is one way to measure (an upper bound on) "how many activities" happened simultaneously. It should be clear that at the lower end one has the case of constant $\text{proc}(n) = 1$, which means that the PTM is in fact (equivalent to) a sequential TM. The other extreme is to have CUs "everywhere". In that case

$\text{proc}(n) \in \Theta(\text{space}(n))$, and one basically has a CA. In other words, processor complexity measures the mount of parallelism of a PTM.

Theorem 7 *For all space bounds s and time bounds t:*

$$\begin{aligned}\text{PTM} - \text{Spc}(s) - \text{Time}(t) - \text{Proc}(1) \\ &= \text{TM} - \text{Spc}(s) - \text{Time}(t) \\ \text{PTM} - \text{Spc}(s) - \text{Time}(t) - \text{Proc}(s) \\ &= \text{CA} - \text{Spc}(s) - \text{Time}(\text{O}(t))\,.\end{aligned}$$

Under additional constructibility conditions it is even possible to get a generalization of Theorem 5:

Theorem 8 *For all functions $s(n) \geq n$, $t(n) \geq n$, and $h(n) \geq 1$, where h is fully* PTM *processor constructable in space s, time t, and with h processors, holds:*

$$\begin{aligned}&\text{CA} - \text{Spc}(\text{O}(s)) - \text{Time}(\text{O}(t)) \\ &\subseteq \text{PTM}-\text{Spc}(\text{O}(s))-\text{Time}(\text{O}(st/h))-\text{Proc}(\text{O}(h)).\end{aligned}$$

Decreasing the processor complexity indeed leads to the expected slowdown.

Relations Between PTM Complexity Classes (part 1) The interesting question now is whether different upper bounds on the processor complexity result in different computational power. In general that is not the case, as PTM with only one CU are TM and hence computationally universal. (As a side remark we note that therefore processor complexity cannot be a Blum measure. In fact that should be more or less clear since, e. g., deciding whether a second CU will ever be generated might require finding out whether the first CU, i. e., a TM, ever reaches a specific state.)

In this first part we consider the case where two complexity measures are allowed to grow in order to get a hierarchy. Results which only need one growing measure are the topic of the second part.

First of all it turns out that for fixed processor complexity between $\log n$ and $s(n)$ there is a space/time hierarchy:

Theorem 9 *Let s and t be two functions such that s is fully* PTM *space constructable in time t and t is* PTM *computable in space s and time t and let $h \geq \log$. Then:*

$$\begin{aligned}\bigcup_{\gamma \notin \text{O}(1)} \text{PTM} - \text{Spc}(\Theta(s/\gamma)) - \text{Time}(\Theta(t/\gamma)) \\ - \text{Proc}(\text{O}(h)) \\ \subsetneqq \text{PTM} - \text{Spc}(\text{O}(s)) - \text{Time}(\text{O}(t)) - \text{Proc}(\text{O}(h))\,.\end{aligned}$$

The proof of this theorem applies the usual idea of diagonalization. Technical details can be found in [34].

Instead of keeping processor complexity fixed and letting space complexity grow, one can also do the opposite. As for analogous results for TM, one needs the additional restriction to one *fixed tape alphabet*. One gets the following result, where the complexity classes carry the additional information about the size of the tape alphabet.

Theorem 10 *Let s, t and h be three functions such that s is fully* PTM *space constructable in time t and with h processors, and that t and h are* PTM *computable in space s and time t and with h processors such that in all cases the tape is not written. Let $b \geq 2$ be the size of the tape alphabet. Then:*

$$\begin{aligned}\bigcup_{\gamma \notin \text{O}(1)} \text{PTM} - \text{Spc}(s) - \text{Time}\Theta(t/\gamma) - \text{Proc}(h/\gamma) \\ - \text{Alph}(b) \\ \subsetneqq \text{PTM} - \text{Spc}(s) - \text{Time}(\Theta(st)) - \text{Proc}(\Theta(h)) \\ - \text{Alph}(b)\,.\end{aligned}$$

Again we do not go into the details of the constructibility definitions which can be found in [34]. The important point here is that one can prove that increasing time and processor complexity by a non-constant factor does increase the (language recognition) capabilities of PTM, even if the space complexity is fixed, provided that one does not allow any changes to the tape alphabet. In particular the theorem holds for the case $\text{space}(n) = n$.

It is now interesting to reconsider Open Problem 2. Let's *assume* that

$$\text{CA} - \text{Spc}(n) - \text{Time}(n) = \text{CA} - \text{Spc}(n) - \text{Time}(2^{\text{O}(n)})\,.$$

One may choose $\gamma(n) = \log n$, $t(n) = 2^{n/\log n}$ and $h(n) = n$ in Theorem 10. Using that together with Theorem 7 the assumption would give rise to

$$\begin{aligned}\text{PTM} - \text{Spc}(n) - \text{Time}\left(\frac{2^{n/\log n}}{\log n}\right) - \text{Proc}\left(\frac{n}{\log n}\right) \\ - \text{Alph}(b) \\ \subsetneqq \text{PTM} - \text{Spc}(n) - \text{Time}(n2^{n/\log n}) - \text{Proc}(n) \\ - \text{Alph}(b) \\ = \text{PTM} - \text{Spc}(n) - \text{Time}(n) - \text{Proc}(n) \\ - \text{Alph}(b)\,.\end{aligned}$$

If the polynomial time hierarchy for n-space bounded CA collapses, then there are languages which cannot be recognized by PTM in almost exponential time with $n/\log n$ processors but which can be recognized by PTM with n processors in linear time, *if the tape alphabet is fixed*.

Relations Between PTM Complexity Classes (part 2) One can get rid of the fixed alphabet condition by using a combinatorial argument for a specific formal language (instead of diagonalization) and even have not only the space but also the processor complexity fixed and still get a time hierarchy. The price to pay is that the range of time bounds is more restricted than in Theorem 10.

Consider the formal language

$$L_{\mathrm{vv}} = \left\{ v\mathtt{c}^{|v|}v \mid v \in \{\mathtt{a},\mathtt{b}\}^{+} \right\} .$$

It contains all words which can be divided into three segments of equal length such that the first and third are identical. Intuitively whatever type of machine is used for recognition, it is unavoidable to "move" the complete information from one end to the other. L_{vv} shares this feature with L_{pal}.

Using a counting argument inspired by Hennie's concept of crossing sequences [10] applied to L_{pal}, one can show:

Lemma 11 ([34]) *If P is a PTM recognizing L_{vv}, then* $\mathrm{time}_P^2 \cdot \mathrm{proc}_P \in \Omega(n^3/\log^2 n)$.

On the other hand, one can construct a PTM recognizing L_{vv} with processor complexity n^a for sufficiently nice a:

Lemma 12 ([34]) *For each $a \in \mathbb{Q}$ with $0 < a < 1$ holds:*

$$L_{\mathrm{vv}} \in \mathrm{PTM{-}S}{\small PC}(n)\mathrm{{-}T}{\small IME}\left(\Theta\left(n^{2-a}\right)\right)\mathrm{{-}P}{\small ROC}\left(\Theta\left(n^{a}\right)\right) .$$

Putting these lemmas together yields another hierarchy theorem:

Theorem 13 *For rational numbers $0 < a < 1$ and $0 < \varepsilon < 3/2 - a/2$ holds:*

$$\begin{aligned} &\mathrm{PTM} - \mathrm{S}{\small PC}(n) - \mathrm{T}{\small IME}\left(\Theta\left(n^{3/2-a/2-\varepsilon}\right)\right) \\ &\qquad\qquad - \mathrm{P}{\small ROC}\left(\Theta\left(n^{a}\right)\right) \\ &\subsetneqq \mathrm{PTM} - \mathrm{S}{\small PC}(n) - \mathrm{T}{\small IME}\left(\Theta\left(n^{2-a}\right)\right) \\ &\qquad\qquad - \mathrm{P}{\small ROC}\left(\Theta\left(n^{a}\right)\right) . \end{aligned}$$

Hence, for a close to 1 a "small" increase in time by some $n^{\varepsilon'}$ suffices to increase the recognition power of PTM while the processor complexity is fixed at n^a and the space complexity is fixed at n as well.

Open Problem 14 For the recognition of L_{vv} there is a gap between the lower bound of $\mathrm{time}_P^2 \cdot \mathrm{proc}_P \in \Omega(n^3/\log^2 n)$ in Lemma 11 and the upper bound of $\mathrm{time}_P^2 \cdot \mathrm{proc}_P \in \mathrm{O}(n^{4-a})$ in Lemma 12. It is not known whether the upper or the lower bound or both can be improved.

An even more difficult problem is to prove a similar result for the case $a = 1$, i. e., cellular automata, as mentioned in Open Problem 2.

State Change Complexity

In CMOS technology, what costs most of the energy is to make a *proper state change*, from zero to one or from one to zero. Motivated by this fact Vollmar [30] introduced the state change complexity for CA.

There are two variants based on the same idea: Given a halting CA computation for an input w and a cell i one can count the number of time points τ, $1 \leq \tau \leq \mathrm{time}'(w)$, such that cell i is in different states at times $\tau - 1$ and τ. Denote that number by $\mathrm{change}'(w, i)$. Define

$$\mathrm{maxchg}'(w) = \max_{i \in G} \mathrm{change}'(w, i) \quad \text{and}$$
$$\mathrm{sumchg}'(w) = \sum_{i \in G} \mathrm{change}'(w, i)$$

and

$$\mathrm{maxchg}(n) = \max\{\mathrm{maxchg}'(w) \mid w \in A^n\}$$
$$\mathrm{sumchg}(n) = \max\{\mathrm{sumchg}'(w) \mid w \in A^n\} .$$

For the language L_{vv} which already played a role in the previous subsection one can show:

Lemma 15 *Let $f(n)$ be a non-decreasing function which is not in $\mathrm{O}(\log n)$, i. e., $\lim_{n\to\infty} \log n / f(n) = 0$. Then any CA C recognizing L_{vv} makes a total of at least $\Omega(n^2/f(n))$ state changes in the segment containing the n input cells and n cells to the left and to the right of them.*

In particular, if $\mathrm{time}_C \in \Theta(n)$, then $\mathrm{sumchg}_C \in \Omega(n^2/f(n))$.

Furthermore $\mathrm{maxchg}_C \in \Omega(n/f(n))$.

In the paper by Sanders et al. [24] a generalization of this lemma to d-dimensional CA is proved.

Open Problem 16 While the processor complexity of PTM measures how many activities happen simultaneously "across space", state change complexity measures how many activities happen over time. For both cases we have made use of the same formal language in proofs. That might be an indication that there are connections between the two complexity measures. But no non-trivial results are known until now.

Asynchronous CA

Until now we have only considered one global mode of operation: the so-called *synchronous* case, where in each global step of the CA all cells must update their states synchronously. Several models have been considered where this requirement has been relaxed.

Generally speaking, asynchronous CA are characterized by the fact that in one global step of the CA *some* cells are active and do update their states (all according to the same local transition function) while others do nothing, i. e., remain in the same state as before. There are then different approaches to specify some restrictions on which cells may be active or not.

Asynchronous update mode. The simplest possibility is to not quantify anything and to say that a configuration c' is a legal successor of configuration c, denoted $c \vdash c'$, iff for all $i \in G$ one has $c'(i) = c(i)$ or $c'(i) = f(c_{i+N})$.

Unordered sequential update mode. In this special case it is required that there is only one active cell in each global step, i. e., $\text{card}(\{i | c'(i) \neq c(i)\}) \leq 1$.

Since CA with an asynchronous update mode are no longer deterministic from a global (configuration) point of view, it is not completely clear how to define, e. g., formal language recognition and time complexity. Of course one could follow the way it is done for nondeterministic TM. To the best of our knowledge this has not considered for asynchronous CA. (There are results for general nondeterministic CA; see for example ► Cellular Automata and Language Theory.)

It should be noted that Nakamura [20] has provided a very elegant construction for simulating a CA C_s with synchronous update mode on a CA C_a with one of the above asynchronous update modes. Each cell stores the "current" and the "previous" state of a C_s-cell before its last activation and a counter value T modulo 3 ($Q_a = Q_s \times Q_s \times \{0, 1, 2\}$). The local transition function f_a is defined in such a way that an activated cell does the following:

- T always indicates how often a cell has already been updated modulo 3.
- If the counters of all neighbors have value T or $T + 1$, the current C_s-state of the cell is remembered as previous state and a new current state is computed according to f_s from the current and previous C_s-states of the neighbors; the selection between current and previous state depends on the counter value of that cell. In this case the counter is incremented.
- If the counter of at least one neighboring cell is at $T - 1$, the activated cell keeps its complete state as it is.

Therefore, if one does want to gain something using asynchronous CA, their local transition functions would have to be designed for that specific usage.

Recently, interest has increased considerably in CA where the "degree of (a-)synchrony" is quantified via probabilities. In these cases one considers CA with only a finite number of cells.

Probabilistic update mode. Let $0 \leq \alpha \leq 1$ be a probability. In probabilistic update mode each legal global step $c \vdash c'$ of the CA is assigned a probability by requiring that each cell i independently has a probability α of updating its state.

Random sequential update mode. This is the case when in each global step one of the cells in G is chosen with even probability and its state updated, while all others do not change their state. CA operating in this mode are called *fully asynchronous* by some authors.

These models can be considered special cases of what is usually called *probabilistic* or *stochastic CA*. For these CA the local transition function is no longer a map from Q^N to Q, but from Q^N to $[0; 1]^Q$. For each $\ell \in Q^N$ the value $f(\ell)$ is a probability distribution for the next state (satisfying $\sum_{q \in Q} f(\ell)(q) = 1$). There are only very few papers about formal language recognition with probabilistic CA; see [18].

On the other hand, probabilistic update modes have received some attention recently. See for example [22] and the references therein. Development of this area is still at its beginning. Until now, specific local rules have mainly been investigated; for an exception see [7].

Communication in CA

Until now we have considered only one-dimensional Euclidean CA where one bit of information can reach $O(t)$ cells in t steps. In this section we will have a look at a few possibilities for changing the way cells communicate in a CA.

First we have a quick look at CA where the underlying grid is $\mathbb{Z}^d$. The topic of the second subsection is CA where the cells are connected to form a tree.

Different Dimensionality

In $\mathbb{Z}^d$ − CA with, e. g., von Neumann neighborhood of radius 1, a cell has the potential to influence $O(t^d)$ cells in t steps. This is a polynomial number of cells. It comes as no surprise that

$$\mathbb{Z}^d - \text{CA} - \textsc{Spc}(s) - \textsc{Time}(t) \subseteq \text{TM} - \textsc{Spc}(\text{Pol}(s)) - \textsc{Time}(\text{Pol}(t))$$

and hence $\mathbb{Z}^d - \text{CA}$ are in the first machine class. One might only wonder why for the TM a space bound of $\Theta(s)$ might not be sufficient. This is due to the fact that the shape of the cells actually used by the CA might have an "irregular" structure and that the TM has to perform some bookkeeping or simulate a whole (hyper-)rectangle of cells encompassing all that are really used by the CA.

Trivially, a d-dimensional CA can be simulated on a d'-dimensional CA, where $d' > d$. The question is how much one loses when *decreasing* the dimensionality. The currently known best result in this direction is by Scheben [26]:

Theorem 17 *It is possible to simulate a d'-dimensional CA with running time t on a d-dimensional CA, $d < d'$ with running time and space* $\mathrm{O}(t^{2^{\mathrm{ld}\lceil d'/d \rceil}})$.

It should be noted that the above result is not directly about language recognition; the redistribution of input symbols needed for the simulation is not taken into account. Readers interested in that as well are referred to [1].

Open Problem 18 Try to find simulations of lower on higher dimensional CA which somehow make use of the "higher connectivity" between cells. It is probably much too difficult or even impossible to hope for general speedups. But efficient use of space (small hypercubes) for computations without losing time might be achievable.

Tree CA and hyperbolic CA

Starting from the root of a full binary tree one can reach an exponential number 2^t of nodes in t steps. If there are some computing capabilities related to the nodes, there is at least the possibility that such a device might exhibit some kind of strong parallelism.

One of the earliest papers in this respect is Wiedermann's article [31] (unfortunately only available in Slovak). The model introduced there one would now call parallel Turing machines, where a tape is not a linear array of cells, but where the cells are connected in such a way as to form a tree. A proof is sketched, showing that these devices can simulate PRAMs in linear time (assuming the so-called logarithmic cost model). PRAMs are in the second machine class.

So, indeed in some sense, trees are powerful. Below we first quickly introduce a **PSPACE**-complete problem which is a useful tool in order to prove the power of computational models involving trees. A few examples of such models are considered afterwards.

Quantified Boolean Formula The instances of the problem *Quantified Boolean Formula* (QBF, sometimes also called QSAT) have the structure

$$Q_1 x_1 Q_2 x_2 \cdots Q_k x_k \colon F(x_1, \ldots, x_k) .$$

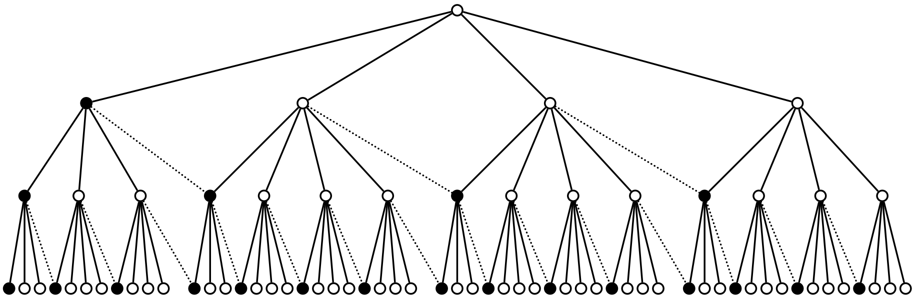
Here $F(x_1, \ldots, x_k)$ is a Boolean formula with variables $x_1, \ldots, x_k$ and connectives $\wedge$, $\vee$ and $\neg$. Each Q_j is one of the quantifiers $\forall$ or $\exists$. The problem is to decide whether the formula is true under the obvious interpretation. This problem is known to be complete for **PSPACE**. All known TM, i. e., all deterministic sequential algorithms, for solving QBF require exponential time.

Thus a proof that QBF can be solved by some model $\mathcal{M}$ in polynomial time (usually) implies that all problems in **PSPACE** can be solved by $\mathcal{M}$ in polynomial time. Often this can be paired with the "opposite" results that problems that can be solved in polynomial time on $\mathcal{M}$ are in **PSPACE**, and hence TM $-$ **PSPACE** $= \mathcal{M} -$ **P**.

This, of course, is not the case only for models "with trees"; see [6] for many alternatives.

Tree CA A tree CA (TCA for short) working on a full d-ary tree can be defined as follows: There is a set of states Q. For the root there is a local transition function $f_0 \colon (A \cup \{\square\}) \times Q \times \mathbb{Q}^d \to Q$, which uses an input symbol (if available), the root cell's own state and those of the d child nodes to compute the next state of the node. And there are d local transition functions $f_i \colon Q \times Q \times Q^d \to Q$, where $1 \leq i \leq d$. The ith child of a node uses f_i to compute its new state depending the state of its parent node, its own state and the states of the d child nodes. For language recognition, input is provided sequentially to the root node during the first n steps and a blank symbol $\square$ afterwards. A word is accepted if the root node enters an accepting state from a designated subset $F_+ \subset Q$.

Mycielski and Niwiński [19] were the first to realize that sequential polynomial reductions can be carried out by TCA and that QBF can be recognized by tree CA as well: A formula to be checked with k variables is copied and distributed to 2^k "evaluation cells". The sequences of left/right choices of the paths to them determine a valuation of the variables with zeros and ones. Each evaluation cell uses the subtree below it to evaluate $F(x_1, \ldots, x_k)$ accordingly. The results are propagated up to the root. Each cell in level i below the root, $1 \leq i \leq k$ above an evalua-



Cellular Automata as Models of Parallel Computation, Figure 3
The first levels of a tree of cells resulting from a tiling of the hyperbolic plane with 6-gons

tion cell combines the results using $\vee$ or $\wedge$, depending on whether the ith quantifier of the formula was $\exists$ or $\forall$.

On the other hand, it is routine work to prove that the result of a TCA running in polynomial time can be computed sequentially in polynomial space by a depth first procedure. Hence one gets:

Theorem 19

$$\mathrm{TCA} - \mathrm{T{\small IME}}(\mathrm{Pol}(n)) = \boldsymbol{PSPACE}$$

Thus tree cellular automata are in the second machine class.

Hyperbolic CA Two-dimensional CA as defined in Sect. "Introduction" can be considered as arising from the tessellation of the Euclidean plane $\mathbb{Z}^2$ with squares. Therefore, more generally, sometimes CA on a grid $G = \mathbb{Z}^d$ are called Euclidean CA. Analogously, some *Hyperbolic CA* arise from tessellation of the hyperbolic plane with some regular polygon. They are covered in depth in a separate article (► Cellular Automata in Hyperbolic Spaces).

Here we just consider one special case: The two-dimensional hyperbolic plane can be tiled with copies of the regular 6-gon with six right angles. If one considers only one quarter and draws a graph with the tiles as nodes and links between those nodes who share a common tile edge, one gets the graph depicted in Fig. 3. Basically it is a tree with two types of nodes, *black* and *white* ones, and some "additional" edges depicted as dotted lines. The root is a white node. The first child of each node is black. All other children are white; a black node has 2 white children, a white node has 3 white children.

For *hyperbolic CA* (HCA) one uses the formalism analogously to that described for tree CA. As one can see, basically HCA are trees with some additional edges. It is therefore not surprising that they can accept the languages from **PSPACE** in polynomial time. The inverse inclusion is also proved similarly to the tree case. This gives:

Theorem 20

$$\mathrm{HCA} - \mathrm{T{\small IME}}(\mathrm{Pol}(n)) = \boldsymbol{PSPACE}$$

It is also interesting to have a look at the analogs of **P**, **PSPACE**, and so on for hyperbolic CA. Somewhat surprisingly Iwamoto et al. [11] have shown:

Theorem 21

$$\begin{aligned}\mathrm{HCA} - \mathrm{T{\small IME}}(\mathrm{Pol}(n)) &= \mathrm{HCA} - \mathrm{S{\small PC}}(\mathrm{Pol}(n)) \\ &= \mathrm{NHCA} - \mathrm{T{\small IME}}(\mathrm{Pol}(n)) = \mathrm{NHCA} - \mathrm{S{\small PC}}(\mathrm{Pol}(n))\end{aligned}$$

where NHCA *denotes nondeterministic hyperbolic CA. The analogous equalities hold for exponential time and space.*

Outlook There is yet another possibility for bringing trees into play: trees of configurations. The concept of *alternation* [4] can be carried over to cellular automata. Since there are several active computational units, the definitions are little bit more involved and it turns out that one has several possibilities which also result in models with slightly different properties. But in all cases one gets models from the second machine class. For results, readers are referred to [13] and [23].

On the other end there is some research on what happens if one restricts the possibilities for communication between neighboring cells: Instead of getting information about the complete states of the neighbors, in the extreme case only *one bit* can be exchanged. See for example [15].

Future Directions

At several points in this paper we have pointed out open problems which deserve further investigation. Here, we want to stress three areas which we consider particularly interesting in the area of "CA as a parallel model".

Proper Inclusions and Denser Hierarchies

It has been pointed out several times, that inclusions of complexity classes are not known to be proper, or that gaps between resource bounds still needed to be "large" in order to prove that the inclusion of the related classes is a proper one. For the foreseeable future it remains a wide area for further research. Most probably new techniques will have to be developed to make significant progress.

Activities

The motivation for considering state change complexity was the energy consumption of CMOS hardware. It is known that irreversible physical computational processes must consume energy. This seems not to be the case for reversible ones. Therefore *reversible* CA are also interesting in this respect. The definition of reversible CA and results for them are the topic of the article by Morita (▶ Reversible Cellular Automata), also in this encyclopedia. Surprisingly, all currently known simulations of irreversible CA on reversible ones (this is possible) exhibit a *large* state change complexity. This deserves further investigation.

Also the examination of CA which are "reversible on the computational core" has been started only recently [16]. There are first surprising results; the impacts on computational complexity are unforeseeable.

Asynchronicity and Randomization

Randomization is an important topic in sequential computing. It is high time that this is also investigated in much more depth for cellular automata. The same holds for cellular automata where not all cells are updating their states synchronously. These areas promise a wealth of new insights into the essence of fine-grained parallel systems.

Article Outline

Glossary

Cellular automaton For our purposes, a (one-dimensional) cellular automaton (CA) is given by a local map $\rho : \Sigma^w \to \Sigma$ where Σ is the underlying alphabet of the automaton and w is its width. As a data structure, suitable as input to a decision algorithm, a CA can thus be specified by a simple lookup table. We abuse notation and write $\rho(x)$ for the result of applying the global map of the CA to configuration $x \in \Sigma^{\mathbb{Z}}$.

Wolfram classes Wolfram proposed a heuristic classification of cellular automata based on observations of typical behaviors. The classification comprises four classes: evolution leads to trivial configurations, to periodic configurations, evolution is chaotic, evolution leads to complicated, persistent structures.

Undecidability It was recognized by logicians and mathematicians in the first half of the 20th century that there is an abundance of well-defined problems that cannot be solved by means of an algorithm, a mechanical procedure that is guaranteed to terminate after finitely many steps and produce the appropriate answer. The best known example of an undecidable problem is Turing's Halting Problem: there is no algorithm to determine whether a given Turing machine halts when run on an empty tape.

Semi-decidability A problem is said to be semi-decidable or computably enumerable if it admits an algorithm that returns "yes" after finitely many steps if this is indeed the correct answer. Otherwise the algorithm never terminates. The Halting Problem is the standard example for a semi-decidable problem. A problem is decidable if, and only if, the problem itself and its negation are semi-decidable.

Universality A computational device is universal it is capable of simulating any other computational device. The existence of universal computers was another central insight of the early days of computability theory and is closely related to undecidability.

Reversibility A discrete dynamical system is reversible if the evolution of the system incurs no loss of information: the state at time t can be recovered from the state at time $t + 1$. For CAs this means that the global map is injective.

Surjectivity The global map of a CA is surjective if every configuration appears as the image of another. By contrast, a configuration that fails to have a predecessor is often referred to as a Garden-of-Eden.

Finite configurations One often considers CA with a special quiescent state: the homogeneous configuration where all cells are in the quiescent state is required to be fixed point under the global map. Infinite configurations where all but finitely many cells are in the quiescent state are often called finite configurations. This is somewhat of a misnomer; we prefer to speak about configurations with finite support.

Definition of the Subject

Cellular automata display a large variety of behaviors. This was recognized clearly when extensive simulations of cellular automata, and in particular one-dimensional CA, became computationally feasible around 1980. Surprisingly, even when one considers only elementary CA, which are constrained to a binary alphabet and local maps involving only nearest neighbors, complicated behaviors are observed in some cases. In fact, it appears that most behaviors observed in automata with more states and larger neighborhoods already have qualitative analogues in the realm of elementary CA. Careful empirical studies lead Wolfram to suggest a phenomenological classification of CA based on the long-term evolution of configurations, see [68,71] and Sect. "Introduction". While Wolfram's four classes clearly capture some of the behavior of CA it turns out that any attempt at formalizing this taxonomy meets with considerable difficulties. Even apparently simple questions about the behavior of CA turn out to be algorithmically undecidable and it is highly challenging to provide a detailed mathematical analysis of these systems.

Introduction

In the early 1980's Wolfram published a collection of 20 open problems in the the theory of CA, see [69]. The first problem on his list is "What overall classification of cellular automata behavior can be given?" As Wolfram points out, experimental mathematics provides a first answer to this problem: one performs a large number of explicit simulations and observes the patterns associated with the long term evolution of a configuration, see [67,71]. Wolfram proposed a classification that is based on extensive simulations in particular of one-dimensional cellular automata where the evolution of a configuration can be visualized naturally as a two-dimensional image. The classification involves four classes that can be described as follows:

- *W1*: Evolution leads to homogeneous fixed points.
- *W2*: Evolution leads to periodic configurations.
- *W3*: Evolution leads to chaotic, aperiodic patterns.
- *W4*: Evolution produces persistent, complex patterns of localized structures.

Thus, Wolfram's first three classes follow closely concepts from continuous dynamics: fixed point attractors, periodic attractors and strange attractors, respectively. They correspond roughly to systems with zero temporal and spatial entropy, zero temporal entropy but positive spatial entropy, and positive temporal and spatial entropy, respectively. *W4* is more difficult to associate with a continuous analogue except to say that transients are typically very long. To understand this class it is preferable to consider CA as models of massively parallel computation rather than as particular discrete dynamical systems. It was conjectured by Wolfram that *W4* automata are capable of performing complicated computations and may often be computationally universal. Four examples of elementary CA that are typical of the four classes are shown in Fig. 1. Li and Packard [32,33] proposed a slightly modified version of this hierarchy by refining the low classes and in particular Wolfram's *W2*. Much like Wolfram's classification, the Li–Packard classification is concerned with the asymptotic behavior of the automaton, the structure and behavior of the limiting configurations. Here is one version of the Li–Packard classification, see [33].

- *LP1*: Evolution leads to homogeneous fixed points.
- *LP2*: Evolution leads to non-homogeneous fixed points, perhaps up a to a shift.
- *LP3*: Evolution leads to ultimately periodic configurations. Regions with periodic behavior are separated by domain walls, possibly up to a shift.
- *LP4*: Configurations produce locally chaotic behavior. Regions with chaotic behavior are separated by domain walls, possibly up to a shift.
- *LP5*: Evolution leads to chaotic patterns that are spatially unbounded.
- *LP6*: Evolution is complex. Transients are long and lead to complicated space-time patterns which may be nonmonotonic in their behavior.

By contrast, a classification closer to traditional dynamical systems theory was introduced by Kůrka, see [27,28]. The classification rests on the notions of equicontinuity, sensitivity to initial conditions and expansivity. Suppose x is a point in some metric space and f a map on that space. Then f is *equicontinuous* at x if

$$\forall\, \varepsilon > 0\, \exists\, \delta > 0\, \forall\, y \in B_\delta(x), n \in \mathbb{N}\, (d(f^n(x), f^n(y)) < \varepsilon)$$

where $d(.,.)$ denotes a metric. Thus, all points in a sufficiently small neighborhood of x remain close to the iterates of x for the whole orbit. Global equicontinuity is a fairly strong condition, it implies that the limit set of the automaton is reached after finitely many steps. The map is *sensitive* (to initial conditions) if

$$\forall\, x, \varepsilon > 0\, \exists\, \delta > 0\, \forall\, y \in B_\delta(x) \exists\, n \in \mathbb{N} \\ (d(f^n(x), f^n(y)) \geq \varepsilon)\,.$$

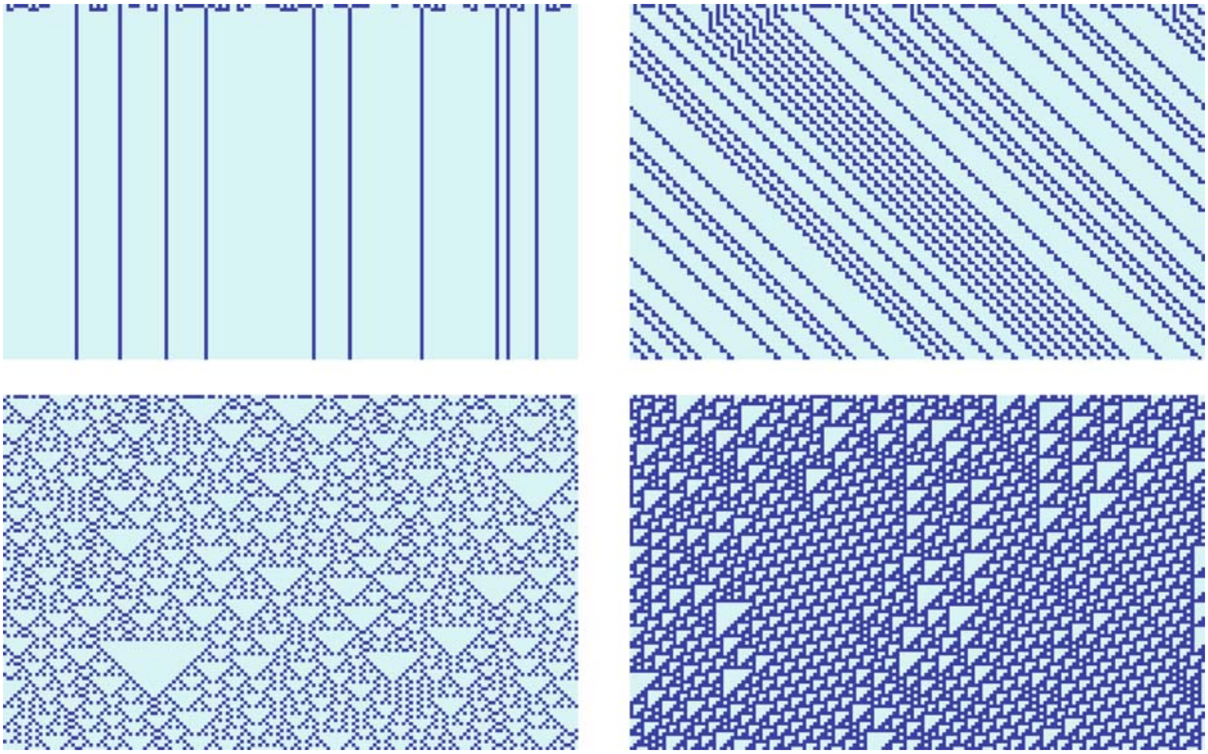
Lastly, the map is *positively expansive* if

$$\exists\, \varepsilon > 0\, \forall\, x \neq y\, \exists\, n \in \mathbb{N}\, (d(f^n(x), f^n(y)) \geq \varepsilon)\,.$$

Kůrka's classification then takes the following form.

- *K1*: All points are equicontinuous under the global map.
- *K2*: Some but not all points are equicontinuous under the global map.
- *K3*: The global map is sensitive but not positively expansive.
- *K4*: The global map is positively expansive.

This type of classification is perfectly suited to the analysis of uncountable spaces such as the Cantor space $\{0,1\}^{\mathbb{N}}$



Cellular Automata, Classification of, Figure 1
Typical examples of the behavior described by Wolfram's classes among elementary cellular automata

or the full shift space $\Sigma^{\mathbb{Z}}$ which carry a natural metric structure. For the most part we will not pursue the analysis of CA by topological and measure theoretic means here and refer to ▶ Topological Dynamics of Cellular Automata in this volume for a discussion of these methods. See Sect. "Definability and Computability" for the connections between topology and computability.

Given the apparent complexity of observable CA behavior one might suspect that it is difficult to pinpoint the location of an arbitrary given CA in any particular classification scheme with any precision. This is in contrast to simple parameterizations of the space of CA rules such as Langton's λ parameter that are inherently easy to compute. Briefly, the λ value of a local map is the fraction of local configurations that map to a non-zero value, see [29,33]. Small λ values result in short transients leading to fixed points or simple periodic configurations. As λ increases the transients grow longer and the orbits become more and more complex until, at last, the dynamics become chaotic. Informally, sweeping the λ value from 0 to 1 will produce CA in *W1*, then *W2*, then *W4* and lastly in *W3*. The last transition appears to be associated with a threshold phenomenon. It is unclear what the connection between Langton's λ-value and computational properties of a CA is, see [37,46]. Other numerical measures that appear to be loosely connected to classifications are the mean field parameters of Gutowitz [20,21], the Z-parameter by Wuensche [72], see also [44]. It seems doubtful that a structured taxonomy along the lines of Wolfram or Li–Packard can be derived from a simple numerical measure such as the λ value alone, or even from a combination of several such values. However, they may be useful as empirical evidence for membership in a particular class.

Classification also becomes significantly easier when one restricts one's attention to a limited class of CA such as additive CA, see ▶ Additive Cellular Automata. In this context, additive means that the local rule of the automaton has the form $\rho(\vec{x}) = \sum_i c_i x_i$ where the coefficients as well as the states are modular numbers. A number of properties starting with injectivity and surjectivity as well as topological properties such as equicontinuity and sensitivity can be expressed in terms of simple arithmetic conditions on the rule coefficients. For example, equicontinuity is equivalent to all prime divisors of the modulus m dividing all coefficients c_i, $i > 1$, see [35] and the references therein. It is also noteworthy that in the linear case methods tend to carry over to arbitrary dimensions; in general there is a significant step in complexity from dimension one to dimension two.

No claim is made that the given classifications are complete; in fact, one should think of them as prototypes rather than definitive taxonomies. For example, one might add the class of *nilpotent* CA at the bottom. A CA is nilpotent if all configurations evolve to a particular fixed point after finitely many steps. Equivalently, by compactness, there is a bound n such that all configurations evolve to the fixed point in no more than n steps. Likewise, we could add the class of *intrinsically universal* CA at the top. A CA is intrinsically universal if it is capable of simulating all other CA of the same dimension in some reasonable sense. For a fairly natural notion of simulation see [45]. At any rate, considerable effort is made in the references to elaborate the characteristics of the various classes. For many concrete CA visual inspection of the orbits of a suitable sample of configurations readily suggests membership in one of the classes.

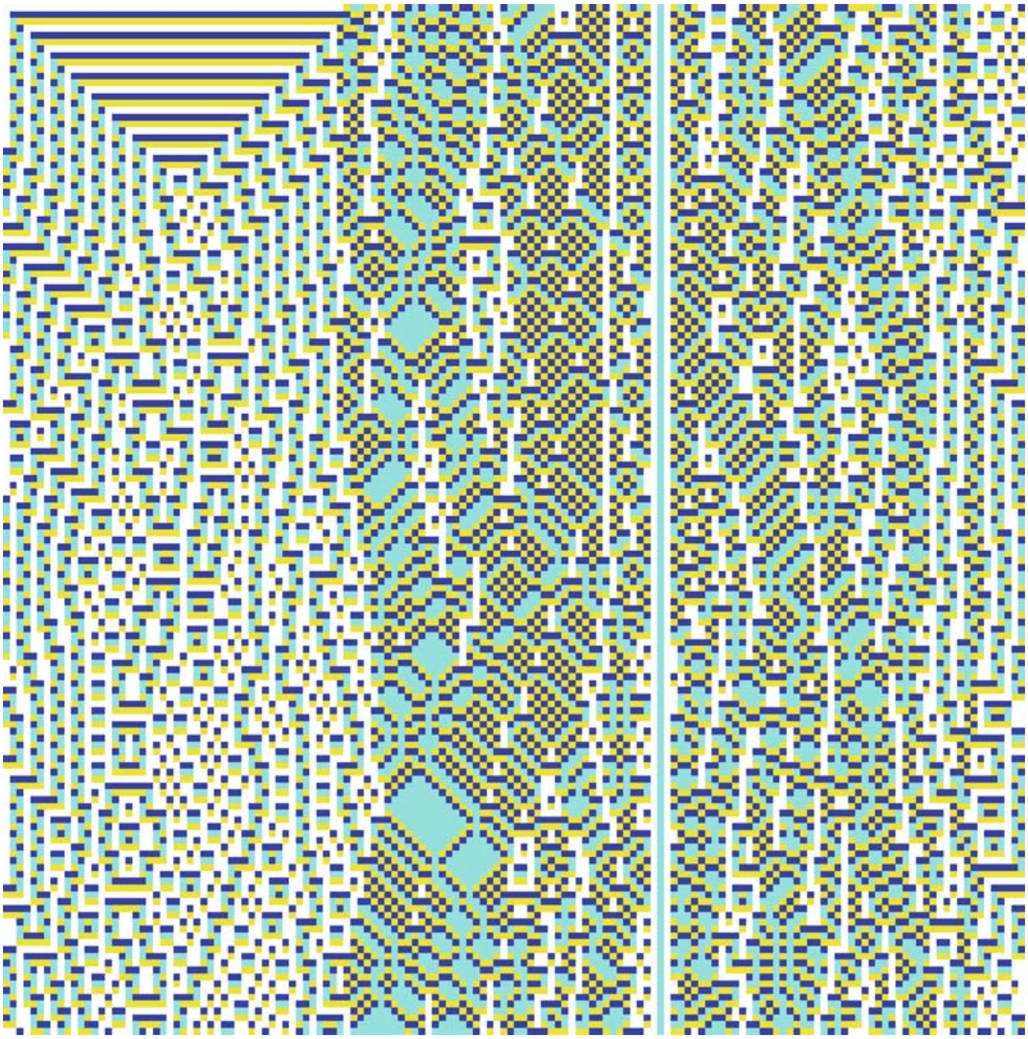
Reversibility and Surjectivity

A first tentative step towards the classification of a dynamical systems is to determine its reversibility or lack thereof. Thus we are trying to determine whether the evolution of the system is associated with loss of information, or whether it is possible to reconstruct the state of the system at time t from its state at time $t + 1$. In terms of the global map of the system we have to decide injectivity. Closely related is the question whether the global map is surjective, i. e., whether there is no Garden-of-Eden: every configuration has a predecessor under the global map. As a consequence, the limit set of the automaton is the whole space. It was shown of Hedlund that for CA the two notions are connected: every reversible CA is also surjective, see [24], ▶ Reversible Cellular Automata. As a matter of fact, reversibility of the global map of a CA implies openness of the global map, and openness implies surjectivity. The converse implications are both false. By a well-known theorem by Hedlund [24] the global maps of CA are precisely the continuous maps that commute with the shift. It follows from basic topology that the inverse global map of a reversible CA is again the global map of a suitable CA. Hence, the predecessor configuration of a given configuration can be reconstructed by another suitably chosen CA. For results concerning reversibility on the limit set of the automaton see [61].

From the perspective of complexity the key result concerning reversible systems is the work by Lecerf [30] and Bennett [7]. They show that reversible Turing machines can compute any partial recursive function, modulo a minor technical problem: In a reversible Turing machine there is no loss of information; on the other hand even simple computable functions are clearly irreversible in the sense that, say, the sum of two natural numbers does not determine these numbers uniquely. To address this issue one has to adjust the notion of computability slightly in the context of reversible computation: given a partial recursive function $f : \mathbb{N} \to \mathbb{N}$ the function $\widehat{f}(x) = \langle x, f(x) \rangle$ can be computed by a reversible Turing machine where $\langle ., . \rangle$ is any effective pairing function. If f itself happens to be injective then there is no need for the coding device and f can be computed by a reversible Turing machine directly. For example, we can compute the product of two primes reversibly. Morita demonstrated that the same holds true for one-dimensional cellular automata [38,40,62], ▶ Tiling Problem and Undecidability in Cellular Automata: reversibility is no obstruction to computational universality. As a matter of fact, any irreversible cellular automaton can be simulated by a reversible one, at least on configurations with finite support. Thus one should expect reversible CA to exhibit fairly complicated behavior in general.

For infinite, one-dimensional CA it was shown by Amoroso and Patt [2] that reversibility is decidable. Moreover, it is decidable if the the global map is surjective. An efficient practical algorithm using concepts of automata theory can be found in [55], see also [10,14,23]. The fast algorithm is based on interpreting a one-dimensional CA as a deterministic transducer, see [6,48] for background. The underlying semi-automaton of the transducer is a de Bruijn automaton $\mathcal{B}$ whose states are words in Σ^{w-1} where Σ is the alphabet of the CA and w is its width. The transitions are given by $ax \xrightarrow{c} xb$ where $a, b, c \in \Sigma$, $x \in \Sigma^{w-2}$ and $c = \rho(axb)$, ρ being the local map of the CA. Since $\mathcal{B}$ is strongly connected, the product automaton of $\mathcal{B}$ will contain a strongly connected component C that contains the diagonal D, an isomorphic copy of $\mathcal{B}$. The global map of the CA is reversible if, and only if, $C = D$ is the only non-trivial component. It was shown by Hedlund [24] that surjectivity of the global map is equivalent with local injectivity: the restriction of the map to configurations with finite support must be injective. The latter property holds if, and only if, $C = D$ and is thus easily decidable. Automata theory does not readily generalize to words of dimensions higher than one. Indeed, reversibility and surjectivity in dimensions higher than one are undecidable, see [26] and ▶ Tiling Problem and Undecidability in Cellular Automata in this volume for the rather intricate argument needed to establish this fact.

While the structure of reversible one-dimensional CA is well-understood, see ▶ Tiling Problem and Undecid-



Cellular Automata, Classification of, Figure 2

A reversible automaton obtained by applying Fredkin's construction to the irreversible elementary CA 77

ability in Cellular Automata, [16], and while there is an efficient algorithm to check reversibility, few methods are known that allow for the construction of interesting reversible CA. There is a noteworthy trick due to Fredkin that exploits the reversibility of the Fibonacci equation $X_{n+1} = X_n + X_{n-1}$. When addition is interpreted as exclusive or this can be used to construct a second-order CA from any given binary CA; the former can then be recoded as a first-order CA over a 4-letter alphabet. For example, for the open but irreversible elementary CA number 90 we obtain the CA shown in Fig. 2.

Another interesting class of reversible one-dimensional CA, the so-called *partitioned cellular automata (PCA)*, is due to Morita and Harao, see [38,39,40]. One can think of a PCA as a cellular automaton whose cells are divided into multiple tracks; specifically Morita uses an alphabet of the form $\Sigma = \Sigma_1 \times \Sigma_2 \times \Sigma_3$. The configurations of the automaton can be written as (X, Y, Z) where $X \in {\Sigma_1}^{\mathbb{Z}}$, $Y \in {\Sigma_2}^{\mathbb{Z}}$ and $Z \in {\Sigma_3}^{\mathbb{Z}}$. Now consider the *shearing map* σ defined by $\sigma(X, Y, Z) = (\mathsf{RS}(X), Y, \mathsf{LS}(Z))$ where RS and LS denote the right and left shift, respectively. Given any function $f : \Sigma \to \Sigma$ we can define a global map $f \circ \sigma$ where f is assumed to be applied point-wise. Since the shearing map is bijective, the CA will be reversible if, and only if, the map f is bijective. It is relatively easy to construct bijections f that cause the CA to perform particular computational tasks, even when a direct construction appears to be entirely intractable.

Definability and Computability

Formalizing Wolfram's Classes

Wolfram's classification is an attempt to categorize the complexity of the CA by studying the patterns observed during the long-term evolution of all configurations. The first two classes are relatively easy to observe, but it is difficult to distinguish between the last two classes. In particular *W4* is closely related to the kind of behavior that would be expected in connection with systems that are capable of performing complicated computations, including the ability to perform universal computation; a property that is notoriously difficult to check, see [52]. The focus on the full configuration space rather than a significant subset thereof corresponds to the worst-case approach well-known in complexity theory and is somewhat inferior to an average case analysis. Indeed, Baldwin and Shelah point out that a product construction can be used to design a CA whose behavior is an amalgamation of the behavior of two given CA, see [3,4]. By combining CA in different classes one obtains striking examples of the weakness of the worst-case approach. A natural example of this mixed type of behavior is elementary CA 184 which displays class II or class III behavior, depending on the initial configuration. Another basic example for this type of behavior is the well-studied elementary CA 30, see Sect. "Conclusion".

Still, for many CA a worst-case classification seems to provide useful information about the structural properties of the automaton. The first attempt at formalizing Wolfram's class was made by Culik and Yu who proposed the following hierarchy, given here in cumulative form, see [11]:

- *CY1*: All configurations evolve to a fixed point.
- *CY2*: All configurations evolve to a periodic configuration.
- *CY3*: The orbits of all configurations are decidable.
- *CY4*: No constraints.

The Culik–Yu classification employs two rather different methods. The first two classes can be defined by a simple formula in a suitable logic whereas the third (and the fourth in the disjoint version of the hierarchy) rely on notions of computability theory. As a general framework for both approaches we consider *discrete dynamical systems*, structures of the form $\mathcal{A} = \langle C, \to \rangle$ where $C \subseteq \Sigma^{\mathbb{Z}}$ is the space of *configurations* of the system and → is the "next configuration" relation on C. We will only consider the deterministic case where for each configuration x there exists precisely one configuration y such that $x \to y$. Hence we are really dealing with algebras with one unary function, but iteration is slightly easier to deal with in the relational setting. The structures most important in this context are the ones arising from a CA. For any local map ρ we consider the structure $\mathcal{A}_\rho = \langle C, \to \rangle$ where the next configuration relation is determined by $x \to \rho(x)$.

Using the standard language of first order logic we can readily express properties of the CA in terms of the system $\mathcal{A}_\rho$. For example, the system is reversible, respectively surjective, if the following assertions are valid over $\mathcal{A}$:

$$\forall\, x, y, z\, (x \to z \text{ and } y \to z \text{ implies } x = y)\,,$$
$$\forall\, x\, \exists\, y\, (y \to x)\,.$$

As we have seen, both properties are easily decidable in the one-dimensional case. In fact, one can express the basic predicate $x \to y$ (as well as equality) in terms of finite state machines on infinite words. These machines are defined like ordinary finite state machines but the acceptance condition requires that certain states are reached infinitely and co-infinitely often, see [8,19]. The emptiness problem for these automata is easily decidable using graph theoretic algorithms. Since regular languages on infinite words are closed under union, complementation and projection, much like their finite counterparts, and all the corresponding operations on automata are effective, it follows that one can decide the validity of first order sentences over $\mathcal{A}_\rho$ such as the two examples above: the model-checking problem for these structures and first order logic is decidable, see [34]. For example, we can decide whether there is a configuration that has a certain number of predecessors. Alternatively, one can translate these sentences into monadic second order logic of one successor, and use well-known automata-based decision algorithms there directly, see [8]. Similar methods can be used to handle configurations with finite support, corresponding to weak monadic second order logic. Since the complexity of the decision procedure is non-elementary one should not expect to be able to handle complicated assertions. On the other hand, at least for weak monadic second order logic practical implementations of the decision method exist, see [17]. There is no hope of generalizing this approach as the undecidability of, say, reversibility in higher dimensions demonstrates.

Write $x \xrightarrow{t} y$ if x evolves to y in exactly t steps, $x \xrightarrow{+} y$ if x evolves to y in any positive number of steps and $x \xrightarrow{*} y$ if x evolves to y in any number of steps. Note that $\xrightarrow{t}$ is definable for each fixed t, but $\xrightarrow{*}$ fails to be so definable in first order logic. This is in analogy to the undefinability of path existence problems in the first order theory of graphs, see [34]. Hence it is natural to extend our language so we can express iterations of the global map, either by adding transitive closures or by moving to some limited system of higher order logic over $\mathcal{A}_\rho$ where $\overset{*}{\rightarrow}$ is definable, see [8].

Arguably the most basic decision problem associated with a system $\mathcal{A}$ that requires iteration of the global map is the *Reachability Problem*: given two configurations x and y, does the evolution of x lead to y? A closely related but different question is the *Confluence Problem*: will two configurations x and y evolve to the same limit cycle? Confluence is an equivalence relation and allows for the decomposition of configuration space into limit cycles together with their basins of attraction. The Reachability and Confluence Problem amount to determining, given configurations x and y, whether

$$x \overset{*}{\rightarrow} y ,$$

$$\exists\, z\, (x \overset{*}{\rightarrow} z \text{ and } y \overset{*}{\rightarrow} z) ,$$

respectively. As another example, the first two Culik–Yu class can be defined like so:

$$\forall\, x\, \exists\, z\, (x \overset{*}{\rightarrow} z \text{ and } z \rightarrow z),$$

$$\forall\, x\, \exists\, z\, (x \overset{*}{\rightarrow} z \text{ and } z \overset{+}{\rightarrow} z) .$$

It is not difficult to give similar definitions for the lower Li–Packard classes if one extends the language by a function symbol denoting the shift operator.

The third Culik–Yu class is somewhat more involved. By definition, a CA lies in the third class if it admits a global decision algorithm to determine whether a given configuration x evolves to another given configuration y in a finite number of steps. In other words, we are looking for automata where the Reachability Problem is algorithmically solvable. While one can agree that *W4* roughly translates into undecidability and is thus properly situated in the hierarchy, it is unclear how chaotic patterns in *W3* relate to decidability. No method is known to translate the apparent lack of tangible, persistent patterns in rules such as elementary CA 30 into decision algorithms for Reachability. There is another, somewhat more technical problem to overcome in formalizing classifications. Recall that the full configuration space is $C = \Sigma^{\mathbb{Z}}$. Intuitively, given $x \in C$ we can effectively determine the next configuration $y = \rho(x)$. However, classical computability theory does not deal with infinitary objects such as arbitrary configuration so a bit of care is needed here. The key insight is that we can determine arbitrary finite segments of $\rho(x)$ using only finite segments of x (and, of course, the lookup table for the local map). There are several ways to model computability on $\Sigma^{\mathbb{Z}}$ based on this idea of finite approximations, we refer to [66] for a particularly appealing model based on so-called type-2 Turing machines; the reference also contains many pointers to the literature as well as a comparison between the different approaches. It is easy to see that for any CA the global map ρ as well as all its iterates ρ^t are computable, the latter uniformly in t. However, due to the finitary nature of all computations, equality is not decidable in type-2 computability: the unequal operator $U_0(x, y) = 0$ if $x \neq y$, $U_0(x, y)$ undefined otherwise, is computable and thus unequality is semi-decidable, but the stronger $U_0(x, y) = 0$ if $x \neq y$, $U_0(x, y) = 1$, otherwise, is not computable. The last result is perhaps somewhat counterintuitive, but it is inevitable if we strictly adhere to the finite approximation principle.

In order to avoid problems of this kind it has become customary to consider certain subspaces of the full configuration space, in particular C_{fin}, the collection of configurations with finite support, C_{per}, the collection of spatially periodic configurations and C_{ap}, the collection of almost periodic configurations of the form $\ldots uuuwvvv \ldots$ where u, v and w are all finite words over the alphabet of the automaton. Thus, an almost periodic configuration differs from a configuration of the form ${}^{\omega}u\, v^{\omega}$ in only finitely many places. Configurations with finite support correspond to the special case where $u = v = 0$ is a special quiescent symbol and spatially periodic configurations correspond to $u = v$, $w = \varepsilon$. The most general type of configuration that admits a finitary description is the class C_{rec} of recursive configurations, where the assignment of state to a cell is given by a computable function.

It is clear that all these subspaces are closed under the application of a global map. Except for C_{fin} there are also closed under inverse maps in the following sense: given a configuration y in some subspace that has a predecessor x in C_{all} there already exists a predecessor in the same subspace, see [55,58]. This is obvious except in the case of recursive configurations. The reference also shows that the recursive predecessor cannot be computed effectively from the target configuration. Thus, for computational purposes the dynamics of the cellular automaton are best reflected in C_{ap}: it includes all configuration with finite support and we can effectively trace an orbit in both directions. It is not hard to see that C_{ap} is the least such class. Alas, it is standard procedure to avoid minor technical difficulties arising from the infinitely repeated spatial patterns and establish classifications over the subspace C_{fin}. There is a arguably not much harm in this simplification since C_{fin} is a dense subspace of C_{all} and compactness can be used to lift properties from C_{fin} to the full configuration space.

The Culik–Yu hierarchy is correspondingly defined over C_{fin}, the class of all configurations of finite support. In this setting, the first three classes of this hierarchy are undecidable and the fourth is undecidable in the disjunctive version: there is no algorithm to test whether a CA admits undecidable orbits. As it turns out, the CA classes are complete in their natural complexity classes within the arithmetical hierarchy [50,52]. Checking membership in the first two classes comes down to performing an infinite number of potentially unbounded searches and can be described logically by a Π_2 expression, a formula of type $\forall\, x\, \exists\, y\, R(x, y)$ where R is a decidable predicate. Indeed, *CY1* and *CY2* are both Π_2-complete. Thus, deciding whether all configurations on a CA evolve to a fixed point is equivalent to the classical problem of determining whether a semi-decidable set is infinite. The third class is even less amenable to algorithmic attack; one can show that *CY3* is Σ_3-complete, see [53]. Thus, deciding whether all orbits are decidable is as difficult as determining whether any given semi-decidable set is decidable. It is not difficult to adjust these undecidability results to similar classes such as the lower levels of the Li–Packard hierarchy that takes into account spatial displacements of patterns.

Effective Dynamical Systems and Universality

The key property of CA that is responsible for all these undecidability results is the fact that CA are capable of performing arbitrary computations. This is unsurprising when one defines computability in terms of Turing machines, the devices introduced by Turing in the 1930's, see [47,63]. Unlike the Gödel–Herbrand approach using general recursive functions or Church's λ-calculus, Turing's devices are naturally closely related to discrete dynamical systems. For example, we can express an instantaneous description of a Turing machine as a finite sequence

$$a_{-l}\, a_{-l+1} \dots a_{-1}\; p\; a_1 a_2 \dots a_r$$

where the a_i are tape symbols and p is a state of the machine, with the understanding that the head is positioned at a_1 and that all unspecified tape cells contain the blank symbol. Needless to say, these Turing machine configurations can also be construed as finite support configurations of a one-dimensional CA. It follows that a one-dimensional CA can be used to simulate an arbitrary Turing machine, hence CA are computational universal: any computable function whatsoever can already be computed by a CA.

Note, though, that the simulation is not entirely trivial. First, we have to rely on input/output conventions. For example, we may insist that objects in the input domain, typically tuples of natural numbers, are translated into a configuration of the CA by a primitive recursive coding function. Second, we need to adopt some convention that determines when the desired output has occurred: we follow the evolution of the input configuration until some "halting" condition applies. Again, this condition must be primitive recursively decidable though there is considerable leeway as to how the end of a computation should be signaled by the CA. For example, we could insist that a particular cell reaches a special state, that an arbitrary cell reaches a special state, that the configuration be a fixed point and so forth. Lastly, if and when a halting configuration is reached, we a apply a primitive recursive decoding function to obtain the desired output.

Restricting the space to configurations that have finite support, that are spatially periodic, and so forth, produces an *effective dynamical system*: the configurations can be coded as integers in some natural way, and the next configuration relation is primitive recursive in the sense that the corresponding relation on code numbers is so primitive recursive. A classical example for an effective dynamical system is given by selecting the instantaneous descriptions of a Turing machine M as configurations, and one-step relation of the Turing machine as the operation of C. Thus we obtain a system $\mathcal{A}_M$ whose orbits represent the computations of the Turing machine. Likewise, given the local map ρ of a CA we obtain a system $\mathcal{A}_\rho$ whose operation is the induced global map. While the full configuration space C_{all} violates the effectiveness condition, any of the spaces C_{per}, C_{fin}, C_{ap} and C_{rec} will give rise to an effective dynamical system. Closure properties as well as recent work on the universality of elementary CA 110, see Sect. "Conclusion", suggests that the class of almost periodic configurations, also known as backgrounds or wallpapers, see [9,58], is perhaps the most natural setting. Both C_{fin} and C_{ap} provide a suitable setting for a CA that simulates a Turing machine: we can interpret $\mathcal{A}_M$ as a subspace of $\mathcal{A}_\rho$ for some suitably constructed one-dimensional CA ρ; the orbits of the subspace encode computations of the Turing machine. It follows from the undecidability of the Halting Problem for Turing machines that the Reachability Problem for these particular CA is undecidable.

Note, though, that orbits in $\mathcal{A}_M$ may well be finite, so some care must be taken in setting up the simulation. For example, one can translate halting configurations into fixed points. Another problem is caused by the worst-case nature of our classification schemes: in Turing machines and their associated systems $\mathcal{A}_M$ it is only behavior on specially prepared initial configurations that matters, whereas the behavior of a CA depends on all configurations. The behavior of a Turing machine on all instantaneous descriptions, rather than just the ones that can occur during a legitimate computation on some actual input, was first studied by Davis, see [12,13], and also Hooper [25].

Call a Turing machine *stable* if it halts on any instantaneous description whatsoever. With some extra care one can then construct a CA that lies in the first Culik–Yu class, yet has the same computational power as the Turing machine. Davis showed that every total recursive function can already be computed by a stable Turing machine, so membership in *CY1* is not an impediment to considerable computational power. The argument rests on a particular decomposition of recursive functions. Alternatively, one directly manipulate Turing machines to obtain a similar result, see [49,53]. On the other hand, unstable Turing machines yield a natural and coding-free definition of universality: a Turing machine is *Davis-universal* if the set of all instantaneous description on which the machine halts is Σ_1-complete.

The mathematical theory of infinite CA is arguably more elegant than the actually observable finite case. As a consequence, classifications are typically concerned with CA operating on infinite grids, so that even a configuration with finite support can carry arbitrarily much information. If we restrict our attention to the space of configurations on a finite grid a more fine-grained analysis is required. For a finite grid of size n the configuration space has the form $C_n = [n] \to \Sigma$ and is itself finite, hence any orbit is ultimately periodic and the Reachability Problem is trivially decidable. However, in practice there is little difference between the finite and infinite case. First, computational complexity issues make it practically impossible to analyze even systems of modest size. The Reachability Problem for finite CA, while decidable, is PSPACE-complete even in the one-dimensional case. Computational hardness appears in many other places. For example, if we try to determine whether a given configuration on a finite grid is a Garden-of-Eden the problem turns out to be NLOG-complete in dimension one and $\mathbb{NP}$-complete in all higher dimensions, see [56].

Second, it stands to reason that the more interesting classification problem in the finite case takes the following parameterized form: given a local map together with boundary conditions, determine the behavior of ρ on all finite grids. Under periodic boundary conditions this comes down to the study of C_{per} and it seems that there is little difference between this and the fixed boundary case. Since all orbits on a finite grid are ultimately periodic one needs to apply a more fine-grained classification that takes into account transient lengths. It is undecidable whether all configurations on all finite grids evolve to a fixed point under a given local map, see [54]. Thus, there is no algorithm to determine whether

$$\langle C_n, \to \rangle \models \forall\, x\, \exists\, z\, (x \overset{*}{\to} z \text{ and } z \to z)$$

for all grid sizes n. The transient lengths are trivially bounded by k^n where k is the size of the alphabet of the automaton. It is undecidable whether the transient lengths grow according to some polynomial bound, even when the polynomial in question is constant.

Restrictions of the configuration space are one way to obtain an effective dynamical system. Another is to interpret the approximation-based notion of computability on the full space in terms of topology. It is well-known that computable maps $C_{\text{all}} \to C_{\text{all}}$ are continuous in the standard product topology. The clopen sets in this topology are the finite unions of cylinder sets where a cylinder set is determined by the values of a configuration in finitely many places. By a celebrated result of Hedlund the global maps of a CA on the full space are characterized by being continuous and shift-invariant. Perhaps somewhat counter-intuitively, the decidable subsets of C_{all} are quite weak, they consist precisely of the clopen sets. Now consider a partition of C_{all} into finitely many clopen sets $C_0, C_2, \dots, C_{n-1}$. Thus, it is decidable which block of the partition a given point in the space belongs to. Moreover, Boolean operations on clopen sets as well as application of the global map and the inverse global map are all computable. The partition affords a natural projection $\pi : C_{\text{all}} \to \Sigma_n$ where $\Sigma_n = \{0, 1, \dots, n-1\}$ and $\pi(x) = i$ iff $x \in C_i$. Hence the projection translates orbits in the full space C_{all} into a class W of ω-words over Σ_n, the symbolic orbits of the system. The Cantor space $\Sigma_n^{\mathbb{Z}}$ together with the shift describes all logically possible orbits with respect to the given partition and W describes the symbolic orbits that actually occur in the given CA. The shift operator corresponds to an application of the global map of the CA. The finite factors of W provide information about possible finite traces of an orbit when filtered through the given partition. Whole orbits, again filtered through the partition, can be described by ω-words. To tackle the classification of the CA in terms of W it was suggested by Delvenne et al., see [15], to refer to the CA as *decidable* if there it is decidable whether W has non-empty intersection with a ω-regular language. Alas, decidability in this sense is very difficult, its complexity being Σ_1^1-complete and thus outside of the arithmetical hierarchy. Likewise it is suggested to call a CA *universal* if the problem of deciding whether the cover of W, the collection of all finite factors, is Σ_1-complete, in analogy to Davis-universality.

Computational Equivalence

In recent work, Wolfram suggests a so-called *Principle of Computational Equivalence*, or PCE for short, see [71],

p. 717. PCE states that most computational processes come in only two flavors: they are either of a very simple kind and avoid undecidability, or they represent a universal computation and are therefore no less complicated than the Halting Problem. Thus, Wolfram proposes a zero-one law: almost all computational systems, and thus in particular all CA, are either as complicated as a universal Turing machine or are computationally simple. As evidence for PCE Wolfram adduces a very large collection of simulations of various effective dynamical systems such as Turing machines, register machines, tag systems, rewrite systems, combinators, and cellular automata. It is pointed out in Chap. 3 of [71], that in all these classes of systems there are surprisingly small examples that exhibit exceedingly complicated behavior – and presumably are capable of universal computation. Thus it is conceivable that universality is a rather common property, a property that is indeed shared by all systems that are not obviously simple. Of course, it is often very difficult to give a complete proof of the computational universality of a natural system, as opposed to carefully constructed one, so it is not entirely clear how many of Wolfram's examples are in fact universal. As a case in point consider the universality proof of Conway's Game of Life, or the argument for elementary CA 110. If Wolfram's PCE can be formally established in some form it stands to reason that it will apply to all effective dynamical systems and in particular to CA. Hence, classifications of CA would be rather straightforward: at the top there would be the class of universal CA, directly preceded by a class similar to the third Culik–Yu class, plus a variety of subclasses along the lines of the lower Li–Packard classes.

The corresponding problem in classical computability theory was first considered in the 1930's by Post and is now known as Post's Problem: is there a semi-decidable set that fails to be decidable, yet is not as complicated as the Halting Set? In terms of Turing degrees the problem thus is to construct a semi-decidable set A such that $\emptyset <_{\mathrm{T}} A <_{\mathrm{T}} \emptyset'$, or to rule out the existence of any such set, see [31,47,52] for background on Turing degrees in general and semi-decidable degrees in particular. Post's Problem resisted all attempts at resolution until Friedberg and Muchnik independently and almost simultaneously discovered a way to construct a set of intermediate complexity, see [18,41]. The construction is based on the idea of a so-called priority argument and is significantly more complicated than any construction of semi-decidable sets previously known [52]. Indeed, priority arguments have since become the hallmark of computability theory and have even engendered some criticism as being so very technical that, occasionally, the proofs seem to attract more attention than the theorems being established, see [65]. Be that as it may, it is striking how much more artificial and ad hoc intermediate sets are, as compared to natural examples such as the theory of the reals (decidable) or of Diophantine equations (equivalent to the Halting Problem). No natural examples of intermediate semi-decidable sets are known to date.

Nonetheless, given an intermediate set A one can construct a one-dimensional CA whose Reachability Problem has the same degree as A. This suggests a degree-based classification: given any computably enumerable degree $\mathbf{d}$, define the class $\mathbb{C}_{\mathbf{d}}$ to consist of all CA whose Reachability Problem has degree exactly $\mathbf{d}$, see [57,59]. The degree classification is non-trivial in the sense that every class is non-empty. Note that the first three Culik–Yu classes are all contained in $\mathbb{C}_{\mathbf{0}}$ whereas $\mathbb{C}_{\mathbf{0}'}$ comprises all computationally universal CA. Unsurprisingly, it is again undecidable whether a CA belongs to any particular class. At the bottom end of the hierarchy it is Σ_3-complete to determine membership in $\mathbb{C}_{\mathbf{0}}$; at the top end it is Σ_4-complete to determine membership in $\mathbb{C}_{\mathbf{0}'}$. Thus, it is easier to determine decidability than universality. In general, deciding membership in $\mathbb{C}_{\mathbf{d}}$ is Σ_3^d-complete for any semi-decidable degree $\mathbf{d}$. Similar results hold for the analogous cumulative classes $\mathbb{C}_{\leq \mathbf{d}} = \bigcup_{\mathbf{e} \leq \mathbf{d}} \mathbb{C}_{\mathbf{e}}$.

Unlike the Culik–Yu classification, the structure of the degree classification between $\mathbb{C}_{\mathbf{0}}$ and $\mathbb{C}_{\mathbf{0}'}$ is exceedingly complicated. For example, the proof of the Friedberg–Muchnik theorem shows that there are incomparable semi-decidable degrees $\mathbf{d}_1$ and $\mathbf{d}_2$. Hence there is are CA whose orbits are undecidable but not as complicated as the Halting Problem. Indeed, complete knowledge of the orbits of one of the two CA will not help in deciding membership in the orbits of the other. Another surprising result in the theory of computably enumerable degrees is Sack's Density Theorem, see [52]: between any two computably enumerable degrees $\mathbf{d}_1 < \mathbf{d}_2$ there lies a third: $\mathbf{d}_1 < \mathbf{d} < \mathbf{d}_2$. Thus, between any two CA of strictly increasing complexity there is an infinite and dense hierarchy of other CA. The computably enumerable degrees form a semi-lattice, so it is natural to try to understand the complexity of the structure by analyzing its first order theory. It is well-known that the Σ_1-theory of this semi-lattice is decidable. However, the reason for this decidability result lies in the fact that any countable partial order can be embedded into the semi-lattice so that the relative computational strength of cellular automata is indeed arbitrarily complicated. On the other hand, the full theory of the semi-lattice of semi-decidable degrees is known to be highly undecidable, see [22]; its degree is $\emptyset^{(\omega)}$. One might hope that restriction to reversible CA would simplify the situation somewhat. Somewhat surprisingly it turns out that each class $\mathbb{C}_{\mathbf{d}}$ already contains an irreversible CA, see [60], so the same difficulties arise in the classification of reversible CA as in the classification of ordinary CA.

While reachability is arguably the most basic relation between configurations, similar difficulties also arise with confluence. As a matter of fact, one can construct a CA whose Reachability Problem has complexity some arbitrarily chosen computably enumerable degree $\mathbf{d}_1$ while the Confluence Problem for the same CA has degree $\mathbf{d}_2$, another arbitrarily chosen computably enumerable degree. Thus, a classification according to reachability is entirely independent of a confluence-based classification.

How do these results relate to PCE? Wolfram would not accept any of the intermediate classes of CA as a counterexample to PCE. The argument is that though intermediate degrees exist, their construction is critically linked to universal computation. While the universal computation is invisible when only the output of the system is observed, the associated computational process includes the whole computation and is thus universal. As a case in point, consider the standard Friedberg–Muchnik construction for an intermediate semi-decidable set A. The construction actually builds two semi-decidable sets A and B that are mutually incomparable with respect to Turing reducibility. Only A is output and B remains hidden. However, even ignoring all the intricate technical details of the whole construction, if we consider both A and B as output then the computation is indeed universal: the disjoint union $A \oplus B$ is Σ_1-complete, see [51]. It remains to be seen if similar arguments can be put forth in connection with priority-free constructions of intermediate degrees or if natural examples of intermediate sets can be found. At any rate, by considering only the reachability relation instead of a whole segment of the orbit we also achieve information-hiding, much as in the classical Friedberg–Muchnik construction.

Conclusion

Classification schemes of cellular automata based on the long-term evolution of pattern are typically undecidable, even if the property in question can be expressed in a fairly week system. While it is easy to construct examples of CA in particular classes it is usually very difficult to establish the position of a given CA in a particular classification. An excellent example for the difficulty of analyzing a given CA is Cook's proof of the universality of elementary CA number 110 whose local rule is given by $\rho(x, y, z) = (\overline{x} \wedge y \wedge z) \oplus y \oplus z$ where $\oplus$ denotes exclusive or, see [9], ► Cellular Automata, Universality of. The argument shows that cyclic tag systems, which are known to be complete, can be simulated by elementary CA 110 provided one allows an almost periodic background. Recent work by Turlough and Woods has shown that the whole simulation can be effected with only a polynomial slow-down, see [42,43]. This result suggests that the appropriate setting for classifications is the space of almost periodic configurations rather than finite ones.

In light of the successful analysis of elementary CA 110 it is tempting to ask about the classification of elementary CA 30. Figure 3 shows a segment of the orbit of a one-point seed configuration under rule 30. It is striking how chaotic and apparently random the image is. As a matter of fact, rule 30 has been used for many years as the default random number generator in the commercial computer algebra system Mathematica, see [70]. The underlying local map is simply $\rho(x, y, z) = x \oplus (y \vee z)$. Alas, there appear to be no structures in the evolution of configurations under rule 30 such as "moving particles" that might be exploited in a universality argument along the lines of rule 110. On the other hand, it is unclear how a decision procedure for reachability could be developed. This makes it tempting to conjecture that rule 30 in C_{ap} might be a member of one of the intermediate classes $\mathbb{C}_{\mathbf{d}}$, though at present there seems to be no way to either establish or refute this conjecture.

While undecidability results rule out the possibility of automatic classification mechanisms there is still ample room for the development of sufficient criteria for membership in certain classes, see [1,64,72]. For example, a proof of computational universality in a CA that has not been artificially constructed to simulate some other device often rests on the presence of "particles" or "gliders" that can be used to send "signals" between spatially separated locations. Moreover, one has to be able to process these signals much in the way of Boolean logic gates, to store state and so forth. A good example for complicate interactions between signals are the various solutions to the firing squad problem, albeit not in the context of simulating arbitrary computations; see Fig. 4, [36]. A more recent example is Cook's ingenious method of using natural gliders in elementary CA 110 to implement a cyclic tag system in C_{ap}, thereby establishing computational universality of rule 110, see [9]. Notable here is the fact that the automaton was fixed from the start and the the appropriate coding mechanisms had to be developed in a very constrained environment. This is in stark contrast to other hardness arguments where the CA is carefully constructed to display the desired behavior. Careful visual inspection of rule 110 orbits was a crucial component in Cook's proof, it is difficult to imagine that the result could have been established in a purely combinatorial or algebraic fashion. Cellular Automata, Emergent Phenomena in

JAMES E. HANSON
IBM T.J. Watson Research Center,
Yorktown Heights, USA

Article Outline

Glossary

Cellular automaton A spatially-extended dynamical system in which spatially-discrete cells take on discrete values, and evolve according to a spatially-localized discrete-time update rule.

Emergent phenomenon A phenomenon that arises as a result of a dynamical system's intrinsic dynamical behavior.

Domain A spatio-temporal region of a cellular automation that conforms to a specific pattern.

Particle A spatially-localized region of a cellular automaton that exists as a boundary or defect in a domain, and persists for a significant amount of time.

Definition of the Subject

In a dynamical system, an "emergent" phenomenon is one that arises out of the system's own dynamical behavior, as opposed to being introduced from outside. Emergent phenomena are ubiquitous in the natural world; as just one example, consider a shallow body of water with a sandy bottom. It often happens that small ridges form in the sand. These ridges emerge spontaneously, have a characteristic size and shape, and move across the bottom in a characteristic way – all due to the interaction of the sand and the water.

In cellular automata (CA), the system's state consists of an N-dimensional array of discrete cells that take on discrete values and the dynamics is given by a discrete time update rule (see below). The "phenomena" that emerge in CA therefore necessarily consist of spatio-temporal patterns and/or statistical regularities in the cell values. Therefore, the study of emergent phenomena is CA is the study of the spatio-temporal patterns and statistical regularities that arise spontaneously in cellular automata.

Introduction

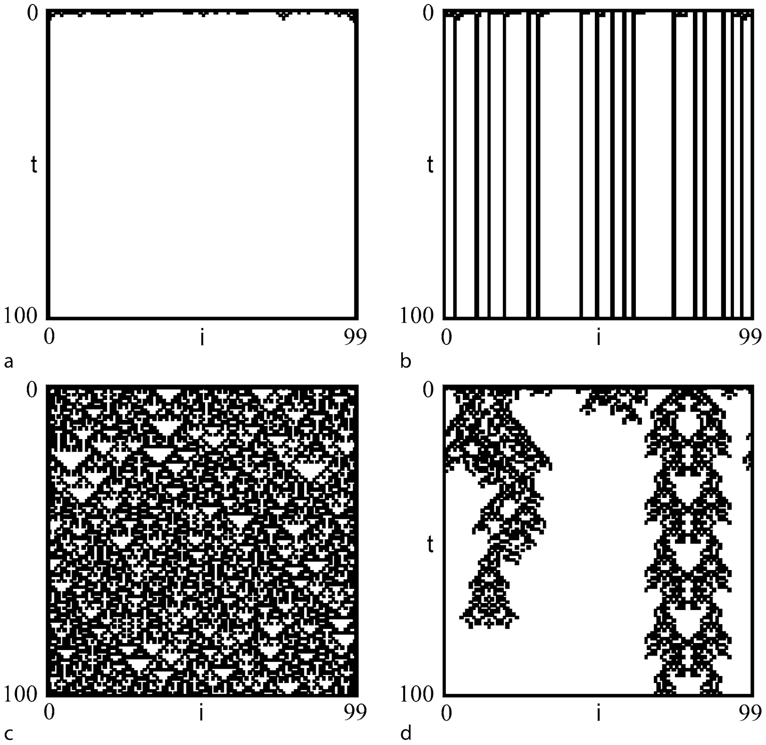
The study of emergent phenomena in cellular automata dates back at least to the beginnings of the modern era of CA investigation inaugurated by Stephen Wolfram and collaborators. Indeed, it was a central theme of the landmark paper that introduced the four "Wolfram classes" [15] shown in Fig. 1. Ever since, emergent phenomena have been the driving force behind a great deal of CA research.

To be genuinely emergent, a phenomenon must arise out of configurations in which it is not present; and furthermore, to be of any significance, it must do so with non-vanishing likehood, and persist for a measurable amount of time. Thus the proper study of emergent phenomena in CA excludes from consideration a broad subcategory of systems in which the initial condition and update rule are chosen a priori to exhibit some particular structural feature (lattice gases are a representative example). The fact that such systems are CA is an implementation detail; the CA is merely a substrate or means for the simulation of higher-order structures. Note also that the essential issue is not whether the phenomena were intentionally designed into the CA rule; it is whether they arise naturally with any degree of frequency from configurations in which they are not present.

Notation and Terminology

A **cellular automaton** (CA) consists of a discrete N-dimensional array of sites or **cells** and a discrete-time **local update rule** ϕ applied to all cells in parallel.

The location of a cell is given by the N integer-valued coordinates $\{i, j, k, \ldots\}$. Cells take on values in a discrete set or **alphabet**, conventionally written $0, 1, \ldots, k-1$,



Cellular Automata, Emergent Phenomena in, Figure 1
Examples of Wolframs four qualitative classes. a Class 1: Spatio-temporally uniform configuration of ECA 32. b Class 2: Separated simple or periodic structures of ECA 44. c Class 3: Chaotic space-time pattern of ECA 90. d Class 4: Complex localized structures of Binary radius-2 CA 1771476584. In all cases the initial condition is random. In this and subsequent figures, cells with value 0 are shown as *white squares*, cells with value 1 are *black*

with k the **alphabet size**. An assignment of values to cells is called the **configuration** of those cells. The value 0 is sometimes treated as a special "quiescent" value, particularly in rules that obey the **quiescence condition** $\phi(\ldots 0 \ldots) = 0$.

The local update rule determines the value of a cell at time $t+1$ as a function of the values at time t of the cells around it. Typical neighborhoods are symmetrical, centered on the cell to be updated, and are parametrized by the **radius** r, which is the greatest distance from the center cell to any cell in the neighborhood. An assignment of values to the cells in a neighborhood is called a **parent neighborhood**, denoted by η, and the value $\phi(\eta)$ to which that parent neighborhood is mapped under the local update rule is its **child value**. The set of ordered pairs $\{\eta, \phi(\eta)\}$ is the **rule table**. The **speed of light** of a CA is the maximal rate at which information about a cell's value may travel; in general it is given by the radius r.

In two dimensions there are two common alternatives for the neighborhood's shape: the **von Neumann** neighborhood includes the center cell and its four neighbors up, down, left, and right; and the **Moore** neighborhood, which also includes the four cells diagonally adjacent to the center cell.

The so-called **elementary** cellular automata (ECA) are one-dimensional CA with $k = 2$, $r = 1$; a cell is denoted σ^i, takes on values in $\{0, 1\}$ and evolves over time according to the rule $\sigma^i_{t+1} = \phi(\sigma^{i-1}_t, \sigma^i_t, \sigma^{i+1}_t)$. A neighborhood consists of three consecutive cells, so there are 8 distinct parent neighborhoods and 256 different rule tables. It is convenient to refer to an elementary CA by its **rule number**, which is determined as follows. The different parent neighborhoods η are regarded as numbers in base k and are arranged in decreasing numerical order, from left to right. Immediately beneath each parent neighborhood its child value $\phi(\eta)$ is written. The rule number is obtained by regarding the sequence of child symbols as another number, again in base k. This numbering scheme may be used for one-dimensional CA with any k and r, and may be extended to higher-dimensional CA by the adoption of a convention for assigning numerical values to parent neighborhoods.

Different formulations of the local update rule are possible for CA in which symmetry or other constraints are present. For example, one important subclass of CA rules are the **totalistic** rules, in which the child value depends only on the sum of the values in the parent neighborhood, not on their positions. Totalistic rules may also be assigned a rule number, by writing down the different possible sums of cell values in the parent neighborhood in order, writing the child cell beneath each such sum, and interpreting the sequence of child cells as a number.

In describing patterns in one-dimensional configurations, it is convenient to adopt a simplified form of regular expression notation, as follows:

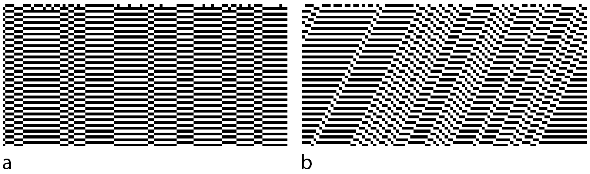
- symbols $0, 1, \ldots, k-1$ denote literal cell values
- the symbol Σ denotes a "wild card" that may take on any value in the alphabet
- the expression x^* denotes any number of repetitions of the pattern x
- $[\ldots]$ denotes grouping
- concatenation denotes spatial adjacency.

For example, 0^* represents any number of consecutive 0s, while $[10]^*1$ is any configuration consisting of some number of repetitions of the pattern 10 followed by a 1: e. g., 101, 10101, 1010101, and so forth.

Synchronization

Possibly the simplest type of emergent phenomenon in CA is **synchronization**, which is the growth of spatial regions in which all cells have the same value. A synchronized region remains synchronized over time (except possibly at its borders) and it may either temporally invariant (i. e., the cell values to not change in time) or periodic (the cells all cycle together through the same temporal sequence of values). The temporal periodicity in the latter case is not greater than the alphabet size k.

About the trivial case in which the CA rule maps all neighborhoods to the same value (e. g., ECA 0 or ECA 255), there is little to be said. However, other cases exist in which the synchronized regions emerge only gradually. Characteristic examples in one dimension are shown in Fig. 1a and c. It is evident from these examples that any initial condition can be roughly, but usefully, described in terms of four patterns: (a) pattern 0^*, which represents the synchronized regions; (b,c) boundary regions $0^*\Sigma^*$ and Σ^*0^*; and (d) Σ^* for the interior of the non-synchronized regions. The behavior of the boundary regions determines whether the synchronized regions grow or shrink. For example, in ECA 32 (Fig. 1a), the parent neighborhoods in the boundary region are $\eta = \{0\Sigma\Sigma, \Sigma\Sigma 0\}$, all of which have child value 0; this means that the synchronized region grows as fast as is possible. Also not that since the only parent neighborhood that is *not* mapped to 0 is $\eta = 101$. the time taken for a given configuration in ECA 32 to reach a globally synchronized state is governed by the length of the longest region of pattern $[10]^*1$.



Cellular Automata, Emergent Phenomena in, Figure 2
Synchronization and phase defects: a ECA 55. b ECA 17

In general, the growth (or shrinkage) of synchronized regions is determined by the aggregate behavior of the neighborhoods that occur its boundaries; if they recede from each other, the region will grow. The boundaries need not move at the speed of light; the left and right boundaries need not move at the same speed; and their motion need not be perfectly uniform over time.

Figure 2a shows ECA 55, in which synchronized regions with temporal period $p = 2$ emerge from random initial conditions. Note, however, that multiple distinct synchronized regions persist indefinitely. This is an example of a **temporal phase defect**, which is a boundary between spatio-temporal regions that have the same overall pattern, but one of which is *ahead* of the other in time.

In general, phase defects need not be stationary: an example is shown in Fig. 2b. Also note that for CA with $k > 2$ it is possible for several different synchronized patterns to emerge and coexist. For example, consider a CA with $k = 3$ in which the pattern 0^* is temporally invariant, while 1^* and 2^* are mapped into each other to form a period-2 cycle.

Domains in One Dimension

Synchronization is a special case of a more general emergent phenomenon, the **domain**. A domain is spatial region that conforms to some specific pattern which persists over time. As has been seen in the case of synchronization, the emergence of a domain is governed by the behavior of its boundaries.

An important subclass of domain is the **regular domain**, in which the spatial pattern may be expressed in terms of a regular language (or equivalently, a finite state machine) [11]. As defined in [9], a regular domain has two properties: all spatial sequences of cells in the domain are in a given regular language; and (2) the set of all sequences in that regular language is itself temporally invariant or periodic. Regular domains are a powerful tool for identify-

Cellular Automata, Emergent Phenomena in, Figure 4
Raw and domain-filtered ECA 18

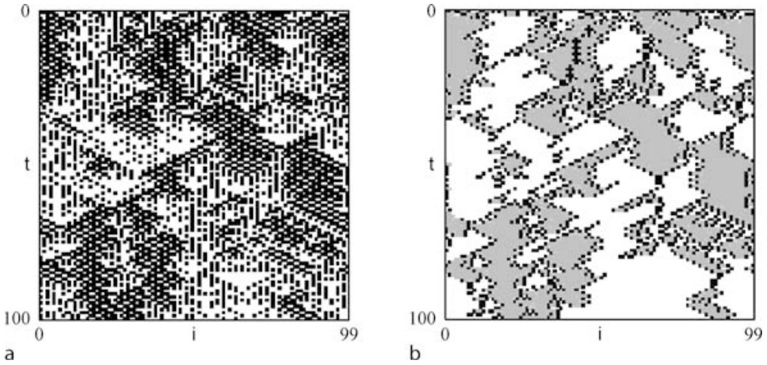
ing and analyzing emergent phenomena in CA of one dimension. Generalization to two or more dimensions has proven challenging, though [12] made a significant step in that direction.

In studying domains in CA, it is useful to pass the space-time data through a **domain filter** to help visualize them. A domain filter, which may be constructed for any regular domain, maps every cell that is in the domain to a chosen value (0, say) and maps all cells not in the domain to other values in a prescribed way. Multi-domain filters may be constructed in a similar fashion, to map cells in any of a set of distinct domains $\Lambda_1, \Lambda_2, \ldots$ onto distinct values $\sigma_1, \sigma_2, \ldots$. See [3] for details.

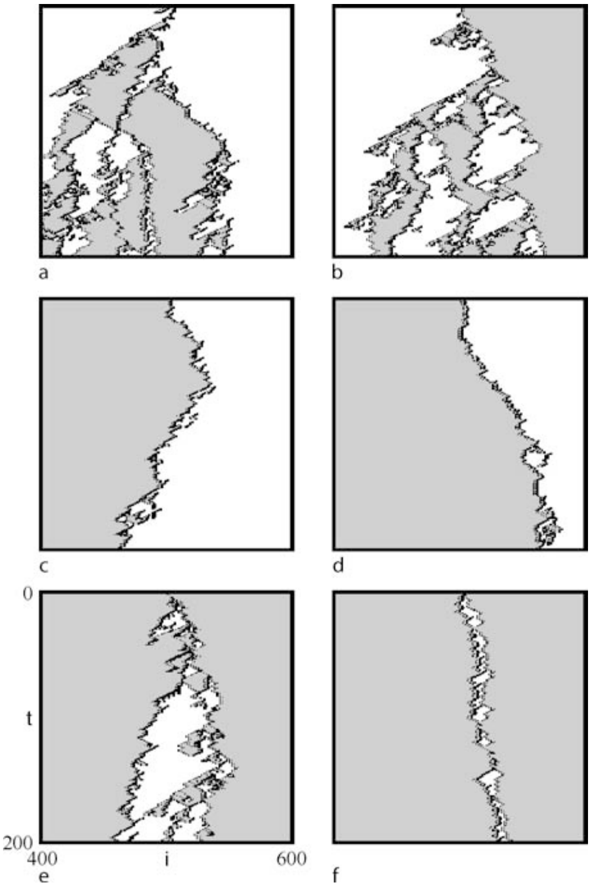
An illustrative example is ECA 54, shown in Fig. 3. On the left is the unfiltered data; and on the right, the same dat after passing through the domain filter for ECA 54's primary domain. The domain has temporal period $p = 2$ and alternates between patterns [0001] and [110] The two patterns line up to form the interlocking white and black "T" shapes visible in the unfiltered data.

As the filtered plot clearly shows, the cells *not* in the domain have patterns of their own; this will be discussed in the next section. For now, it is sufficient to note that, in addition to the *temporal* phase defects seen in the emergence of temporally periodic synchronized regions, domains with nontrivial spatial structure may also show *spatial* phase defects, in which the pattern, in effect, skips or slips by a few cells.

The spatial regions that make up a domain may themselves contain disorder; such domains are called **chaotic**. ECA 90 is the archetypical example of this see Fig. 1c. From a random initial condition, ECA 90 quickly evolves so that entire configuration is in the domain $[0\Sigma]^*$. ECA 18 see Fig. 4a, attempts to do the same, except that the global synchronization is frustrated by long-lived spatial phase defects. This is clearly visible in the filtered space-time diagram shown in Fig. 4b. In this case the boundaries of the domain are inherently ambiguous: the pattern $[0\Sigma]^*[00]^*[\Sigma 0]^*$ contains exactly one spatial phase defect, but it may be regarded as lying anywhere in the cen-



Cellular Automata, Emergent Phenomena in, Figure 5
Multiple coexisting chaotic domains



Cellular Automata, Emergent Phenomena in, Figure 6
Domain interfaces in the CA of Fig. 5

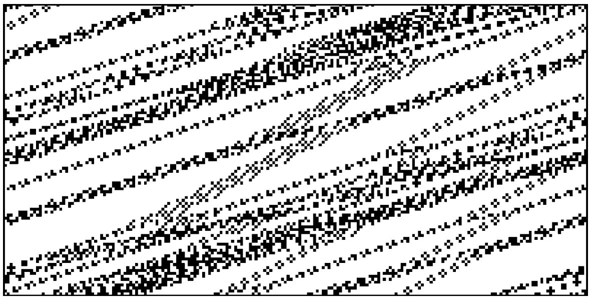
tral [00]* region. The filter used maps all cells in regions that contain a spatial phase defect to 1s.

A single CA may support the emergence of multiple different domain patterns. In many cases one domain dominates and will eventually take over. But this is not always true. An interesting case in which two domains, both chaotic, compete on roughly equal status, is binary radius-2 rule 2614700074, shown in Fig. 5. The two domains have patterns $\Lambda_0 = [0\Sigma]^*$ and $\Lambda_1 = [110\Sigma]^*$, respectively. In the filtered plot, cells in Λ_0 are shown in white, cells in Λ_1 are gray, and all other cells are black. It appears that by about $t = 200$ Λ_0 appears to be winning, but in fact, by about $t = 700$, the entire configuration was in Λ_1, where it remained indefinitely. Depending on the initial condition, one or the other domain was always found to eventually take over with Λ_0 winning about 80% of the time.

The coexistence of multiple domains, each with its own spatial structure, gives rise to a large number of possible interfaces. in general, the number of distinct interface types is governed by the complexity of the pattern in each domain; for 2614700074 it turns out that there are 8 distinct possibilities. Six of these show qualitatively distinct behavior, and are plotted (in filtered form only) in Fig. 6. Note that of the six interfaces, two show a quickly growing region in which defects continually multiply, three of them appear to remain spatially localized, and one (at bottom left) is ambiguous.

Particles in One Dimension

An immediate consequence of the emergence of domains is the simultaneous emergence of boundaries between them. These boundaries may be phase defects, as mentioned in Sect. "Synchronization", but they may also take the form of **particles**. A particle is a small region of cells that separates two domains, persists for a relatively long period of time and remains spatially localized. Particles may be stationary or may move; they may themselves exhibit a pattern that is temporally invariant, periodic, or even disordered.



Cellular Automata, Emergent Phenomena in, Figure 7
Examples of solitons in the one-dimensional Filtering Rule

Solitons

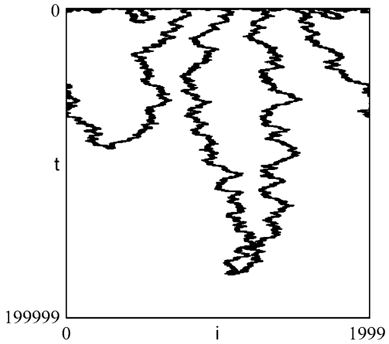
An interesting type of particle emerges in the so-called **soliton** CA, shown in Fig. 7. These CA rules received their name in analogy with the solitons of fluid dynamics, which are solitary traveling waves with the interesting property that two solitons may collide, interact, and pass safely through each other, ultimately recovering their original form as if no collision had taken place. In soliton CA, something similar occurs.

In the simplest case, $k = 2$, the quiescence condition holds with the usual quiescent symbol 0. The solitons or particles embedded in a large lattice of 0s are finite sequences of 1s and 0s that are both temporally periodic (up to a spatial shift) and can collide and pass through each other without being destroyed. A particle consists of a finite sequence of basic strings of length $r + 1$ (where r is the CA radius). The leftmost cell of a particle is always a non-quiescent cell. A particle is bounded on the right by a sequence of $r + 1$ quiescent cells. Under the action of the CA rule, a particle may move to the left or right, may grow or shrink, but ultimately will come back to its original configuration after a finite time p – though possibly shifted by some number of cells. The ratio of the shift and temporal period p determines the particle's velocity V defined in the obvious way: $V =$ (spatial shift)/(temporal period).

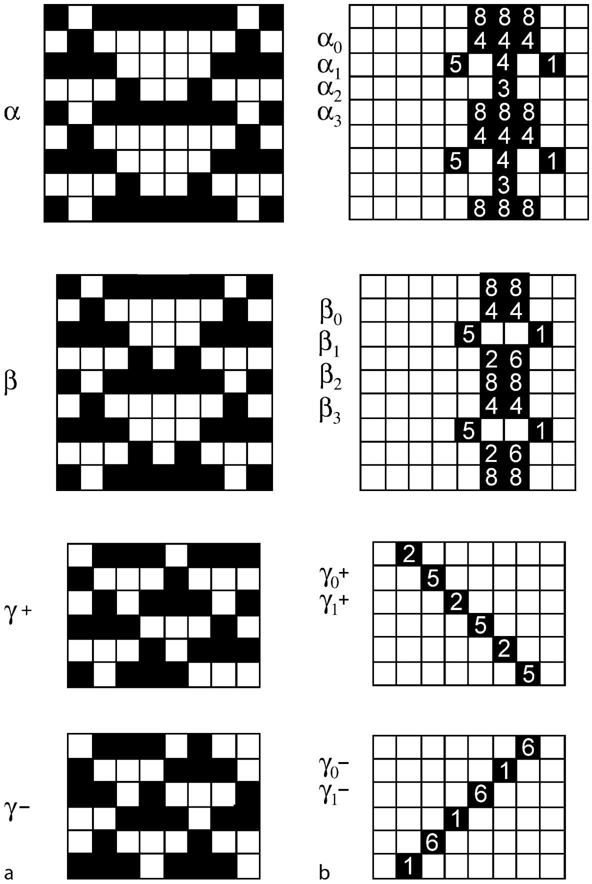
A particle may even temporarily split into two or more smaller particles, so long as eventually they rejoin to form the original configuration. And, as the name implies, two particles with different velocities may collide and pass through each other without being destroyed.

Particles and Defects Defined by Domains

Given the wide variety of domains that arise in CA, the resultant variety of particles that they support is apparently limitless. However, two simple examples may suffice to illustrate these phenomena: ECA 18 and ECA 54, both of which were discussed in the previous section.



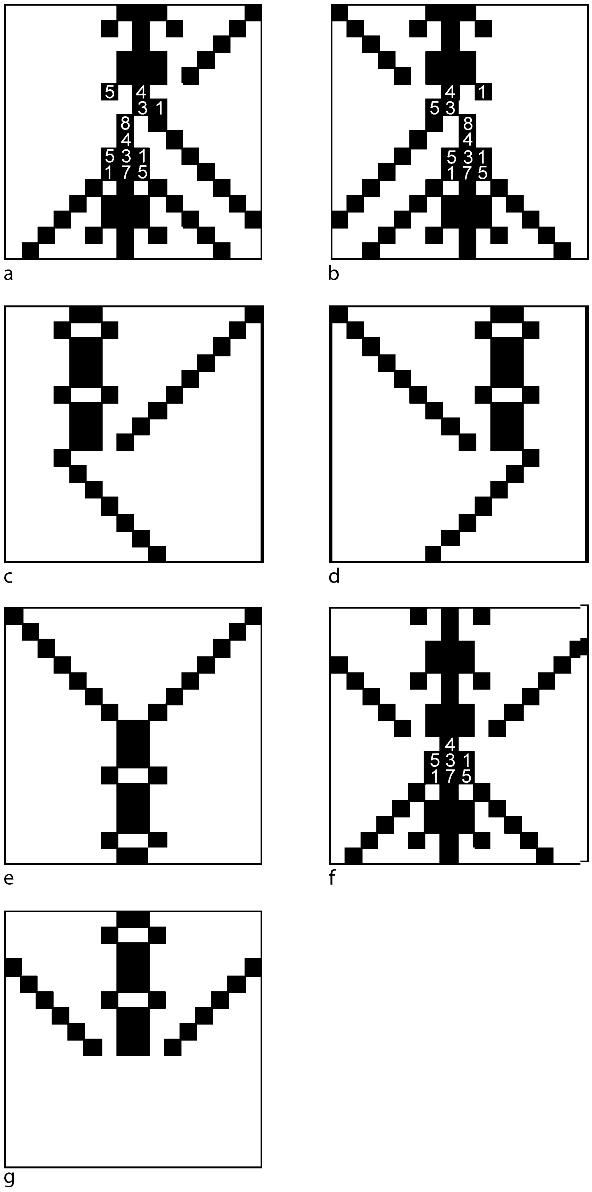
Cellular Automata, Emergent Phenomena in, Figure 8
Long-term behavior of ECA 18



Cellular Automata, Emergent Phenomena in, Figure 9
Fundamental particles in ECA54

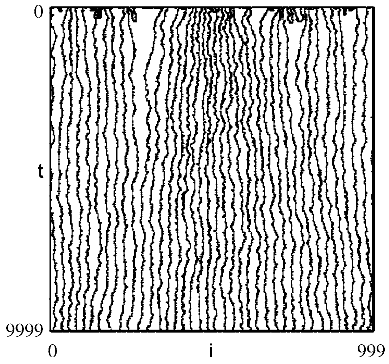
Particles in ECA 18

The spatial phase defects that occur in the domain of ECA 18 (see Fig. 4b) appear, on casual inspection, to be moving more or less at random. It turns out that to a very good approximation, an isolated defect performs a random walk



Cellular Automata, Emergent Phenomena in, Figure 10
Pairwise interactions between fundamental particles in ECA 54

on the lattice [4,7]. When two of them meet, they mutually annihilate. This behavior is purely deterministic, of course; it is caused entirely by the iterated action of the update rule on the initial condition. In effect, the disorder in the domains is causing disorder in the motion of their boundaries. For small systems, and *eventually* on all systems, finite-size effects cause departures from statistical randomness; but otherwise, except for a few highly atypical system-sizes, the defects' behavior is statistically indistinguishable from random motion. Figure 8 shows the long-term behavior of a random initial condition on a relatively large lattice.



Cellular Automata, Emergent Phenomena in, Figure 11
Long-term behavior of ECA 54

Particles in ECA 54

ECA 54 represents an interesting case which can serve to illustrate many the emergent phenomena in one dimensional CA [1,10]. The primary domain gives rise to the so-called "fundamental particles" α, β and γ, shown in Fig. 9. The unfiltered space-time diagrams are shown on the left, and their filtered counterparts on the right. The interactions between the fundamental particles are shown in Fig. 10. In the filtered figures, the numbers inscribed in the black squares are the different outputs of the domain filter; each different sequence of numbers represents a different way in which the domain pattern has been violated.

The long-term behavior of the particles can be seen in Fig. 11. The βs decay relatively quickly, leaving only αs and γs – except for rare cases where a β is created by the interaction in Fig. 10e and persists for a short while, and rarer cases where some other pattern is momentarily present. (Note that the scale of the figure is so compressed that only the αs are visible.) It appears, and is borne out by numerical experiments, that the number of αs decays extremely slowly, and that the system settles into a state in which the αs are roughly equidistant, but move back and forth slightly in a disordered way. Unlike the case of ECA 18, the domains are not disordered, so the particle motion cannot be caused by disorder in the domain. Instead, it comes from the α–γ interactions.

Emergent Phenomena in Two and Higher Dimensions

As might be expected, the emergent phenomena in CA of more than one spatial dimension are at once richer and less systematically studied. All of the phenomena that are observed in one dimension have their analogues in higher dimensions: domains and particle abound. In 2 or more dimensions, "particle" is no longer synonymous with "boundary"; one sees particles that are entirely surrounded by a domain, and spatially-extended boundaries that separate domains. Fundamentally new types of emergent phenomena appear as well.

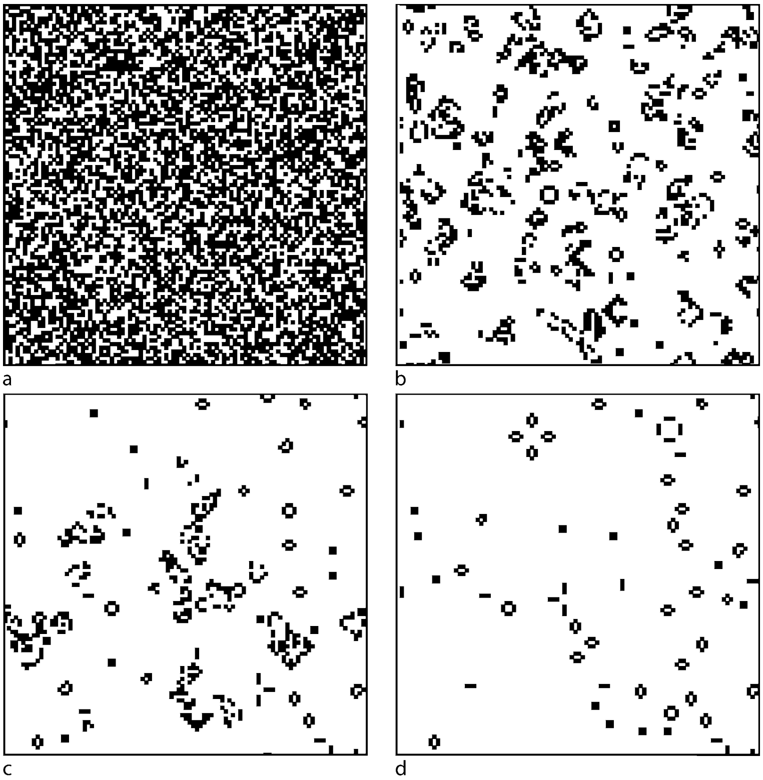
Domains, Particles, and Interfaces

Many of the coherent structures found to exist in Conway's famous Game of Life can be observed to arise spontaneously from random initial conditions, so they properly fall into the category of emergent phenomena. In Fig. 12 a configuration of 100x100 cells is shown at four successive times $t = 0, 50, 900, 1350$. From the random initial condition, a background pattern of 0s quickly emerges, against which there exist a rich variety of particles and disordered structures. By $t = 1350$ the configuration has settled to its final state, in which only a few particles remain, all of which are stationary and have temporal period $p = 1$ or $p = 2$. At intermediate times, various moving structures may be identified: see, for example, the "glider" at $t = 900$, about halfway between the center and the top. In moving about, these inevitably collide with each other or with the stationary particles, eventually leading to the final state.

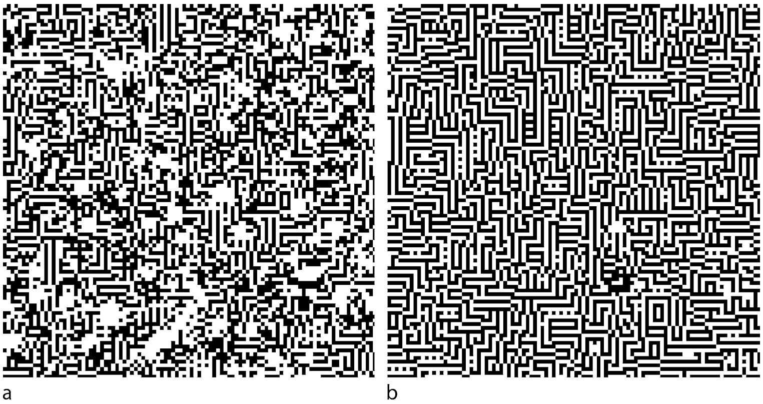
Interestingly enough, a minor variation on the rule gives rise to the patterns shown in Fig. 13. Small regions of horizontal or vertical stripes emerge quickly. Boundaries between them settle down. By $t = 100$, a few non-striped areas persist, along with a few "dotted lines" that take the place of a stripe, and in which the "dots" oscillate. The non-striped areas eventually all disappear. The dotted lines persist indefinitely.

As these examples suggest, 2-dimensional CA support the emergence of synchronized regions, "domains", and particles in close analogy to 1-D CA. The striped regions in Fig. 13 are an example of a two-dimensional, temporally-invariant domain.

Fundamentally new features also appear in two and higher dimensions as well. The most obvious of these is the spatially-extended **interface** or boundary between two adjacent domains. Unlike the one-dimensional case, in



Cellular Automata, Emergent Phenomena in, Figure 12
Conway's Game of Life, starting from a random initial condition. a $t = 0$. b $t = 50$. c $t = 900$. d $t = 1350$

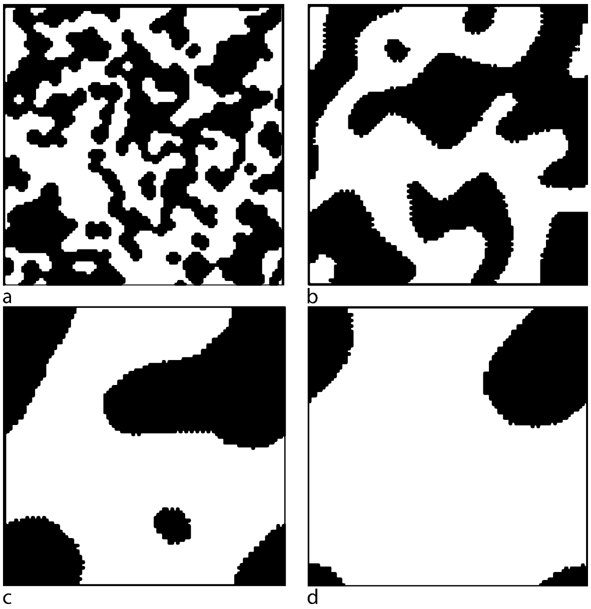


Cellular Automata, Emergent Phenomena in, Figure 13
Variant on Conway's Game of Life, starting from the same random initial condition as in Fig. 12. a $t = 10$. b $t = 100$

which particles and interfaces are more or less the same thing, interfaces in two dimensions are themselves one-dimensional. A characteristic example is seen in the *voting rule*, a 2-D binary CA with von Neumann neighborhood, in which the child cell is determined by the majority of the the local update rule maps a the child cell is equal to the value held by the majority of cells in the parent neighborhood, or if the vote is a tie, by a 0. Figure 14a shows a snapshot at $t = 50$ of the voting rule starting from a random initial condition. The system has organized itself into regions of two domain patterns. The pattern has stabilized by this time and does not change thereafter.

A stochastic variation on the voting rule uses a random variable to break tie votes, resulting it patterns such as Fig. 14b, c and d. Over time, the long boundaries gradually straighten, and small regions of one domain embedded in the other gradually shrink.

A number of extensive tours of patterns observed in selected 2-d CA may be found online; see, for example, [8,14].



Cellular Automata, Emergent Phenomena in, Figure 14

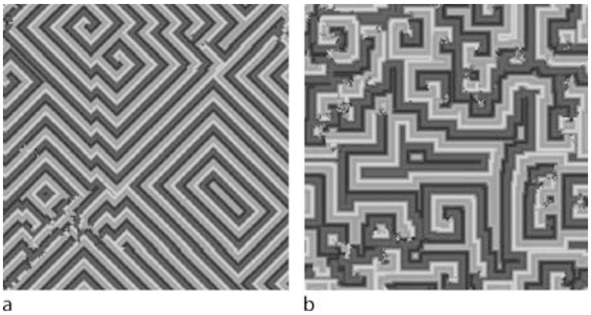
Spiral Waves

Another important class of patterns in 2-D CA are expanding wavelike patterns, as shown in Fig. 15. These are typical of the class of rules called **cyclic CA** [5], and generally evolve to configurations of spirals (as shown). These patterns are not domains in the usual sense, because they have a geometric center. The shape of the spiral is closely related to the shape of the parent neighborhood. Starting from a random initial condition, eventually some number of centers form out from which the spiral waves emanate.

Quasiperiodicity

The final phenomenon to be mentioned here is an intriguing form of emergent phenomenon fundamentally different from what has been discussed above: the emergence of quasiperiodic oscillations in coarse statistical properties of the configuration (such as, percentage of 1s). [2,6] The evidence consists of **return maps**, in which the fraction m_t of 1s at time t, is plotted against the fraction m_{t+1} at time $t + 1$. A synchronized system would show a return map consisting of a single point: $m_t = m_{t+1}$. A periodic sys-



Cellular Automata, Emergent Phenomena in, Figure 15
Spiral waves. a Cyclic CA with $k = 16$, von Neumann neighborhood. b Cyclic CA with $k = 16$, Moore neighborhood

tem would show a sequence of points for the different values of m at the different temporal phases of the sequence, and would have $m_t = m_{t+p}$, where p is the period. The observed return plots, however, showed the characteristic shape of quasiperiodic behavior in nonlinear dynamical systems, which is a sequence of points that eventually map out a roughly continuous, closed curve in the plane. This quasiperiodic behavior was found to occur only in CA of dimension $N > 3$.

Future Directions

This short survey has only been able to hint at the vast wealth of emergent phenomena that arise in CA. Much work yet remains to be done, in classifying the different structures, identifying general laws governing their behavior, and determining the the causal mechanisms that lead them to arise.

For example, there are as yet no general techniques for determining whether a given domain is stable in a given CA; for characterizing the set of initial conditions that will eventually give rise to it; or for working out the particles that it supports. In CA or two or more dimensions, a large body of *descriptive* results are available, but these are more frequently anecdotal than systematic. A significant barrier to progress has been the lack of good mathematical techniques for identifying, describing, and classifying domains. One promising development in this area is an information-theoretic filtering technique that can operate on configurations of any dimension [13].

Glossary

Groups A *group* is a set G endowed with a binary operation $G \times G \ni (g, h) \mapsto gh \in G$, called the *multiplication*, that satisfies the following properties: (i) for all g, h and k in G, $(gh)k = g(hk)$ (associativity); (ii) there exists an element $1_G \in G$ (necessarily unique) such that, for all g in G, $1_G g = g 1_G = g$ (existence of the identity element); (iii) for each g in G, there exists an element $g^{-1} \in G$ (necessarily unique) such that $gg^{-1} = g^{-1}g = 1_G$ (existence of the inverses).

A group G is said to be *Abelian* (or *commutative*) if the operation is commutative, that is, for all $g, h \in G$ one has $gh = hg$.

A group F is called *free* if there is a subset $S \subset F$ such that any element g of F can be uniquely written as a *reduced word* on S, i. e. in the form $g = s_1^{\alpha_1} s_2^{\alpha_2} \cdots s_n^{\alpha_n}$, where $n \geq 0$, $s_i \in S$ and $\alpha_i \in \mathbb{Z} \setminus \{0\}$ for $1 \leq i \leq n$, and such that $s_i \neq s_{i+1}$ for $1 \leq i \leq n-1$. Such a set S is called a *free basis* for F. The cardinality of S is an invariant of the group F and it is called the *rank* of F.

A group G is *finitely generated* if there exists a finite subset $S \subset G$ such that every element $g \in G$ can be expressed as a product of elements of S and their inverses, that is, $g = s_1^{\epsilon_1} s_2^{\epsilon_2} \cdots s_n^{\epsilon_n}$, where $n \geq 0$ and $s_i \in S$, $\epsilon_i = \pm 1$ for $1 \leq i \leq n$. The minimal n for which such an expression exists is called the *word length* of g with respect to S and it is denoted by $\ell(g)$. The group G is a (discrete) metric space with the distance function $d\colon G \times G \to \mathbb{R}_+$ defined by setting $d(g, g') = \ell(g^{-1}g')$ for all $g, g' \in G$. The set S is called a *finite generating subset* for G and one says that S is *symmetric* provided that $s \in S$ implies $s^{-1} \in S$.

The *Cayley graph* of a finitely generated group G w.r.t. to a symmetric finite generating subset $S \subset G$ is the (undirected) graph $Cay(G, S)$ with vertex set G and where two elements $g, g' \in G$ are joined by an edge if and only if $g^{-1}g' \in S$.

A group G is *residually finite* if the intersection of all subgroups of G of finite index is trivial.

A group G is *amenable* if it admits a *right-invariant mean*, that is, a map $\mu\colon \mathcal{P}(G) \to [0, 1]$, where $\mathcal{P}(G)$ denotes the set of all subsets of G, satisfying the following conditions: (i) $\mu(G) = 1$ (*normalization*); (ii) $\mu(A \cup B) = \mu(A) + \mu(B)$ for all $A, B \in \mathcal{P}(G)$ such that $A \cap B = \varnothing$ (*finite additivity*); (iii) $\mu(Ag) = \mu(A)$ for all $g \in G$ and $A \in \mathcal{P}(G)$ (*right-invariance*).

Rings A *ring* is a set R equipped with two binary operations $R \times R \ni (a, b) \mapsto a + b \in R$ and $R \times R \ni (a, b) \mapsto ab \in R$, called the *addition* and the *multiplication*, respectively, such that the following properties are satisfied: (i) R, with the addition operation, is an Abelian group with identity element 0, called the *zero element*, (the inverse of an element $a \in R$ is denoted by $-a$); (ii) the multiplication is associative and admits an identity element 1, called the *unit element*; (iii) multiplication is distributive with respect to addition, that is, $a(b+c) = ab + ac$ and $(b+c)a = ba + ca$ for all a, b and $c \in R$.

A ring R is *commutative* if $ab = ba$ for all $a, b \in R$.

A *field* is a commutative ring $\mathbb{K} \neq \{0\}$ where every non-zero element $a \in \mathbb{K}$ is invertible, that is there exists $a^{-1} \in \mathbb{K}$ such that $aa^{-1} = 1$.

In a ring R a non-trivial element a is called a *zero-divisor* if there exists a non-zero element $b \in R$ such that either $ab = 0$ or $ba = 0$.

A ring R is *directly finite* if whenever $ab = 1$ then necessarily $ba = 1$, for all $a, b \in R$. If the ring $M_d(R)$ of $d \times d$ matrices with coefficients in R is directly finite for all $d \geq 1$ one says that R is *stably finite*.

Let R be a ring and let G be a group. Denote by $R[G]$ the set of all formal sums $\sum_{g \in G} \alpha_g g$ where $\alpha_g \in R$ and $\alpha_g = 0$ except for finitely many elements $g \in G$. We define two binary operations on $R[G]$, namely the addition, by setting

$$\left(\sum_{g \in G} \alpha_g g\right) + \left(\sum_{h \in G} \beta_h h\right) = \sum_{g \in G} (\alpha_g + \beta_g) g \,,$$

and the multiplication, by setting

$$\left(\sum_{g \in G} \alpha_g g\right)\left(\sum_{h \in G} \beta_h h\right) = \sum_{g,h \in G} \alpha_g \beta_h gh$$
$$\equiv_{k=gh} \sum_{g,k \in G} \alpha_g \beta_{g^{-1}k} k.$$

Then, with these two operations, $R[G]$ becomes a ring; it is called the *group ring* of G with coefficients in R.

Cellular automata Let G be a group, called the *universe*, and let A be a set, called the *alphabet*. A *configuration* is a map $x \colon G \to A$. The set A^G of all configurations is equipped with the right action of G defined by $A^G \times G \ni (x, g) \mapsto x^g \in A^G$, where $x^g(g') = x(gg')$ for all $g' \in G$.

A *cellular automaton* over G with coefficients in A is a map $\tau \colon A^G \to A^G$ satisfying the following condition: there exists a finite subset $M \subset G$ and a map $\mu \colon A^M \to A$ such that $\tau(x)(g) = \mu(x^g|_M)$ for all $x \in A^G$, $g \in G$, where $x^g|_M$ denotes the restriction of x^g to M. Such a set M is called a *memory set* and μ is called a *local defining map* for τ.

If $A = V$ is a vector space over a field $\mathbb{K}$, then a cellular automaton $\tau \colon V^G \to V^G$, with memory set $M \subset G$ and local defining map $\mu \colon V^M \to V$, is said to be *linear* provided that μ is linear.

Two configurations $x, x' \in A^G$ are said to be *almost equal* if the set $\{g \in G; x(g) \neq x'(g)\}$ at which they differ is finite. A cellular automaton is called *pre-injective* if whenever $\tau(x) = \tau(x')$ for two almost equal configurations $x, x' \in A^G$ one necessarily has $x = x'$.

A *Garden of Eden configuration* is a configuration $x \in A^G \setminus \tau(A^G)$. Clearly, GOE configurations exist if and only if τ is not surjective.

Definition of the Subject

A cellular automaton is a self-mapping of the set of configurations of a group defined from local and invariant rules. Cellular automata were first only considered on the n-dimensional lattice group $\mathbb{Z}^n$ and for configurations taking values in a finite alphabet set but they may be formally defined on any group and for any alphabet. However, it is usually assumed that the alphabet set is endowed with some mathematical structure and that the local defining rules are related to this structure in some way. It turns out that general properties of cellular automata often reflect properties of the underlying group. As an example, the Garden of Eden theorem asserts that if the group is amenable and the alphabet is finite, then the surjectivity of a cellular automaton is equivalent to its pre-injectivity (a weak form of injectivity). There is also a linear version of the Garden of Eden theorem for linear cellular automata and finite-dimensional vector spaces as alphabets. It is an amazing fact that famous conjectures of Kaplansky about the structure of group rings can be reformulated in terms of linear cellular automata.

Introduction

The goal of this paper is to survey results related to the Garden of Eden theorem and the surjunctivity problem for cellular automata.

The notion of a cellular automaton goes back to John von Neumann [37] and Stan Ulam [34]. Although cellular automata were firstly considered only in theoretical computer science, nowadays they play a prominent role also in physics and biology, where they serve as models for several phenomena (► Cellular Automata Modeling of Physical Systems, ► Chaotic Behavior of Cellular Automata), and in mathematics. In particular, cellular automata are studied in ergodic theory (► Entropy in Ergodic Theory, ► Ergodic Theory: Basic Examples and Constructions, ► Ergodic Theory of Cellular Automata, ► Ergodicity and Mixing Properties) and in the theory of dynamical systems (► Topological Dynamics of Cellular Automata, ► Symbolic Dynamics), in functional and harmonic analysis (▶ Spectral Theory of Dynamical Systems), and in group theory.

In the classical framework, the universe U is the lattice $\mathbb{Z}^2$ of integer points in Euclidean plane and the alphabet A is a finite set, typically $A = \{0, 1\}$. The set $A^U = \{x : U \to A\}$ is the configuration space, a map $x : U \to A$ is a configuration and a point $(n, m) \in U$ is called a cell. One is given a neighborhood M of the origin $(0, 0) \in U$, typically, for some $r > 0$, $M = \{(n, m) \in \mathbb{Z}^2 : |n| + |m| \leq r\}$ (von Neumann r-ball) or $M = \{(n, m) \in \mathbb{Z}^2 : |n|, |m| \leq r\}$ (Moore's r-ball) and a local map $\mu : A^M \to A$. One then "extends" μ to the whole universe obtaining a map $\tau : A^U \to A^U$, called a cellular automaton, by setting $\tau(x)(n, m) = \mu(x(n + s, m + t)_{(s,t)\in M})$. This way, the value $\tau(x)(n, m) \in A$ of the configuration x at the cell $(n, m) \in U$ only depends on the values $x(n+s, m+s)$ of x at its neighboring cells $(x + s, y + t) \equiv (x, y) + (s, t) \in (x, y) + M$, in other words, τ is $\mathbb{Z}^2$-equivariant. M is called a *memory set* for τ and μ a *local defining map*.

In 1963 E.F. Moore proved that if a cellular automaton $\tau : A^{\mathbb{Z}^2} \to A^{\mathbb{Z}^2}$ is surjective then it is also pre-injective, a weak form of injectivity. Shortly later, John Myhill proved the converse to Moore's theorem. The equivalence of surjectivity and pre-injectivity of cellular automata is referred to as the Garden of Eden theorem (briefly GOE theorem), this biblical terminology being motivated by the fact that it gives necessary and sufficient conditions for the existence of configurations x that are not in the image of τ, i. e. $x \in A^{\mathbb{Z}^2} \setminus \tau(A^{\mathbb{Z}^2})$, so that, thinking of $(\tau, A^{\mathbb{Z}^2})$ as a discrete dynamical system, with τ being the time, they can appear only as "initial configurations".

It was immediately realized that the GOE theorem was holding also in higher dimension, namely for cellular automata with universe $U = \mathbb{Z}^d$, the lattice of integer points in the d-dimensional space. Then, Machì and Mignosi [27] gave the definition of a cellular automaton over a finitely generated group and extended the GOE theorem to the class of groups G having sub-exponential growth, that is for which the growth function $\gamma_G(n)$, which counts the elements $g \in G$ at "distance" at most n from the unit element 1_G of G, has a growth weaker than the exponential, in formulæ, $\lim_{n\to\infty} \sqrt[n]{\gamma_G(n)} = 1$. Finally, in 1999 Ceccherini-Silberstein, Machì and Scarabotti [9] extended the GOE theorem to the class of amenable groups. It is interesting to note that the notion of an amenable group was also introduced by von Neumann [36]. This class of groups contains all finite groups, all Abelian groups, and in fact all solvable groups, all groups of sub-exponential growth and it is closed under the operation of taking subgroups, quotients, directed limits and extensions. In [27] two examples of cellular automata with universe the free group F_2 of rank two, the prototype of a non-amenable group, which are surjective but not pre-injective and, conversely, pre-injective but not surjective, thus providing an instance of the failure of the theorems of Moore and Myhill and so of the GOE theorem. In [9] it is shown that this examples can be extended to the class of groups, thus necessarily non-amenable, containing the free group F_2. We do not know whether the GOE theorem only holds for amenable groups or there are examples of groups which are non-amenable and have no free subgroups: by results of Olshanskii [30] and Adyan [1] it is know that such class is non-empty. In 1999 Misha Gromov [20], using a quite different terminology, reproved the GOE for cellular automata whose universes are infinite amenable graphs Γ with a dense pseudogroup of holonomies (in other words such Γs are rich in symmetries). In addition, he considered not only cellular automata from the full configuration space A^Γ into itself but also between subshifts $X, Y \subset A^\Gamma$. He used the notion of entropy of a subshift (a concept hidden in the papers [27] and [9].

In the mid of the fifties W. Gottschalk introduced the notion of surjunctivity of maps. A map $f : X \to Y$ is surjunctive if it is surjective or not injective. We say that a group G is surjunctive if all cellular automata $\tau : A^G \to A^G$ with finite alphabet are surjunctive. Lawton [18] proved that residually finite groups are surjunctive. From the GOE theorem for amenable groups [9] one immediately deduce that amenable groups are surjunctive as well. Finally Gromov [20] and, independently, Benjamin Weiss [38] proved that all sofic groups (the class of sofic groups contains all residually finite groups and all amenable groups) are surjunctive. It is not known whether or not all groups are surjunctive.

In the literature there is a notion of a linear cellular automaton. This means that the alphabet is not only a finite set but also bears the structure of an Abelian group and that the local defining map μ is a group homomorphism, that is, it preserves the group operation. These are also called *additive cellular automata* (▶ Additive Cellular Automata).

In [5], motivated by [20], we introduced another notion of linearity for cellular automata. Given a group G and a vector space V over a (not necessarily finite) field $\mathbb{K}$, the configuration space is V^G and a cellular automaton $\tau : V^G \to V^G$ is linear if the local defining map $\mu : V^B \to V$ is $\mathbb{K}$-linear. The set $\mathrm{LCA}(V, G)$ of all linear cellular automata with alphabet V and universe G naturally bears a structure of a ring.

The finiteness condition for a set A in the classical framework is now replaced by the finite dimensionality of V. Similarly, the notion of entropy for subshifts $X \subset A^G$

is now replaced by that of mean-dimension (a notion due to Gromov [20]). In [5] we proved the GOE theorem for linear cellular automata $\tau\colon V^G \to V^G$ with alphabet a finite dimensional vector space and with G an amenable group. Moreover, we proved a linear version of Gottschalk surjunctivity theorem for residually finite groups.

In the same paper we also establish a connection with the theory of group rings. Given a group G and a field $\mathbb{K}$, there is a one-to-one correspondence between the elements in the group ring $\mathbb{K}[G]$ and the cellular automata $\tau\colon \mathbb{K}^G \to \mathbb{K}^G$. This correspondence preserves the ring structures of $\mathbb{K}[G]$ and $\mathrm{LCA}(\mathbb{K}, G)$. This led to a reformulation of a long standing problem, raised by Irving Kaplansky [23], about the absence of zero-divisors in $\mathbb{K}[G]$ for G a torsion-free group, in terms of the pre-injectivity of all $\tau \in \mathrm{LCA}(\mathbb{K}, G)$.

In [6] we proved the linear version of the Gromov–Weiss surjunctivity theorem for sofic groups and established another application to the theory of group rings. We extended the correspondence above to a ring isomorphism between the ring $\mathrm{Mat}_d(\mathbb{K}[G])$ of $d \times d$ matrices with coefficients in the group ring $\mathbb{K}[G]$ and $\mathrm{LCA}(\mathbb{K}^d, G)$. This led to a reformulation of another famous problem, raised by Irving Kaplansky [24] about the structure of group rings. A group ring $\mathbb{K}[G]$ is stably finite if and only if, for all $d \geq 1$, all linear cellular automata $\tau\colon (\mathbb{K}^d)^G \to (\mathbb{K}^d)^G$ are surjunctive. As a byproduct we obtained another proof of the fact that group rings over sofic groups are stably finite, a result previously established by G. Elek and A. Szabó [11] using different methods.

The paper is organized as follows. In Sect. “Cellular Automata” we present the general definition of a cellular automaton for any alphabet and any group. This includes a few basic examples, namely Conway's Game of Life, the majority action and the discrete Laplacian. In the subsequent section we specify our attention to cellular automata with a finite alphabet. We present the notions of Cayley graphs (for finitely generated groups), of amenable groups, and of entropy for G-invariant subsets in the configuration space. This leads to a description of the setting and the statement of the Garden of Eden theorem for amenable groups. We also give detailed expositions of a few examples showing that the hypotheses of amenability cannot, in general, be removed from the assumption of this theorem. We also present the notion of surjunctivity, of sofic groups and state the surjunctivity theorem of Gromov and Weiss for sofic groups. In Sect. “Linear Cellular Automata” we introduce the notions of linear cellular automata and of mean dimension for G-invariant subspaces in V^G. We then discuss the linear analogue of the Garden of Eden theorem and, again, we provide explicit examples showing that the assumptions of the theorem (amenability of the group and finite dimensionality of the underlying vector space) cannot, in general, be removed. Finally we present the linear analogue of the surjunctivity theorem of Gromov and Weiss for linear cellular automata over sofic groups. In Sect. “Group Rings and Kaplansky Conjectures” we give the definition of a group ring and present a representation of linear cellular automata as matrices with coefficients in the group ring. This leads to the reformulation of the two long standing problems raised by Kaplansky about the structure of group rings.

Finally, in Sect. “Future Directions” we present a list of open problems with a description of more recent results related to the Garden of Eden theorem and to the surjunctivity problem.

Cellular Automata

The Configuration Space

Let G be a group, called the *universe*, and let A be a set, called the *alphabet* or the *set of states*. A *configuration* is a map $x\colon G \to A$. The set A^G of all configurations is equipped with the right action of G defined by $A^G \times G \ni (x, g) \mapsto x^g \in A^G$, where $x^g(g') = x(gg')$ for all $g' \in G$.

Cellular Automata

A *cellular automaton* over G with coefficients in A is a map $\tau\colon A^G \to A^G$ satisfying the following condition: there exists a finite subset $M \subset G$ and a map $\mu\colon A^M \to A$ such that

$$\tau(x)(g) = \mu(x^g|_M) \tag{1}$$

for all $x \in A^G$, $g \in G$, where $x^g|_M$ denotes the restriction of x^g to M. Such a set M is called a *memory set* and μ is called a *local defining map* for τ.

It follows directly from the definition that every cellular automaton $\tau\colon A^G \to A^G$ is *G-equivariant*, i. e., it satisfies

$$\tau(x^g) = \tau(x)^g \tag{2}$$

for all $g \in G$ and $x \in A^G$.

Note that if M is a memory set for τ, then any finite set $M' \subset G$ containing M is also a memory set for τ. The local defining map associated with such an M' is the map $\mu'\colon A^{M'} \to A$ given by $\mu' = \mu \circ \pi$, where $\pi\colon A^{M'} \to A^M$ is the restriction map. However, there exists a unique memory set M_0 of minimal cardinality. This memory set M_0 is called the *minimal* memory set for τ.

We denote by $\mathrm{CA}(G, A)$ the set of all cellular automata over G with alphabet A.

Examples

Example 1 (Conway's Game of Life [3]*)* The most famous example of a cellular automaton is the *Game of Life* of John Horton Conway. The set of states is $A = \{0, 1\}$. State 0 corresponds to *absence of life* while state 1 indicates *life*. Therefore passing from 0 to 1 can be interpreted as *birth*, while passing from 1 to 0 corresponds to *death*.

The universe for Life is the group $G = \mathbb{Z}^2$, that is, the free Abelian group of rank 2. The minimal memory set is $M = \{-1, 0, 1\}^2 \subset \mathbb{Z}^2$. The set M is the *Moore neighborhood* of the origin in $\mathbb{Z}^2$. It consists of the origin $(0, 0)$ and its eight neighbors $\pm(1, 0), \pm(0, 1), \pm(1, 1), \pm(-1, 1)$. The corresponding local defining map $\mu\colon A^M \to A$ given by

$$\mu(y) = \begin{cases} 1 & \text{if } \begin{cases} \sum_{s\in S} y(s) = 3 \\ \text{or} \\ \sum_{s\in S} y(s) = 4 \text{ and } y((0,0)) = 1\,, \end{cases} \\ 0 & \text{otherwise}\,. \end{cases}$$

Example 2 (The majority action [21]*)* Let G be a group, M a finite subset of G, and $A = \{0, 1\}$. The automaton $\tau\colon A^G \to A^G$ with memory set M and local defining map $\mu\colon A^M \to A$ given by

$$\mu(y) = \begin{cases} 1 & \text{if } \sum_{m\in M} y(m) > \frac{|M|}{2}\,, \\ 0 & \text{if } \sum_{m\in M} y(m) < \frac{|M|}{2}\,, \\ y(1_G) & \text{if } \sum_{m\in M} y(m) = \frac{|M|}{2}\,, \end{cases}$$

for all $y \in A^M$, is the *majority action automaton* associated with G and M.

Example 3 Let G be a group and let A be any alphabet. Let $f\colon A \to A$ be a map and consider the map $\tau_f\colon A^G \to A^G$ defined by setting $\tau_f(x)(g) = f(x(g))$ for all $x \in A^G$ and $g \in G$. Then τ_f is a cellular automaton with memory set $M = \{1_G\}$ and the local defining map $\mu\colon A^M \to A$ given by $y \mapsto f(y(1_G))$ for all $y \in A^M$. When $f = \iota_A$ is the identity map on A then $\tau_{\iota_A} =: I$ is the identity map on A^G. On the other hand, given $c \in A$, if $f = f_c$ is the constant map given by $f_c(a) = c$ for all $a \in A$, then τ_{f_c} is the *constant* cellular automaton defined by $\tau_{f_c}(x) = x_c$ for all $x \in A^G$, where $x_c(g) = c$ for all $g \in G$.

Example 4 (The discrete Laplacian) Let G be a group, S a finite subset of G not containing 1_G, and $A = \mathbb{R}$, the field of *real numbers*. The (linear) map $\Delta_S\colon \mathbb{R}^G \to \mathbb{R}^G$ defined by

$$\Delta_S(x)(g) = x(g) - \frac{1}{|S|}\sum_{s\in S} x(gs)$$

is a cellular automaton over G with memory set $M = S \cup \{1_G\}$ and local defining map $\mu\colon \mathbb{R}^M \to \mathbb{R}$ given by $\mu(y) = y(1_G) - \frac{1}{|S|}\sum_{s\in S} y(s)$, for all $y \in \mathbb{R}^M$. It is called the *Laplacian* or *Laplace operator* on G relative to S.

Let $\tau_1, \tau_2 \in \mathrm{CA}(G, A)$ be two cellular automata (with memory sets M_1 and M_2, respectively). It is easy to see that their composition $\tau_1 \circ \tau_2$, defined by $[\tau_1 \circ \tau_2](x) = \tau_1(\tau_2(x))$ for all $x \in A^G$, is a cellular automaton (admitting $M = M_1M_2$ as a memory set). Since the identity map $I\colon A^G \to A^G$ is a cellular automaton, it follows that $\mathrm{CA}(G, A)$ is a monoid for the composition operation.

Cellular Automata with a Finite Alphabet

The Configuration Space as a Metric Space

Let G be a countable group, e. g., a finitely generated group (see Subsect. "Cayley Graphs") and let A be a finite alphabet with at least two elements.

The set A^G of all configurations can be equipped with a metric space structure as follows. Let $\emptyset = E_1 \subset E_2 \subset \cdots \subset E_n \subset E_{n+1} \subset \cdots$ be an increasing sequence of finite subsets of G such that $\cup_{n\geq 1} E_n = G$. Then, given any two configurations $x, x' \in A^G$, we set:

$$d(x, x') = 1/\sup\left\{n \in \mathbb{N} : x|_{E_n} = x'|_{E_n}\right\} \qquad (3)$$

(we use the convention that $1/\infty = 0$). In this way, A^G becomes a compact totally disconnected space homeomorphic to the middle third Cantor set.

We then have Hedlund's topological characterization of cellular automata.

Theorem 1 (Hedlund) *Suppose that A is a finite set. A map $\tau\colon A^G \to A^G$ is a cellular automaton if and only if it is continuous and G-equivariant.*

Corollary 1 *Suppose that A is a finite set. Let $\tau\colon A^G \to A^G$ be a bijective cellular automaton. Then the inverse map $\tau^{-1}\colon A^G \to A^G$ is also a cellular automaton.*

The Garden of Eden Theorem of Moore and Myhill

Let G be any group and A be any alphabet. Let $F \subset G$ be a finite subset. A *pattern* with *support* F is a map $p\colon A^F \to A$.

Let now $\tau\colon A^G \to A^G$ be a cellular automaton. One says that τ is *surjective* if $\tau(A^G) = A^G$. One often thinks of τ as describing time evolution: if $x \in A^G$ is the configuration of the universe at time t, then $\tau(x)$ is the configuration of the universe at time $t + 1$. An *initial configuration* is a configuration at time $t = 0$. A configuration x which is not in the image of τ, namely such that

$x \in A^G \setminus \tau(A^G)$, is called a *Garden of Eden* (briefly *GOE*) *configuration*. This biblical terminology is motivated by the fact that GOE configurations may only appear as initial configurations. Analogously, a pattern p with support $F \subset G$ is called a *GOE pattern* if $p \neq \tau(x)|_F$ for all $x \in A^G$. Using topological methods it is easy to see that, when the alphabet is finite, the existence of GOE patterns for τ is equivalent to the existence of GOE configurations for τ, i. e., to the non-surjectivity of τ.

One says that τ is *injective* if, for $x, x' \in A^G$, one has $x = x'$ whenever $\tau(x) = \tau(x')$.

Two configurations $x, x' \in A^G$ are *almost equal*, and we write $x \sim_{a.e.} x'$, if they coincide outside a finite subset of G, namely $|\{g \in G : x(g) \neq x'(g)\}| < \infty$. Finally, using terminology introduced by Gromov, one says that τ is *pre-injective* if, for $x, x' \in A^G$ s.t. $x \sim_{a.e.} x'$, one has $x = x'$ whenever $\tau(x) = \tau(x')$.

Two patterns p, p' with the same support F are *mutually erasable* if they are distinct and whenever $x, x' \in A^G$ are two configurations which extend in the same way p and p' outside of F (i. e. $x|_F = p$, $x'|_F = p'$ and $x|_{G\setminus F} = x'|_{G\setminus F}$), then $\tau(x) = \tau(x')$. The non-existence of mutually erasable patterns is equivalent to the pre-injectivity of the cellular automaton. Finally note that injectivity implies pre-injectivity (but the converse is false, in general).

The following is the celebrated Garden of Eden theorem of Moore and Myhill.

Theorem 2 (Moore and Myhill) *Let $\tau \in CA(\mathbb{Z}^2, A)$ be a cellular automaton with coefficients in a finite set A. Then τ is surjective if and only if it is pre-injective.*

The necessary condition is due to Moore, the converse implication to Myhill.

As Conway's Game of Life is concerned, we have that this cellular automaton is clearly not pre-injective (the constant dead configuration and the configuration with only one live cell have the same image) and by the previous theorem it is not surjective either. We mention that the non-surjectivity of the Game of Life is not trivial: the smallest GOE pattern known up to now has as a support a rectangle 13 × 12 with 81 live cells.

Cayley Graphs

A group G is said to be *finitely generated* if there exists a finite subset $S \subset G$ such that every element $g \in G$ can be expressed as a product of elements of S and their inverses, that is, $g = s_1^{\epsilon_1} s_2^{\epsilon_2} \cdots s_n^{\epsilon_n}$, where $n \geq 0$ and $s_i \in S, \epsilon_i = \pm 1$ for $1 \leq i \leq n$. The minimal n for which such an expression exists is called the *word length* of g with respect to S and it is denoted by $\ell(g)$. The group G is a (discrete) metric space with the distance function $d \colon G \times G \to \mathbb{R}_+$ defined by setting $d(g, g') = \ell(g^{-1}g')$ for all $g, g' \in G$. The set S is called a *finite generating subset* for G and one says that S is *symmetric* provided that $s \in S$ implies $s^{-1} \in S$.

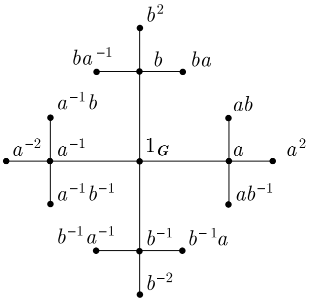
The ball $B(2, 1_G)$ in $\mathbb{Z}$ and in $\mathbb{Z}^2$, respectively



Cellular Automata and Groups, Figure 2
The ball $B(2, 1_G)$ in F_2

Suppose that G is finitely generated and let S be a symmetric finite generating subset of G. The *Cayley graph* of G w.r.t. S is the (undirected) graph $Cay(G, S)$ with vertex set G and two elements $g, g' \in G$ are joined by an edge if and only if $g^{-1}g' \in S$. The group G becomes a (discrete) metric space by introducing the distance $d \colon G \times G \to \mathbb{R}_+$ defined by $d(g, g') = \ell(g^{-1}g')$ for all $g, g' \in G$. Note that the distance d coincides with the graph distance on the Cayley graph $Cay(G, S)$. For $g \in G$ and $n \in \mathbb{N}$ we denote by $B(n, g) = \{g' \in G \colon d(g, g') \leq n\}$ the *ball of radius n with center g*.

Amenable Groups

The notion of an amenable group is also due to J. von Neumann [36]. Let G be a group and denote by $\mathcal{P}(G)$ the set of all subsets of G. The group G is said to be *amenable* if there exists a *right-invariant mean*, that is, a map $\mu \colon \mathcal{P}(G) \to [0, 1]$ satisfying the following conditions:

1. $\mu(G) = 1$ (*normalization*);

2. $\mu(A \cup B) = \mu(A) + \mu(B)$ for all $A, B \in \mathcal{P}(G)$ such that $A \cap B = \varnothing$ (*finite additivity*);
3. $\mu(Ag) = \mu(A)$ for all $g \in G$ and $A \in \mathcal{P}(G)$ (*right-invariance*).

We mention that if G is amenable, namely such a right-invariant mean exists, then also left-invariant and in fact even bi-invariant means do exist. The class of amenable groups includes, in particular, all finite groups, all Abelian groups (and, more generally, all solvable groups), and all finitely generated groups of subexponential growth. It is closed under the operations of taking subgroups, taking factors, taking extensions and taking direct limits.

It was observed by von Neumann himself [36] that the free group F_2 based on two generators is non-amenable. Therefore, all groups containing a subgroup isomorphic to the free group F_2 are non-amenable as well.

However, there are examples of non-amenable groups which do not contain subgroups isomorphic to F_2. The first examples are due to Olshanski [30]; later Adyan [1] showed that also the free Burnside groups $B(m, n) = \langle s_1, s_2, \dots, s_m : w^n \rangle$ of rank $m \geq 2$ and odd *exponent* $n \geq 665$ are non-amenable.

It follows from a result of Følner [16] that a countable group G is amenable if and only if it admits a *Følner sequence*, i. e., a sequence $(F_n)_{n\in\mathbb{N}}$ of non-empty finite subsets of G such that

$$\lim_{n\to\infty} \frac{|F_n \triangle gF_n|}{|F_n|} = 0 \quad \text{for all } g \in G, \tag{4}$$

where $F_n \triangle gF_n = (F_n \cup gF_n) \setminus (F_n \cap gF_n)$ is the symmetric difference of F_n and gF_n.

For instance, for $G = \mathbb{Z}$ one can take as Følner sets the intervals $[-n, n]$ where $[-n, n] = \{-n, -n+1, \dots, -1, 0, 1, \dots, n\}$, $n \in \mathbb{N}$. Analogously, for $G = \mathbb{Z}^2$ one can take as Følner sets the squares $F_n = [-n, n] \times [-n, n]$.

Suppose that G is countable and amenable, and fix a Følner sequence $(F_n)_{n\in\mathbb{N}}$. Let A be a finite alphabet. A subset $X \subset A^G$ is said to be *G-invariant* if $x \in X$ implies that $x^g \in X$ for all $g \in G$. The *entropy* $\operatorname{ent}(X)$ of a G-invariant subset $X \subset A^G$ is defined by

$$\operatorname{ent}(X) = \lim_{n\to\infty} \frac{\log |X_{F_n}|}{|F_n|} \tag{5}$$

where, for any subset $F \subset G$

$$X_F = \{x|_F : x \in X\} \tag{6}$$

denotes the set of restrictions to F of all configurations in X.

By using a result of Ornstein and Weiss [31], it can be shown that the above limit in (5) exists and does not depend on the particular Følner sequence $(F_n)_{n\in\mathbb{N}}$.

One clearly has $\operatorname{ent}(A^G) = \log |A|$ and $\operatorname{ent}(X) \leq \operatorname{ent}(Y)$ if $X \subset Y$ are G-invariant subsets of A^G.

Theorem 3 (Ceccherini-Silberstein, Machì and Scarabotti [9]) *Let G be a countable amenable group and let A be a finite set. Let $\tau\colon A^G \to A^G$ be a cellular automaton. The following are equivalent:*

(a) τ is surjective (i. e. there are no GOE configurations);
(b) τ is pre-injective;
(c) $\operatorname{ent}(\tau(A^G)) = \log |A|$.

Example 5 Let G be a group. Let M be a finite subset of G with at least three elements. Let $A = \{0, 1\}$ and consider the majority action cellular automaton $\tau\colon A^G \to A^G$ associated with G and M (see Subsect. "Cellular Automata"). Clearly τ is not pre-injective. Indeed the configurations $x_1, x_2 \in A^G$ defined by $x_1(g) = 0$ for all $g \in G$ and

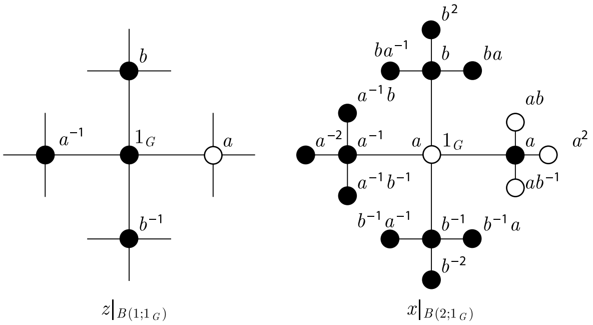
$$x_2(g) = \begin{cases} 1 & \text{if } g = 1_G \\ 0 & \text{otherwise} \end{cases}$$

are almost equal and $\tau(x_2) = x_1 = \tau(x_1)$. By applying Theorem 3 we deduce that τ is not surjective when G is a countable amenable group.

In the example below we show that for the non-amenable group F_2, the free group of rank two, the implication (a) $\Rightarrow$ (b) fails to hold. In Example 9 in Sect. "Linear Cellular Automata" we show that also the converse implication fails to hold, in general, for cellular automata over F_2.

Example 6 Let $G = F_2$ be the free group on two generators a and b. Take $A = \{0, 1\}$ and $M = \{a, a^{-1}, b, b^{-1}\} = S$. Consider the majority action cellular automaton $\tau\colon A^G \to A^G$ associated with G and M. As observed above, τ is not pre-injective. However, τ is surjective. To see this, let $z \in A^G$. Let us show that there exists $x \in A^G$ such that $\tau(x) = z$. We first set $x(1_G) = 0$. For $g \in G$ such that $g \neq 1_G$, denote by $g' \in G$ the unique element such that $\ell(g') = \ell(g) - 1$ and $g = g's'$ for some $s' \in S$. Then set $x(g) = z(g')$. We clearly have $\tau(x) = z$. This shows that τ is surjective (see Fig. 3).

Recently, Laurent Bartholdi [2] proved that if G is a non-amenable group, then there exists a cellular automaton $\tau\colon A^G \to A^G$ with finite alphabet which is surjective but not pre-injective. In other words, the implication "(a) τ is surjective $\Rightarrow$ (b) τ is pre-injective" in Theorem 3 (which corresponds to the generalization of Moore's theorem)



Cellular Automata and Groups, Figure 3
The construction of $x \in A^G$ such that $\tau(x) = z$

holds true only if the group G is amenable. In particular, the Garden of Eden Theorem (Theorem 3) holds true if and only if the universe G is amenable. This clearly gives a new characterization of amenability for groups in terms of cellular automata.

However, up to now, it is not known whether the validity of the implication (b) ⇒ (a) in Theorem 3 (which corresponds to the generalization of Myhill's theorem) holds true only if the group G is amenable.

Surjunctivity

A group G is said to be *surjunctive* (a terminology due to Gottschalk [17]) if given any finite alphabet A, every injective cellular automaton $\tau: A^G \to A^G$ is surjective. In other words, uniqueness implies existence for solutions of the equation $y = \tau(x)$. This property is reminiscent of several other classes of mathematical objects for which injective endomorphisms are always surjective (finite sets, finite-dimensional vector spaces, Artinian modules, complex algebraic varieties, co-Hopfian groups, etc.).

Recall that a group G is said to be *residually finite* if for every element $g \neq 1_G$ in G there exist a finite group F and a homomorphism $h: G \to F$ such that $h(g) \neq 1_F$. This amounts to saying that the intersection of all subgroups of finite index of G is reduced to the identity element. From a dynamical viewpoint we have the following characterization of residual finiteness. Given a finite set A a configuration $x \in A^G$ is said to be *periodic* if its *G-orbit* $\{x^g: g \in G\} \subset A^G$ is finite. Then G is residually finite if and only if the set of periodic configurations is dense in A^G.

The class of residually finite groups is quite large. For instance, every finitely generated subgroup of $\mathrm{GL}_n(\mathbb{C})$, the group of n by n invertible matrices over the complex numbers, is residually finite. However, there are finitely generated amenable groups which are not residually finite.

Lawton [17,18] proved that residually finite groups are surjunctive.

From Theorem 3 one immediately deduces the following

Corollary 2 *Amenable groups are surjunctive.*

Note that the implication "surjectivity ⇒ injectivity" fails to hold, in general, for cellular automata with finite alphabet over amenable groups, even for $G = \mathbb{Z}$. Take, for instance $A = \{0, 1\}$ and $\tau: A^{\mathbb{Z}} \to A^{\mathbb{Z}}$ defined by $\tau(x)(n) = x(n+1) - x(n)$ for all $x \in A^{\mathbb{Z}}$ and $n \in \mathbb{Z}$. This cellular automaton is surjective but not injective. See also Example 8 below.

Sofic Groups

Let S be a set. An *S-labeled graph* is a triple (Q, E, λ), where Q is a set, E is a symmetric subset of $Q \times Q$ and λ is a map from E to S. The set Q is the set of *vertices*, E is the set of *edges* and $\lambda: E \to S$ is the *labeling map* of the S-labeled graph (Q, E, λ). We shall view every subgraph of a labeled graph as a labeled graph in the obvious way. Also, for $r \in \mathbb{R}$ and $q \in Q$, we denote by $B(q, r) = \{q' \in Q: d(q, q') \leq r\}$ the *ball* of *radius* r centered at q (here d denotes the *graph distance* in Q).

Let (Q, E, λ) and (Q', E', λ') be S-labeled graphs. Two vertices $q \in Q$ and $q' \in Q'$ are said to be *r-equivalent*, and we write $q \sim_r q'$, if the balls $B(q, r)$ and $B(q', r)$ are isomorphic as labeled graphs (i. e. there is a bijection $\varphi: B(q, r) \to B(q', r)$ sending q to q' such that $(q_1, q_2) \in E \cap (B(q, r) \times B(q, r))$ if and only if $(\varphi(q_1), \varphi(q_2)) \in E' \cap (B(q', r) \times B(q', r))$ and $\lambda(q_1, q_2) = \lambda'(\varphi(q_1), \varphi(q_2))$.

Let G be a finitely generated group and let S be a finite symmetric ($S = S^{-1}$) generating subset of G. We denote by *Cay*(G, S) the *Cayley graph* of G with respect to S. Its vertex set is G and $(g, g') \in G \times G$ is an edge if $s := g^{-1}g' \in S$, if this is the case, its label is $\lambda(g, g') = s$.

The group G is said to be *sofic* if for all $\varepsilon > 0$ and $r \in \mathbb{N}$ there exists a finite S-labeled graph (Q, E, λ) such that the set $Q(r) \subset Q$ defined by $Q(r) = \{q \in Q: q \sim_r 1_G\}$ (here 1_G is considered as a vertex in *Cay*(G, S)) satisfies

$$|Q(r)| \geq (1 - \varepsilon)|Q|. \qquad (7)$$

It can be shown (see [38]) that this definition does not depend on the choice of S and that it can be extended as follows. A (not necessarily finitely generated) group G is said to be *sofic* if all of its finitely generated subgroups are sofic.

Sofic groups were introduced by M. Gromov in [20]. The sofic terminology is due to B. Weiss [38]. The class of sofic groups contains, in particular, all residually finite groups, all amenable groups, and it is closed under direct products, free products, taking subgroups and extensions by amenable groups, and taking direct limits [12].

The following generalizes Lawton's result mentioned in Subsect. "Surjunctivity" as well as Corollary 2.

Theorem 4 (Gromov and Weiss [20,38]) *Sofic groups are surjunctive.*

We end this section by mentioning that there is no known example of a non-surjunctive group nor even of a non-sofic group up to now.

Linear Cellular Automata

Let G be a group and V be a vector space over a field $\mathbb{K}$. The configuration space $V^G = \{x\colon G \to V\}$ is a vector space over $\mathbb{K}$. Simply set $(x+y)(g) = x(g) + y(g)$ and $(\lambda x)(g) = \lambda x(g)$ for all $x, y \in V^G$, $g \in G$ and $\lambda \in \mathbb{K}$. The zero vector is the zero configuration $\mathbf{0}(g) = 0$ for all $g \in G$. The *support* of a configuration $x \in A^G$ is the subset $\mathrm{supp}(x) = \{g \in G\colon x(g) \neq 0\} \subset G$. We denote by $V[G] = \{x \in V^G\colon x \sim_{a.e.} \mathbf{0}\}$ the subspace of all configurations with *finite* support.

A linear cellular automaton is a cellular automaton $\tau\colon V^G \to V^G$ which is a linear map, that is, $\tau(x+y) = \tau(x) + \tau(y)$ and $\tau(\lambda x) = \lambda\tau(x)$ for all $x, y \in V^G$ and $\lambda \in \mathbb{K}$. This is equivalent to the linearity of the local defining map $\mu\colon V^M \to V$. We denote by $\mathrm{LCA}(G, V)$ the space of all linear cellular automata over G with coefficients in V.

Example 7 The Laplacian (cf. Example 4) is a linear cellular automaton.

Remark If the field is finite, so that necessarily $|\mathbb{K}| = p^n$ with p a prime number, and V has finite dimension over $\mathbb{K}$, then the vector space V is also finite.

It is easy to see that if $\tau \in \mathrm{LCA}(G, V)$ and $x \in V^G$ has finite support, then $\tau(x)$ also has finite support (in fact $\mathrm{supp}(\tau(x)) \subset \mathrm{supp}(x)M$). In other words $\tau(V[G]) \subset V[G]$. We denote by $\tau_0 = \tau|_{V[G]}\colon V[G] \to V[G]$ the restriction of τ to $V[G]$. We then have the following characterization of pre-injectivity for linear cellular automata.

Proposition 1 *The linear cellular automaton* $\tau \in \mathrm{LCA}(G, V)$ *is pre-injective if and only if* $\tau_0\colon V[G] \to V[G]$ *is injective.*

Note that if G is countable, V^G admits also a structure of a *metric space* (the distance function (3) is defined in the same way). Then $V[G]$ is dense in V^G with respect to the topology induced by the distance (3). However, V^G is no longer a compact space so that many topological arguments based on compactness need to be obtained with an alternative method. As an example, the following linear analogue of Corollary 2 needs an appropriate proof.

Theorem 5 ([6]) *Let G be a countable group and let V be a finite-dimensional vector space over a field $\mathbb{K}$. Suppose that $\tau\colon V^G \to V^G$ is a linear cellular automaton.*

(i) $\tau(V^G)$ is a closed subspace of V^G.
(ii) If τ is bijective then the inverse map $\tau^{-1}\colon V^G \to V^G$ is also a linear cellular automaton.

Mean Dimension and the GOE Theorem

Let G be a countable amenable group and V a finite-dimensional vector space over a field $\mathbb{K}$. Fix a Følner sequence $(F_n)_{n\in\mathbb{N}}$ for G. The *mean dimension* of a G-invariant vector subspace $X \subset V^G$, which plays the role of entropy used in the finite alphabet case, is the non-negative number

$$\mathrm{mdim}(X) = \lim_{n\to\infty} \frac{\dim(X_{F_n})}{|F_n|}\,, \tag{8}$$

where X_{F_n} is defined as in (6).

The result of Ornstein and Weiss [31] already mentioned above implies that the limit (8) exists and does not depend on the particular choice of the Følner sequence $(F_n)_{n\in\mathbb{N}}$ for G.

Note that it immediately follows from this definition that $\mathrm{mdim}(V^G) = \dim(V)$ and that $\mathrm{mdim}(X) \leq \mathrm{mdim}(Y) \leq \dim(V)$ for all G-invariant vector subspaces $X \subset Y$ of V^G.

The linear analogue of the Garden of Eden theorem for linear cellular automata states as follows.

Theorem 6 (Ceccherini-Silberstein and Coornaert, [5]) *Let V be a finite-dimensional vector space over a field $\mathbb{K}$ and let G be a countable amenable group. Let $\tau\colon V^G \to V^G$ be a linear cellular automaton. Then the following are equivalent.*

(a) τ is surjective (i. e. there are no GOE configurations);
(b) τ is pre-injective;
(c) $\mathrm{mdim}(\tau(V^G)) = \dim(V)$.

As an application we present the following example.

Example 8 Let G be a finitely generated group. Let $S \subset G$ be a finite generating subset (not necessarily symmetric) such that $1_G \notin S$, and denote by $\Delta_S\colon \mathbb{R}^G \to \mathbb{R}^G$ the corresponding Laplacian (cf. Example 4). It follows from the Maximum Principle, see also Proposition 6.4 in [5], that if the group G is infinite, then the linear cellular automaton

Δ_S is pre-injective (though not injective since the constant configurations are in the kernel of Δ_S).

Thus, as a consequence of Theorem 6, we deduce that Δ_S is also surjective if G is an infinite amenable group.

Actually, one has that Δ_S is always surjective whenever G is infinite. Indeed, denoting by $P_S = I - \Delta_S$ the *Markov operator* associated with S, one has that if G is non-amenable then G is *transient* i. e. the series $\sum_{n=0}^{\infty}(P_S)^n$ converges [39] (in fact, by a profound result of N. Varopoulos (1986, see, e. g. [35]), G is transient if and only if it has no finite index subgroup isomorphic to either $\mathbb{Z}$ or $\mathbb{Z}^2$). We denote by $\mathcal{G}_S$ the sum of this series. It is called the *Green operator* of G.

But then, for $f \in \mathbb{R}[G]$ the function $g = \mathcal{G}_S f \in \mathbb{R}^G$ clearly satisfies $\Delta_S g = (I - P_S)g = f$. This shows that $\Delta_S(\mathbb{R}^G) \supset \mathbb{R}[G]$ and, by virtue of Theorem 5 (i) and the density of $\mathbb{R}[G]$ in $\mathbb{R}^G$, one has indeed $\Delta_S(\mathbb{R}^G) = \mathbb{R}^G$, that is, Δ_S is surjective. We thank Vadim Kaimanovich and Nic Varopoulos for clarifying this point to us.

In the example below we show that the implication (b) $\Rightarrow$ (a) in Theorem 6 fails to hold, in general, for linear cellular automata over the free group of rank two. Note that if the field is finite, then this example also provides an instance of the failure of the implication (b) $\Rightarrow$ (a) in Theorem 3 when $G = F_2$.

Example 9 Let $G = F_2$ be the free group on two generators a and b. Let $\mathbb{K}$ be a field and set $V = \mathbb{K}^2$. Consider the endomorphisms p and q of V defined by $p(\alpha,\beta) = (\alpha, 0)$ and $q(\alpha,\beta) = (\beta, 0)$ for all $(\alpha,\beta) \in V$. Let $\tau\colon V^G \to V^G$ be the linear cellular automaton, with memory set $M = \{a, b, a^{-1}, b^{-1}\}$, given by

$$\tau(x)(g) = p(x(ga)) + q(x(gb)) + p(x(ga^{-1})) + q(x(gb^{-1}))$$

for all $x \in V^G$, $g \in G$. The image of τ is contained in $(\mathbb{K} \times \{0\})^G$. Therefore τ is not surjective. Let us show that τ is pre-injective. Assume that there is an element $x_0 \in V^G$ with non-empty finite support $\Omega \subset G$ such that $\tau(x_0) = 0$. Consider a vertex $g_0 \in \Omega$ at maximal distance n_0 from the identity in the Cayley graph of G. The vertex g_0 has at least three adjacent vertices at distance $n_0 + 1$ from the identity. It follows from the definition of τ that $\tau(x_0)$ does not vanish at (at least) one of these three vertices. This gives a contradiction. Thus τ is pre-injective.

The following, which is a linear version of Example 6, provides an instance of the failure of the implication (a) $\Rightarrow$ (b) in Theorem 6 when $G = F_2$.

Example 10 Let $G = F_2$ be the free group on two generators a and b. Let $\mathbb{K}$ be a field and set $V = \mathbb{K}^2$. Consider the endomorphisms p' and q' of V defined by $p'(\alpha,\beta) = (\alpha, 0)$ and $q'(\alpha,\beta) = (0,\alpha)$ for all $(\alpha,\beta) \in V$.

Let $\tau\colon V^G \to V^G$ be the $\mathbb{K}$-linear cellular automaton, with memory set $S = \{a, b, a^{-1}, b^{-1}\}$, given by

$$\tau(x)(g) = p'(x(ga)) + p'(x(ga^{-1})) + q'(x(gb)) + q'(x(gb^{-1}))$$

for all $x \in V^G$ and $g \in G$.

Consider the configuration $x_0 \in V^G$ defined by

$$x_0(g) = \begin{cases} (0,1) & \text{if } g = 1_G \\ (0,0) & \text{otherwise}\,. \end{cases}$$

Then, x_0 is almost equal to 0 and $\tau(x_0) = 0$. This shows that τ is not pre-injective (cf. Proposition 1).

However, τ is surjective. To see this, let $z = (z_1, z_2) \in \mathbb{K}^G \times \mathbb{K}^G = V^G$. Let us show that there exists $x \in V^G$ such that $\tau(x) = z$. We define $x(g)$ by induction on the graph distance, which we denote by $|g|$, of $g \in G$ from 1_G in the Cayley graph of G. We first set $x(1_G) = (0, 0)$.

Then, for $s \in S$ we set

$$x(s) = \begin{cases} (z_1(1_G), 0) & \text{if } s = a \\ (z_2(1_G), 0) & \text{if } s = b \\ (0,0) & \text{otherwise}\,. \end{cases}$$

Suppose that $x(g)$ has been defined for all $g \in G$ with $|g| \le n$, for some $n \ge 1$. For $g \in G$ with $|g| = n$, let $g' \in G$ and $s' \in S$ be the unique elements such that $|g'| = n - 1$ and $g = g's'$. Then, for $s \in S$ with $s's \neq 1_G$, we set

$$x(gs) = \begin{cases} (z_1(g) - x_1(g'), 0) & \text{if } s' \in \{a, a^{-1}\} \text{ and } s = s' \\ (z_2(g), 0) & \text{if } s' \in \{a, a^{-1}\} \text{ and } s = b \\ (z_1(g), 0) & \text{if } s' \in \{b, b^{-1}\} \text{ and } s = a \\ (z_2(g) - x_2(g'), 0) & \text{if } s' \in \{b, b^{-1}\} \text{ and } s = s' \\ (0,0) & \text{otherwise}\,. \end{cases}$$

Then one easily checks that $\tau(x) = z$. This shows that τ is surjective.

We now show that, for any group, both implications of the equivalence (a) $\Leftrightarrow$ (b) in Theorem 6 fail to hold, in general, when the vector space V is infinite-dimensional.

Example 11 Let V be an infinite-dimensional vector space over a field $\mathbb{K}$ and let G be any group. Let us choose a basis B for V. Every map $\alpha\colon B \to B$ uniquely extends to a linear map $\widetilde{\alpha}\colon V \to V$. The product map $\tau = \widetilde{\alpha}^G\colon V^G \to V^G$ is a linear cellular automaton with memory set $M = \{1_G\}$ and local defining map $\widetilde{\alpha}$. Since B

is infinite, we can find a map $\alpha\colon B \to B$ which is surjective but not injective (resp. injective but not surjective). Clearly, the associated linear cellular automaton τ is surjective but not pre-injective (resp. injective but not surjective).

We say that a group G is *L-surjunctive* if for any field $\mathbb{K}$ and for any finite dimensional vector space V over $\mathbb{K}$, every injective linear cellular automaton $\tau\colon V^G \to V^G$ is surjective.

The following is the linear analogue of the Gromov–Weiss theorem (Theorem 4).

Theorem 7 ([6]) *Sofic groups are L-surjunctive.*

Group Rings and Kaplansky Conjectures

Irving Kaplansky [23,24] posed some famous problems in the theory of group rings. Here we establish some connections between these problems and the theory of linear cellular automata.

Group Rings

Let G be a group and $\mathbb{K}$ a field. A natural basis for $\mathbb{K}[G]$, the subspace of finitely supported configurations in $\mathbb{K}^G$, is given by $\{\delta_g\colon g \in G\}$, where $\delta_g\colon G \to \mathbb{K}$ is defined by $\delta_g(g) = 1$ and $\delta_g(g') = 0$ if $g' \neq g$. Also, $\mathbb{K}[G]$ can be endowed with a ring structure by defining the *convolution* product xy of two elements $x, y \in \mathbb{K}[G]$ by setting, for all $g \in G$,

$$[xy](g) = \sum_{h\in G} x(h)y(h^{-1}g). \tag{9}$$

One has $\delta_g\delta_h = \delta_{gh}$ and $\delta_h x = x^{h^{-1}}$ for all $g, h \in G$ and $x \in \mathbb{K}[G]$, in particular, δ_{1_G} is the unit element in $\mathbb{K}[G]$. The ring $\mathbb{K}[G]$ is called the *group ring* of G with coefficients in $\mathbb{K}$. Note that the product map $(x, y) \to xy$ is $\mathbb{K}$-linear so that $\mathbb{K}[G]$ is in fact a $\mathbb{K}$-algebra.

Note also that (9) makes sense for $x, y \in K^G$ and at least one is finitely supported. Moreover, the group G, via the map $G \ni g \mapsto \delta_g \in \mathbb{K}[G]$, can be identified with a subgroup of the group of invertible elements in $\mathbb{K}[G]$. This way, every element x of $\mathbb{K}[G]$ can be uniquely expressed as $x = \sum_{g\in G} x(g)g$.

The Matrix Representation of Linear Cellular Automata

Let $d \geq 1$ be an integer. Denote by $\mathrm{Mat}_d(\mathbb{K}[G])$ the $\mathbb{K}$-algebra of $d \times d$ matrices with coefficients in $\mathbb{K}[G]$. For $x = (x_1, x_2, \dots, x_d) \in (\mathbb{K}^G)^d$ and $\alpha = (\alpha_{ij})_{i,j=1}^d \in \mathrm{Mat}_d(\mathbb{K}[G])$, we define $x\alpha = (y_1, y_2, \dots, y_d) \in (\mathbb{K}^G)^d$ by setting $y_j = \sum_{i=1}^d x_i\alpha_{ij}$ for all $j = 1, 2, \dots, d$, where $x_i\alpha_{ij}$ is the convolution product of $x_i \in \mathbb{K}^G$ and $\alpha_{ij} \in \mathbb{K}[G]$ defined using (1).

The map $\mathrm{Mat}_d(\mathbb{K}[G]) \ni \alpha \mapsto \overline{\alpha} \in \mathrm{Mat}_d(\mathbb{K}[G])$, where $\overline{\alpha}_{ij}(g) = \alpha_{ji}(g^{-1})$ for all $g \in G$ and $i, j = 1, 2, \dots, d$ is an *anti-involution* of the algebra $\mathrm{Mat}_d(\mathbb{K}[G])$, since $\overline{\overline{\alpha}} = \alpha$ and $\overline{\alpha\beta} = \overline{\beta}\overline{\alpha}$, for all $\alpha, \beta \in \mathrm{Mat}_d(\mathbb{K}[G])$.

Let $\alpha \in \mathrm{Mat}_d(\mathbb{K}[G])$ and define the map $\tau_\alpha : (\mathbb{K}^d)^G \to (\mathbb{K}^d)^G$ by setting

$$\tau_\alpha(x) = x\overline{\alpha}$$

for all $x = (x_1, x_2, \dots, x_d) \in (\mathbb{K}^G)^d = (\mathbb{K}^d)^G$.

Theorem 8 ([6]) *For $\alpha \in \mathrm{Mat}_d(\mathbb{K}[G])$ the map $\tau_\alpha\colon (K^d)^G \to (\mathbb{K}^d)^G$ is a linear cellular automaton. Moreover, the map $\mathrm{Mat}_d(\mathbb{K}[G]) \ni \alpha \to \tau_\alpha \in \mathrm{LCA}(G, \mathbb{K}^d)$ is an isomorphism of $\mathbb{K}$-algebras.*

Remark When $G = \mathbb{Z}$ and $\mathbb{K}$ is a finite field, linear cellular automata $\tau_\alpha \in \mathrm{LCA}(\mathbb{Z}, \mathbb{K}^d)$ with $\alpha \in \mathrm{Mat}_d(\mathbb{K}[\mathbb{Z}])$, are called *convolutional encoders* in Sect. 1.6 of [26].

Zero-Divisors in Group Rings

Let R be a ring. A non zero element $a \in R$ is said to be a *left* (resp. *right*) *zero-divisor* provided there exists a non zero element $b \in R$ such that $ab = 0$ (resp. $ba = 0$).

The following result relates the notion of a zero-divisor in a group ring $\mathbb{K}[G]$ with the pre-injectivity of one-dimensional linear cellular automata over the group G. We use the same notation as in Theorem 8 (here $d = 1$).

Lemma 1 ([5]) *Let G be a group and let $\mathbb{K}$ be a field. An element $\alpha \in \mathbb{K}[G]$ is a left zero-divisor if and only if the linear cellular automaton $\tau_\alpha\colon \mathbb{K}^G \to \mathbb{K}^G$ is not pre-injective.*

Let G be a group and suppose that it contains an element g_0 of finite order $n \geq 2$. Then we have

$$(1_G - g_0)\left(1_G + g_0 + g_0^2 + \dots + g_0^{n-1}\right) = 0\,,$$

showing that $\mathbb{K}[G]$ has zero-divisors.

A group is *torsion-free* if it has no non-trivial element of finite order. *Kaplansky zero-divisor problem* [23] asks whether $\mathbb{K}[G]$ has no zero-divisors whenever G is torsion-free. In virtue of Lemma 1 and Theorem 8 we can state it as follows (see [5]).

Problem 1 (Kaplansky zero-divisor problem reformulated in terms of cellular automata) *Let G be a torsion-free group and let $\mathbb{K}$ be a field. Is it true that every non-identically-zero linear cellular automaton $\tau\colon \mathbb{K}^G \to \mathbb{K}^G$ is pre-injective?*

The zero-divisor problem is known to have an affirmative answer for a wide class of groups including the free groups, the free Abelian groups, the fundamental groups of surfaces and the braid groups B_n.

Combining Lemma 1 with Theorem 6 we deduce the following.

Corollary 3 *Let G be a countable amenable group and let $\mathbb{K}$ be a field. Suppose that $\mathbb{K}[G]$ has no zero-divisors. Then every non-identically-zero linear cellular automaton $\tau\colon \mathbb{K}^G \to \mathbb{K}^G$ is surjective.*

The class of *elementary amenable* groups is the smallest class of groups containing all finite and all Abelian groups that is closed under taking extensions and directed unions. It is known, see Theorem 1.4 in [25], that if G is a torsion-free elementary amenable group, then $\mathbb{K}[G]$ has no zero-divisor for any field $\mathbb{K}$. As a consequence, the conclusion of Corollary 3 holds for all torsion-free elementary amenable groups.

Stable Finiteness of Group Rings

Recall that a ring R with identity element 1_R is said to be *directly finite* if one-sided inverses in R are also two-sided inverses, i. e., $ab = 1_R$ implies $ba = 1_R$ for $a, b \in R$. The ring R is said to be *stably finite* if the ring $M_d(R)$ of $d \times d$ matrices with coefficients in R is directly finite for all integers $d \geq 1$.

Commutative rings and finite rings are obviously directly finite. Also observe that if elements a and b of a ring R satisfy $ab = 1_R$ then $(ba)^2 = ba$, that is, ba is an idempotent. Therefore if the only idempotent of R are 0_R and 1_R (e. g. if R has no zero-divisors) then R is directly finite. The ring of endomorphisms of an infinite-dimensional vector space yields an example of a ring which is not directly finite.

Kaplansky [24] observed that, for any group G and any field $\mathbb{K}$ of characteristic 0, the group ring $\mathbb{K}[G]$ is stably finite and asked whether this property remains true for fields of characteristic $p > 0$. We have that this holds for L-surjunctive groups.

Using the matrix representation of linear cellular automata (Theorem 8) one has the following characterization of L-surjunctivity.

Theorem 9 *For a group G, a field $\mathbb{K}$, and an integer $d \geq 1$ the following conditions are equivalent:*

(a) Every injective linear cellular automaton $\tau\colon (\mathbb{K}^d)^G \to (\mathbb{K}^d)^G$ is surjective;
(b) The ring $\mathrm{Mat}_d(\mathbb{K}[G])$ is directly finite.

As a consequence, a group G is L-surjunctive if and only if the group ring $\mathbb{K}[G]$ is stably finite for any field $\mathbb{K}$.

From Theorem 7 and Theorem 9 we deduce the following result previously established by G. Elek and A. Szabó using different methods.

Corollary 4 ([6,11]) *Let G be a sofic group and $\mathbb{K}$ any field. Then the group ring $\mathbb{K}[G]$ is stably finite.*

Future Directions

We indicate some open problems related to the topics that we have treated in this article.

Garden of Eden Theorem

As we mentioned in the Subsect. "Amenable Groups", it would be interesting to determine whether the Myhill theorem (i. e. the implication (b) ⇒ (a) in Theorem 3), which holds for amenable groups, but fails to hold for groups containing the free group F_2 (cf. Example 9), holds or not for the non-amenable groups with no free subgroups (such as the free Burnside groups $B(m, n)$, $m \geq 665$ odd, see [1]). Note that a negative answer would give another new characterization of amenability for groups.

Problem 2 *Determine whether the Myhill theorem (pre-injectivity implies surjectivity) for cellular automata with finite alphabet holds only for amenable groups.*

It turns out that Bartholdi's cellular automata ([2], see Subsect. "Amenable Groups") are not linear, so that the question whether the linear GOE theorem (Theorem 6) holds also for non-amenable groups remains an open problem.

Problem 3 *Determine whether the GOE theorem for linear cellular automata over finite-dimensional vector spaces holds only for amenable groups or not. More precisely, determine whether Moore's theorem and/or Myhill's theorem for linear cellular automata over finite dimensional vector spaces hold only for amenable groups or not.*

In [7] we generalized the GOE theorem to linear cellular automata over semisimple modules (over a, not necessarily commutative, ring R) of finite length with universe an amenable group. A vector space is a (semisimple) left module over a field. The finite length condition for modules (which corresponds to the ascending chain condition (Noetherianity) and to the descending chain condition (Artinianity)) is the natural analogue of the notion of finite dimension for vector spaces.

The Garden of Eden theorem can be also generalized by looking at subshifts. Given an alphabet A and a countable group G a *subshift* $X \subset A^G$ is a subset which is closed (in the topology induced by the metric (3)) and G-invariant (if $x \in X$ then $x^g \in X$ for all $g \in G$). If G is amenable and $X \subset A^G$ is a subshift the quantity (5) is the entropy of X. Given two subshifts $X, Y \subset A^G$ we define a cellular automaton $\tau \colon X \to Y$ as the restriction to X of a cellular automaton $\overline{\tau} \colon A^G \to A^G$ such that $\overline{\tau}(X) \subset Y$.

Problem 4 *Let G be a countable amenable group, A a finite alphabet and $X, Y \subset A^G$ two subshifts with* $\mathrm{ent}(X) = \mathrm{ent}(Y)$. *Prove, under suitable conditions, the GOE theorem for cellular automata $\tau \colon X \to Y$.*

We mention that the GOE theorem for subshifts over amenable groups fails to hold in general with no additional hypotheses on the subshifts.

Let $G = \mathbb{Z}$ be the infinite cyclic group and let A be a finite alphabet. For $n, m \in \mathbb{Z}$ we set $[n, m] = \{x \in \mathbb{Z} \colon n \leq x \leq m\}$. Also, we denote by $A^* = \{a_1 a_2 \cdots a_n \colon a_i \in A, 1 \leq i \leq n, n \in \mathbb{N}\}$ the set of all *words* over A. The *length* of a word $w = a_1 a_2 \cdots a_n \in A^*$ is $\ell(w) = n$. Given a subset $X \subset A^G$ we denote by $W(X) = \{w \in A^* \colon \exists x \in X, \text{ s.t. } w = x|_{[0,\ell(w)]}\}$ the *language* associated with X. Then one says that a subshift $X \subset A^{\mathbb{Z}}$ is irreducible if, for any two subwords $w_1, w_2 \in W(X)$ there exists $w_3 \in A^*$ (necessarily in $W(X)$) such that $w_1 w_3 w_2 \in W(X)$.

Also it can be shown that, for a subshift $X \subset A^{\mathbb{Z}}$, there exists a set $\mathcal{F} \subset A^*$ of so-called *forbidden words*, such that setting

$$X_{\mathcal{F}} := \{x \in A^{\mathbb{Z}} \colon x^g|_{[0,n]} \notin \mathcal{F}, \forall n \in \mathbb{N}, \forall g \in \mathbb{Z}\} ,$$

one has $X = X_{\mathcal{F}}$. Then a subshift $X \subset A^{\mathbb{Z}}$ is of *finite type* if $X = X_{\mathcal{F}}$ for some *finite* set $\mathcal{F} \subset A^*$. Finally, X is *sofic* (same etymology but a different meaning from that used for groups in Subsect. "Sofic Groups") if $X = \tau(Y)$ for some cellular automaton $\tau \colon A^{\mathbb{Z}} \to A^{\mathbb{Z}}$ and some subshift $Y \subset A^{\mathbb{Z}}$ of finite type.

In [13], F. Fiorenzi considered cellular automata on irreducible subshifts of finite type inside $A^{\mathbb{Z}}$(A finite). She proved the GOE theorem for such cellular automata and provided examples of cellular automata on subshifts of finite type which are not irreducible and for which both implications of the GOE theorem fail to hold. She also provided an example of a cellular automaton on an irreducible subshift which is sofic but not of finite type for which the Moore theorem (namely the implication (a) ⇒ (b) in Theorem 3) fails to hold. Note that it is well known (cf. 2.1 in [13]) that, under the same hypotheses, the Myhill theorem (namely the implication (b) ⇒ (a) in Theorem 3) always holds true ($G = \mathbb{Z}$).

More generally, for groups G other than the integers $\mathbb{Z}$, one needs appropriate notions of *irreducibility* for the subsets $X \subset A^G$ as investigated by Fiorenzi [14,15].

Surjunctivity

Problem 5 *Prove or disprove that all groups are surjunctive.*

A positive answer to the previous problem could be derived by positively answering to the following

Problem 6 *Prove or disprove that all groups are sofic.*

By considering the linear analogue of Problem 5 we have

Problem 7 (Kaplansky's conjecture on stable finiteness of group rings) *Prove or disprove that all groups are L-surjunctive. Equivalently (cf. Theorem 9), prove or disprove that the group ring $\mathbb{K}[G]$ is stably finite for any group G and any field $\mathbb{K}$.*

Also, one could look for surjunctivity results for cellular automata with alphabets other than the finite ones and the finite dimensional vector spaces. A ring is called *left Artinian* (see [40]) if it satisfies the *descending condition on left ideals*, namely every decreasing sequence $R \supset I_1 \supset I_2 \cdots \supset I_n \supset I_{n+1} \supset \cdots$ of left ideals eventually stabilizes (there exists n_0 such that $I_n = I_{n_0}$ for all $n \geq n_0$).

In [4] we showed that if G is a residually finite group and M is an Artinian left module over a ring R (e. g. if M is a finitely generated left module over a left Artinian ring R), then every injective R-linear cellular automaton $\tau \colon M^G \to M^G$ is surjective.

In [8] we showed that if G is a sofic group (thus a weaker condition than being residually finite) and M is a left module of finite length over a ring R (thus a stronger condition than being just Artinian), then every injective R-linear cellular automaton $\tau \colon M^G \to M^G$ is surjective. As a consequence (cf. Theorem 9) we have that the group ring $R[G]$ is stably finite for any left (or right) Artinian ring R and any sofic group G.

It is therefore natural to consider the following generalization of Problem 7.

Problem 8 *Prove or disprove that the group ring $R[G]$ is stably finite for any group G and any left (or right) Artinian ring R.*

Problem 9 (Kaplansky's zero divisor conjecture for group rings) *Prove or disprove that if G is torsion-free then any non-identically zero linear cellular automaton $\tau \colon \mathbb{K}^G \to \mathbb{K}^G$, where $\mathbb{K}$ is a field, is preinjective. Equivalently (cf. Lemma 1 and Theorem 8), prove or disprove that if G is torsion-free, the group ring $\mathbb{K}[G]$ has no zero divisors.*

Cellular Automata in Hyperbolic Spaces

MAURICE MARGENSTERN
Université Paul Verlaine, Metz, France

Article Outline

Glossary

Fibonacci sequence A sequence of natural integers, denoted by f_n and defined by the recurrent equation $f_{n+2} = f_{n+1} + f_n$, for all $n \in \mathbf{N}$, and by the initial values $f_0 = f_1 = 1$.

Hyperbolic geometry This geometry was discovered independently by both Nikolaj Lobachevsky and Jànos Bolyai around 1830. This geometry satisfies the axioms of Euclidean geometry, the axiom of parallels being excepted and replaced by the following one: through a point out of a line, there are exactly two parallels to the line. In this geometry, there are also lines which never meet: they are called **non-secant**. They are characterized by the existence, for any couple of such lines, of a unique common perpendicular. Also, in this geometry, the sum of the interior angles of a triangle is always less than π. The difference to π defines the area of the triangle. In hyperbolic geometry, distances are absolute: there is no notion of similarity. See also **Poincaré's disc**.

Pentagrid The tiling $\{5, 4\}$, with five sides and four tiles around a vertex. The angles are right angles.

Poincaré's disc A model of the hyperbolic plane inside the Euclidean plane. The points are the points which are interior to a fixed disc D. The lines are the trace in D of diameters or circles which are orthogonal to the border of D. The model was first found by Beltrami and then by Poincaré who also devised the half-plane model also called after his name. The half-plane model is a conformal image of the disc model.

Ternary heptagrid The tiling $\{7, 3\}$ with seven sides and three tiles around a vertex.

Tessellation A particular case of a finitely generated tiling. It is defined by a polygon and by its reflections in its sides and, recursively, of the images in their sides.

Tiling A partition of a geometric space; the closure of the elements of the partition are called the **tiles**. An important case is constituted by **finitely generated** tilings: there is a finite set of tiles G such that any tile is a copy of an element of G.

Tiling $\{p, q\}$ This is tessellation based on the regular polygon with p sides and with vertex angle $2\pi/q$.

Invariant group of a tiling A group of transformations which define a **bijection** on the set of tiles. Usually, in a geometrical space, they are required to belong to the group of isometries of the space.

Definition of the Subject

Cellular Automata in Hyperbolic Spaces, in short **hyperbolic cellular automata** (abbreviated HCA), consists in the implementation of Cellular Automata in the environment of a regular tiling of a hyperbolic space.

The first implementation of such an object appeared in a paper by the present author and Kenichi Morita in 1999, see [18]. In this first paper, a first solution to the location problem in this context was given. The paper also focused on one advantage of this implementation: it allows to solve **NP**-problems in polynomial time. In 2000, a second paper appeared, by the present author, where a decisive solution of the location problem was given.

The study of HCA's is a new domain in computer science, at the border of mathematics and physics. They involve hyperbolic geometry as well as elementary arithmetics and algebra with the connections of polynomials with matrices, and also some theory of fields. They also involve the theory of formal languages in connection with their properties of elementary arithmetics.

To be a melting pot of such different techniques is already something which is very interesting.

But the new field has very striking properties. Their complexity classes offer a very different landscape than that of the classical theory of complexity based on the Turing machine. They also provide a bridge between the classical theory of computation and super-Turing computations.

HCA's are a novel object with rich properties: they inherit the richness of the infinitely many regular tilings which live in the hyperbolic plane. We are at the beginning of the study and still, there are a lot of surprising results. HCA's might appear as successful as their Euclidean relatives in various domains as astrophysics, nuclear physics and computer science.

For many results indicated in this paper, we quote the book [15], where the results and its proof can be found there.

Introduction

Before the appearance of HCA's, there were a few papers on possible implementations of cellular automata in abstract contexts, especially in the case of Caley graphs, see [25]. However, as infinitely many tilings of the hyperbolic plane are not Caley graphs of a their invariant group, this method cannot solve the problem in full generality. The difficulty was the location of the tiles, the **locating**

problem. The problem is already difficult in the simple case of tessellations. Note that there are infinitely many of them in the hyperbolic plane.

The study appeared to be possible thanks to a partial solution to the locating problem, see [18,19]. A decisive step was done in [7], where the already mentioned mixing of various techniques appear. This first solution in the case of a particular tiling, the pentagrid, is dealt with in Sect. "The Locating Problem in Hyperbolic Tilings". A significant advance was performed at the occasion of the meetings organized in 2002 for the bicentury of the birth of Jànos Bolyai, the co-inventor with Nikolaj Lobachevsky of hyperbolic geometry, and also at the occasion of SCI'2002. At this conference, seven papers were presented on the topic of this article, and they had a strong impact on the later development.

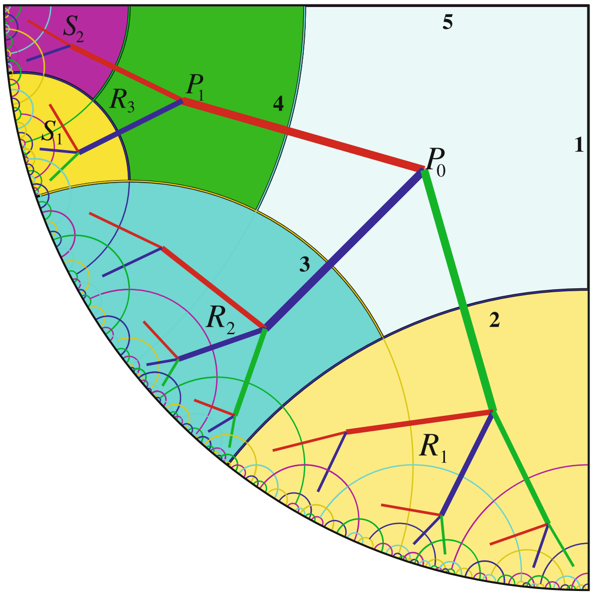
This introduction should contain a paragraph on hyperbolic geometry. If the reader is not familiar with this geometry and has some time, we recommend to him/her the first chapter of [15], or any other book introducing hyperbolic geometry. For a reader which is not familiar and who has no time, we recommend the following solution. First, forget everything of Euclidean geometry and try to remember the few elements given in the glossary. Don't worry, the Euclidean objects will always be the first thing to come to your mind and, most often, they will be misleading. Second, never forget that in traveling over hyperbolic spaces, you are in the situation of a pilot of a plane flying with instruments only. You can see nothing in the usual sense of these words and, sorry to repeat it again, the usual intuition is misleading. The best introduction is to imagine that when you venture into the hyperbolic plane, always keep with you the Ariadne thread of the way backwards. Otherwise you will definitely be lost. With this precaution, you will never regret the trip. The landscape changes very quickly and you are always fascinated by its unbelievable beauty.

The Locating Problem in Hyperbolic Tilings

The Classical Case of the Pentagrid

The method introduced in [18] consists of constructing a bijection between the tiling and a tree, the **spanning tree** of the tiling. The tree is constructed in a recursive way, defined as follows, also see Fig. 1.

> *Initial step*: P_0 is the root of the tree; it is called the **leading pentagon** of the quarter $\mathcal{Q}_0$ it is defined by its sides 1 and 5;
>
> *Induction step*: Let P be the current pentagon;
> if P is the leading pentagon of a quarter $\mathcal{Q}$, see P_0 in Fig. 1, the complement of P in $\mathcal{Q}$ splits into two quarters, $\mathcal{R}_1$ and $\mathcal{R}_3$ and a remaining region, $\mathcal{R}_3$ which we call a **strip**;
> if P is the leading pentagon of a strip S, see P_1 in Fig. 1, the complement of P in S splits into a quarter S_1 and again a strip, S_2.

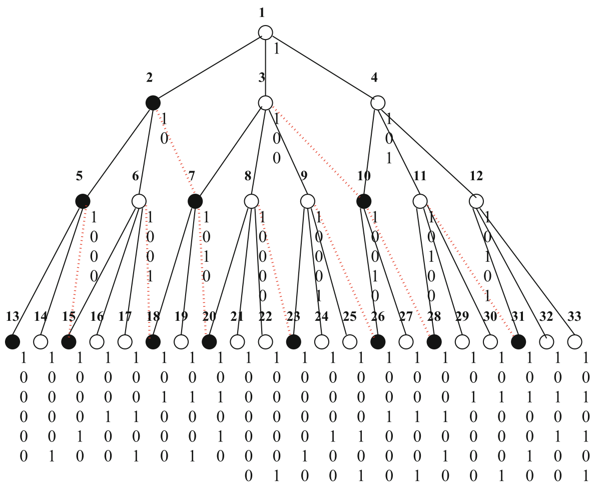


Cellular Automata in Hyperbolic Spaces, Figure 1
The pentagrid: regular pentagons with vertex angle $\pi/2$

As proved in [15], the set of tiles attached to the tree generated in this way, the **leading pentagons** of the above algorithm, is exactly the set of pentagons contained in the quarter $\mathcal{Q}_0$.

With [7,15], a new ingredient is brought in: number the nodes of the tree from the root, to which we attach 1, and then level by level, from left to right on each level, see Fig. 2. As already noticed in [18], the number of nodes of the tree which spans the tiling of a quarter which are on the same level n is f_{2n+1}, where $\{f_n\}_{n\in N}$ with $f(0) = f(1) = 1$. For this reason, the spanning tree of the pentagrid is called the **standard Fibonacci tree**, illustrated by Fig. 2.

The above splitting induces a particular structure on the standard Fibonacci tree. Define **white nodes** as nodes which have three sons and **black nodes** as nodes which have two sons. Black and white are the two possible values of the **status** of a node. Then, there is a **rule** to define the status of the sons of a node. We can write them as follows, in self-explained notations:



Cellular Automata in Hyperbolic Spaces, Figure 2
The Fibonacci tree

$$
\begin{aligned}
W &\longrightarrow BWW\\
B &\longrightarrow BW
\end{aligned}
$$

Now, let us represent the numbers attached to the nodes of the Fibonacci tree in the numeration basis defined by the Fibonacci sequence itself, starting from f_1. The representation is not unique. Choose the longest representation with respect to the lexicographic order and call it the **coordinate** of the node to which the corresponding number is attached.

First, we have that the set of coordinates is a **regular language**, which is a corollary of a well known theorem, see [2]. Now we have a more interesting property, which was noticed in [7] and which we call the **preferred son property**. Let $\alpha_k..\alpha_0$ be the coordinate of a node ν of the standard Fibonacci tree, with α_0 as the lightest digit of the representation. The property says that for each node ν of the standard Fibonacci tree, with coordinate $\alpha_k..\alpha_0$, there is exactly one son of ν whose coordinate is $\alpha_k..\alpha_0 00$. This son is called **preferred**. Moreover, there is a rule to find out the preferred son from the status of a node: in a black node, the preferred son is the black son; in a white node, the preferred son is the middle one.

Generalization: The Splitting Method

The generalization was first announced in [8]. It was then presented in [9], with a new visit to Poincaré's theorem, at the occasion of the second century of the birth of Jànos Bolyai.

The method defines a **basis of splitting** and then, the notion of a **combinatoric tiling**. Two important consequences can be derived from these very definitions to which we turn now.

Let $S_0, \dots, S_k$ be finitely many parts of some geometric metric space X which are supposed to be closed, with nonempty interior, unbounded and simply connected. Consider also finitely many closed simply connected bounded sets $P_1, \dots, P_h$ with $h \leq k$. Say that the S_i's and P_ℓ's constitute a **basis of splitting** *if and only if: (i) X splits into finitely many copies of S_0, (ii) any S_i splits into one copy of some P_ℓ, the* **leading tile** *of S_i, and finitely many copies of S_j's, where* **copy** *means an* **isometric image**, *and where, in the condition (ii), the copies may be of different S_j's, S_i possibly included. As usual, it is assumed that the interiors of the copies of P_ℓ and of the copies of the S_j's are pairwise disjoint. The set S_0 is called the* **head** *of the basis and the P_ℓ's are called the* **generating tiles** *and the S_i's are called the* **regions** *of the splitting.*

On the example of the pentagrid, a basis of splitting is given by a quarter $\mathcal{Q}$ and a strip S. When there is a basis of a splitting, we then define:

Say that a tiling of X is **combinatoric** *if X has a basis of splitting and if the spanning tree of the splitting yields exactly the restriction of the tiling to the head S_0 of the basis.*

In [15,18], the pentagrid is proven to be combinatoric. A lot of other tilings of the hyperbolic plane are combinatoric. In particular, all the tilings $\{p, q\}$, with $q \geq 4$, possess this property. In higher dimensions, the following tilings were proved combinatoric: the 3D tiling $\{5, 3, 4\}$, based on Poincaré's dodecahedron, see [15,21] and the 4D tiling $\{5, 3, 3, 4\}$, based on the 120-cell, see [11,15].

Once a tiling is combinatoric, from the definition of its basis of splitting, we can derive a square matrix M called the **matrix of the splitting**, see [8,15]. Its lines indicate, for each column, the number of copies of S_j's entering in the splitting of S_i. The **polynomial of the splitting** is the characteristic polynomial of M, divided by the greatest power of X it contains as a factor. In our cases, this polynomial has a greatest real root. The polynomial of the splitting induces a recurrent equation which defines the **sequence of the splitting** with appropriate initial values. The maximal representations of numbers in the basis defined by the sequence of the splitting constitute the **language of the splitting**. As proved in [15,20], the language of the splitting of the tilings $\{p, q\}$ is regular when $q \geq 4$ and $p \geq 4$.

Implementation of Cellular Automata in Hyperbolic Spaces

The implementation of HCA's is induced by the results mentioned in the previous section.

But first, let us go back to the general definition of CA's. Three conditions must be fulfilled by a set of cells to be called a cellular automaton. The cells of the automaton must uniformly be distributed in the considered space. The neighborhood of each cell is defined in a uniform way. At each top of the discrete clock, all the cells update their own state according to the same function applied to the state of the cell and the sequence of states of its neighbors.

To implement cellular automata, we have to satisfy these three requirements.

The first two conditions are easily satisfied in a tessellation. Note that this is the standard frame for CA's in the Euclidean plane and in the 3D Euclidean space.

The third condition already requires that we have a system of coordinates for the tiles at our disposal. More than three centuries after Descartes' discovery of the system of coordinates which everybody uses for the Euclidean plane, this condition is trivially fulfilled. This is not only the three-century usage. This is also the case because the mathematical structure of the group of displacements which leaves the considered tessellations of the Euclidean plane globally invariant is a very simple structure.

The situation is very different in the case of hyperbolic spaces. Before [7], there was no convenient, or at least fast, procedure to define the coordinates of the tiles in a way which is in connection with the geometrical properties of the tiling.

Now, the splitting method gives such a solution. First, it effectively exhibits a tree which generates the tiling. As Gormov pointed out, [3], hyperbolic spaces are characterized by a tree structure. Second, it provides **fast** algorithms to handle these coordinates. By fast, we mean that the basic algorithms we need are **linear** in time with respect to the coordinate of the initial point. Note that nobody really matters with the fact that addition of vectors in Euclidean coordinates is linear while multiplication of coordinates by a scalar is not. Here, we have no addition, no multiplication, no nice formula. We have algorithms only, but they turn out to work in the best time.

The result of these considerations is that the directions, **north**, **south**, **east** and **west** which play a nice role in the Euclidean case no longer exist. In fact, we have infinitely many directions, each of which defines an essential direction in the space: if you follow other directions, you will never go to the area covered by this one. Of course, an infinite amount of information is ruled out in computer science. And so, we replace this basic indetermination of the direction by the direction of the **father**. Of course, we are led to a root and a central cell, but nobody complains about using an origin in the Euclidean case. Moreover, as shown in [12,15], it is also possible in the case of tessellations of the hyperbolic plane to get rid of the origin. We just mention this point, here, and refer the interested reader to the quoted papers for a closer study.

Once again, we illustrate how we proceed by the case of the pentagrid. It is repeated in the case of the ternary heptagrid, see [12,14] and in the case of the 3D tiling of Poincaré's dodecahedron, see [13].

For the implementation, we first fix a basis of splitting and the representation of the tiling. As indicated in [7,15], there are a lot of choices with the same basis of splitting. Moreover, in the case of the pentagrid and of the ternary heptagrid in which the standard Fibonacci tree is also a spanning tree, we have the choice between using the Fibonacci sequence, as we did in Sect. "The Locating Problem in Hyperbolic Tilings", or using the basis derived from the polynomial of the splitting. The difference is that the Fibonacci sequence is defined by the golden mean $(1+\sqrt{5})/2$, while the sequence of the splitting is defined by the square of the golden mean, $(3+\sqrt{5})/2$.

Let us go on with the Fibonacci sequence, as is it used in the majority of papers.

The preferred son property allows us to compute very easily the coordinates of the neighbors of a cell ν from the coordinate c of ν: the computation is linear in time with respect to the length of c, see [10,15]. Similarly, the path from a cell c to the root of its tree can be computed in a linear time with respect to the length of c, again see [10,15]. As a simple example, if $c = \alpha_k \ldots \alpha_1\alpha_0$, the father of ν has for number $\mathcal{A}(\alpha_k..\alpha_2) + \alpha_1$, where $\mathcal{A}(\beta_h \ldots \beta_0)$ computes the number m whose coordinate is $\beta_{\mathrm{h}} \ldots \beta_0$.

What we indicated up to now fixes the coordinates for a cell whose supporting tile is in a given quarter. Now, it is enough to number the five initial quarters which lie around the central pentagon in order to completely define the coordinates of a cell. The central pentagon has 0 as an unique coordinate. All other cells are defined by two numbers: (α, ν). The first number, α is in $\{1..5\}$ and defines the quarter. The second number, ν, defines the tile in the indicated quarter. Together with its coordinate, a cell is associated with other data: the status of its supporting tile, and the indication of which side is shared with its father. On one hand, note that the coordinate is a hardware feature: it is never known by the cell and it cannot: it does not have a bounded size. Note that this is the same for CA's in Euclidean spaces. On the other hand, the status of the supporting node can be known by the cell. As shown in [10], one can define rules for a cellular automaton to dispatch this information. As it is a finite information which can be provided by the hardware, we may assume that the cell knows it.

Complexity of Cellular Automata in Hyperbolic Spaces

Now, we are ready to give the results about the complexity classes of HCA's.

SAT and NP-complete Problems

In [18], HCA's are proved to be able to solve **SAT** in polynomial time. Historically, the possibility to solve **NP**-complete problems in the hyperbolic plane was first announced in [24]. Although the authors of [18] were not aware of paper [24], the latter paper does not involve cellular automata and does not provide a precise description of how **SAT** can be solved in the new frame. On the contrary, [18] describes an HCA which is able to solve the problem. In [18], the computation is estimated as quadratic. In fact it can be proved to be linear in the size of the input.

The solution for **SAT** is easy: it makes use of a Fibonacci tree, in which only two nodes are selected among the sons of a node. Each level represents the possible assignment of true and false values to the variable indexed by this level. The computation of all possible assignments until the level n, where n is the number of variables is triggered at initial time. Once it is reached, the information comes back to the root from the leaves of the tree, i. e. the nodes which are on the level n of the tree: each node computes the OR on the values of its left-hand side and right-hand side sons. Accordingly, the root gives **true** if and only if there is a branch from it to a leaf along which the value is always **true**.

From this, applying classical tools of the theory of complexity, we obtain that any **NP**-complete problem can be solved in polynomial time by an appropriate cellular automaton of the hyperbolic plane.

P = NP in the Hyperbolic Plane

From what we have seen previously, we have that the classical class **NP** is contained in the class of HCA's which work in polynomial time, denoted by $\mathbf{P}_h$. Now, it is also possible to define $\mathbf{NP}_h$ for HCA's, taking the classical definition of non-deterministic computations in polynomial time.

As shown in [6], it turns out that $\mathbf{P}_h = \mathbf{NP}_h$. The key point is that the computation of a non-deterministic Turing machine in time $O(t(n))$, with $t(n) \geq n$, can be computed by a deterministic HCA in time $O(t^2(n))$.

From this theorem, the following surprising result can easily be derived, see [6]:

$$\mathbf{P}_h = \mathbf{NP}_h = \mathbf{PSPACE}$$

where **PSPACE** is the classical class of functions computed in polynomial space by a Turing machine.

Of course, in these results, a basic ingredient is the possibility, given by the hyperbolic plane, to occupy a working space of exponential area within a polynomial time. The above process for solving **SAT** is a basic example of such a possibility.

Other Parts of the Complexity Hierarchy of HCA's

In fact, if we look at the hierarchy of complexity classes for HCA's, we get a landscape which is very different from the classical situation.

We have the following situation, described in [5]:

$$\begin{aligned}\mathbf{DLOG}_h &= \mathbf{NLOG}_h = \mathbf{P}_h = \mathbf{NP}_h = \mathbf{PSPACE}\\ &\subsetneq \mathbf{PSPACE}_h = \mathbf{EXPTIME}_h = \mathbf{NEXPTIME}_h\\ &= \mathbf{EXPSPACE}\end{aligned}$$

We notice that compared to the Euclidean analogs, the hyperbolic hierarchy seems to be very flat. As, by construction, $\mathbf{P}_h \subsetneq \mathbf{EXPTIME}_h$, there are indeed two classes on which the hierarchy concentrates.

We also have $\mathbf{NP}_h \subsetneq \mathbf{AP}_h$, unless $\mathbf{PSPACE} = \mathbf{NEXPTIME}$, where $\mathbf{AP}_h$ denotes the class of alternate HCA's. As with classical machines, an alternate HCA is defined on the set of configurations of a non-deterministic HCA. In the tree of these configurations, certain nodes are called existential, others are called universal. At an existential node, the node is accepting if and only if it has at least one accepting child. At a universal node, the node is accepting if and only if all its children are accepting. The result about $\mathbf{AP}_h$ indicates a similar situation with the Euclidean classes where $\mathbf{P} \subsetneq \mathbf{AP}$, unless $\mathbf{P} = \mathbf{PSPACE}$. Accordingly, we may expect that alternating HCA's should be more powerful than HCA's, either deterministic or non-deterministic.

On Specific Problems of Cellular Automata

Synchronization of an HCA

Although no paper is especially devoted to this problem, we mention it because it has an analog to the standard problem of the firing squad in one-dimensional CA's, and we shall use it in the next section.

In fact, as mentioned more or less explicitly in papers devoted to HCA, see [5,16], for instance, it is very easy to synchronize a disc or a sector inside a disc, defined by a tree rooted at the center of the disc. The idea is simply to simulate any classical algorithm of synchronization of a one-dimensional CA on each branch of the tree or each radius of the disc.

The synchronization is linear in the radius of the disc or the height of the tree.

Communications between HCA's

Another problem, more specific to HCA's is the communication between HCA's, possibly distant ones. Two papers study the problem in different settings, see [12] and [14].

In [12] the question is: how to establish a contact between two cells of a HCA, possibly distant ones? The paper provides a solution based on a new system of coordinates in which there is not an origin. The new system is based on the possibility to represent the hyperbolic plane as a union of growing quarters. We fix such a sequence in an appropriate way. Each term of the sequence is a Fibonacci tree, indexed by an integer n, and it contains all the trees indexed by m when $m > n$. Inside a given Fibonacci tree, we use the standard system of coordinates, indicated in Sect. "The Locating Problem in Hyperbolic Tilings". In the construction, the roots of the mentioned trees belong to a line δ. It is not difficult to see that sending signals on δ makes it possible for the cell to establish a contact in a linear time with respect to their mutual distance. Once the signals of each cell reach δ, they send in both directions a new signal at speed 1/2. A pair of such signals meet, which triggers both the communication signal and a killing signal, at speed 1, to erase the now useless signals sent in the wrong directions.

In [14], another problem is considered. This time all cells may dispatch messages, and each cell forwards the messages it receives and to which it does not want to reply. Accordingly, the same cell may be an emitter of messages, a receiver of messages, and a relay in the message system. The idea is to use the tree property to be in bijection with the tiling as follows: each emitting cell considers that it is the center of the hyperbolic plane, and the message is accompanied by an address which is updated by the relays and which is the address in the tree whose root is the sender of the message. This allows any receiver willing to answer the message to send it to the right emitter. Again, the complexity of the computation is linear in the mutual distance of a sender and a receiver.

Universality in Cellular Automata in Hyperbolic Spaces

Of course, from the existence of universal cellular automata on the line, we conclude that there are universal HCA's. This means that there are HCA's which are able to simulate any universal device, a Turing machine for instance.

Paradoxically, the study of universal HCA's has very few results. There is a universal HCA in the hyperbolic plane with 9 states, see [22], a recent result improving [4] where the HCA had 22 states. There is a universal HCA in the hyperbolic 3D space with 5 states, see [13]. At last, there is an intrinsically universal HCA in the hyperbolic plane, see [16].

Universal HCA's with a Small Number of States

First, we have to notice that the just mentioned universal HCA's with a small number of states are in fact **weakly** universal HCA's. The term **weak** refers to two conditions:

- the HCA needs an infinite initial configuration;
- the initial configuration is ultimately periodic.

Note that these conditions are standardly used with ordinary CA's where universality with a small number of states is reached with such conditions in many cases.

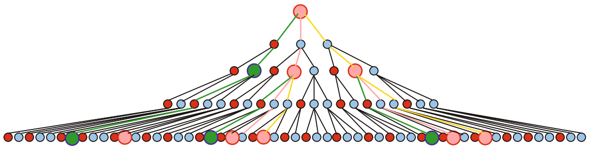
The second condition requires some explanation. In the context of a hyperbolic space, the notion of periodicity is not as clear as it is in the Euclidean case. Accordingly, we mean, by ultimate periodicity that at a large, *i. e.* outside a big enough domain, the configuration is globally invariant under a shift.

The above mentioned universal HCA's with a small number of states are obtained by a similar construction. They both simulate a railway circuit with the kind of switches, described by [26]. While in [26] a Turing machine is simulated, in [4,22] and in [13], we simulate a register machine. It can be remarked that the bigger number of states in the hyperbolic plane is due to the management of **crossings** of tracks which can be simply replaced by **bridges** in the hyperbolic 3D space. Moreover, as a cell in the hyperbolic 3D space has 12 neighbors, there are much more combinations of states which can be used to differentiate the relevant steps of the computation.

An Intrinsically Universal HCA

The intrinsically universal HCA is required to simulate any HCA in the same space. Of course, both the simulating HCA and the simulated one are required to work starting from finite configurations only.

In [16], two ingredients are used to achieve the simulation. One ingredient is the synchronization algorithm mentioned in Sect. "On Specific Problems of Cellular Automata". The second is the construction of **scaled** trees. The construction consists of building a new Fibonacci tree inside the tiling, but with a constant distance k between two consecutive nodes on a same branch. It is not difficult to construct such a tree, which is illustrated by Fig. 3.



Cellular Automata in Hyperbolic Spaces, Figure 3
A scaled tree by a factor 2

The constant k is computed in such a way that a disc of radius k contains both an encoding of the initial configuration of the HCA to be simulated, say A, and an encoding of the transition table of A. Figure 4 illustrates the mechanism of propagation of the scaled tree.

Each step of the simulated HCA A is simulated by a **cycle** of steps of the simulating HCA U. The number of steps of U in a cycle is not constant. It may be increasing, especially if the simulated configuration is growing during its own computation. The synchronization algorithm of Sect. “On Specific Problems of Cellular Automata” is used to delimit the stages into which a cycle is split. These stages are the reception of the current states of the neighbors of the simulated cell of A, for each simulating cell of U. When this is achieved, possibly at different times for each simulating cell, the new state is determined and it is installed in the appropriate region, controlled by the simulating cell. When this is performed, the cell waits until it is informed by its simulating sons that their step of computation is completed. When this is the case, the cell informs its father in the scaled tree that it finished its computation. Accordingly, when the central cell receives the message of completion from all its neighbors of the scaled tree, it knows that the computation of this step of A is finished. Then the comparison with the previous configuration is performed, thanks to a synchronization. Depending on the result of the comparison, the computation is stopped if there was no difference, or it goes on, when a difference was noticed.

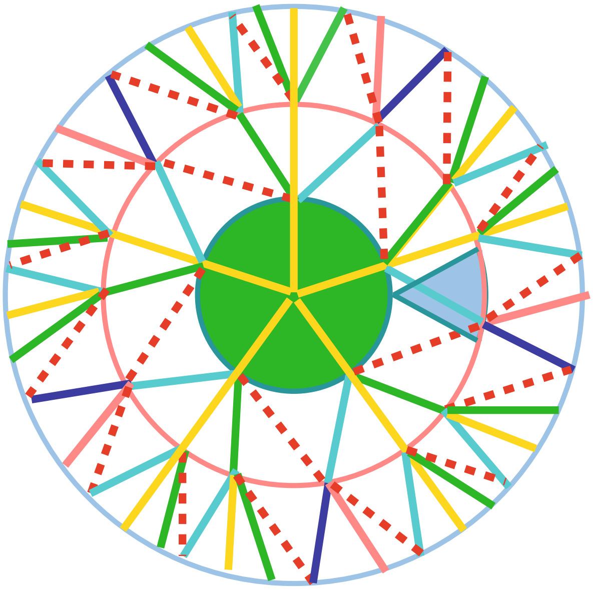
The Connection with Tiling Problems

As usual, cellular automata have deep connections with tilings.

This is probably the case with HCA’s, although, up to now, the single connection is the possibility to implement them in the tilings, thanks to the coordinate system.

However, this system itself appeared to be useful in order to investigate the properties of tilings in the hyperbolic plane and in the hyperbolic spaces of higher dimensions, namely the dimensions 3 and 4.

Indeed, the splitting method could be applied to the tiling $\{5, 3, 4\}$ of the hyperbolic 3D space, see [15,21]. It turned out to be possible to use an old tool of the late 19th century, Schlegel diagrams, to both represent the tiles and the construction of the tiling as a process which is infinite in time. The application of the splitting method revealed an interesting property. The language of the splitting of this tiling provides us with a **natural** example of a language which is neither rational nor context free. As a corollary, the algorithm to compute the path from a tile to the root of its tree is cubic in time with respect to the size of the coordinate of the cell supported by the tile.



Cellular Automata in Hyperbolic Spaces, Figure 4
Propagation of a scaled tree

The splitting method could also be applied to the tiling $\{5, 3, 3, 4\}$ of the hyperbolic 4D space. It provides us with a simple system of coordinates to explore this tiling which is the natural extension of the tiling $\{5, 3, 4\}$ of the hyperbolic 3D space. Note that the same process which allows to go from the pentagon with right angles to Poicaré’s dodecahedron also allows to go from that dodecahedron to the 120-cell. This process is called **orthogonal completion** in [11,15]. Together with an appropriate notion of interior and exterior, it allows to get a correct orientation in the hyperbolic 4D space and to correctly use the dimensional analogy with the spaces of lower dimension.

There are also important applications to tilings of the hyperbolic plane. As already mentioned about the communication between cells of a HCA, these algorithms benefit from the study of the tilings which are made possible by using the splitting method. The new results which are obtained in an algorithmic way are indicated in [15], in particular in its Chapter 4. An important application to the study of tilings in the hyperbolic plane is given by the recent result given in [17]: there, it is proved that the tiling problem of the hyperbolic plane is undecidable.

Future Directions

There are still a lot of problems to investigate about cellular automata in hyperbolic spaces. Let us look at a few of them.

In the classical study of cellular automata in an Euclidean space, there are well known theorems about the characterization of cellular automata in terms of mappings over the space of configurations. There are also well known studies about properties of the global transition function, which transforms a given configuration into the next one which is obtained, for each cell, by application of the transition table of the automaton. What can be said in the hyperbolic spaces? Are these theorems, or their adaptions, still valid in this new setting?

Another direction is a closer study of HCA in the hyperbolic 4D space. The foundation is ready: it is enough, now, to pave the way.

In the very beginning of this article, we mentioned possible applications. We think that this is also a promising direction for future investigations. A few applications were recently performed, see [1,23], for instance, but nothing significant enough to enter this article. We think that what was said in Sect. "Communications Between HCA's" is a serious foundation for future developments.

At last, the connection with tilings gives us the hope that the method initiated by the implementation of cellular automata in hyperbolic spaces will still help to improve the study of tilings in hyperbolic spaces.

Acknowledgments

The author is particularly in debt to Andrew Adamatzky for giving him the task to write this article.

Article Outline

Glossary

Cellular automaton A (one-dimensional) cellular automaton is a linear array of cells which are connected to both of their nearest neighbors. The total number of cells in the array is determined by the input data. They are exactly in one of a finite number of states, which is changed according to local rules depending on the current state of a cell itself and the current states of its neighbors. The state changes take place simultaneously at discrete time steps. The input mode for cellular automata is called parallel. One can suppose that all cells fetch their input symbol during a pre-initial step.

Iterative array Basically, iterative arrays are cellular automata whose leftmost cell is distinguished. This so-called communication cell is connected to the input supply and fetches the input sequentially. The cells are initially empty, that is, in a special quiescent state.

Formal language The data on which the devices operate are strings built from input symbols of a finite set or alphabet. A subset of strings over a given alphabet is a formal language.

Signal Signals are used to transmit and encode information in cellular automata. If a cell changes to the state of its neighbor after some k time steps, and if subsequently its neighbors and their neighbors do the same, then the basic signal moves with speed $\frac{1}{k}$ through the array. With the help of auxiliary signals, rather complex signals can be established.

Closure property Closure properties of families of formal languages indicate their robustness under certain operations. A family of formal languages is closed under some operation, if any application of the operation on languages from the family yields again a language from the family.

Turing machine A Turing machine is the simplest form of a universal computer. It captures the idea of an effective procedure or algorithm. At any time the machine is in any one of a finite number of states. It is equipped with an infinite tape divided into cells and a read-write head scanning a single cell. Each cell may contain a symbol from a finite set or alphabet. Initially, the finite input is written in successive cells. All other cells are empty. Dependent on a list of instructions, which serve as the program for the machine, the action is determined completely by the current state and the symbol currently scanned by the head. The action comprises the symbol to be written on the current cell, the new state of the machine, and the information of whether the head should move left or right.

Decidability A formal problem with two alternatives is decidable, if there is an algorithm or a Turing machine that solves it and halts on all inputs. That is, given an encoding of some instance of the problem, the algorithm or Turing machine returns the correct answer *yes* or *no*. The problem is semidecidable, if the algorithm halts on all instances for which the answer is *yes*.

Definition of the Subject

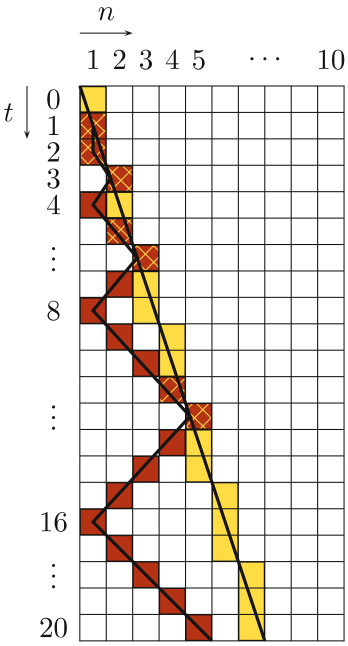
One of the cornerstones in the theory of automata is the early result of John von Neumann, who solved the logical problem of nontrivial self-reproduction. He employed a mathematical device which is a multitude of interconnected identical finite-state machines operating in parallel to form a larger machine. He showed that it is logically possible for such a nontrivial computing device to replicate itself ad infinitum [97]. Such devices are commonly called cellular automata (abbreviated, CA), and can be considered as homogeneously structured models for massively parallel computing systems. The global behavior of cellular automata is achieved by local interactions only. While the underlying rules are quite simple, the global behavior may be rather complex. In general, it is unpredictable.

The data supplied to CAs can be arranged as strings of symbols. Instances of problems to solve can be encoded as strings with a finite number of different symbols. Furthermore, complex answers to problems can be encoded as binary sequences such that the answer is computed bit by bit. In order to compute one piece of the answer, the set of possible inputs is split into two sets associated with the binary outcome. From this point of view, the computational capabilities of CAs are studied in terms of string acceptance, that is, the determination to which of the two sets a given string belongs. These investigations are with respect to and with the methods of language theory. They originated in Stephen N. Cole [18,19] and Alvy R. Smith [76,80]. Over the years substantial progress has been achieved, but there are still some basic open problems with deep relations to other fields. So, exploring the capabilities of cellular automata may benefit the understanding of the nature of parallelism and nondeterminism.

Introduction

In general, the specification of a cellular automaton includes the type and specification of the cells, their interconnection scheme (which can imply a dimension of the system), the local rules which are formalized as local transition function, and the input and output modes. With an eye towards language acceptance, we consider one-dimensional synchronous devices with nearest neighbor connections whose cells are deterministic finite-state machines. They are commonly called cellular automata in case of parallel input mode, and iterative arrays (abbreviated, IA) if the input mode is sequential. If each cell is connected to only one of its neighbors, say to the right one, then the flow of information through the array is from right to left. The corresponding device is a one-way cellular automaton (abbreviated, OCA). In any case the number of cells is determined by the length of the input string; there is one cell per symbol. If the input is in parallel, then all cells fetch their input symbol during a pre-initial step. To this end, the set of symbols has to be a subset of the set of states. Sometimes for practical reasons and for the design of systolic algorithms, a sequential input mode is more convenient than the parallel one. In iterative arrays the leftmost cell is distinguished to be the communication cell. It is equipped with a one-way read-only input tape.

In order to obtain the binary answer of a system we have to overcome a problem with the end of the computation. It follows from the definitions that the machines never halt. A way to cope with the situation is to define a predicate on configurations. The answer depends on whether a configuration satisfies the predicate or not. Here we apply the common predicate that requires a border cell or the communication cell to be in some state designated to be an accepting state. Further predicates are studied, e. g., in [38,82], while more general input modes are considered in [57]. Due to the bounded number of cells in a computation, the time complexity is exponentially bounded. After exceeding the bound, the computation runs into a loop and is rather useless. With respect to the wide language classes obeying an exponential or polynomial time bound, parallel devices cannot take advantage of their large number of processing elements. They are just a factor to be multiplied with the size of the input. So, there is a particular interest in fast computations, that is, in real-time and linear-time computations. Real time is determined by the shortest time necessary for nontrivial computations, whereas linear time is real time multiplied by an arbitrary but fixed constant greater than or equal to one. In addition, we consider general computations without time bounds which, actually, are exponentially time bounded. The following well-known example from [17] joins several notions. It uses signals in order to construct the mapping $n \longmapsto 2^n$ in time; i. e., the leftmost cell recognizes the time steps 2^n, $n \geq 1$. The time constructor is then extended to a real-time CA and IA.



Cellular Automata and Language Theory, Figure 1
Space-time diagram showing signals of a real-time two-way acceptor of the language $\{a^{2^n} \mid n \geq 1\}$

Example 1 The unary language consisting of the strings $\{a^{2^n} \mid n \geq 1\}$ is accepted by IAs as well as by CAs in real time.

At initial time the leftmost cell emits a signal which moves with speed $\frac{1}{3}$ to the right; i. e., the signal alternates from moving one cell to the right and staying for two time steps in a cell (see Fig. 1). In addition, another signal is emitted which moves with maximal speed (speed 1). It bounces between the slow signal and the leftmost cell. It is easy to see that the signal passes through the leftmost cell exactly at the time steps 2^n, $n \geq 1$. Finally, an iterative array can accept its input when the last input symbol is read at one of these time steps. Similarly, in a CA computation the rightmost cell can emit a third signal which moves with maximal speed to the left. This signal arrives at the leftmost cell at the time step which corresponds to the length of the input. If it meets the bouncing signal at its arrival, the input is accepted. □

More results about mappings that are constructible in the above sense can be found in [13,63,93]. In [27,94] the series of prime numbers is constructed in real-time devices.

The investigations of iterative arrays and cellular automata as cellular language acceptors originated in [18,19] and [76,80]. In [18,19], it is shown that the family of languages accepted by real-time IAs is closed under intersection, union, and complementation, but is not closed under concatenation and reversal; and in [76,80], where among other results the identity of the sequential complexity class DSPACE(n) (i. e., the class of languages accepted by deterministic Turing machines whose tape is bounded by the length of the input n) and the family of languages accepted by CAs without time bound is shown. A long-standing open problem is the question whether or not one-way information flow is a strict weakening of two-way information flow for unbounded time. In [16,32] it is proved that a PSPACE-complete language is accepted by OCAs, from which one can draw conclusions about the hardness of sequential OCA simulations. Furthermore, in the same papers strong closure properties are derived for the family of OCA languages. In addition, it is a proper superset of the context-free languages which, in turn, are of great practical relevance.

The proofs are based on characterizations of the parallel language families by certain types of customized sequential machines. Such machines have been developed for all classes of acceptors which are here under consideration [32,36,37]. In particular, speed-up theorems are given that allow to speed up the time beyond real time linearly. Therefore, linear-time computations can be sped up close to real time. Nevertheless, for OCAs and IAs linear time is strictly more powerful than real time. The problem is still open for CAs. In fact, it is an open question whether real-time CAs are strictly weaker than unbounded time CAs. If both classes coincide, then a PSPACE-complete language would be accepted in polynomial time! Apart from that it is known that linear-time CAs can be simulated by unbounded time OCAs [16,32].

The rest of the article is organized as follows. In the following section (Sect. "Cellular Language Acceptors"), some basic notions and formal definitions are given. The problem in connection with the end of computations is discussed in more detail, and honest time complexities are derived informally. Then, in Sect. "Tools and Techniques" selected tools and techniques are presented that can be applied to prove or to disprove that certain languages are accepted by certain devices. In particular, it is shown that two-way devices can simulate the data structure *stack* without loss of time. It is often much harder to disprove the acceptance of languages than to prove it, since the technique of a suitable construction is trivially not applicable. Some techniques based on counting and pumping arguments are shown and applied in order to obtain witness languages. In Sect. "Computational Capacities" computational capacity aspects are investigated. A basic hierarchy of language families defined by cellular automata and iterative arrays is established. The levels are compared with well-known linguistic families. Next, Sect. "Closure Properties" is devoted to exploring the closure properties of the language families in question. For example, it turns out that the languages accepted by unbounded time one-way and two-way cellular automata as well as iterative arrays share the strong closure properties of the class DSPACE(n) which characterizes the deterministic context-sensitive languages. Decidability problems are considered in Sect. "Decidability Problems". By reductions of Turing machine problems, it follows that almost all interesting properties are undecidable. In fact, they are not even semidecidable for the weakest devices in question. This emphasizes once more the power gained in parallelism even if the number of cells is bounded. In general, their behavior is unpredictable. Finally, in Sect. "Future Directions", some future directions of cellular language acceptors are discussed.

Cellular Language Acceptors

We denote the set of nonnegative integers by $\mathbb{N}$. In connection with formal languages, strings are called *words*. Let A^* denote the set of all words over a finite alphabet A. The *empty word* is denoted by λ, and we set $A^+ = A^* - \{\lambda\}$. For the *reversal of a word w* we write w^R and for its *length* we write $|w|$. For the *number of occurrences* of a symbol a in w we use the notation $|w|_a$. We use $\subseteq$ for *inclusions* and $\subset$ for *strict inclusions*. In order to avoid technical overloading in writing, two languages L and L' are considered to be equal, if they differ at most by the empty word, i. e., $L - \{\lambda\} = L' - \{\lambda\}$. Throughout the article, two automata or grammars are said to be *equivalent* if and only if they accept or generate the same language.

The cells of a cellular automaton are identified by positive integers. In order to handle the application of the local transition function to the border cells, we assume that the missing neighbors are in a permanent so-called border state. A formal definition is:

Definition 2 *A* two-way cellular automaton *(CA) is a system* $\langle S, \delta, \#, A, F\rangle$, *where*

1. *S is the finite, nonempty set of* cell states,
2. *$\# \notin S$ is the permanent* boundary state,
3. *$A \subseteq S$ is the nonempty set of* input symbols,
4. *$F \subseteq S$ is the set of* accepting states, *and*
5. *$\delta : (S \cup \{\#\}) \times S \times (S \cup \{\#\}) \to S$ is the* local transition function.

If the flow of information is restricted to one-way, the resulting device is a one-way cellular automaton (abbreviated, OCA). In such devices, the next state of each cell depends on the state of the cell itself and the state of its immediate neighbor to the right.

Cellular Automata and Language Theory, Figure 2
A (two-way) cellular automaton

Cellular Automata and Language Theory, Figure 3
A one-way cellular automaton

A *configuration* of a cellular automaton $\langle S, \delta, \#, A, F\rangle$ at time $t \geq 0$ is a description of its global state, which is formally a mapping $c_t\{1, \ldots, n\} \to S$, for $n \geq 1$. The configuration at time 0 is defined by the given input $w = a_1 \cdots a_n \in A^+$. We set $c_0(i) = a_i$, for $1 \leq i \leq n$. Configurations may be represented as words over the set of cell states in their natural ordering. For example, the initial configuration for w is represented by $\#a_1 a_2 \cdots a_n\#$. Successor configurations are computed according to the global transition function Δ. Let c_t, $t \geq 0$, be a configuration with $n \geq 2$, then its successor c_{t+1} is defined as follows:

$$c_{t+1} = \Delta(c_t)$$

$$\iff \begin{cases} c_{t+1}(1) = \delta(\#, c_t(1), c_t(2)) \\ c_{t+1}(i) = \delta(c_t(i-1), c_t(i), c_t(i+1)) , \\ \quad i \in \{2, \ldots, n-1\} \\ c_{t+1}(n) = \delta(c_t(n-1), c_t(n), \#) \end{cases}$$

for CAs, and

$$c_{t+1} = \Delta(c_t)$$

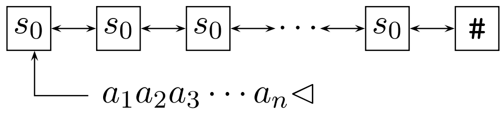
$$\iff \begin{cases} c_{t+1}(i) = \delta(c_t(i), c_t(i+1)) , \\ \quad i \in \{1, \ldots, n-1\} \\ c_{t+1}(n) = \delta(c_t(n), \#) \end{cases}$$

for OCAs. For $n = 1$, the next state of the sole cell is $\delta(\#, c_t(1), \#)$. Thus, Δ is induced by δ.

A computation can be represented as a space-time diagram, where each row is a configuration and the rows appear in chronological ordering.

In order to define iterative arrays formally we have to provide an initial (quiescent) state for the cells. We assume that once the whole input is consumed an end-of-input symbol is supplied permanently.

Definition 3 *An* iterative array *(IA) is a system* $\langle S, \delta, \delta_0, s_0, \#, \triangleleft, A, F\rangle$, *where*



Cellular Automata and Language Theory, Figure 4
An iterative array

1. *S is the finite, nonempty set of* cell states,
2. $s_0 \in S$ *is the* quiescent state,
3. $\# \notin S$ *is the permanent* boundary state,
4. $\triangleleft \notin A$ *is the* end-of-input symbol,
5. *A is the finite, nonempty set of* input symbols,
6. $F \subseteq S$ *is the set of* accepting states,
7. $\delta : S \times S \times (S \cup \{\#\}) \to S$ *is the* local transition function for non-communication cells *satisfying* $\delta(s_0, s_0, s_0) = \delta(s_0, s_0, \#) = s_0$,
8. $\delta_0 : (A \cup \{\triangleleft\}) \times S \times (S \cup \{\#\}) \to S$ *is the* local transition function for the communication cell.

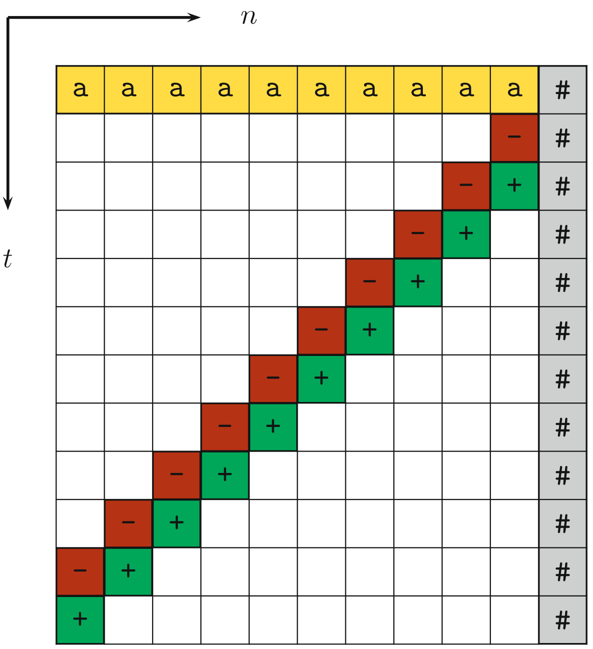
A configuration of an iterative array $\langle S, \delta, \delta_0, s_0, \#, \triangleleft, A, F\rangle$ at time $t \geq 0$ is a pair (w_t, c_t), where $w_t \in A^*$ is the remaining input sequence and $c_t : \{1, \dots, n\} \to S$, for $n \geq 1$, is a mapping that maps the single cells to their current states. The configuration (w_0, c_0) at time 0 is defined by the input word w_0 and the mapping $c_0(i) = s_0$, $1 \leq i \leq n$. The global transition function Δ is induced by δ and δ_0 as follows: Let (w_t, c_t), $t \geq 0$, be a configuration and $i \in \{2, \dots, n-1\}$. Then

$$(w_{t+1}, c_{t+1}) = \Delta((w_t, c_t))$$
$$\iff \begin{cases} c_{t+1}(1) = \delta_0(a, c_t(1), c_t(2)) \\ c_{t+1}(i) = \delta(c_t(i-1), c_t(i), c_t(i+1)) \\ c_{t+1}(n) = \delta(c_t(n-1), c_t(n), \#) \end{cases}$$

where $a = \triangleleft$, $w_{t+1} = \lambda$ if $w_t = \lambda$, and $a = a_1$, $w_t + 1 = a_2 \cdots a_n$ if $w_t = a_1 \cdots a_n$.

An input w is accepted by a CA, OCA, or an IA $\mathcal{M}$ if at some time i during its course of computation the leftmost cell enters an accepting state. The *language accepted by* $\mathcal{M}$ is denoted by $L(\mathcal{M})$. Let $t : \mathbb{N} \to \mathbb{N}$, $t(n) \geq n$ ($t(n) \geq n+1$ for IAs) be a mapping. If all $w \in L(\mathcal{M})$ are accepted with at most $t(|w|)$ time steps, then $L(\mathcal{M})$ is said to be of time complexity t.

Observe that time complexities do not have to meet any further conditions. This general treatment is made possible by the way of acceptance. An input w is accepted if the leftmost cell enters an accepting state at some time $i \leq t(|w|)$. But what if afterwards, a final configuration has been reached? Subsequent states of the leftmost cell are not relevant.



Cellular Automata and Language Theory, Figure 5
An OCA accepting any unary language. Here + is an accepting and — a non-accepting state

Following the different approach to gather the result of a computation at time step $t(|w|)$ by the outside world does not yield the desired outcome in general. In this case, the intrinsic computation may be hidden in the determination of the time step $t(|w|)$. That is, computational power may be added from the outside world. For example, let $L \in \{a\}^+$ be an arbitrary language. Then L is accepted by some OCA with time complexity

$$t(n) = \begin{cases} n & \text{if} \quad a^n \notin L \\ n+1 & \text{if} \quad a^n \in L \end{cases},$$

where the local transition function is easily designed to realize the behavior depicted in the space-time diagram of Fig. 5.

So, it is reasonable to consider only such time complexities t that allow the leftmost cell to recognize the time step $t(n)$. For example, the identity $t(n) = n$ is an honest time complexity for OCAs and CAs. A signal which is initially emitted by the rightmost cell and moves with maximal speed arrives at the leftmost cell exactly at time step n. By slowing down the signal to speed $\frac{x}{y}$, i. e., the signal alternating moves x cells to the left and stays for $y-x$ time steps in a cell, it is seen that the time complexities $\frac{x}{y} \cdot n$, for any positive integers x,y, are also honest. Another example are exponential time complexities $t(n) = k^n$, for any integer $k \geq 2$. Without going too deep into technical details, a corresponding device can be set up as a $k$ary counter. The rightmost cell simulates the least significant digit and adds one to the counter at every time step. The neighboring cell to the left observes when a carry-over appears, increases its own digit and so on. Then, the leftmost cell produces a first carry-over exactly at time step k^n.

The family of languages that are accepted by IAs (and CAs, OCAs) with time complexity t is denoted by $\mathcal{L}_t(\text{IA})$ (and $\mathcal{L}_t(\text{CA})$, $\mathcal{L}_t(\text{OCA})$, respectively). The index is omitted for arbitrary time. Actually, arbitrary time is exponential time due to the space bound. If t is the function $n+1$ (the function n), acceptance is said to be in *real time* and we write $\mathcal{L}_{\text{rt}}(\text{IA})$ ($\mathcal{L}_{\text{rt}}(\text{CA})$, $\mathcal{L}_{\text{rt}}(\text{OCA})$). Since for nontrivial computations an IA has to read at least one end-of-input symbol, real time has to be defined as $(n+1)$-time. The *linear-time* languages $\mathcal{L}_{\text{lt}}(\text{IA})$ are defined according to $\mathcal{L}_{\text{lt}}(\text{IA}) = \bigcup_{k \in \mathbb{Q}, k \geq 1} \mathcal{L}_{k \cdot n}(\text{IA})$, and similarly for CAs and OCAs.

Tools and Techniques

An elementary technique in automata theory is the usage of multiple tracks. Basically, this means to consider the state set as Cartesian product of some smaller sets. Each component of a state is called a *register*, and the same register of all cells together forms a *track*.

The first goal of this section is to show how to simulate pushdown stores, i. e., stores obeying the principle *last in first out*, by IAs and CAs in real time. Assume without loss of generality that at most one symbol is pushed onto or popped from the stack at each time step. We distinguish one cell that simulates the top of the pushdown store. It suffices to use three additional tracks for the simulation. Let the three pushdown registers of each cell be numbered one, two and three from top to bottom. Each cell prefers to have only the first two registers filled. The third register is used as a buffer. In order to reach that charge it obeys the following rules (cf. Fig. 6).

a) If all three registers of its left (upper) neighbor are filled, it takes over the symbol from the third register of the neighbor and stores it in its first register. The old contents of the first and second registers are shifted to the second and third register.

b) If there is only the first register of its left (upper) neighbor filled, the cell erases its first register and shifts the contents of the second and third registers to the first and second register. Observe that the erased symbol is taken over by the left neighbor.

c) Possibly, more than one of these actions are superimposed.

From the simulation, it follows immediately that real-time IAs as well as real-time CAs accept all languages accepted by sequential pushdown automata as long as they work in real time.

Theorem 4 *Given some real-time deterministic pushdown automaton, an equivalent real-time IA and CA can effectively be constructed, i. e., every real-time deterministic context-free language belongs to the families $\mathcal{L}_{rt}$(IA) and $\mathcal{L}_{rt}$(CA).*

Now we turn to a technique for disproving that languages are accepted. In general, the method is based on equivalence classes which are induced by formal languages. If some language induces a number of equivalence classes which exceeds the number of classes distinguishable by a certain device, then the language is not accepted by that device. First we give the definition of an equivalence relation which applies to real-time IAs.

Definition 5 *Let $L \subseteq A^*$ be a language and $l \geq 1$ be a constant. Two words $w \in A^*$ and $w' \in A^*$ are l-equivalent with respect to L if and only if*

$$wu \in L \iff w'u \in L$$

for all $u \in A^*$, $|u| \leq l$. The number of l-equivalence classes with respect to L is denoted by $E(L, l)$.

In [19] the following upper bound for the number of equivalence classes distinguishable by real-time IA is derived.

Lemma 6 *If $L \in \mathcal{L}_{rt}$(IA), then there exists a constant $p \geq 1$ such that $E(l, L) \leq p^l$.*

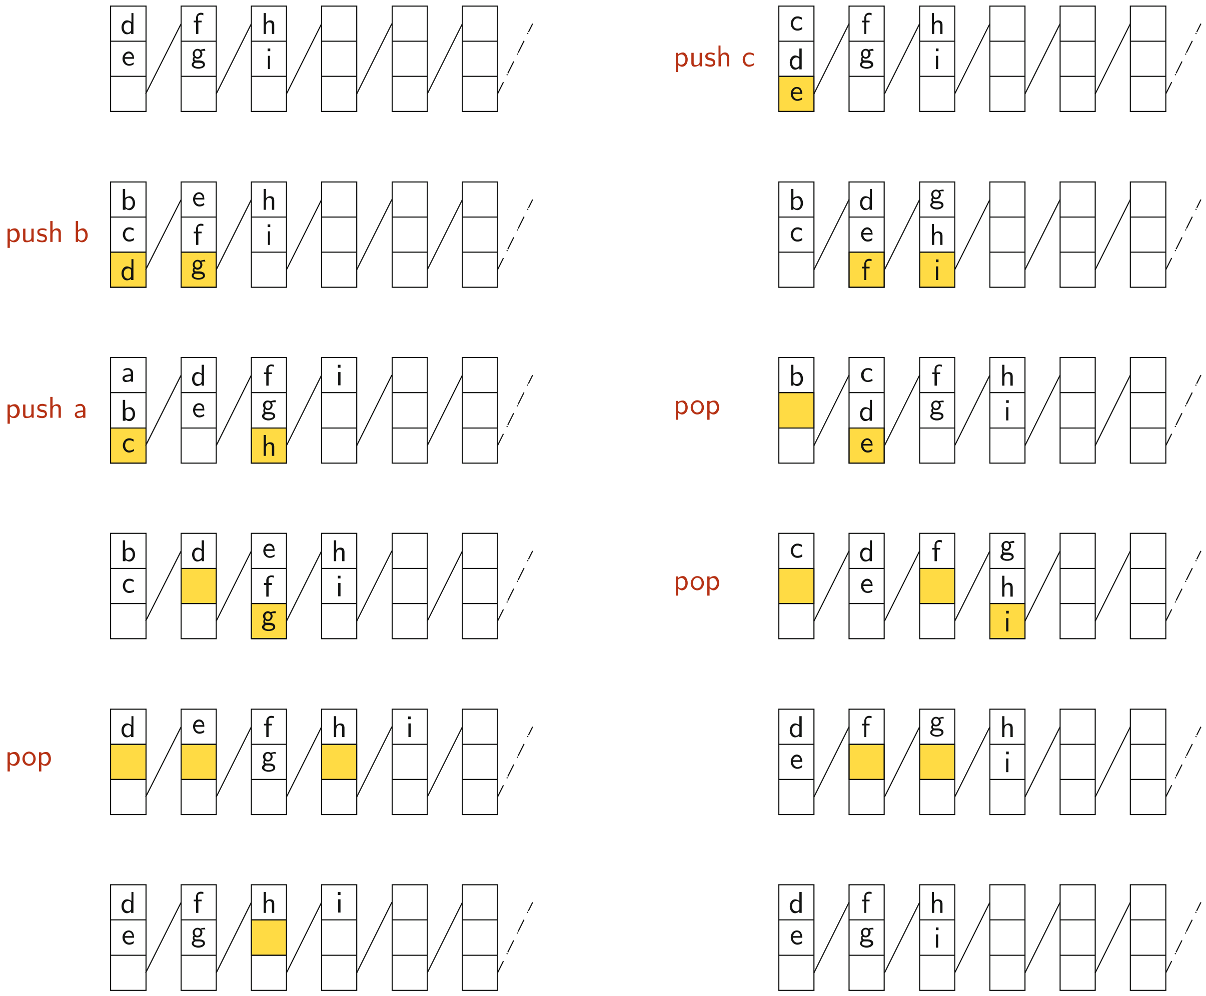
Proof Let $\mathcal{M}$ be a real-time IA with state set S. In order to determine an upper bound for the number of l-equivalence classes with respect to $L(\mathcal{M})$, we consider the possible configurations of $\mathcal{M}$ after reading all but l input symbols. The remaining computation depends on the last l input symbols and the states of the cells $1, \ldots, l+2$. For the $l+2$ states there are at most $|S|^{l+2}$ different possibilities. Setting $p = |S|^3$, we derive $|S|^{l+2} \leq |S|^{3l} = p^l$, and obtain at most p^l different possibilities. Since the number of equivalence classes is not affected by the last l input symbols, there are at most p^l equivalence classes. □

Example 7 The language

$$L = \{\&x_k\& \cdots \&x_1 ? y_1\& \cdots \&y_k\& \mid k \geq 1, x_i^R = y_i z_i \\ \text{and} \quad x_i, y_i, z_i \in \{a, b\}^*\}$$

does not belong to $\mathcal{L}_{\text{rt}}(\text{IA})$.

For a pair of different prefixes $w = \&x_k \& \cdots \& x_1 ?$ and $w' = \& x'_k\& \cdots \& x'_1 ?$ with $|x_i| = |x'_i| = k$, $1 \leq i \leq k$, there exists at least one $1 \leq j \leq k$ such that $x_j \neq x'_j$. This



Cellular Automata and Language Theory, Figure 6
Principle of a pushdown store simulation. Subfigures are in row-major order

implies $w\,\&^{j-1}\,x_j^R\,\&^{k-j+1} \in L$ and $w'\,\&^{j-1}\,x_j^R\,\&^{k-j+1} \notin L$. Since there are 2^{k^2} different prefixes of the given form, language L induces at least 2^{k^2} classes.

On the other hand, if L would be accepted by some real-time IA, then by Lemma 6 there is a constant $p \geq 1$ such that $E(L,2k) \leq p^{2k}$. Since L is infinite, we may choose k large enough such that $2^{k^2} > p^{2k}$, which is a contradiction. □

Now we change to real-time OCAs. The next result is a tool which allows us to show that languages do not belong to the family $\mathscr{L}_{\mathrm{rt}}(\mathrm{OCA})$. It is based on pumping arguments for cyclic strings [68].

Lemma 8 *Let L be a real-time OCA language. Then there exists a constant $p \geq 1$ such that any pair of a word w and an integer k that meets the condition $w^k \in L$ and $k > p^{|w|}$ implies that there is some $1 \leq q \leq p^{|w|}$ such that $w^{k+jq} \in L$, for all $j \geq 0$.*

Proof For a given real-time OCA $\mathcal{M} = \langle S, \delta, \#, A, F \rangle$, we set $p = |S|^2$. Let $w^k \in L(\mathcal{M})$, where $k > p^{|w|}$. Then we consider an accepting computation of $\mathcal{M}$ on input w^k. The initial configuration is represented by $\#w^k\#$. Clearly, a cyclic left part of some configuration leads again to a cyclic left part, though the new left part gets one cell shorter at any time step. Therefore, after $|w|$ time steps the left part of the configuration which still may influence the overall computation result is represented by $\#w_1^{k-1}s_1$, where $|w_1| = |w|$ and $s_1 \in S$. After another $|w|$ time steps, we obtain $\#w_2^{k-2}s_2$, where $|w_2| = |w|$ and $s_2 \in S$. In general, the relevant part of a configuration at time $i \cdot |w|$, $1 \leq i \leq k$, is represented by

$\# w_i^{k-i} s_i$, where $|w_i| = |w|$ and $s_i \in S$. In addition, state s_k is an accepting one.

Since the number of different words w_i is bounded by $|S|^{|w|}$, for $w_i s_i$ there are at most

$$|S|^{|w|+1} \le |S|^{2\left\lceil \frac{|w|+1}{2} \right\rceil} \le p^{|w|}$$

different possibilities. Now $k > p^{|w|}$ implies that $w_i s_i = w_l s_l$ for some $1 \le i < l \le k$. Therefore, there is a loop and, for $q = l - i$, the word w^{k+jq} is accepted, for any $j \ge 0$. □

Example 9 The language $L = \{a^{2^n} \mid n \ge 1\}$ is not accepted by any real-time OCA.

Contrarily assume there is a real-time OCA accepting L. Then we set $w = a, k = 2^p$ and observe that the conditions of Lemma 8 are met. Therefore, a^{2^p+q} as well as a^{2^p+2q} belong to L. If $2^p + q$ is not a power of two, we obtain a contradiction. So, let $2^p + q = 2^{p+r}$, for some $r \ge 1$. We derive $2^{p+r} < 2^{p+r} + q = 2^{p+r} + 2^{p+r} - 2^p = 2^{p+r+1} - 2^p < 2^{p+r+1}$, and conclude that $2^p + 2q$ is strictly in between two consecutive powers of two. Hence, a^{2^p+2q} does not belong to L. □

Next we come back to equivalence classes. By a similar idea as for iterative arrays an equivalence relation can be defined such that the number of equivalence classes distinguishable by real-time OCAs is bounded. But due to the nature of OCA computations, both the prefixes as well as the suffixes of inputs have to be regarded [84,85]. We continue with the equivalence relation:

Definition 10 *Let $L \subseteq A^*$ be a language and $X \subseteq A^*$ and $Y \subseteq A^*$ be two sets of words. Two words $w \in A^*$ and $w' \in A^*$ are (L, X, Y)-equivalent if and only if*

$$xwy \in L \iff xw'y \in L$$

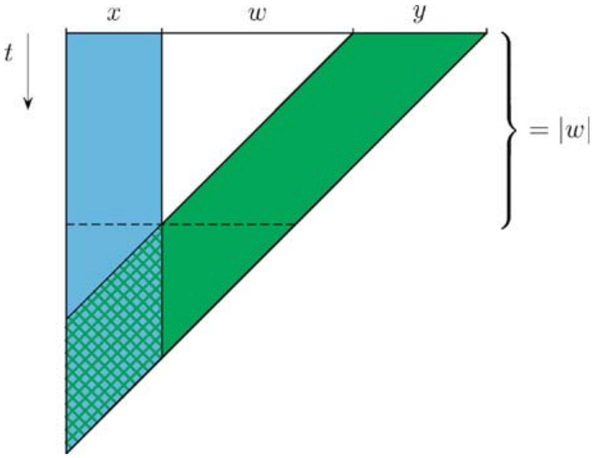
for all $x \in X$ and $y \in Y$.

The next step is to derive an upper bound for the number of equivalence classes which can be distinguished by some real-time OCA.

Theorem 11 *Let $L \subseteq A^*$ be a real-time OCA language and $X = A^{m_1}$ and $Y = A^{m_2}$ be two sets of words for positive integers m_1 and m_2. Then there exists a constant $p \ge 1$ such that the number N of (L, X, Y)-equivalence classes is bounded by*

$$N \le p^{|X|} p^{(m_2+1)|Y|} .$$

Proof For any word w and any $x \in X$ and $y \in Y$ the input xwy implies exactly one real-time OCA configuration at time $|w|$ (see Fig. 7). At this time only the leftmost $|xy| + 1$ cells can still influence the overall computation result, i. e., the cells $1, \dots, |xy| + 1$. The cells $1, \dots, |x|$ are not affected by the cells $|xw| + 1, \dots, |xwy|$ up to time $|w|$. So, they are not affected by y up to that time. Furthermore, the cells $|x| + 1, \dots, |xy| + 1$ are not affected by the cells $1, \dots, |x|$, that is, not by x. On the other hand, different w may cause different configurations for x and y, where x and y are independent of each other.



Cellular Automata and Language Theory, Figure 7
Dependencies in the proof of Theorem 11

It follows that w and w' are equivalent, if the cells $1, \dots, |xy| + 1$ at time step $|w|$ respectively $|w'|$ are in the same states for all $x \in X$ and $y \in Y$. For any $y \in Y$, there are $|S|^{m_2} + 1$ different configurations for the cells $|x| + 1, \dots, |xy| + 1$. So, there are altogether at most $|S|^{(m_2+1)|Y|}$ different possibilities to distinguish the words w.

The possibilities for the cells $1, \dots, |x|$ are as follows. For a word $x = x_{m_1} \dots x_1$ the state s_i of cells $1 \le i \le m_1$ at time $|w|$ depends only on $x_i, \dots, x_1$ and w. So, for s_i there are at most $|S|^{|A|^i}$ different possibilities to distinguish the words w. Together we obtain

$$\prod_{i=1}^{m_1} |S|^{|A|^i} < |S|^{|A|^{m_1+1}}$$

possibilities. For $p = |S|^{|A|}$ this implies $|S|^{|A|^{m_1+1}} = p^{|A|^{m_1}} = p^{|X|}$. Thus, the number of equivalence classes is bounded by $p^{|X|} p^{(m_2+1)|Y|}$. □

As an example we show that the language $L_d \subset \{0, 1, (,), |\}^+$ whose words are of the form

$$x(x_1|y_1) \cdots (x_n|y_n)y ,$$

where $x,x_i,y,y_i \in \{0,1\}^*$, for $1 \le i \le$ n, and $(x|y) = (x_i|y_i)$ for at least one $i \in \{1, \dots, n\}$, is not a real-time OCA language.

It can be thought of as a dictionary. The task for the OCA is to check whether the pair $(x|y)$ occurs in the dictionary or not.

Example 12 Let $X = Y = \{0,1\}^*$. Two words $w = (x_1|y_1)\cdots(x_n|y_n)$ and $w' = (x'_1|y'_1)\cdots(x'_m|y'_m)$ are (L_d, X, Y)-equivalent if and only if $\{(x_1|y_1), \dots, (x_n|y_n)\} = \{(x'_1|y'_1), \dots, (x'_m|y'_m)\}$.

First assume that the two sets are equal. Let $x \in X$ and $y \in Y$, then $xwy \in L_d$ implies $(x|y) = (x_i|y_i)$, for some i. Since the two sets are equal, we have $(x|y) = (x'{}_j|y'{}_j)$, for some j. Therefore, $xwy \in L_d$ implies $xw'y \in L_d$ and vice versa, i. e., w and w' are (L_d, X, Y)-equivalent.

Now assume the two sets are different. Without loss of generality, we can assume that there exist $x \in X$ and $y \in Y$ with $(x|y) = (x_i|y_i)$, for some i, but $(x|y) \neq (x'_j|y'_j)$, for all $j = 1, \dots, m$. Then $xwy \in L_d$ but $xw'y \notin L_d$ and, thus, w and w' are not (L_d,X,Y)-equivalent.

In order to derive a lower bound for the number of (L_d, X, Y) equivalence classes induced by L_d, let $m_1, m_2 \geq 1$, $X = \{0,1\}^{m_1}$ and $Y = \{0,1\}^{m_2}$. Then the number N of (L_d,X,Y)-equivalence classes is at least $2^{2^{m_1+m_2}}$.

For fixed $m_1 \geq 1$ and $m_2 \geq 1$, we consider all words of the form $(x_1|y_1)\cdots(x_k|y_k)$ with $x_i \in \{0,1\}^{m_1}$ and $y_i \in \{0,1\}^{m_2}$, for all $i \in \{1, \dots, k\}$, and $(x_i|y_i) \neq (x_j|y_j)$, for $i \neq j$. These words are said to be of type (m_1,m_2). Following the argumentation above, two words are equivalent if and only if the sets of subwords are equal. There are $2^{2^{m_1+m_2}}$ words of type (m_1,m_2) which belong to different equivalence classes with respect to L_d, $X = \{0,1\}^{m_1}$ and $Y = \{0,1\}^{m_2}$.

Now assume that L_d is accepted by some real-time OCA. For all $m_1,m_2 \geq 1$ there is a constant p such that the number of equivalence classes is at most $p^{2^{m_1}} p^{(m_2+1)2^{m_2}}$. For large enough m_1 and m_2 we obtain a contradiction to the lower bound $2^{2^{m_1+m_2}}$. □

Helpful tools of a different nature are speed-up theorems. Strong results are obtained in [34,36], where the parallel language families are characterized by certain types of customized sequential machines. Such machines have been developed for all classes of acceptors which are here under consideration. In particular, speed-up theorems are given that allow to speed up the time beyond real time linearly. Therefore, linear-time computations can be sped up close to real time. The question whether or not real time is strictly weaker than linear time is discussed in detail later.

Theorem 13 *Let $\mathcal{M}$ be a CA, OCA, or IA obeying time complexity $rt + r(n)$, where $r\colon \mathbb{N} \to \mathbb{N}$ is a mapping and rt denotes real time. Then for all $k \geq 1$ an equivalent device $\mathcal{M}'$ of the same type obeying time complexity $rt + \lfloor \frac{r(n)}{k} \rfloor$ can effectively be constructed.*

The next two examples are frequently used applications of the linear speed-up theorem.

Example 14 Let $k_0 \geq 1$ and $\mathcal{M}$ be a device in question with time complexity $rt + k_0$. Then there is an equivalent real-time device $\mathcal{M}'$ of the same type. It suffices to set $k = k_0 + 1$ and to apply Theorem 13 in order to obtain $rt + \lfloor \frac{k_0}{k} \rfloor = rt + \lfloor \frac{k_0}{k_0+1} \rfloor = rt$ for the time complexity of $\mathcal{M}'$. □

Example 15 Let $k_0 \geq 1$ and $\mathcal{M}$ be a device in question with time complexity $rt + k_0 \cdot rt$. Then for all rational numbers $\varepsilon > 0$ there is an equivalent device $\mathcal{M}'$ of the same type with time complexity $\lfloor (1+\epsilon) \cdot rt \rfloor$. We set $k = \lceil \frac{k_0}{\epsilon} \rceil$ and apply Theorem 13 in order to obtain $rt + \left\lfloor \frac{k_0 \cdot rt}{\lceil k_0/\epsilon \rceil} \right\rfloor \leq rt + \left\lfloor \frac{k_0 \cdot rt}{k_0/\epsilon} \right\rfloor = rt + \lfloor \epsilon \cdot rt \rfloor = \lfloor (1+\epsilon) \cdot rt \rfloor$. □

Computational Capacities

In this section we explore the computational capacities of real-time, linear-time, and unbounded time devices. The goal is to establish a hierarchy of language families and to compare the levels with well-known linguistic families of the Chomsky hierarchy language family. The properness of some inclusions are long-standing open problems with deep relations to sequential complexity problems. In order to establish the hierarchy we start at the upper and lower end. Straightforward constructions of linearly space-bounded Turing machines from IAs, of IAs from CAs, and of CAs from linearly space-bounded Turing machines show the following lemma [80].

Lemma 16 *The families $\mathcal{L}(CA)$ and (IA) are identical with the deterministic context-sensitive languages, i. e., with the complexity class DSPACE(n).*

At the lower end we consider the regular languages. Since already the communication cell is a deterministic finite-state machine, clearly, the regular languages are a subset of $\mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$. In Theorem 4 the stronger result that any real-time deterministic context-free language belongs to $\mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$ has been shown. So, the properness of the following inclusion is obvious.

Corollary 17 *The regular languages are a proper subset of $\mathcal{L}_{rt}(IA)$.*

The question arises whether the real-time condition of Theorem 4 can be relaxed in order to obtain a larger sub-family of the context-free languages which is accepted by real-time IAs. The answer is negative. The following lemma marks a sharp boundary between context-free languages acceptable and non-acceptable by real-time IAs. Recall that linear context-free languages are accepted by nondeterministic one-turn pushdown automata. Since here we deal with deterministic devices, the alternative grammar characterization is more suitable for our purposes.

A grammar $\mathcal{G} = \langle N,T,S,P \rangle$ is said to be *linear context free*, if the productions in P are of the forms $(X \to a)$, $(X \to Ya)$, or $(X \to aY)$, where $X,Y \in N$ are nonterminals and $a \in T$ is a terminal symbol (e. g. [72]).

Lemma 18 *There exists a deterministic, linear context-free language that does not belong to $\mathcal{L}_{rt}$(IA).*

Proof Clearly, language

$$L = \{\&x_k\& \cdots \&x_1?y_1\& \cdots \&y_k\& \mid k \geq 1, x_i^R = y_i z_i \\ \text{and} \quad x_i, y_i, z_i \in \{a,b\}^*\}$$

is deterministic and linear context free. By Example 7 it does not belong to $\mathcal{L}_{\text{rt}}$(IA). □

We turn to real-time OCAs. Similar as above, the linear context-free languages serve as sub-family of the context-free languages which is contained in $\mathcal{L}_{\text{rt}}$(OCA) [76].

Theorem 19 *Given some linear context-free grammar, an equivalent real-time OCA can effectively be constructed, i. e., every linear context-free language belongs to $\mathcal{L}_{rt}$(OCA).*

Proof Let $\mathcal{G} = \langle N, T, S, P \rangle$ be a linear context-free grammar, and $w = a_1 a_2 \cdots a_n$ be a word in $L(\mathcal{G})$. If $X \Rightarrow^* a_i \cdots a_j$, $1 \leq i < j \leq n$, then there exists a $Y \in N$ such that either $(Y \Rightarrow^* a_i \cdots a_{j-1} \wedge X \Rightarrow Ya_j)$ or $(Y \Rightarrow^* a_{i+1} \cdots a_j \wedge X \Rightarrow a_i Y)$. Based on this fact we define sets of nonterminals for the given word w as follows:

$$N(i,i) = \{X \in N \mid (X \to a_i) \in P\}\,, \quad 1 \leq i \leq n$$
$$N(i,j) = N_1(i,j) \cup N_2(i,j)\,, \quad 1 \leq i < j \leq n\,,$$
$$\text{where } N_1(i,j) = \{X \in N \mid (X \to Ya_j) \in P \\ \wedge\ Y \in N(i,j-1)\}$$
$$\text{and } N_2(i,j) = \{X \in N \mid (X \to a_i Y) \in P \\ \wedge\ Y \in N(i+1,j)\}\,.$$

So, the word $a_1 \cdots a_n$ is generated by $\mathcal{G}$ if and only if $S \in N(1,n)$.

A real-time OCA $\mathcal{M} = \langle S', \delta, \#, T, F \rangle$ accepting $L(\mathcal{G})$ behaves as follows. It analyzes its input $a_1 \cdots a_n$ in such a way that the cells successively compute certain sets $N(i,j)$. In the first step, all cells $1 \leq i \leq n$ compute $N(i,i)$ and (a_i, a_i). In subsequent steps $k \geq 2$, they compute $N(i, i+k-1)$ and (a_i, a_{i+k-1}) if $k \leq n+1-i$, and keep their state otherwise. The new values can be determined by the state of the cell itself and the state of its right neighbor, i. e., $N(i, i+k-2)$, (a_i, a_{i+k-1}) and $N(i+1, i+k-1)$, (a_{i+1}, a_{i+k}). Thus, the leftmost cell computes $N(1,n)$ at time step n. □

Corollary 20 *The regular languages are a proper subset of $\mathcal{L}_{rt}$(OCA).*

Again, the question arises whether the condition of Theorem 19 can be relaxed in order to obtain a larger sub-family of the context-free languages that is accepted by real-time OCAs. Again, the answer is negative.

Lemma 21 *There exists a two-linear context-free language that does not belong to $\mathcal{L}_{rt}$(OCA).*

Proof Consider the linear language $L = \{a^n b^n \mid n \geq 1\} \cup \{a^n bvab^n \mid n \geq 1, v \in \{a,b\}^*\}$. By counting arguments, in [85] it is shown that the two-linear concatenation LL is not accepted by any real-time OCA. □

Beginning with the regular languages at the bottom of the hierarchy, next we deal with the proper supersets given by real-time deterministic and linear context-free languages. Since both families are known to be incomparable with respect to inclusion, the hierarchy splits into two strands. Unfortunately we have to continue with these two strands for a moment.

Theorem 22 *The families $\mathcal{L}_{rt}$(OCA) and $\mathcal{L}_{rt}$(IA) are incomparable.*

Proof By Lemma 18 there exists a linear context-free language not accepted by any real-time IA, but by Theorem 19 it belongs to a real-time OCA.

Conversely, one can show that the two-linear language of Lemma 21 belongs to $\mathcal{L}_{\text{rt}}$(IA). □

The next step is to go beyond $\mathcal{L}_{\text{rt}}$(OCA) and $\mathcal{L}_{\text{rt}}$(IA). Structurally this concerns CAs, but first we increase the time complexity. For the proof of infinite hierarchies in between real time and linear time, it is necessary to control the lengths of words with respect to some internal substructures. The following notion of constructibility expresses the idea that the length of a word relative to the length of a subword should be computable. To this end, a function $f\colon \mathbb{N} \to \mathbb{N}$ is said to be *OCA-constructible*, if there exist an λ-free homomorphism h and a language $L \in \mathcal{L}_{\text{rt}}$(OCA) such that $h(L) = \{a^{f(n)-n} b^n \mid n \geq 1\}$. Since constructible functions describe the length of the whole word dependent on the length of a subword, it is obvious that each constructible function must be greater than or equal to the identity. At a glance, this notion of constructibility might look somehow unusual or restrictive. However, λ-free homomorphisms are very powerful, so that the family of (in this sense) constructible functions is very rich. Examples and the next theorem are presented in [45].

Theorem 23 *Let $r_1, r_2 \colon \mathbb{N} \to \mathbb{N}$ be two increasing functions. If $r_2 \cdot \log(r_2) \in o(r_1)$ and r_1^{-1} is OCA constructible, then $\mathcal{L}_{n+r_2(n)}(OCA) \subset \mathcal{L}_{n+r_1(n)}(OCA)$.*

Example 24 Let $0 \leq p < q \leq 1$ be two rational numbers. Clearly, $n^p \cdot \log(n^p)$ is of order $o(n^q)$. Moreover, the inverse of n^q is OCA-constructible. Thus, an application of Theorem 23 yields the strict inclusion

$$\mathcal{L}_{n+n^p}(\mathrm{OCA}) \subset \mathcal{L}_{n+n^q}(\mathrm{OCA})\,. \qquad \square$$

Example 25 Let $i < j$ be two positive integers, then $\log^{[j]}(n) \cdot \log^{[j+1]}(n)$ is of order $o(\log^{[i]}(n))$. Since the inverse of $\log^{[i]}(n)$ is OCA-constructible, we obtain the strict inclusion

$$\mathcal{L}_{n+\log^{[j]}(n)}(\mathrm{OCA}) \subset \mathcal{L}_{n+\log^{[i]}(n)}(\mathrm{OCA})\,. \qquad \square$$

Similar results are known for iterative arrays. The infinite strict hierarchies in the range between real time and linear time are established in [9]. The constructibility is defined differently. A strictly increasing function $f \colon \mathbb{N} \to \mathbb{N}$ is *IA-constructible*, if there exists an IA with infinitely many cells to the right, such that the leftmost cell enters some state from a distinguished subset of states exactly at all time steps $f(i)$, $1 \leq i$. Example 1 shows that the function 2^n is IA-constructible.

Theorem 26 *Let $r_1, r_2 \colon \mathbb{N} \to \mathbb{N}$ be two increasing functions. If $r_2 \in o(r_1)$ and r_1^{-1} is IA-constructible, then $\mathcal{L}_{n+r_2(n)}(IA) \subset \mathcal{L}_{n+r_1(n)}(IA)$.*

The following example is based on natural functions.

Example 27 Since the family of IA-constructible functions is closed under composition and contains 2^n and n^k, $k \geq 1$, the functions $\log^{[i]}(n)$, $i \geq 1$, and $\sqrt[k]{n}$ are inverses of constructible functions. Actually, the inverses of 2^n and n^k are $\lceil \log(n) \rceil$ and $\lceil n^{\frac{1}{k}} \rceil$ but for convenience we simplify the notation. Therefore, an application to the hierarchy theorem yields

$$\mathcal{L}_{\mathrm{rt}}(\mathrm{IA}) \subset \cdots \subset \mathcal{L}_{n+\log^{[i+1]}(n)}(\mathrm{IA}) \subset \mathcal{L}_{n+\log^{[i]}(n)}(\mathrm{IA}) \subset \cdots \subset \mathcal{L}_{\mathrm{lt}}(\mathrm{IA})$$

and

$$\mathcal{L}_{\mathrm{rt}}(\mathrm{IA}) \subset \cdots \subset \mathcal{L}_{n+n^{\frac{1}{i+1}}}(\mathrm{IA}) \subset \mathcal{L}_{n+n^{\frac{1}{i}}}(\mathrm{IA}) \subset \cdots \subset \mathcal{L}_{\mathrm{lt}}(\mathrm{IA})\,,$$

or in combination, e. g.,

$$\begin{aligned}\mathcal{L}_{\mathrm{rt}}(\mathrm{IA}) &\subset \cdots \subset \mathcal{L}_{n+(\log^{[j+1]}(n))^{\frac{1}{i+1}}}(\mathrm{IA}) \\ &\subset \mathcal{L}_{n+(\log^{[j+1]}(n))^{\frac{1}{i}}}(\mathrm{IA}) \subset \cdots \subset \mathcal{L}_{n+(\log^{[j]}(n))^{\frac{1}{i+1}}}(\mathrm{IA}) \\ &\subset \mathcal{L}_{n+(\log^{[j]}(n))^{\frac{1}{i}}}(\mathrm{IA}) \subset \cdots \subset \mathcal{L}_{\mathrm{lt}}(\mathrm{IA})\,.\end{aligned}$$

□

Example 9 reveals a unary language not accepted by any real-time OCA. Note that the witness language $\{a^{2^n} \mid n \geq 1\}$ is not context free. Next, we generalize this observation and show that even massively parallel real-time OCAs cannot accept more unary languages than a single deterministic finite-state machine [73].

Theorem 28 *Each unary real-time OCA language is regular.*

Proof Let $A = \{a\}$ be an alphabet, $L \subseteq A^+$ a language, and $\mathcal{M} = \langle S, \delta, \#, A, F \rangle$ be an OCA accepting L in real time. We construct an equivalent deterministic finite-state machine $\mathcal{E}$ with state set $S \times S$, initial state s_0, set of accepting states F', and transition function δ' as follows.

$$\begin{aligned}&s_0 = (\#, a)\,, \qquad F' = \{(s_1, s_2) \in S \times S \mid s_1 \in F\}\,,\\ &\quad \delta'((s_1, s_2), a) = (\delta(s_2, s_1), \delta(s_2, s_2))\,,\\ &\quad \text{for all } (s_1, s_2) \in S \times S\end{aligned}$$

In order to give evidence that the construction is correct, we depict two correspondent computations in Fig. 8. □

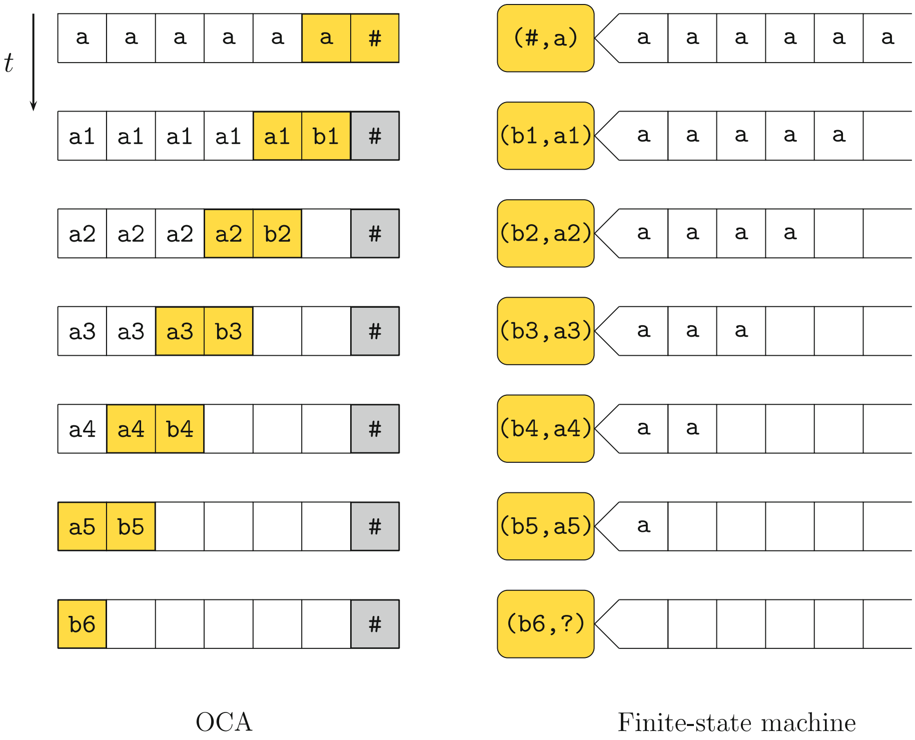
Next we can join the two strands of the hierarchy again. The superfamily is $\mathcal{L}_{\mathrm{rt}}(\mathrm{CA})$.

Theorem 29 *The family $\mathcal{L}_{rt}(OCA)$ is properly included in $\mathcal{L}_{rt}(CA)$.*

Proof The inclusion follows for structural reasons. For the properness we argue as follows. Since the language $L = \{a^{2^n} \mid n \geq 1\}$ is not regular, it does not belong to $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$. On the other hand, Example 1 shows that it belongs to $\mathcal{L}_{\mathrm{rt}}(\mathrm{CA})$. □

Theorem 30 *The family $\mathcal{L}_{rt}(IA)$ is properly included in $\mathcal{L}_{rt}(CA)$.*

Proof First we give evidence of the inclusion $\mathcal{L}_{\mathrm{rt}}(\mathrm{IA}) \subseteq \mathcal{L}_{\mathrm{rt}}(\mathrm{CA})$. A real-time CA can be set up in such a way that it shifts its input successively to the left on an additional track. So, the leftmost cell receives the input symbol by symbol. Therefore, the CA can simulate the iterative array, where the leftmost cell simulates the communication cell.



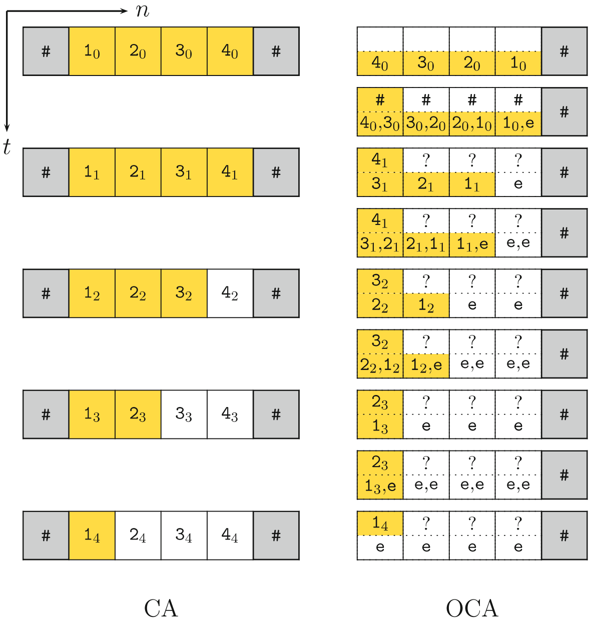
Cellular Automata and Language Theory, Figure 8
A finite-state machine simulating a real-time OCA on unary input

The properness of the inclusion follows by the inclusion $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA}) \subset \mathcal{L}_{\mathrm{rt}}(\mathrm{CA})$ and the incomparability of $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$ and $\mathcal{L}_{\mathrm{rt}}(IA)$. □

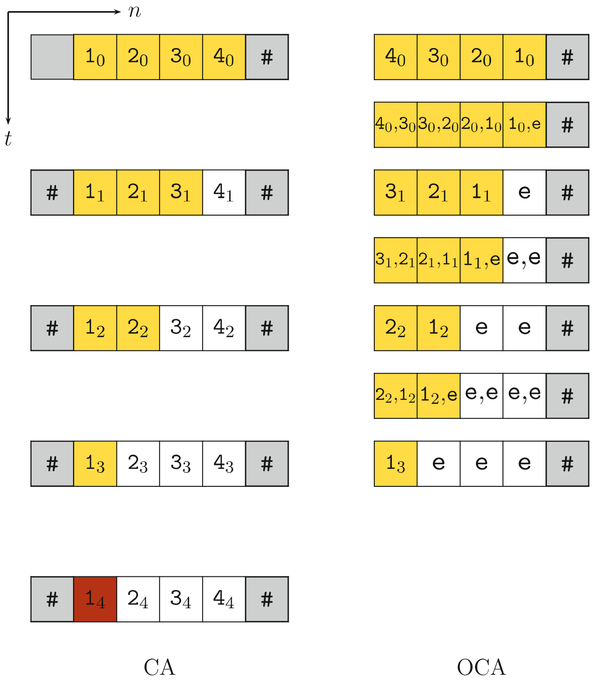
Once we know that, in general, a real-time CA language cannot be accepted by any real-time OCA, the question arises of how much time is necessary for that, if possible at all. The next result gives an upper bound for the time [17,95]. Admittedly, to this end the input has to be reversed. Alternatively, one could reverse the neighborhood of the cells in an OCA. Then the rightmost cell indicates the result of the computation. In this case the input could remain as it is. In any case, the condition cannot be relaxed since it is an open problem whether the corresponding language families are closed under reversal.

Theorem 31 *A language is accepted by a linear-time OCA if and only if its reversal is accepted by a CA in real time.*

Proof Let $\mathcal{M}$ be a real-time CA. The cells of a linear-time OCA $\mathcal{M}'$ accepting $L(\mathcal{M})^R$ collect the information necessary to simulate one transition of $\mathcal{M}$, in an intermediate step. Therefore, the first step of $\mathcal{M}$ is simulated in the second step of $\mathcal{M}'$. We obtain a behavior as depicted in Fig. 9.



Cellular Automata and Language Theory, Figure 9
Intermediate steps in the construction of the proof of Theorem 31



Cellular Automata and Language Theory, Figure 10
Example of a linear-time OCA simulation of a real-time CA computation on reversed input

Altogether, $\mathcal{M}'$ cannot simulate the last step of $\mathcal{M}$. So, the construction has to be extended slightly. Each cell has an extra register that is used to simulate transitions of $\mathcal{M}$ under the assumption that the cell is the leftmost one (see Fig. 10). The transitions of the real leftmost cell now correspond to the missing transitions of the previous simulation. □

Climbing up one level, the hierarchy continues with two-way linear-time devices.

Theorem 32 *A language is accepted by a linear-time IA if and only if it is accepted by a linear-time CA.*

Proof The inclusion $\mathcal{L}_{\mathrm{lt}}(\mathrm{IA}) \subseteq \mathcal{L}_{\mathrm{lt}}(\mathrm{CA})$ follows by the proof of Theorem 30.

Conversely, a linear-time iterative array can simulate a linear-time CA as follows. In the first phase, it reads the input and stores it successively in its cells. Next, the iterative array starts a time optimal firing squad synchronization algorithm (see for example [62,98]). That is, an algorithm which is initiated by the communication cell, and which synchronizes the n cells within $2n - 2$ time steps. Finally, all cells start the simulation of the CA at the same time. Clearly, the iterative array obeys a linear time bound if the cellular automaton does. □

Cellular Automata and Language Theory, Figure 11
Basic hierarchy of language families. A solid arrow indicates a proper inclusion and a dashed arrow an inclusion. In addition, the linear languages (LIN) are properly included in the context-free languages (CFL). Deterministic and real-time deterministic context-free languages are denoted by DCFL and DCFL_λ, regular languages by REG, and deterministic context-sensitive languages by DCSL

The next inclusion does not follow for structural reasons. It is proved in [16,32] in terms of simulations of equivalent sequential machines. The properness is an open problem.

Theorem 33 *Each linear-time CA language belongs to the family $\mathcal{L}(OCA)$.*

The family $\mathcal{L}(\mathrm{OCA})$ is very powerful. It contains the context-free languages as well as a PSPACE-complete language [16,32]. Altogether we obtained the hierarchy depicted in Fig. 11, where the only known proper inclusions are at the lower end. Nevertheless, even the real-time OCA languages contain important families, e. g., the Dyck languages [73] and the bracketed context-free languages [26]. Furthermore, the non-semilinear language $\{(a^i b)^* \mid i \geq 0\}$ [73] and the inherently ambiguous language $\{a^i b^j c^k \mid i = j \text{ or } j = k \text{ for } i, j, k \geq 1\}$ [80] belong to $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$. On the other hand, the context-free languages have been shown to be incomparable with $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$. Whether or not they are a subset of the family $\mathcal{L}_{\mathrm{rt}}(\mathrm{CA})$ is an open question raised in [80].

We conclude this section with a real-time OCA based characterization of the recursively enumerable languages and its implication to incomparability [58].

Lemma 34 *A language is recursively enumerable if and only if there exists a homomorphism h and a language $L' \in \mathcal{L}_{\mathrm{rt}}(OCA)$ such that $L = h(L')$. The same holds for $\mathcal{L}_{\mathrm{rt}}(IA)$.*

Proof It is known that the recursively enumerable languages can be represented by $h(L_1 \cap L_2)$, where h is a homomorphism and L_1, L_2 are either linear context-free languages [4] or real-time deterministic context-free languages [29]. In fact, in the latter paper deterministic pushdown automata are constructed that use λ-moves. But the constructions can easily be modified to obtain real-time pushdown automata. So, the assertions follow since $\mathcal{L}_{\text{rt}}(\text{OCA})$ contains the linear context-free languages, $\mathcal{L}_{\text{rt}}(\text{IA})$ contains the real-time deterministic context-free languages, and both families are closed under intersection (Theorem 39). □

The homomorphic characterization of the recursively enumerable languages reveals the following general incomparability result.

Theorem 35 *Both families $\mathcal{L}_{rt}(OCA)$ and $\mathcal{L}_{rt}(IA)$ are incomparable to each language family $\mathcal{L}$ that contains the context-free languages, is itself properly contained in the recursively enumerable languages, and is closed under homomorphism.*

Proof Since there is a context-free language not belonging to $\mathcal{L}_{\text{rt}}(\text{OCA})$, we obtain $\mathcal{L} \not\subseteq \mathcal{L}_{\text{rt}}(\text{OCA})$. Conversely, if $\mathcal{L}_{\text{rt}}(\text{OCA}) \subseteq \mathcal{L}$, then the recursively enumerable languages are a subset of $\mathcal{L}$ by Lemma 34. This contradicts the proper containment in the recursively enumerable languages. The same argumentation applies to $\mathcal{L}_{\text{rt}}(\text{IA})$. □

Example 36 The families $\mathcal{L}_{\text{rt}}(\text{OCA})$ and $\mathcal{L}_{\text{rt}}(\text{IA})$ are incomparable to the languages of indexed grammars, certain grammars with regulated rewriting, certain contextual grammars, and certain Lindenmayer systems, e. g., ET0L systems. □

Closure Properties

Closure properties of families of formal languages indicate their robustness under certain operations. A family of languages is *closed under some operation*, if any application of the operation on languages from the family yields again a language from the family. It is *effectively closed* if the result of the operation can be constructed from the given language(s). The knowledge of closure properties often reveals insights in particular features, structures, and capabilities. Moreover, positive closure properties are a useful tool for modular constructions and decompositions in a natural way. Negative properties may serve, for example, as valuable basis for extensions. That is, for building the smallest family of languages which is closed under the operation and contains the family in question. In any case closure properties are filigree tools for dealing with language families.

Boolean Operations

The operations union, intersection, complementation and set difference are commonly called *Boolean operations* or *elementary operations*.

For deterministic devices, the closure under complementation is often shown by interchanging accepting and non-accepting states. But, in general, this requires halting computations.

Theorem 37 *For $X \in \{CA, OCA, IA\}$, the families $\mathcal{L}_{rt}(X)$ and $\mathcal{L}_{lt}(X)$ are effectively closed under complementation.*

Proof We show the closure exemplarily for linear-time OCAs. The other proofs are similar. The reason that the complementary device cannot be constructed by simply interchanging accepting and non-accepting states is that an input is accepted when the leftmost cell enters an accepting state at some arbitrary time step. So, in general, the leftmost cell will enter accepting as well as non-accepting states during a computation. To cope with this problem we modify a given linear-time OCA $\mathcal{M}$ in the following way. At initial time a signal is emitted by the rightmost cell. The signal moves on an extra track with speed $\frac{1}{2}$ to the left. It will arrive at the leftmost cell at twice real time, i. e., linear time. This is the time step at which we wish to make the final decision whether to accept or to reject the input. To this end, the leftmost cell has to remember if it has entered an accepting state at some time before. So, we use a copy S' of the state set S of $\mathcal{M}$, and modify the local transition function to drive the leftmost cell into a state of S' when it enters an accepting state. Subsequently, the normal behavior of the leftmost cell is simulated, except that states of S' are used instead of states of S. Now the modified automaton $\mathcal{M}'$ accepts input if and only if the leftmost cell is in some state of S' when the signal arrives. In order to accept the complement of $L(\mathcal{M}) = L(\mathcal{M}')$, it suffices to let the automaton accept input if and only if the leftmost cell is in some state of S when the signal arrives. □

Devices without any time bounds are, in fact, exponentially time bounded due to the space limitation.

Lemma 38 *For $X \in$ {CA, OCA, IA}, the families $\mathcal{L}(X)$ are effectively closed under complementation.*

Proof The construction of Theorem 37 is modified as follows. Some device in question with n cells and state set S may run through at most $|S|^n$ different configurations until its behavior becomes cyclic. So, it suffices to check whether the input is accepted during the first $|S|^n$ time steps. As discussed briefly in Sect. "Cellular Language Acceptors", exponential time complexities are honest. That is, the leftmost cell can recognize the time step $|S|^n$. To this end, an

$|S|$ary counter is set up on an extra track. The rightmost cell simulates the least significant digit and adds one to the counter at every time step. The neighboring cell to the left observes when a carry-over appears, increases its own digit and so on. The time step at which the first carry-over appears in the leftmost cell is the desired one. □

Now we turn to intersection, union, and set difference.

Theorem 39 *For $X \in \{CA, OCA, IA\}$, the families $\mathscr{L}_{rt}(X)$, $\mathscr{L}_{lt}(X)$, and (X) are effectively closed under intersection, union, and set difference.*

Proof In order to prove the closures, the well-known two-track technique is applicable. That is, on two different tracks acceptors for the languages in question are simulated independently of each other. By the same construction as in the previous proof, the leftmost cell can remember whether the single tracks accept or not. The accepting states are composed by the accepting and non-accepting components for the single tracks in the usual way. For example, to show intersection both components have to be accepting ones. □

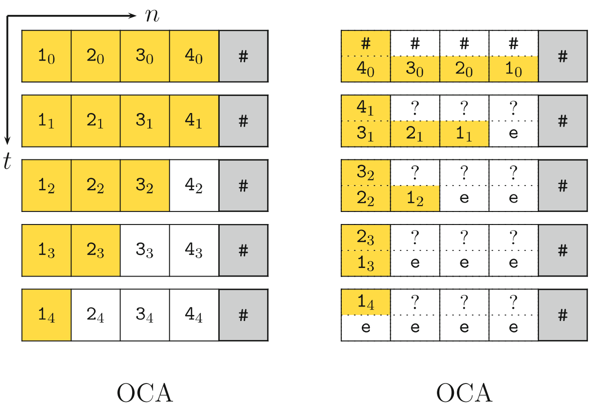
Reversal

The closure under reversal is of crucial importance. It is an open problem for $\mathscr{L}_{\mathrm{rt}}(\mathrm{CA})$ and, equivalently, for $\mathscr{L}_{\mathrm{lt}}(\mathrm{OCA})$. Moreover, it is linked with the open closure property under concatenation for the same family and, hence, with the question whether linear-time CAs are more powerful than real-time CAs. So, it remains open whether the computational capacities of CAs differ if the rightmost or the leftmost cell indicates acceptance.

Theorem 40 *The family $\mathscr{L}_{rt}(OCA)$ is effectively closed under reversal.*

Proof Let $\mathcal{M}$ be some real-time OCA. In order to obtain a real-time OCA $\mathcal{M}'$ for the language $L(\mathcal{M})^R$, the arguments of the local transition function are interchanged. That is, δ’$(s_2, s_1) = s_3$ if $\delta(s_1, s_2) = s_3$. In addition, we have to pay special attention to the boundary state. The further construction is as in the proof of Theorem 31, with the exception that we do not need to collect information in intermediate steps, since the information flow is one-way in both devices. (see Fig. 12). □

As mentioned above, the closure under reversal can be interpreted in two different ways. On one hand, one can construct an OCA that accepts the reversal of a given OCA language. On the other hand, one can construct an OCA that accepts the same language with the rightmost cell. The latter point of view yields immediately the closure under reversal of two-way linear-time cellular automata.



Cellular Automata and Language Theory, Figure 12
Construction showing the closure of real-time OCA languages under reversal

Theorem 41 *The family $\mathscr{L}_{lt}(CA) = \mathscr{L}_{lt}(IA)$ is effectively closed under reversal.*

Proof Let $\mathcal{M}$ be some linear-time CA. In order to obtain a linear-time CA $\mathcal{M}'$ for the language $L(\mathcal{M})^R$, the first and third arguments of the local transition function are interchanged. That is, δ’$(s_3, s_2, s_1) = s_4$ if $\delta(s_1, s_2, s_3) = s_4$. The resulting device accepts $L(\mathcal{M})^R$ with the rightmost cell. Then the result is sent as a signal to the leftmost cell. Altogether, $\mathcal{M}'$ still obeys a linear time bound. □

The closure under reversal of the devices without time bounds follows from the known closures of the characterizing linguistic language family, i. e., the deterministic context-sensitive languages DSPACE(n).

Corollary 42 *The family $\mathscr{L}(CA) = \mathscr{L}(IA)$ is effectively closed under reversal.*

In [16,32] unbounded time OCAs are simulated by a variant of unbounded time one-way iterative arrays and vice versa. Moreover, it is shown that the family of accepted languages forms an AFL, i. e., an *abstract family of languages*, (e. g. [72]) which is in addition closed under reversal.

Lemma 43 *The family $\mathscr{L}(OCA)$ is effectively closed under reversal.*

In order to show negative closure properties it is sometimes convenient to have witness languages not belonging to the family in question. By Example 7 the language

$$L = \{\&x_k\& \cdots \&x_1 ? y_1 \& \cdots \& y_k \& \mid k \geq 1, x_i^R = y_i z_i \\ \text{and} \quad x_i, y_i, z_i \in \{a, b\}^*\}$$

is known not to belong to $\mathscr{L}_{\mathrm{rt}}(\mathrm{IA})$.

Theorem 44 *The family $\mathcal{L}_{rt}(IA)$ is not closed under reversal.*

Proof It suffices to show that L^R belongs to $\mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$. To this end, a real-time deterministic pushdown automaton accepting L^R is easily constructed. Then by Theorem 4 the containment $L^R \in \mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$ follows. □

If the answer to the open reversal closure of $\mathcal{L}_{\mathrm{rt}}(\mathrm{CA})$ is negative, we have to deal with two different language families. Since the properness of the inclusion $\mathcal{L}_{\mathrm{rt}}(\mathrm{CA}) \subseteq \mathcal{L}_{\mathrm{lt}}(\mathrm{CA})$ is also open, the problem gains in importance. A negative answer of the former problem would imply a proper inclusion. A language $L \in \mathcal{L}_{\mathrm{rt}}(\mathrm{CA})$ whose reversal does not belong to $\mathcal{L}_{\mathrm{rt}}(\mathrm{CA})$ may serve as witness since $\mathcal{L}_{\mathrm{lt}}(\mathrm{CA})$ is closed under reversal by Theorem 41. In fact, the following stronger relation is shown in [33] by a long proof.

Theorem 45 *The family $\mathcal{L}_{rt}(CA)$ is closed under reversal if and only if $\mathcal{L}_{rt}(CA)$ and $\mathcal{L}_{lt}(CA)$ are identical.*

Concatenation

Concerning the closure properties under concatenation, the situation is similar to reversal. Either the properties are trivial due to the characterizations by well-known language families, or they are negative, or open problems. For devices without time bounds we have, again, the closures of the deterministic context-sensitive languages DSPACE(n).

Corollary 46 *The family $\mathcal{L}(CA) = \mathcal{L}(IA)$ is effectively closed under concatenation.*

Since any AFL is closed under concatenation and, as mentioned before, $\mathcal{L}(\mathrm{OCA})$ is an AFL [16,32] whose closure properties are shown by simulations, the next lemma follows immediately.

Lemma 47 *The family $\mathcal{L}(OCA)$ is effectively closed under concatenation.*

In order to show that $\mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$ is not closed under concatenation, once more the witness is

$$L = \{\&x_k\& \cdots \&x_1?y_1\& \cdots \&y_k\& \mid k \geq 1, x_i^R = y_i z_i \text{ and } x_i, y_i, z_i \in \{a,b\}^*\} .$$

Theorem 48 *The family $\mathcal{L}_{rt}(IA)$ is not closed under concatenation.*

Proof In contrast to the assertion, assume that $\mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$ is closed under concatenation. The language

$$L_1 = \{\&x(\&\{a,b\}^+)^k ?\&^k y\& \mid x^R = yz,\ x, y, z \in \{a,b\}^*\}$$

is clearly a real-time deterministic context-free and, thus, a real-time IA language. The language

$$L_2 = (\&\{a,b\}^+)^*$$

is regular and, therefore, accepted by some real-time IA, too. Due to the assumption, the language

$$L_3 = L_2 L_1 \&^*$$

belongs also to $\mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$. Next, the language

$$L_4 = \{(\&\{a,b\}^+)^k ?(\{a,b\}^* \&)^k \mid k \geq 1\}$$

is a real-time deterministic context-free language and therefore accepted by some real-time IA. Finally, from the closure under intersection we obtain

$$L_5 = L_3 \cap L_4 \in \mathcal{L}_{\mathrm{rt}}(\mathrm{IA}) .$$

However, the language $L_5 \subset L$ contains the words used to show $L \notin \mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$. We conclude $L_5 \notin \mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$, a contradiction. □

The question whether or not the family $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$ is closed under concatenation was open for a long time. It has been solved negatively in [84]. Here we utilize the language L_d of Example 12. Recall that $L_d \subset \{0,1,(,),|\}^+$ is the language whose words are of the form

$$x(x_1|y_1)\cdots(x_n|y_n)y ,$$

where $x, x_i, y, y_i \in \{0,1\}^*$, for $1 \leq i \leq n$, and $(x|y) = (x_i|y_i)$, for at least one $i \in \{1,\ldots,n\}$.

The following example will be helpful.

Example 49 The language $L_c = \{w \bullet w \mid w \in \{0,1\}^+\}$ is a real-time OCA language.

An acceptor for L_c has several tracks. On one track the input is preserved. On two different tracks the input is successively shifted to the left. The shifting is in such a way that a symbol moves to the left one cell per time step until it passes through the center cell with input •. Subsequently, it moves to the left every other time step. In order to achieve this slow-down, the second track is used. Symbols are received in the first register, then shifted to the second one and, finally, send to the left neighbor. In addition, at initial time a signal is emitted at the right border. When the signal has passed through the center cell, it starts to compare the original input symbol with the symbol to be shifted out of the cell next.

Let the input be $a_m \cdots a_1 \bullet a'_m \cdots a'_1$. At time step $m+1+i$, $1 \leq i \leq m$, the signal arrives in the cell with input a_i. The symbol $a'{}_i$ takes $m+1-i$ time steps to arrive at the center, and is to be shifted out of the cell carrying the original input a_i at time $m+1-i+2i$. So, the signal compares a'_i with a_i as required. □

Theorem 50 *The family $\mathscr{L}_{rt}(OCA)$ is not closed under concatenation.*

Proof Consider the language L_1 whose words are of the form

$$x(x_1|y_1)\cdots(x_n|y_n)(x| ,$$

where $x, x_i, y_i \in \{0,1\}^*$, for $1 \le i \le n$.

Similar to Example 49 we obtain a simple construction of a real-time OCA accepting L_1. For symmetry reasons the language L_2 whose words are of the form

$$y)(x_1|y_1)\cdots(x_n|y_n)y ,$$

where $y, x_i, y_i \in \{0,1\}^*$, for $1 \le i \le n$, is a real-time OCA language, too.

However, the concatenation L_1L_2 equals L_d, which does not belong to $\mathscr{L}_{\mathrm{rt}}(\mathrm{OCA})$. □

The question whether or not one of the families $\mathscr{L}_{\mathrm{rt}}(\mathrm{CA}) = \mathscr{L}_{\mathrm{lt}}^{R}(\mathrm{OCA})$ or $\mathscr{L}_{\mathrm{lt}}(\mathrm{CA}) = \mathscr{L}_{\mathrm{lt}}(\mathrm{IA})$ is closed under concatenation is another famous open problem in this field. Nevertheless, it is shown in [33] that the closure of $\mathscr{L}_{\mathrm{rt}}(\mathrm{CA})$ under reversal implies its closure under concatenation. Since in this case we obtain $\mathscr{L}_{\mathrm{rt}}(\mathrm{CA}) = \mathscr{L}_{\mathrm{lt}}(\mathrm{CA})$, the family of linear-time CA languages were also closed under concatenation.

Theorem 51 *If the family $\mathscr{L}_{rt}(CA)$ is closed under reversal, then it is closed under concatenation.*

Proof If $\mathscr{L}_{\mathrm{rt}}(\mathrm{CA})$ is closed under reversal, then by Theorem 45 we have the identity $\mathscr{L}_{\mathrm{rt}}(\mathrm{CA}) = \mathscr{L}_{\mathrm{lt}}(\mathrm{CA})$. So, it suffices to construct a linear-time CA $\mathcal{M}$ for the concatenation of two real-time CA languages L_1 and L_2. By the closure under reversal, Theorem 31, and the speed-up theorems, there are $2n$-time OCAs $\mathcal{M}_1$ and $\mathcal{M}_2$ for L_1^R and L_2.

During a first phase, automaton $\mathcal{M}$ reverses its input, say $a_1 \cdots a_n$, on an extra track. This takes n time steps.

During a second phase, automaton $\mathcal{M}$ simulates automaton $\mathcal{M}_1$ on $a_n \cdots a_1$ and $\mathcal{M}_2$ on $a_1 \cdots a_n$ in parallel. When some cell enters an accepting state during the simulations, the cell is marked on the corresponding track. If a cell at position $n+1-i$ carrying the input symbol a_i is marked by the simulation of $\mathcal{M}_1$, we have $a_i \cdots a_1 \in L_1^R$ and, thus, $a_1 \cdots a_i \in L_1$. If a cell at position i carrying the input symbol a_i is marked by the simulation of $\mathcal{M}_2$, we have $a_i \cdots a_n \in L_2$. So, the input $a_1 \cdots a_n$ belongs to the concatenation $L_1\,L_2$ if and only if $\mathcal{M}_1$ marks a cell at position $n+1-i$ and $\mathcal{M}_2$ a cell at position $i+1$, for $1 \le i < n$. In order to check this condition, $\mathcal{M}$ reverses the result of the simulation of $\mathcal{M}_1$. Now a cell at position i is marked if and only if previously a cell at position $n+1-i$ was marked. Therefore, it suffices to verify by a signal whether two adjacent cells are marked. □

The concatenation closure for *unary* real-time CA languages has been solved in the affirmative [33].

Table 1 summarizes some closure properties of the language families in question.

Decidability Problems

It is well known that all nontrivial decidability problems for Turing machines are undecidable [69]. Moreover, many of them are not even semidecidable, e. g., neither finiteness nor infiniteness. Now we turn to explore undecidable properties for cellular automata and iterative arrays. Most of the early results are shown in [73] by reductions of the the Post Correspondence Problem. In terms of trellis automata the undecidability of emptiness, equivalence, and universality is derived in [22]. Here we present improved results that show the *non-semidecidability* of the properties. Almost all results in this section are obtained by Andreas Malcher in [58,59].

In [30] large Turing machine computations have been encoded in small grammars. These encodings and variants thereof are of tangible advantage for our purposes. To this end, we consider *valid computations of Turing machines*. Roughly speaking, these are histories of accepting Turing machine computations. It suffices to consider deterministic Turing machines with a single tape and a single read-write head. Without loss of generality and for technical reasons, one can assume that any accepting computation has at least three and, in general, an odd number of steps. Therefore, it is represented by an even number of configurations. Moreover, it is assumed that the Turing machine cannot print blanks, and that a configuration is halting if and only if it is accepting.

Let S be the state set of some Turing machine $\mathcal{M}$, where s_0 is the initial state, $T \cap S = \emptyset$ is the tape alphabet containing the blank symbol, $A \subset T$ is the input alphabet, and $F \subseteq S$ is the set of accepting states. Then a configuration of $\mathcal{M}$ can be written as a word of the form T^*ST^* such that $t_1 \cdots t_i\, s\, t_{i+1} \cdots t_n$ is used to express that $\mathcal{M}$ is in state s, scanning tape symbol t_{i+1}, and t_1 to t_n is the support of the tape inscription. The set of valid computations VALC($\mathcal{M}$) is now defined to be the set of words of the form $w_1 \$ w_3 \$ \cdots \$ w_{2k-1} ¢\, w_{2k}^R \$ \cdots \$ w_4^R \$ w_2^R$, where w_i are configurations, \$ and ¢ are symbols not appearing in w_i, w_1 is an initial configuration of the form s_0A^*, w_{2k} is an accepting configuration of the form $T^*\ FT^*$, and w_{i+1} is the successor configuration of w_i, for $1 \le i \le 2k$. The set of *invalid computations* INVALC($\mathcal{M}$) is the complement of VALC($\mathcal{M}$) with respect to the coding alphabet $\{\$,¢\} \cup T \cup S$. The following lemma shows some of the important properties of valid computations.

Lemma 52 *Let $\mathcal{M}$ be some Turing machine.*

1. *$L(\mathcal{M})$ is empty if and only if VALC($\mathcal{M}$) is empty.*
2. *$L(\mathcal{M})$ is finite if and only if VALC($\mathcal{M}$) is finite.*
3. *$L(\mathcal{M})$ is finite if and only if VALC($\mathcal{M}$) is context free.*
4. *$L(\mathcal{M})$ is finite if and only if INVALC($\mathcal{M}$) is regular.*
5. *VALC($\mathcal{M}$) can be represented by the intersection of two real-time deterministic, linear context-free languages, such that both deterministic pushdown automata and both linear context-free grammars can effectively be constructed from $\mathcal{M}$.*
6. *INVALC($\mathcal{M}$) is a linear context-free language, such that its grammar can effectively be constructed from $\mathcal{M}$.*

Proof Assertions 1 and 2 are immediate observations. In order to show assertion 3 assume that $L(\mathcal{M})$ is finite. Then VALC($\mathcal{M}$) is finite and, clearly, context free. If conversely $L(\mathcal{M})$ is infinite, then an application of the pumping lemma shows that VALC($\mathcal{M}$) is not context free [30]. Now, assertion 4 is shown as follows. If $L(\mathcal{M})$ is finite, then VALC($\mathcal{M}$) is finite. Therefore, INVALC($\mathcal{M}$) is co-finite and, thus, regular. Conversely, if INVALC($\mathcal{M}$) is regular, then VALC($\mathcal{M}$) is regular since the regular languages are closed under complementation. Therefore, VALC($\mathcal{M}$) is context free which implies that $L(\mathcal{M})$ is finite. The two deterministic, linear context-free languages for assertion 5 are constructed in [4]. Assertion 6 has been shown in [30] for a similar definition of invalid computations. The proof can easily be adapted. □

Lemma 53 *Let $\mathcal{M}$ be a Turing machine. Then both languages VALC($\mathcal{M}$) and INVALC($\mathcal{M}$) are accepted by real-time OCAs as well as by real-time IAs.*

Proof Given some Turing machine $\mathcal{M}$, by Lemma 52 item 6 we can effectively construct a linear context-free grammar for the language INVALC($\mathcal{M}$). Due to Theorem 19, a real-time OCA accepting INVALC($\mathcal{M}$) can be constructed from the grammar. Since $\mathcal{L}_{rt}$(OCA) is effectively closed under complementation, we obtain a real-time OCA that accepts the valid computations of $\mathcal{M}$.

Similarly, by Lemma 52 item 5 we can effectively construct two real-time deterministic pushdown automata whose intersection represents the language VALC($\mathcal{M}$). Due to Theorem 4, two real-time IAs can be constructed from the pushdown automata. Since the family $\mathcal{L}_{rt}$(IA) is effectively closed under intersection and complementation, we obtain real-time IAs that accept the valid and the invalid computations of $\mathcal{M}$. □

Now we are prepared to reduce the finiteness and infiniteness problems of Turing machines to some of the decidability problems in question.

Theorem 54 *For any language family that effectively contains $\mathcal{L}_{rt}$(OCA) or $\mathcal{L}_{rt}$(IA), emptiness, universality, finiteness, infiniteness, context-freeness, and regularity are not semidecidable.*

Proof Given some Turing machine $\mathcal{M}$, by Lemma 53 we can effectively construct a real-time OCA and a real-time IA for the language VALC($\mathcal{M}$). Therefore, by Lemma 51 item 1, if emptiness were semidecidable for real-time OCAs or IAs, then emptiness is semidecidable for Turing machines, too.

Since $L(\mathcal{M}) = A^*$ if and only if the complement of $L(\mathcal{M})$ is empty, the non-semidecidability of universality follows from the effective closure under complementation and the non-semidecidability of emptiness.

In the same way as emptiness and universality the non-semidecidability of finiteness and infiniteness follows.

Since we have constructed real-time OCAs and IAs for INVALC($\mathcal{M}$) as well as for VALC($\mathcal{M}$), the finiteness problem for Turing machines immediately reduces to the context-freeness and to the regularity problem for $\mathcal{L}_{\mathrm{rt}}$(OCA) and $\mathcal{L}_{\mathrm{rt}}$(IA) by Lemma 52 items 3 and 4. □

Theorem 55 *For any language family that effectively contains $\mathcal{L}_{rt}$(OCA) or $\mathcal{L}_{rt}$(IA) equivalence and inclusion are not semidecidable.*

Proof It is easy to construct a real-time OCA and a real-time IA that accept the empty language. So, the semidecidability of equivalence would imply the semidecidability of emptiness. Since $L(\mathcal{M}) = L(\mathcal{M}')$ if and only if $L(\mathcal{M}) \subseteq L(\mathcal{M}')$ and $L(\mathcal{M}') \subseteq L(\mathcal{M})$, inclusion is not semidecidable either. □

Next the question arises whether some structural properties of cellular language acceptors are (semi)decidable. For example, whether or not a real-time two-way language is a real-time one-way language. We also compare sequential input mode and two-way information flow with parallel input mode and one-way information flow from a decidability point of view. The questions turn out to be not even semidecidable. So the resources inherent in the structures of cellular automata seem to be fairly different.

Let $\mathcal{M}$ be some Turing machine. We consider the language

$$L_{\mathcal{M}} = \{w^{|w|!} \mid w \in \triangleright\mathrm{VALC}(\mathcal{M})\triangleleft\}\,,$$

where $\triangleright$ and $\triangleleft$ are new symbols not appearing in VALC($\mathcal{M}$), and deal with its acceptance.

Lemma 56 *Given some Turing machine $\mathcal{M}$, a real-time IA accepting $L_{\mathcal{M}}$ can effectively be constructed from $\mathcal{M}$, i. e., the language $L_{\mathcal{M}}$ belongs to $\mathcal{L}_{rt}$(IA).*

Proof We set B to be the alphabet of VALC($\mathcal{M}$), and represent $L_{\mathcal{M}}$ as intersection of the three languages

$$L_{\mathcal{M},1} = \{w \mid w \in (\triangleright\mathrm{VALC}(\mathcal{M})\triangleleft)^*\}\,,$$
$$L_{\mathcal{M},2} = \{w^i \mid w \in \triangleright B^*\triangleleft,\ i \geq 2,\ i \quad \text{even}\}, \text{ and}$$
$$L_{\mathcal{M},3} = \{wu \mid w \in \triangleright B^*\triangleleft,\ u \in (\triangleright B^*\triangleleft)^*, |wu|_{\triangleright} = |w|!\}.$$

Since $\mathcal{L}_{\mathrm{rt}}$(IA) is closed under intersection, it remains to be shown that each of the languages is accepted by some real-time IA. Language $L_{\mathcal{M},1}$ is the marked iteration of $\triangleright$VALC($\mathcal{M}$) followed by a single $\triangleleft$, where $\triangleleft$ is the marking symbol. Since VALC($\mathcal{M}$) $\in \mathcal{L}_{\mathrm{rt}}$(IA) and due to its closure under concatenation with single symbols and under marked iteration [73], we obtain $L_{\mathcal{M},1} \in \mathcal{L}_{\mathrm{rt}}$(IA).

The copy language $\{vv \mid v \in B^*\}$ belongs to $\mathcal{L}_{\mathrm{rt}}$(IA) [19]. So, $L = \{vv \mid v \in \triangleright B^*\triangleleft\}$ is accepted by some real-time IA. Since $\mathcal{L}_{\mathrm{rt}}$(IA) is closed under marked iteration and intersection, the languages L^* and $\triangleright B^* \triangleleft L^* \triangleright B^*\triangleleft$ as well as their intersection are accepted by some real-time IA. Here the marking is hidden in a regular structure. The new word starts after the second symbol $\triangleleft$, respectively. Clearly, the intersection equals $L_{\mathcal{M},2}$.

The construction of a real-time IA accepting the language $L_{\mathcal{M},3}$ makes use of the IA-constructibility of the factorials (cf. Example 1 and the discussion before Theorem 26). Recall, that this means that there is an IA which indicates by states of the leftmost cell the time steps $n!$, for $n \geq 1$. For further results on IA-constructibility we refer to [13,27,63].

Since all constructions and closures are effective, the assertion follows. □

Lemma 57 *Let $\mathcal{M}$ be some Turing machine. Then $L_{\mathcal{M}}$ belongs to $\mathcal{L}_{rt}$(OCA) if and only if $L(\mathcal{M})$ is finite.*

Proof We observe that a finite language is regular and that the regular languages are accepted by real-time OCAs. Conversely, if $L(\mathcal{M})$ is infinite, then we apply Lemma 8 in order to show $L_{\mathcal{M}} \notin \mathcal{L}_{\mathrm{rt}}$(OCA). Assume the contrary, and let p be the constant of Lemma 8. Clearly, due to the infinity of $L(\mathcal{M})$ there is some $w \in \triangleright\mathrm{VALC}(\mathcal{M})\triangleleft$ such that $|w|! > p^{|w|}$. We conclude $w^{|w|!} \in L_{\mathcal{M}}$, and the conditions of Lemma 8 are met with $k = |w|!$. Therefore, there is some $1 \leq q \leq p^{|w|}$ such that $w^{|w|!+q} \in L_{\mathcal{M}}$. But $|w|! < |w|!+q < (|w|+1)!$ and, thus, $|w|!+q$ is not a factorial which implies the contradiction $w^{|w|!+q} \notin L_{\mathcal{M}}$. □

Now we may obtain the next (un)decidability result.

Theorem 58 *For any language family $\mathcal{L}$ that effectively contains $\mathcal{L}_{rt}$(IA), it is not semidecidable whether $L \in \mathcal{L}$ is a real-time OCA language.*

Proof If the problem in question were semidecidable, then the finiteness for Turing machines is also semidecidable. To this end, given some Turing machine $\mathcal{M}$ we construct a real-time IA for the language $L_{\mathcal{M}}$ according to Lemma 56. If $L_{\mathcal{M}}$ is accepted by some real-time OCA, then $L_{\mathcal{M}}$ is finite by Lemma 57. This implies the finiteness of VALC($\mathcal{M}$) and, thus, the finiteness of $L(\mathcal{M})$. □

Since the families $\mathcal{L}_{\mathrm{rt}}$(OCA) and $\mathcal{L}_{\mathrm{rt}}$(IA) are incomparable with respect to set inclusion, there is a natural interest to know whether the incomparability is also with respect to the decidability in question. Therefore, we turn to the converse question of Theorem 58, i. e., whether it is (semi)decidable that a real-time OCA language is accepted by some real-time IA. First we need some preliminaries.

A Turing machine $\mathcal{M}$ is converted into a Turing machine $\mathcal{M}'$ such that the input alphabet A' of $\mathcal{M}'$ contains at least two symbols and, furthermore, $\mathcal{M}'$ accepts any input of length n if and only if there is at least one input of length n accepted by $\mathcal{M}$. Clearly, this conversion is always effectively possible. Extending a frequently used witness language, we set

$$L'_{\mathcal{M}} = \{\&x_k\& \cdots \&x_1 ? y_1\& \cdots \&y_k\& \mid k \geq 1, x_i^R = y_i z_i \\ \text{and} \quad y_i z_i \in (A')^* \quad \text{and} \quad x_i \in \mathrm{VALC}(\mathcal{M}')^R\},$$

where $\&$ and $?$ are new symbols not appearing in $\mathrm{VALC}(\mathcal{M}')$.

Lemma 59 *Let $\mathcal{M}$ be some Turing machine. Then $L'_{\mathcal{M}}$ belongs to $\mathcal{L}_{rt}(IA)$ if and only if $L(\mathcal{M})$ is finite.*

Proof If $L(\mathcal{M})$ is finite, then so is $L(\mathcal{M}')$ and, thus, $\mathrm{VALC}(\mathcal{M}')^R$ is finite, say $\mathrm{VALC}(\mathcal{M}')^R = \{v_1, v_2, \ldots, v_r\}$. A real-time deterministic pushdown automaton accepting $L'_{\mathcal{M}}$ has r different stack symbols representing the elements in $\{v_1, v_2, \ldots, v_r\}$. It reads the input until the $?$ appears. For any occurring $v \in \mathrm{VALC}(\mathcal{M}')^R$ the corresponding stack symbol is pushed onto the stack. After reading the $?$, the pushdown automaton matches each y_i with the suffix of the $v \in \mathrm{VALC}(\mathcal{M}')^R$ which is identified by the symbol at the top of the stack. By Theorem 4, we obtain $L'_{\mathcal{M}} \in \mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$.

Now let $L(\mathcal{M})$ be infinite. Then $L(\mathcal{M}')$, $\mathrm{VALC}(\mathcal{M}')^R$, and $L'_{\mathcal{M}}$ are infinite, as well. In order to show that in this case $L'_{\mathcal{M}}$ does not belong to $\mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$ we apply Lemma 6 as follows. Assume in contrast to the assertion that $L'_{\mathcal{M}}$ is accepted by some real-time IA with state set S. Every $v \in \mathrm{VALC}(\mathcal{M}')^R$ has a suffix of the form $\$\, u\, s_0$, where s_0 is the initial state and $u = \mathit{input}(v)$ is the reversal of the input. Let $|u| = k$. Moreover, due to the construction of $\mathcal{M}'$, for every input word with length k there is an element in $\mathrm{VALC}(\mathcal{M}')^R$. We denote the set of these elements by $V(k)$ and conclude $|V(k)| = |A'|^k$. For two different prefixes $w = \&\, x_k\, \& \cdots \&\, x_1\ ?$ and $w' = \&\, x'_k\, \& \cdots \&\, x'_1\ ?$ with $x_i, x'_i \in V(k)$, $1 \leq i \leq k$, there exists at least one $1 \leq j \leq k$ such that $x_j \neq x'_j$. Therefore, $w\, \&^{j-1}\, s_0\, \mathit{input}(x_j)^R\, \&^{k-j+1} \in L'_{\mathcal{M}}$ and $w'\, \&^{j-1}\, s_0\, \mathit{input}(x_j)^R\, \&^{k-j+1} \notin L'_{\mathcal{M}}$. Since the number of such prefixes is $|A'|^{k^2}$ and $|A'| \geq 2$, we obtain at least 2^{k^2} different $2k$-equivalence classes with respect to $L'_{\mathcal{M}}$. On the other hand, there is a constant $p \geq 1$ such that $E(L'_{\mathcal{M}}, 2k) \leq p^{2k}$. Since $L(\mathcal{M})$ is infinite, we may choose k large enough such that $2^{k^2} > p^{2k}$, which is a contradiction. □

Lemma 60 *Given some Turing machine $\mathcal{M}$, a real-time OCA accepting $L'_{\mathcal{M}}$ can effectively be constructed from $\mathcal{M}$, i. e., the language $L'_{\mathcal{M}}$ belongs to $\mathcal{L}_{rt}(OCA)$.*

Proof The language $L'_{\mathcal{M}}$ can be represented as the intersection of L_1 and L_2, where $L_1 = \{\&x_k\& \cdots \&x_1 ? y_1\& \cdots \&y_k\& \mid k \geq 1, x_i^R = y_i\, z_i \text{ and } x_i, y_i, z_i \in (A')^*\}$ and $L_2 = (\&\mathrm{VALC}(\mathcal{M}')^R)^* ?((A')^*\&)^*$. Since L_1 is a linear context-free language, it belongs to $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$. The family $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$ contains $\mathrm{VALC}(\mathcal{M}')$, is closed under reversal, marked iteration and right concatenation with regular sets [73]. Therefore, L_2 belongs to $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$, as well. From its closure under intersection we derive $L'_{\mathcal{M}} \in \mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$. □

Similarly to Theorem 58 we obtain the next undecidability of a structural property.

Theorem 61 *For any language family $\mathcal{L}$ that effectively contains $\mathcal{L}_{rt}(OCA)$ it is not semidecidable whether $L \in \mathcal{L}$ is a real-time IA language.*

Proof If the problem in question were semidecidable, then also the finiteness for Turing machines. To this end, given some Turing machine $\mathcal{M}$, we construct a real-time OCA for the language $L'_{\mathcal{M}}$ according to Lemma 60. If $L'_{\mathcal{M}}$ is accepted by some real-time IA, then $L(\mathcal{M})$ is finite by Lemma 59. □

In general, a family $\mathcal{L}$ of languages possesses a *pumping lemma in the narrow sense* if for each $L \in \mathcal{L}$ there exists a constant $n \geq 1$ computable from L such that each $z \in L$ with $|z| > n$ admits a factorization $z = uvw$, where $|v| \geq 1$ and $u' v^i\, w' \in L$, for infinitely many $i \geq 0$. The prefix u' and the suffix w' depend on u, w and i.

Theorem 62 *Any language family whose word problem is semidecidable and that effectively contains $\mathcal{L}_{rt}(OCA)$ or $\mathcal{L}_{rt}(IA)$ does not possess a pumping lemma (in the narrow sense).*

Proof Let $\mathcal{M}$ be a real-time OCA or IA and assume there is a pumping lemma. Clearly, $L(\mathcal{M})$ is infinite if and only if it contains some w with $|w| > n$. So, we can semidecide infiniteness by first computing n and then verifying for all words longer than n whether they belong to $L(\mathcal{M})$. If at least for one word the answer is in the affirmative, then by pumping infinitely many words belong to $L(\mathcal{M})$. □

Example 63 The families $\mathcal{L}_{\mathrm{rt}}(\mathrm{OCA})$ and $\mathcal{L}_{\mathrm{rt}}(\mathrm{IA})$ itself as well as, e. g., the families $\mathcal{L}_{\mathrm{rt}}(\mathrm{CA})$, $\mathcal{L}_{\mathrm{lt}}(\mathrm{OCA})$, $\mathcal{L}_{\mathrm{lt}}(\mathrm{CA}) = \mathcal{L}_{\mathrm{lt}}(\mathrm{IA})$, and $\mathcal{L}(\mathrm{CA}) = \mathcal{L}(\mathrm{IA}) = \mathrm{DSPACE}(n)$ do not possess a pumping lemma. □

Theorem 64 *There is no minimization algorithm converting some CA, OCA or IA with arbitrary time complexity to an equivalent automaton of the same type with a minimal number of states.*

Proof For a given input alphabet A, we consider a minimal CA or OCA accepting the empty language. It has $|A|$ states and no accepting states. Assume there is a minimization algorithm. Then we can minimize an arbitrary CA and OCA and check whether the result has $|A|$ states and no accepting states. In this case the accepted language is empty. If the minimal automaton has $|A|$ states and at least one accepting state, there is an input such that the leftmost cell is initially accepting. So, the input is accepted and the accepted language is not empty. Hence emptiness is decidable, which is a contradiction to Theorem 54. Similar arguments apply for IAs. □

It remains to be mentioned that there is a nontrivial decidable property of (unbounded) cellular automata. It is known that injectivity of the global transition function is equivalent to the reversibility of the automaton. It is shown in [3] that global reversibility is decidable for one-dimensional CAs, whereas the problem is undecidable for higher dimensions [41].

Future Directions

The investigation of cellular language acceptors obeying a linear space bound reveals the hierarchy of language families in between the regular and the deterministic context-sensitive languages established in Sect. "Computational Capacities" (see Fig. 11). If the space bound is omitted, that is, if there is a potentially unlimited number of cells, then computation universality is achieved by direct simulation of Turing machines [78]. In particular, the universality can be achieved in spite of additional structural and computational limitations [2,60,64,66]. Similarly, some space bound supposed for cellular language acceptors does not yield to new language families. A Turing machine sweeping back and forth over the nonempty part of the tape can simulate the parallel device obeying the same space bound.

On the other hand, if the cellular language acceptor is simultaneously $s(n)$ space and $t(n)$ time bounded, a Turing machine simulation takes $s(n) \cdot t(n)$ time. A challenging question for further investigations is to identify languages and language classes for which homogeneously structured massive parallelism can significantly decrease the time complexity of sequential devices. Of particular interest are languages which allow a maximal saving. That is, for a sequential time complexity $t(n)$, the parallel time complexity is bounded by $t(n)/s(n)$, where $s(n)$ is the parallel space complexity. For example, in case of unary real-time languages, OCAs cannot do better than deterministic finite-state machine. Conversely, it is well known that any one-tape Turing machine takes at least $O(n^2)$ time to accept the language of palindromes $\{w \mid w = w^R, w \in \{a,b\}^*\}$. Since it is a linear context-free language, it is accepted by some real-time OCA, achieving the maximal saving in time.

From a more general point of view, central questions for future studies concern the power of additional limited resources at the disposal of time or space bounded computations. For example, nondeterminism, dimensions, the number of bits communicated to neighboring cells, or the restriction to reversible computations, all these can be seen as limited resources. We discuss some approaches in more detail.

Traditionally, nondeterministic devices have been viewed as having as many nondeterministic guesses as time steps. The studies of this concept of unlimited nondeterminism led, for example, to the famous open LBA-problem or the unsolved question whether or not P equals NP. In order to gain further understanding of the nature of nondeterminism, in [28,44] it has been viewed as an additional limited resource. In [11,46,52] cellular automata started to be considered from this point of view.

In classical computations the states of the neighboring cells are communicated in one time step. That is, the number of bits exchanged is determined by the number of states. A natural and interesting restriction is to limit the number of bits to some constant being independent of the number of states. Iterative arrays with restricted inter-cell communication have been investigated in [93,94], where algorithmic design techniques for sequence generation are shown. In particular, several important infinite, non-regular sequences such as exponential or polynomial, Fibonacci and prime sequences can be generated in real time. Connectivity recognition problems are dealt with in [92], whereas in [99] the computational capacity of one-way cellular automata with restricted inter-cell communication is considered. First results concerning formal language aspects of IAs with restricted inter-cell communication are shown in [53,54].

Finally, we turn to reversibility. Reversibility in the context of computing devices means that deterministic computations are also backward deterministic. Roughly speaking, in a reversible device no information is lost and every configuration occurring in any computation has at most one predecessor. Many different formal models have been studied in connection with reversibility. An early result on general reversible CAs is the possibility to make any CA, possibly irreversible, reversible by increasing the dimension. In detail, in [91] it is shown that any k-dimensional CA can be embedded into a $(k+1)$-dimensional reversible CA. This result has significantly been improved by showing how to make irreversible one-dimensional CAs reversible without increasing the dimension [65]. Furthermore, it is known that even reversible one-dimensional one-way CAs are computationally universal [64,66]. These results concern cellular automata with unbounded space. Moreover, in order to obtain a reversible device the neighborhood as well as the time complexity may be increased. In [23] it is shown that the neighborhood of a reversible CA is at most $n-1$ when the given reversible CA has n states. Additionally, this upper bound is shown to be tight. Cellular language acceptors with bounded space that are reversible on the core of computation, that is, from initial configuration to the configuration given by the time complexity, are introduced in [55,56]. At first glance, such a setting should simplify matters. However, it is quite the contrary, and such real-time reversibility is undecidable. There are many properties and relations still to be discovered in this setting.

Article Outline

Glossary

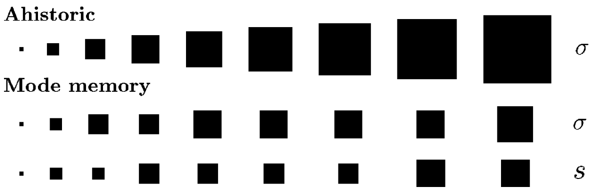
Cellular automata Cellular Automata (CA) are discrete, spatially explicit extended dynamic systems composed of adjacent cells characterized by an internal state whose value belongs to a finite set. The updating of these states is made simultaneously according to a common local transition rule involving only a neighborhood of each cell.

Memory Standard CA are ahistoric (memoryless): i. e., the new state of a cell depends on the neighborhood configuration only at the preceding time step. The standard framework of CA can be extended by the consideration of all past states (history) in the application of the CA rules by implementing memory capabilities in cells and links when topology is dynamic.

Definition

Cellular Automata (CA) are discrete, spatially explicit extended dynamic systems. A CA system is composed of adjacent cells characterized by an internal state whose value belongs to a finite set. The updating of these states is made simultaneously according to a common local transition rule involving only a neighborhood of each cell. Thus, if $\sigma_i^{(T)}$ is taken to denote the value of cell i at time step T, the site values evolve by iteration of the mapping: $\sigma_i^{(T+1)} = \phi\big(\{\sigma_j^{(T)}\} \in \mathcal{N}_i\big)$, where ϕ is an arbitrary function which specifies the cellular automaton *rule* operating on $\mathcal{N}_i$, i. e. the set of cells in the neighborhood of the cell i. Last but not least, standard CA are ahistoric (memoryless): i. e., the new state of a cell depends on the neighborhood configuration only at the preceding time step.

The standard framework of CA can be extended by the consideration of all past states (history) in the application of the CA rules by implementing memory capabilities in cells: $\sigma_i^{(T+1)} = \phi\big(\{s_j^{(T)}\} \in \mathcal{N}_i\big)$, with $s_j^{(T)} = s\big(\sigma_j^{(1)}, \ldots, \sigma_j^{(T-1)}, \sigma_j^{(T)}\big)$ being a state function of the series of states of the cell j up to time-step T. Thus, in CA with memory here: while the transition functions φ of the CA remain unaltered, historic memory of all past iterations is retained by featuring each cell by a summary of its past states.



Cellular Automata with Memory, Figure 1
The *speed of light* starting from a single active cell

The memory mechanism considered here is different from that of other CA with memory reported in the literature (e. g., p. 7 in [1], p. 43 in [35], p. 118 in [56]). Typically, these are higher-order-in-time rules that incorporate memory into the transition rule, determining the new configuration in terms of the configurations at previous time-steps. Thus, in *second order in time* rules: $\sigma_i^{(T+1)} = \Phi\big(\{\sigma_j^{(T)}\} \in \mathcal{N}_i, \{\sigma_j^{(T-1)}\} \in \mathcal{N}_i\big)$. CA with memory in cells are cited in [58], but just to state that "CA with memory in cells would result in a qualitatively different behavior". Some authors [55], define rules with *memory* as those with dependence in ϕ on the state of the cell to be updated. So, one-dimensional rules with no *memory*, take the form: $\sigma_i^{(T+1)} = \phi\big(\sigma_{i-1}^{(T)}, \sigma_{i+1}^{(T)}\big)$. Our use of the term memory is not any of these.

Introduction

As a simple example, in the two-dimensional, two-state automaton labeled ahistoric in Fig. 1, a cell becomes (or remains) alive if any cell in its nearest neighborhood is alive, but becomes (or remains) dead on the contrary case. The initial single perturbation in Fig. 1 spreads as fast as possible, i. e. at the *speed of light*.

The lower series of patterns in Fig. 1 shows the effect of featuring cells by their most frequent state, i. e. *mode* memory: $s_i^{(T)} = \text{mode}(\sigma_i^{(1)}, \dots, \sigma_i^{(T)})$ (with $s_i^{(T)} = \sigma_i^{(T)}$ in case of a tie) on the *speed of light*. Memory has a characteristic inertial effect.

Average Memory

Cells can be featured by a weighted mean value of all their previous states through powers of some parameter $\alpha \in [0,1]$ acting as a memory factor. Thus, at every time-step T, the weighted mean of the states up to T is computed for every cell i:

$$m_i^{(T)}(\sigma_i^{(1)}, \dots, \sigma_i^{(T)}) = \frac{\sigma_i^{(T)} + \sum_{t=1}^{T-1} \alpha^{T-t} \sigma_i^{(t)}}{1 + \sum_{t=1}^{T-1} \alpha^{T-t}} \equiv \frac{\omega_i^{(T)}}{\Omega(T)}$$

and then, the featuring states s are obtained by rounding the m ones to 1 for $m > 0.5$ and to 0 for $m < 0.5$. If m is exactly 0.5, then the last state is assigned ($s_i^{(T)} = \sigma_i^{(T)}$). This memory mechanism is *accumulative* in their demand of knowledge of past history: to calculate the memory charge $\omega_i^{(T)}$ it is not necessary to know the whole $\{\sigma_i^{(t)}\}$ series, while it can be sequentially calculated as: $\omega_i^{(T)} = \alpha\omega_i^{(T-1)} + \sigma_i^{(T)}$. It is, $\Omega(T) = (\alpha^T - 1)/(\alpha - 1)$.

The choice of the memory factor α simulates the long-term or remnant memory effect: the limit case $\alpha = 1$ corresponds to memory with equally weighted records (*full* memory, equivalent to *mode* if $k = 2$), whereas $\alpha \ll 1$ intensifies the contribution of the most recent states and diminishes the contribution of the past ones (short term working memory). The choice $\alpha = 0$ leads to the ahistoric model.

In the most unbalanced scenario up to T, i. e.: $\sigma_i^{(1)} = \dots = \sigma_i^{(T-1)} \neq \sigma_i^{(T)}$, it is:

$$m(0,0,\dots,0,1) = \frac{1}{2} \Rightarrow \frac{\alpha - 1}{\alpha^T - 1} = \frac{1}{2}$$
$$m(1,1,\dots,1,0) = \frac{1}{2} \Rightarrow \frac{\alpha^T - \alpha}{\alpha^T - 1} = \frac{1}{2}\,.$$

Thus, memory is only operative if α is greater than a critical α_T that verifies:

$$\alpha_T^T - 2\alpha_T + 1 = 0\,, \tag{1}$$

in which case cells will be featured at T with state values different to the last one. Initial operative values are: $\alpha_3 = 0.61805$, $\alpha_4 = 0.5437$. When $T \to \infty$, Eq. 1 becomes: $-2\alpha_\infty + 1 = 0$, thus, in the $k = 2$ scenario, α-memory is not effective if $\alpha \leq 0.5$.

A Worked Example: The Parity Rule

The so-called *parity* rule states: cell alive if the number of neighbors is odd, dead on the contrary case. Figure 2 shows the effect of memory on the parity rule starting from a single live cell in the Moore neighborhood. In accordance with the above given values of α_3 and α_4: (*i*) The pattern at $T = 4$ is the ahistoric one if $\alpha \leq 0.6$, altered when $\alpha \geq 0.7$, and (*ii*) the patterns at $T = 5$ for $\alpha = 0.54$ and $\alpha = 0.55$ differ.

Not low levels of memory tend to freeze the dynamics since the early time-steps, e. g. over 0.54 in Fig. 2. In the particular case of full memory small oscillators of short

range in time are frequently generated, such as the period-two oscillator that appears as soon as at $T = 2$ in Fig. 2. The group of evolution patterns shown in the [0.503,0.54] interval of α variation of Fig. 2, is rather unexpected to be generated by the parity rule, because they are too *sophisticated* for this simple rule. On the contrary, the evolution patterns with very small memory, $\alpha = 0.501$, resemble those of the ahistoric model in Fig. 2. But this similitude breaks later on, as Fig. 3 reveals: from $T = 19$, the parity rule with minimal memory evolves producing patterns notably different to the ahistoric ones. These patterns tend to be framed in squares of size not over $T \times T$, whereas in the ahistoric case, the patterns tend to be framed in $2T \times 2T$ square regions, so even minimal memory induces a very notable reduction in the affected cell area in the scenario of Fig. 2. The patterns of the featured cells tend not to be far to the actual ones, albeit examples of notable divergence can be traced in Fig. 2. In the particular case of the minimal memory scenario of Fig. 2, that of $\alpha = 0.501$, memory has no effect up to $T = 9$, when the pattern of featured live cells reduces to the initial one; afterward both evolutions are fairly similar up to $T = 18$, but at this time step both kinds of patterns notably differs, and since then the evolution patterns in Fig. 3 notably diverge from the ahistoric ones.

To give consideration to previous states (historic memory) in two-dimensional CA tends to confine the disruption generated by a single live cell. As a rule, full memory tends to generate oscillators, and less historic information retained, i. e. smaller α value, implies an approach to the ahistoric model in a rather smooth form. But the transition which decreases the memory factor from $\alpha = 1.0$ (full memory) to $\alpha = 0.5$ (ahistoric model), is not always regular, and some kind of *erratic* effect of memory can be traced.

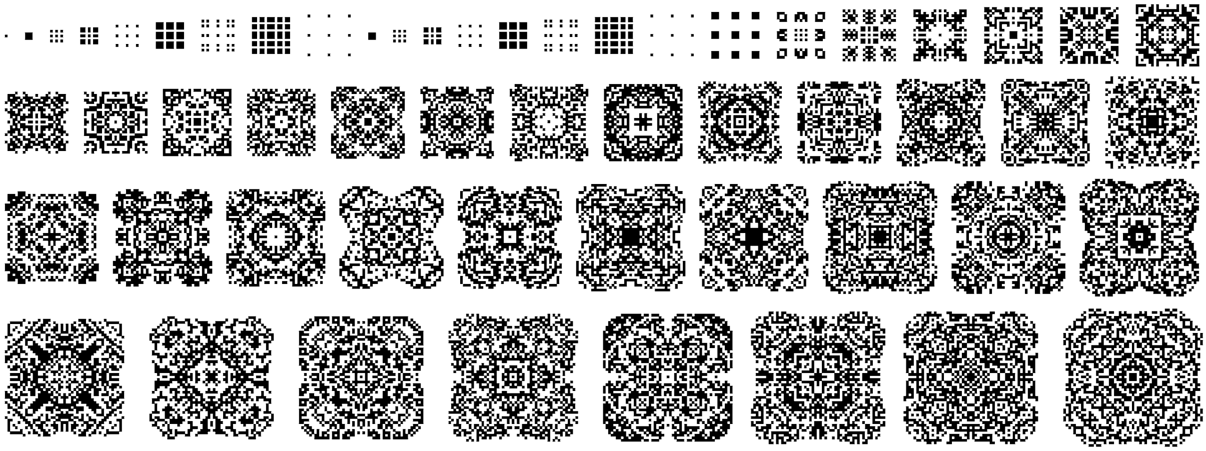
The inertial (or conservating) effect of memory dramatically changes the dynamics of the semitotalistic LIFE rule. Thus, (*i*) the *vividness* that some small clusters exhibit in LIFE, has not been detected in LIFE with memory. In particular, the *glider* in LIFE does not *glide* with memory, but stabilizes very close to its initial position as the *tub* , (*ii*) as the size of a configuration increases, often live clusters tend to persist with a higher number of live cells in LIFE with memory than in the ahistoric formulation, (*iii*) a single *mutant* appearing in a stable *agar* can lead to its destruction in the ahistoric model, whereas its effect tends to be restricted to its proximity with memory [26].

One-Dimensional CA *Elementary* rules are one-dimensional, two-state rules operating on nearest neighbors. Following Wolfram's notation, these rules are characterized by a sequence of binary values (β) associated with each of the eight possible triplets

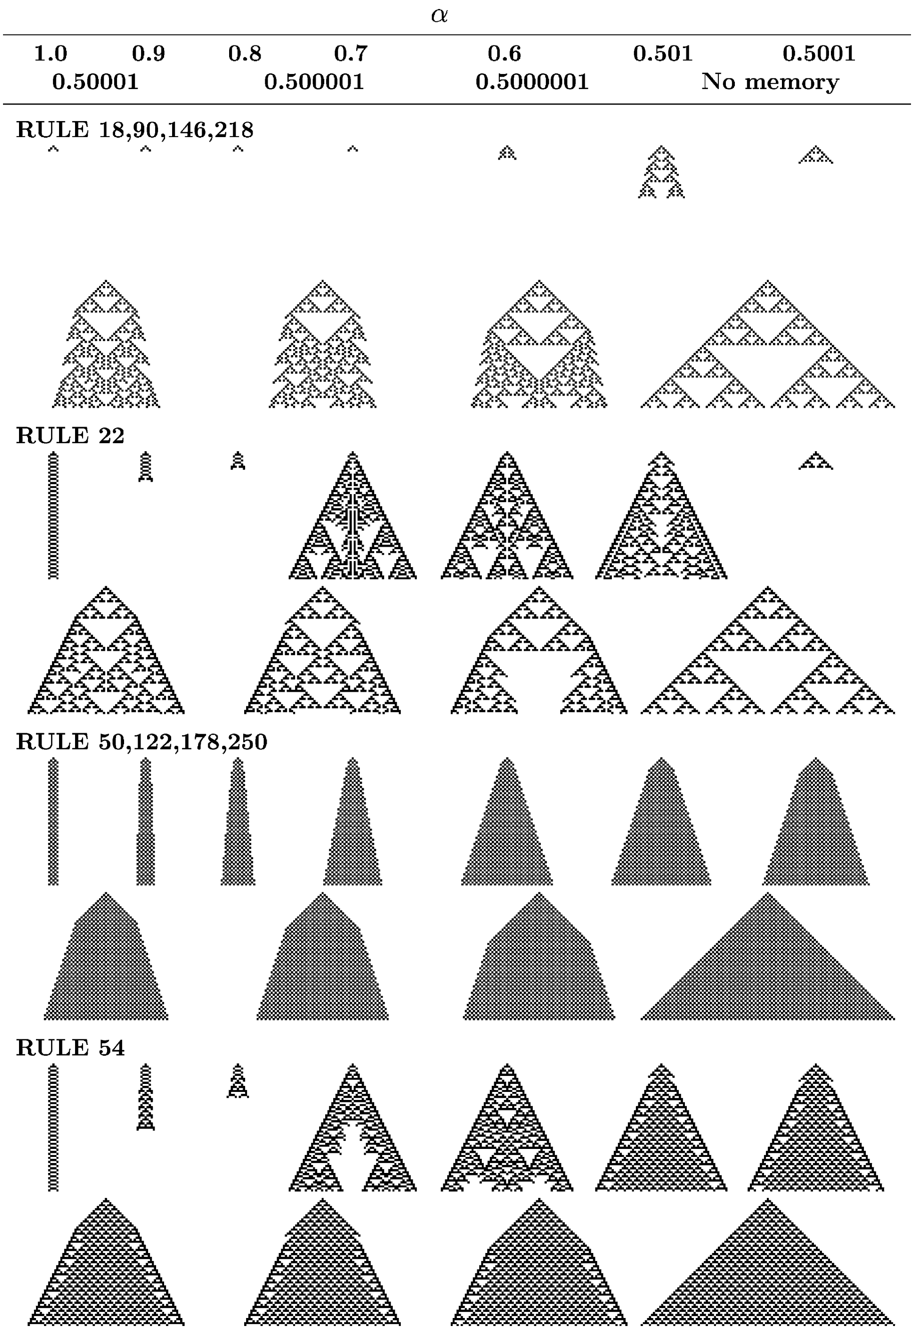
$$\left(\sigma_{i-1}^{(T)}, \sigma_{i}^{(T)}, \sigma_{i+1}^{(T)}\right) :$$

$$\begin{array}{cccccccc} 111 & 110 & 101 & 100 & 011 & 010 & 001 & 000 \\ \beta_1 & \beta_2 & \beta_3 & \beta_4 & \beta_5 & \beta_6 & \beta_7 & \beta_8 \end{array}$$

The rules are conveniently specified by their *rule number* $\mathcal{R} = \sum_{i=1}^{8} \beta_i 2^{8-i}$. *Legal* rules are *reflection symmetric* ($\beta_5 = \beta_2, \beta_7 = \beta_4$), and *quiescent* ($\beta_8 = 0$), restrictions that leave 32 possible *legal* rules.

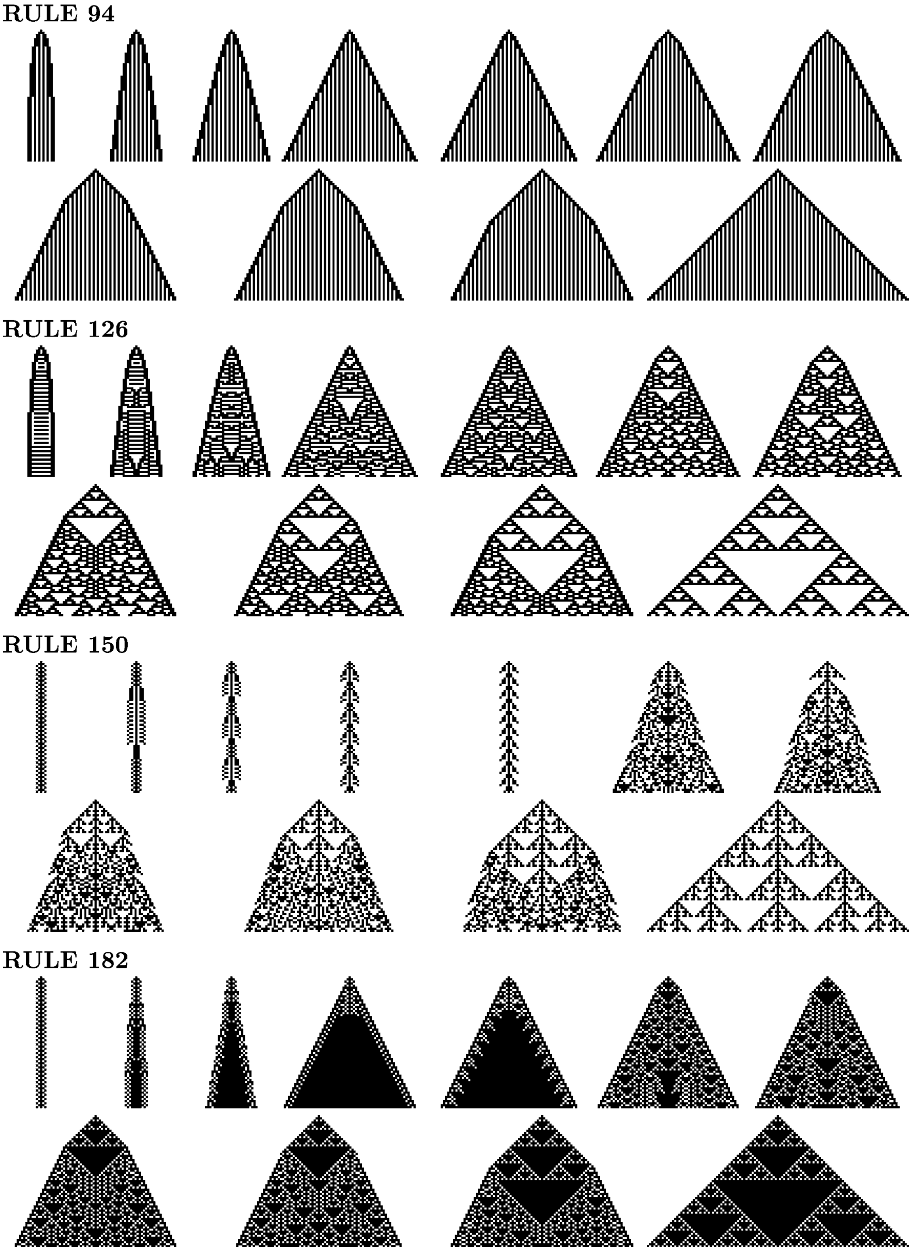


Cellular Automata with Memory, Figure 3
The 2D parity rule with $\alpha = 0.501$ memory starting from a single site live cell up to $T = 55$



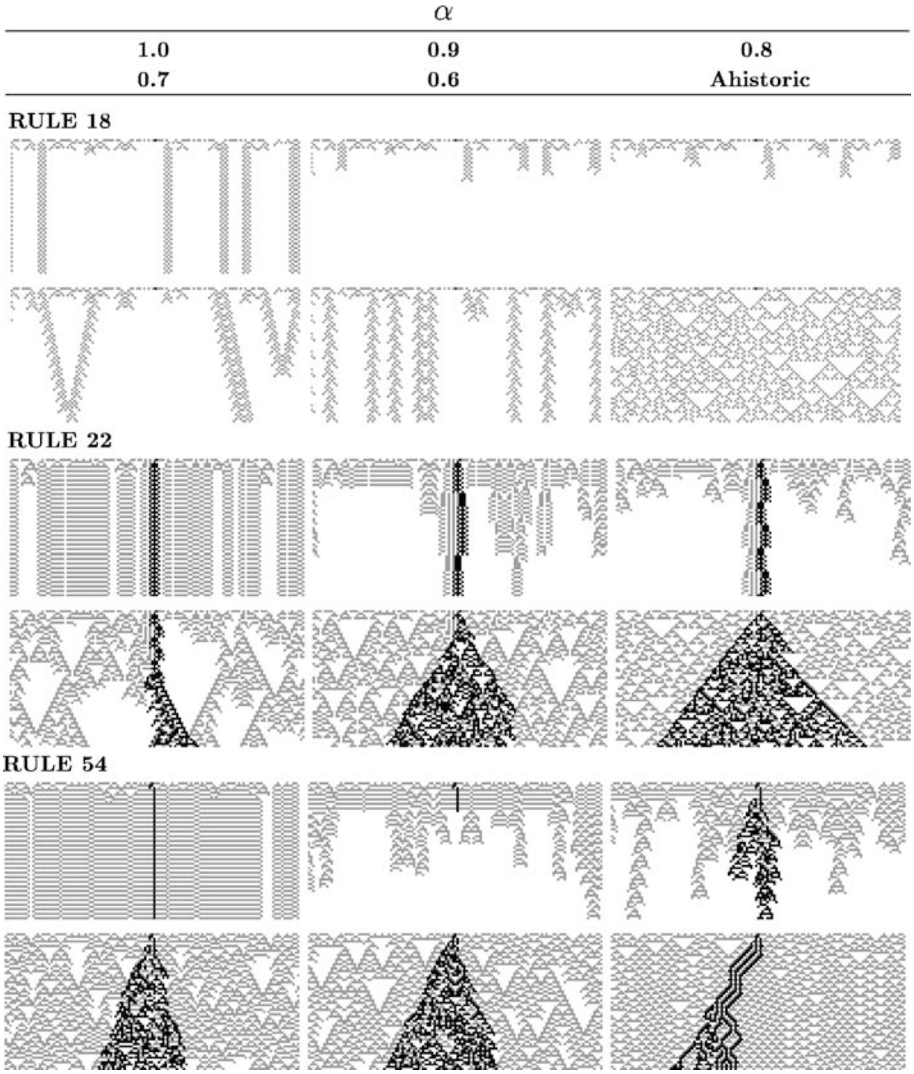
Cellular Automata with Memory, Figure 4
Elementary, legal rules with memory from a single site live cell

Figure 4 shows the spatio-temporal patterns of legal rules affected by memory when starting from a single live cell [17]. Patterns are shown up to $T = 63$, with the memory factor varying from 0.6 to 1.0 by 0.1 intervals, and adopting also values close to the limit of its effectivity: 0.5. As a rule, the transition from the $\alpha = 1.0$ (fully historic) to the ahistoric scenario is fairly gradual, so that the patterns become more expanded as less historic memory is retained (smaller α). Rules 50, 122, 178,250, 94, and 222,254 are paradigmatic of this smooth evolution. Rules 222 and



Cellular Automata with Memory, Figure 4
(***continued***)

254 are not included in Fig. 4 as they evolve as rule 94 but with the *inside* of patterns full of active cells. Rules 126 and 182 also present a gradual evolution, although their patterns with high levels of memory models hardly resemble the historic ones. Examples without a smooth effect of memory are also present in Fig. 4: (*i*) rule 150 is sharply restrained at $\alpha = 0.6$, (*ii*) the important rule 54 extinguish in [0.8,0.9], but not with full memory, (*iii*) the rules in the group {18,90,146,218} become extinct from $\alpha = 0.501$. Memory kills the evolution for these rules already at $T = 4$ for α values over α_3 (thus over 0.6 in Fig. 4): after $T = 3$ all the cells, even the two outer cells alive at $T = 3$, are featured as dead, and (*iv*) rule 22 becomes extinct for $\alpha = 0.501$, not in 0.507, 0.6, and 0.7, again extinguish at 0.8 and 0.9, and finally generate an oscillator with full memory. It has been argued that rules

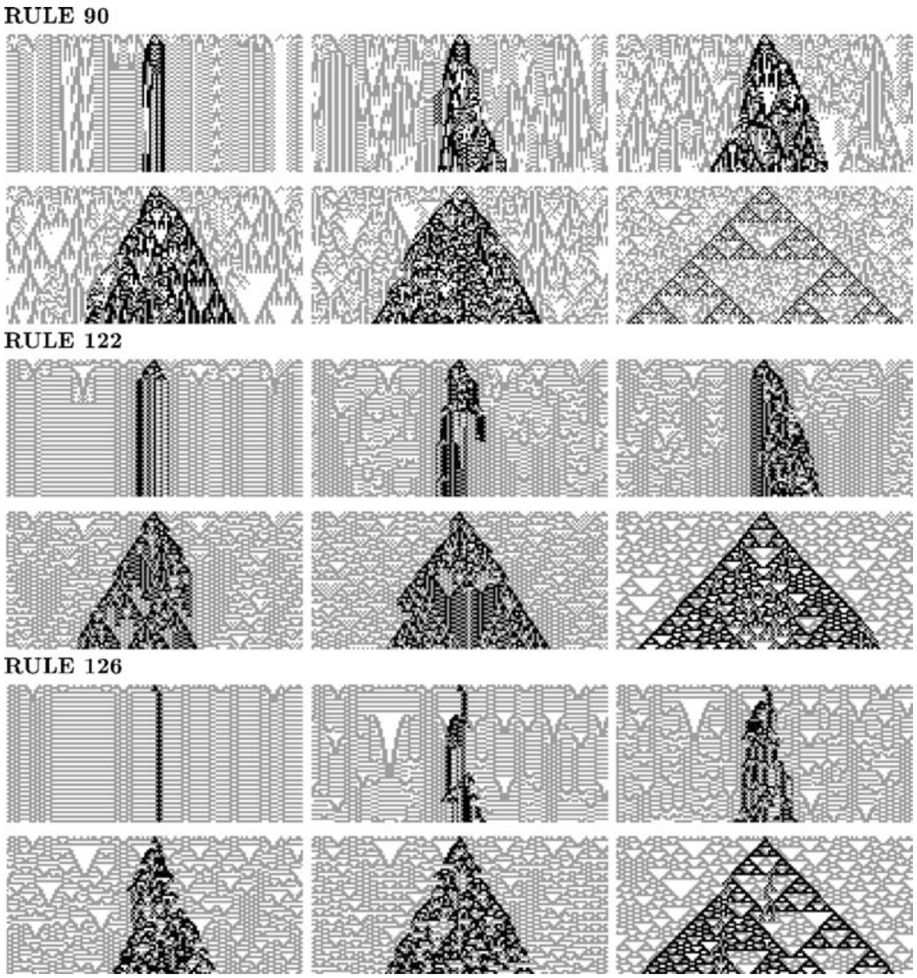


Cellular Automata with Memory, Figure 5
Elementary, legal rules with memory starting at random

18, 22, 122, 146 and 182 *simulate* Rule 90 in that their behavior coincides when restricted to certain spatial subsequences. Starting with a single site live cell, the coincidence fully applies in the historic model for rules 90, 18 and 146. Rule 22 shares with these rules the extinction for high α values, with the notable exception of no extinction in the fully historic model. Rules 122 and 182 diverge in their behavior: there is a gradual decrease in the width of evolving patterns as α is higher, but they do not reach extinction.

Figure 5 shows the effect of memory on legal rules when starting at random: the values of sites are initially uncorrelated and chosen at random to be 0 (*blank*) or 1 (*gray*) with probability 0.5. Differences in patterns resulting from reversing the center site value are shown as *black* pixels. Patterns are shown up to $T = 60$, in a line of size 129 with periodic boundary conditions imposed on the edges. Only the nine legal rules which generate non-periodic patterns in the ahistoric scenario are significantly affected by memory. The patterns with inverted triangles dominate the scene in the ahistoric patterns of Fig. 5, a common appearance that memory tends to eliminate.

History has a dramatic effect on Rule 18. Even at the low value of $\alpha = 0.6$, the appearance of its spatio-temporal pattern fully changes: a number of isolated periodic structures are generated, far from the distinctive inverted triangle world of the ahistoric pattern. For $\alpha = 0.7$, the live structures are fewer, advancing the extinction found in



Cellular Automata with Memory, Figure 5
(*continued*)

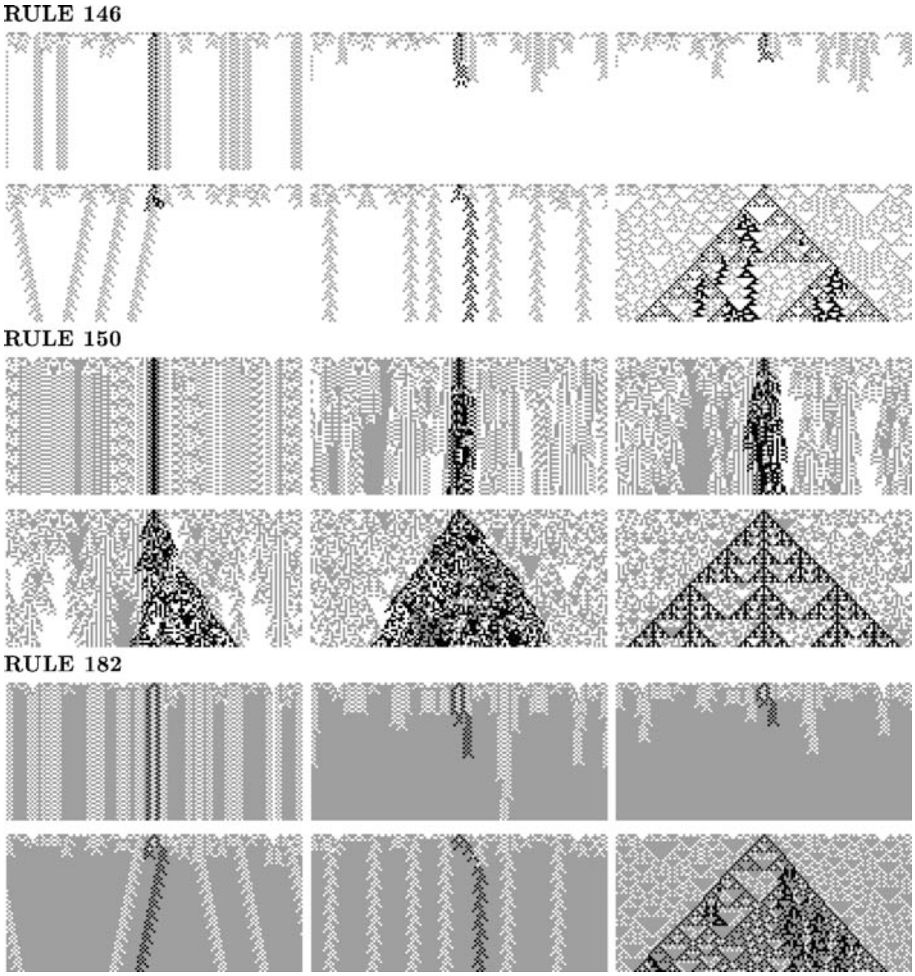
[0.8,0.9]. In the fully historic model, simple periodic patterns survive.

Rule 146 is affected by memory in much the same way as Rule 18 because their binary codes differ only in their β_1 value. The spatio-temporal of rule 182 and its equivalent Rule 146 are reminiscent, though those of Rule 182 look like a *negatives* photogram of those of Rule 146.

The effect of memory on rule 22 and the *complex* rule 54 is similar. Their spatio-temporal patterns in $\alpha = 0.6$ and $\alpha = 0.7$ keep the essential of the ahistoric, although the inverted triangles become enlarged and tend to be more sophisticated in their *basis*. A notable discontinuity is found for both rules ascending in the value of the memory factor: in $\alpha = 0.8$ and $\alpha = 0.9$ only a few simple structures survive. But unexpectedly, the patterns of the fully historic scenario differ markedly from the others, showing a high degree of synchronization.

The four remaining chaotic legal rules (90, 122, 126 and 150) show a much smoother evolution from the ahistoric to the historic scenario: no pattern evolves either to full extinction or to the preservation of only a few isolated persistent propagating structures (solitons). Rules 122 and 126, evolve in a similar form, showing a high degree of synchronization in the fully historic model.

As a rule, the effect of memory on the differences in patterns (DP) resulting from reversing the value of its initial center site is reminiscent of that on the spatio-temporal patterns, albeit this very much depends on the actual simulation run. In the case of rule 18 for example, damage is not present in the simulation of Fig. 5. The group of rules 90, 122, 126 and 150 shows a, let us say *canonical*, fairly gradual evolution from the ahistoric to the historic scenario, so that the DP appear more constrained as more historic memory is retained, with no extinction for any α



Cellular Automata with Memory, Figure 5
(*continued*)

value. Figure 6 shows the evolution of the fraction ρ_T of sites with value 1, starting at random ($\rho_0 = 0.5$). The simulation is implemented for the same rules as in Fig. 4, but with notably wider lattice: $N = 500$. A visual inspection of the plots in Fig. 6, ratifies the general features observed in the patterns in Fig. 5 regarding density. That also stands for damage spreading: as a rule, memory depletes the damaged region.

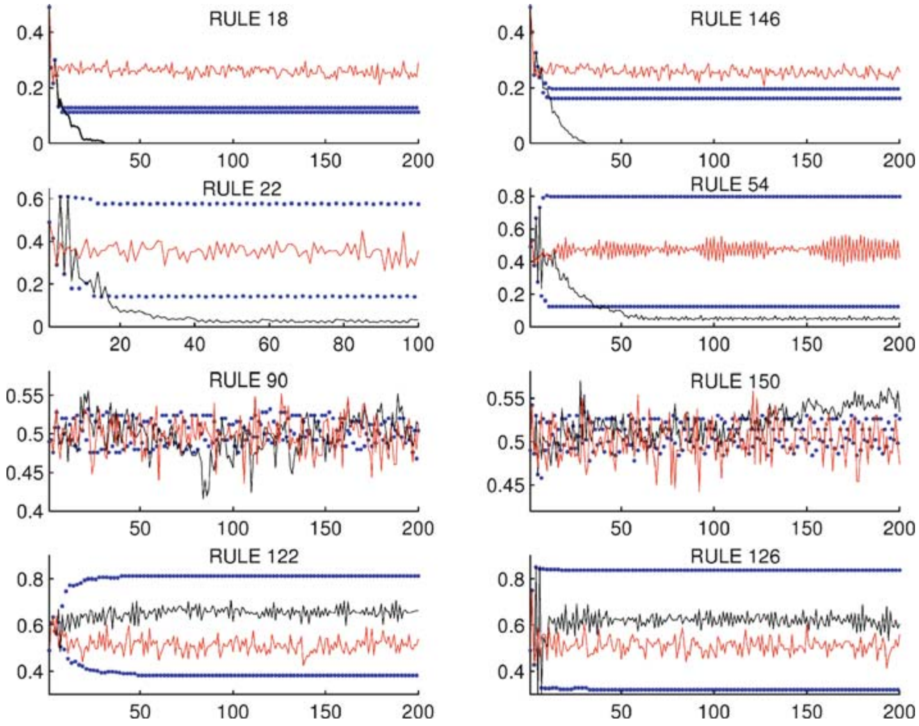
In one-dimensional $r = 2$ CA, the value of a given site depends on values of the nearest and next-nearest neighbors. *Totalistic* $r = 2$ rules with memory have the form: $\sigma_i^{(T+1)} = \phi\big(s_{i-2}^{(T)} + s_{i-1}^{(T)} + s_i^{(T)} + s_{i+1}^{(T)} + s_{i+2}^{(T)}\big)$. The effect of memory on these rules follows the way traced in the $r = 1$ context, albeit with a rich casuistic studied in [14].

Probabilistic CA So far the CA considered are deterministic. In order to study perturbations to deterministic CA as well as transitional changes from one deterministic CA to another, it is natural to generalize the deterministic CA framework to the probabilistic scenario. In the elementary scenario, the β are replaced by probabilities

$$p = P\big(\sigma_i^{(T+1)} = 1 \big/ \sigma_{i-1}^{(T)}, \sigma_i^{(T)}, \sigma_{i+1}^{(T)}\big) \ :$$

111	110	101	100	011	010	001	000	
β_1	β_2	β_3	β_4	β_5	β_6	β_7	β_8	$\beta \in \{0,1\}$
p_1	p_2	p_3	p_4	p_5	p_6	p_7	p_8	$p \in [0,1]$

As in the deterministic scenario, memory can be embedded in probabilistic CA (PCA) by featuring cells by a summary of past states s_i instead of by their last state σ_i: $p = P\big(\sigma_i^{(T+1)} = 1/s_{i-1}^{(T)}, s_i^{(T)}, s_{i+1}^{(T)}\big)$. Again, memory is embedded into the characterization of cells but not in the construction of the stochastic transition rules, as done in the canonical approach to PCA. We have



Cellular Automata with Memory, Figure 6

Evolution of the density starting at random in elementary legal rules. Color code: *blue* → full memory, *black* → $\alpha = 0.8$, *red* → ahistoric model

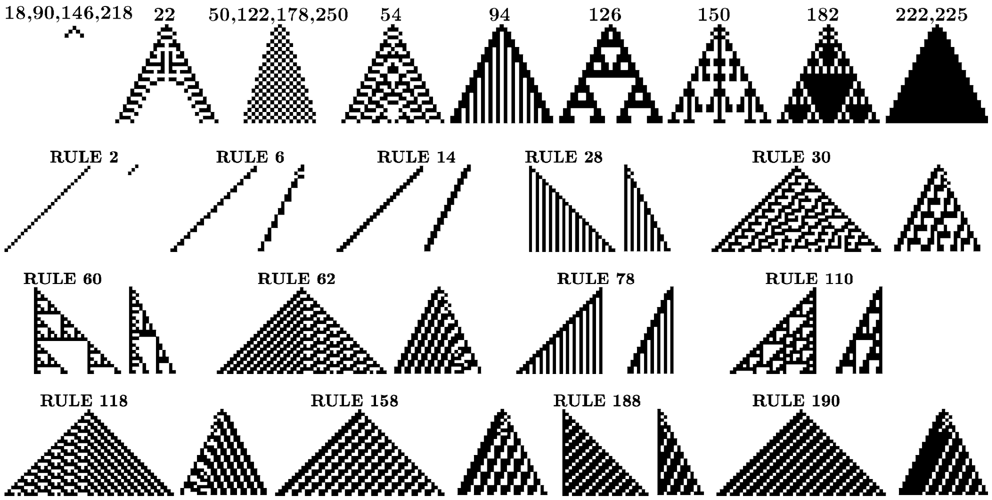
explored the effect of memory on three different subsets $(0, p_2, 0, p_4, p_2, 0, p_4, 0)$, $(0, 0, p_3, 1, 0, p_6, 1, 0)$, and $(p_1, p_2, p_1, p_2, p_2, 0, p_2, 0)$ in [9].

Other Memories

A number of average-like memory mechanisms can readily be proposed by using weights different to that implemented in the α-memory mechanism: $\delta(t) = \alpha^{T-t}$. Among the plausible choices of δ, we mention the weights $\delta(t) = t^c$ and $\delta(t) = c^t$, $c \in \mathbb{N}$, in which the larger the value of c, the more heavily is the recent past taken into account, and consequently the closer the scenario to the ahistoric model [19,21]. Both weights allow for integer-based arithmetics (*à la* CA) comparing $2\omega^{(T)}$ to $2\Omega(T)$ to get the featuring states s (a clear computational advantage over the α-based model), and are accumulative in respect to charge: $\omega_i^{(T)} = \omega_i^{(T-1)} + T^c \sigma_i^{(T)}$, $\omega_i^{(T)} = \omega_i^{(T-1)} + c^T \sigma_i^{(T)}$. Nevertheless, they share the same drawback: powers *explode*, at high values of t, even for $c = 2$.

Limited trailing memory would keep memory of only the last τ states. This is implemented in the context of average memory as: $\omega_i^{(T)} = \sum_{t=\top}^{T} \delta(t)\sigma_i^{(t)}$, with $\top = \max(1, T - \tau + 1)$. Limiting the trailing memory would approach the model to the ahistoric model ($\tau = 1$). In the geometrically discounted method, such an effect is more appreciable when the value of α is high, whereas at low α values (already close to the ahistoric model when memory is not limited) the effect of limiting the trailing memory is not so important. In the $k = 2$ context, if $\tau = 3$, provided that $\alpha > \alpha_3 = 0.61805$, the memory mechanism turns out to be that of selecting the mode of the last three states: $s_i^{(T)} = mode\left(\sigma_i^{(T-2)}, \sigma_i^{(T)}, \sigma_i^{(T-1)}\right)$, i. e. the elementary rule 232.

Figure 7 shows the effect of this kind of memory on legal rules. As is known, history has a dramatic effect on Rules 18, 90, 146 and 218 as their pattern dies out as early as at $T = 4$. The case of Rule 22 is particular: two *branches* are generated at $T = 17$ in the historic model; the patterns of the remaining rules in the historic model are much reminiscent of the ahistoric ones, but, let us say, *compressed*. Figure 7 shows also the effect of memory on some relevant quiescent asymmetric rules. Rule 2 *shifts* a single site live cell one space at every time-step in the ahistoric model; with the pattern dying at $T = 4$. This evolution is common



Cellular Automata with Memory, Figure 7

Legal (first row of patterns) and quiescent asymmetric elementary rules significantly affected by the *mode* of the three last states of memory

to all rules that just shift a single site cell without increasing the number of living cells at $T = 2$, this is the case of the important rules 184 and 226. The patterns generated by rules 6 and 14 are *rectified* (in the sense of having the lines in the spatio-temporal pattern slower slope) by memory in such a way that the total number of live cells in the historic and ahistoric spatio-temporal patterns is the same. Again, the historic patterns of the remaining rules in Fig. 7 seem, as a rule, like the ahistoric ones compressed [22].

Elementary rules (ER, noted f) can in turn act as memory rules:

$$s_i^{(T)} = f\left(\sigma_i^{(T-2)}, \sigma_i^{(T)}, \sigma_i^{(T-1)}\right)$$

Figure 8 shows the effect of ER memories up to $R = 125$ on rule 150 starting from a single site live cell up to $T = 13$. The effect of ER memories with $R > 125$ on rule 150 as well as on rule 90 is shown in [23]. In the latter case, complementary memory rules (rules whose rule number adds 255) have the same effect on rule 90 (regardless of the role played by the three last states in ϕ and the initial configuration). In the ahistoric scenario, Rules 90 and 150 are *linear* (or *additive*): i. e., any initial pattern can be decomposed into the superposition of patterns from a single site seed. Each of these configurations can be evolved independently and the results superposed (module two) to obtain the final complete pattern. The additivity of rules 90 and 150 remains in the historic model with linear memory rules.

Figure 9 shows the effect of elementary rules on the 2D parity rule with von Neumann neighborhood from a singe site live cell. This figure shows patterns from $T = 4$, being the three first patterns: ▪ ✚ ⁘. The consideration of CA rules as memory induces a fairly unexplored *explosion* of new patterns.

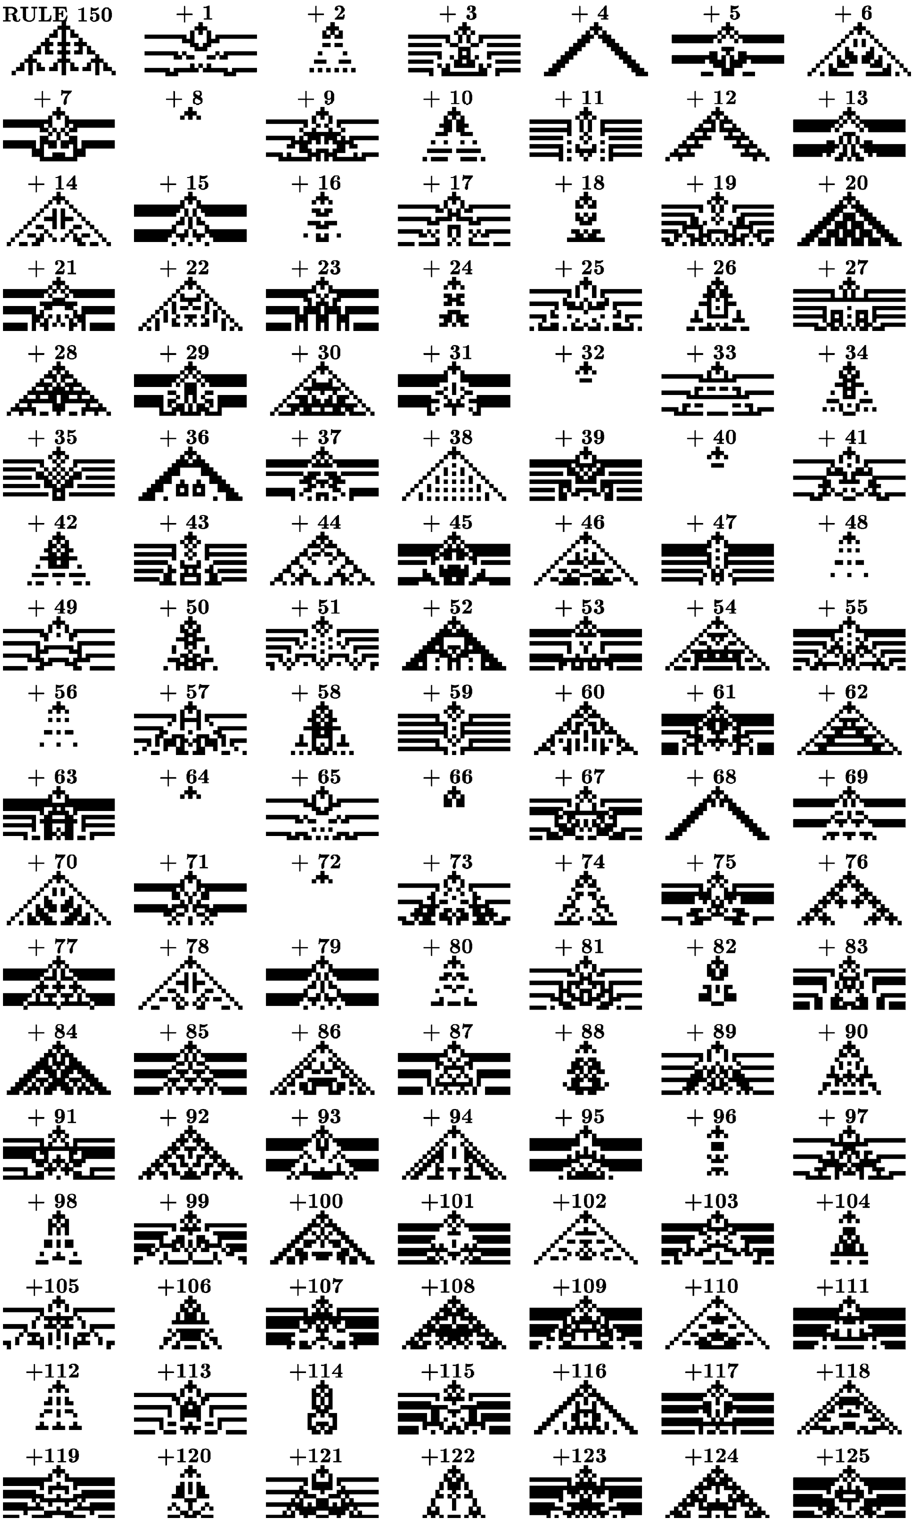
CA with Three Statesk

This section deals with CA with three possible values at each site ($k = 3$), noted $\{0, 1, 2\}$, so the rounding mechanism is implemented by comparing the unrounded weighted mean m to the hallmarks 0.5 and 1.5, assigning the last state in case on an equality to any of these values. Thus,

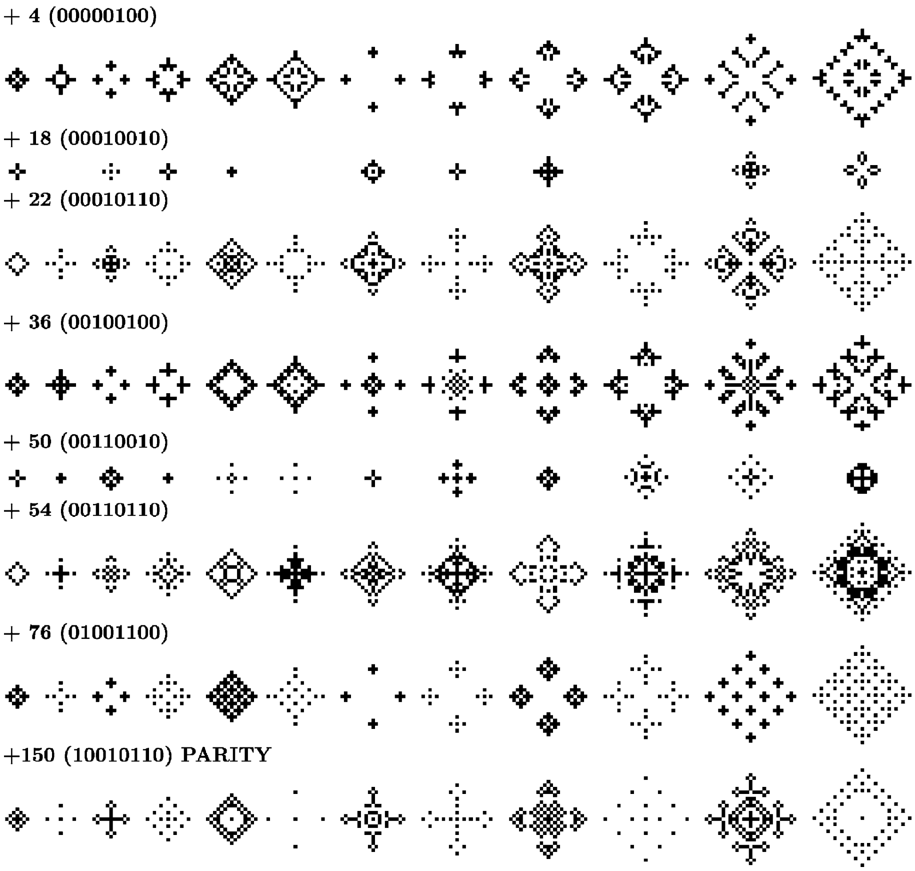
$$s^T = 0 \text{ if } m^T < 0.5, s^T = 1 \text{ if } 0.5 < m^T < 1.5, s^T = 2$$
$$\text{if } m^T > 1.5, \text{ and } s^T = \sigma^T \text{ if } m^T = 0.5 \text{ or } m^T = 1.5\,.$$

In the most unbalanced cell dynamics, historic memory takes effect after time step T only if $\alpha > \alpha_T$, with $3\alpha_T^T - 4\alpha_T + 1 = 0$, which in the temporal limit becomes $-4\alpha_* + 1 = 0 \Leftrightarrow \alpha_* = 0.25$. In general, in CA with k states (termed from 0 to $k-1$), the characteristic equation at T is $(2k-3)\alpha_T^T - (2k-1)\alpha_T + 1 = 0$, which becomes $-2(k-1)\alpha_* + 1 = 0$ in the temporal limit. It is then concluded that memory does not affect the scenario if $\alpha \le \alpha_*(k) = 1/(2(k-1))$.

We study first *totalistic* rules: $\sigma_i^{(T+1)} = \phi\left(\sigma_{i-1}^{(T)} + \sigma_i^{(T)} + \sigma_{i+1}^{(T)}\right)$, characterized by a sequence of ternary values (β_s) associated with each of the seven possible values of the sum (s) of the neighbors: $(\beta_6, \beta_5, \beta_4, \beta_3, \beta_2,$



Cellular Automata with Memory, Figure 8
The Rule 150 with elementary rules up to $R = 125$ as memory



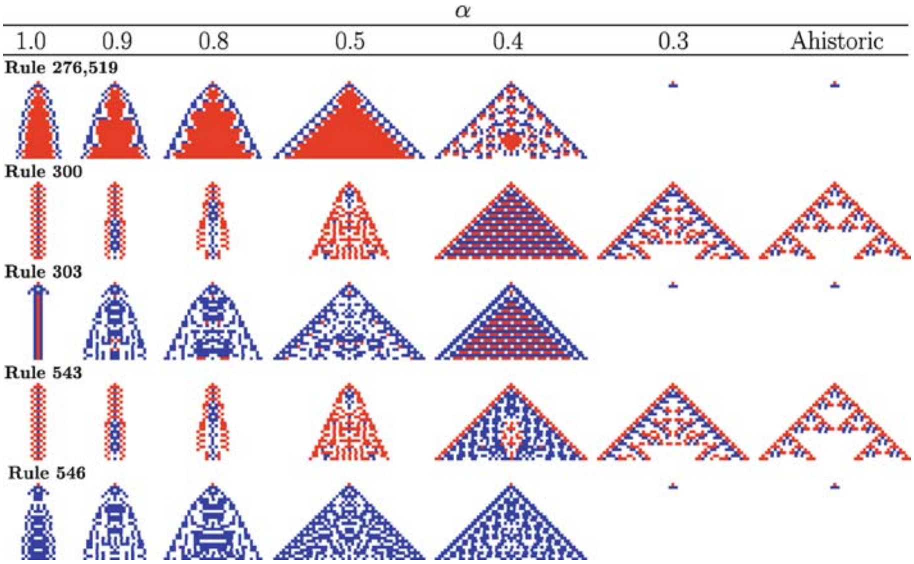
Cellular Automata with Memory, Figure 9
The parity rule with elementary rules as memory. Evolution from $T = 4 — 15$ in the Neumann neighborhood starting from a singe site live cell

β_1, β_0), with associated rule number $\mathcal{R} = \sum_{s=0}^{6} \beta_s 3^s \in [0, 2186]$.

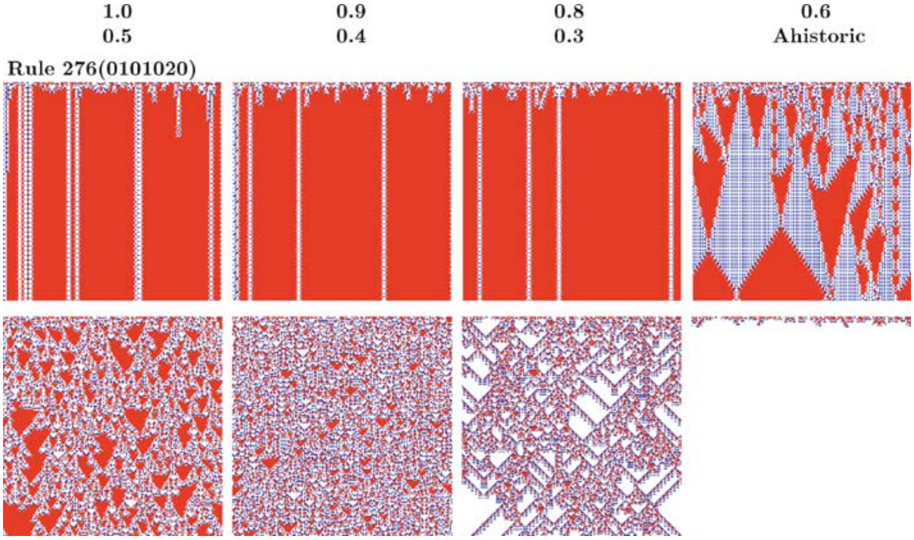
Figure 10 shows the effect of memory on quiescent ($\beta_0 = 0$) *parity* rules, i. e. rules with β_1, β_3 and β_5 non null, and $\beta_2 = \beta_4 = \beta_6 = 0$. Patterns are shown up to $T = 26$. The pattern for $\alpha = 0.3$ is shown to test its proximity to the ahistoric one (recall that if $\alpha \leq 0.25$ memory takes no effect). Starting with a single site seed it can be concluded, regarding proper three-state rules such as those in Fig. 10, that: *(i)* as an overall rule the patterns become more expanded as less historic memory is retained (smaller α). This characteristic *inhibition of growth* effect of memory is traced on rules 300 and 543 in Fig. 10, *(ii)* the transition from the fully historic to the ahistoric scenario tends to be gradual in regard to the amplitude of the spatio-temporal patterns, although their composition can differ notably, even at close α values, *(iii)* in contrast to the two-state scenario, memory fires the pattern of some three-state rules that die out in the ahistoric model, and no rule with memory dies out. Thus, the effect of memory on rules 276, 519, 303 and 546 is somewhat unexpected: they die out at $\alpha \leq 0.3$ but at $\alpha = 0.4$ the pattern expands, the expansion being inhibited (in Fig. 10) only at $\alpha \geq 0.8$. This activation under memory of rules that die at $T = 3$ in the ahistoric model is unfeasible in the $k = 2$ scenario.

The features in the evolving patterns starting from a single seed in Fig. 10 are qualitatively reflected starting at random as shown with rule 276 in Fig. 11, which is also *activated* (even at $\alpha = 0.3$) when starting at random. The effect of average memory (α and integer-based models, unlimited and limited trailing memory, even $\tau = 2$) and that of the mode of the last three states has been studied in [21].

When working with more than three states, it is an inherent consequence of averaging the tendency to *bias* the featuring state to the *mean* value: 1. That explains the *red-shift* in the previous figures. This led us to focus on a much more fair memory mechanism: the *mode*, in what follows.



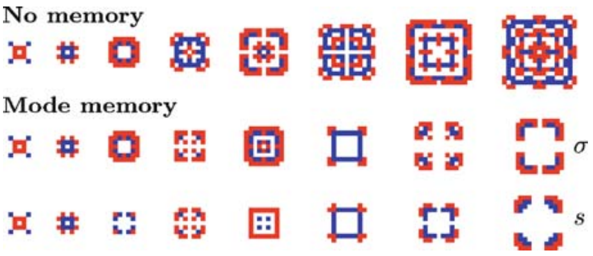
Cellular Automata with Memory, Figure 10
Parity $k = 3$ rules starting from a single $\sigma = 1$ seed. The red cells are at state 1, the blue ones at state



Cellular Automata with Memory, Figure 11
The $k = 3, \mathcal{R} = 276$ rule starting at random

Mode memory allows for manipulation of pure symbols, avoiding any computing/arithmetics.

In *excitable* CA, the three states are featured: resting *0*, excited *1* and refractory *2*. State transitions from excited to refractory and from refractory to resting are unconditional, they take place independently on a cell's neighborhood state: $\sigma_i^{(T)} = 1 \rightarrow \sigma_i^{(T+1)} = 2$, $\sigma_i^{(T)} = 2 \rightarrow \sigma_i^{(T+1)} = 0$. In [15] the excitation rule adopts a Pavlovian phenomenon of defensive inhibition: when strength of stimulus applied exceeds a certain limit the system 'shuts down', this can be naively interpreted as an inbuilt protection of energy loss and exhaustion. To simulate the phenomenon of defensive inhibition we adopt interval excitation rules [2], and a resting cell becomes excited only if one or two of its neighbors are excited: $\sigma_i^{(T)} = 0 \rightarrow \sigma_i^{(T)} = 1$ if $\sum_{j \in \mathcal{N}_i} \left(\sigma_j^{(T)} = 1\right) \in \{1, 2\}$ [3].



Cellular Automata with Memory, Figure 12
Effect of mode memory on the defensive inhibition CA rule

Figure 12 shows the effect of mode of the last three time steps memory on the defensive-inhibition CA rule with the Moore neighborhood, starting from a simple configuration. At $T = 3$ the outer excited cells in the actual pattern are not featured as excited but as resting cells (twice resting versus one excited), and the series of evolving patterns with memory diverges from the ahistoric evolution at $T = 4$, becoming less expanded. Again, memory tends to restrain the evolution.

The effect of memory on the *beehive* rule, a totalistic two-dimensional CA rule with three states implemented in the hexagonal tessellation [57] has been explored in [13].

Reversible CA

The second-order in time implementation based on the subtraction modulo of the number of states (noted $\ominus$): $\sigma_i^{(T+1)} = \phi(\sigma_j^{(T)} \in \mathcal{N}_i) \ominus \sigma_i^{(T-1)}$, readily reverses as: $\sigma_i^{(T-1)} = \phi(\sigma_j^{(T)} \in \mathcal{N}_i) \ominus \sigma_i^{(T+1)}$. To preserve the reversible feature, memory has to be endowed only in the pivotal component of the rule transition, so: $\sigma_i^{(T-1)} = \phi(s_j^{(T)} \in \mathcal{N}_i) \ominus \sigma_i^{(T+1)}$.

For reversing from T it is necessary to know not only $\sigma_i^{(T)}$ and $\sigma_i^{(T+1)}$ but also $\omega_i^{(T)}$ to be compared to $\Omega(T)$, to obtain:

$$s_i^{(T)} = \begin{cases} 0 & \text{if} \quad 2\omega_i^{(T)} < \Omega(T) \\ \sigma_i^{(T+1)} & \text{if} \quad 2\omega_i^{(T)} = \Omega(T) \\ 1 & \text{if} \quad 2\omega_i^{(T)} > \Omega(T) \, . \end{cases}$$

Then to progress in the reversing, to obtain $s_i^{(T-1)} = \text{round}\big(\omega_i^{(T-1)}/\Omega(T-1)\big)$, it is necessary to calculate $\omega_i^{(T-1)} = \big(\omega_i^{(T)} - \sigma_i^{(T)}\big)/\alpha$. But in order to avoid dividing by the memory factor (recall that operations with real numbers are not exact in computer arithmetic), it is preferable to work with $\gamma_i^{(T-1)} = \omega_i^{(T)} - \sigma_i^{(T)}$, and to compare these values to $\Gamma(T-1) = \sum_{t=1}^{T-1} \alpha^{T-t}$. This leads to:

$$s_i^{(T-1)} = \begin{cases} 0 & \text{if} \quad 2\gamma_i^{(T-1)} < \Gamma(T-1) \\ \sigma_i^{(T)} & \text{if} \quad 2\gamma_i^{(T-1)} = \Gamma(T-1) \\ 1 & \text{if} \quad 2\gamma_i^{(T-1)} > \Gamma(T-1) \, . \end{cases}$$

In general: $\gamma_i^{(T-\tau)} = \gamma_i^{(T-\tau+1)} - \alpha^{\tau-1}\sigma_i^{(T-\tau+1)}$, $\Gamma(T-\tau) = \Gamma(T-\tau+1) - \alpha^{\tau-1}$.

Figure 13 shows the effect of memory on the reversible parity rule starting from a single site live cell, so the scenario of Figs. 2 and 3, with the reversible qualification. As expected, the simulations corresponding to $\alpha = 0.6$ or below shows the ahistoric pattern at $T = 4$, whereas memory leads to a pattern different from $\alpha = 0.7$, and the pattern at $T = 5$ for $\alpha = 0.54$ and $\alpha = 0.55$ differ. Again, in the reversible formulation with memory, *(i)* the configuration of the patterns is notably altered, *(ii)* the speed of diffusion of the area affected are notably reduced, even by minimal memory ($\alpha = 0.501$), *(iii)* high levels of memory tend to freeze the dynamics since the early time-steps.

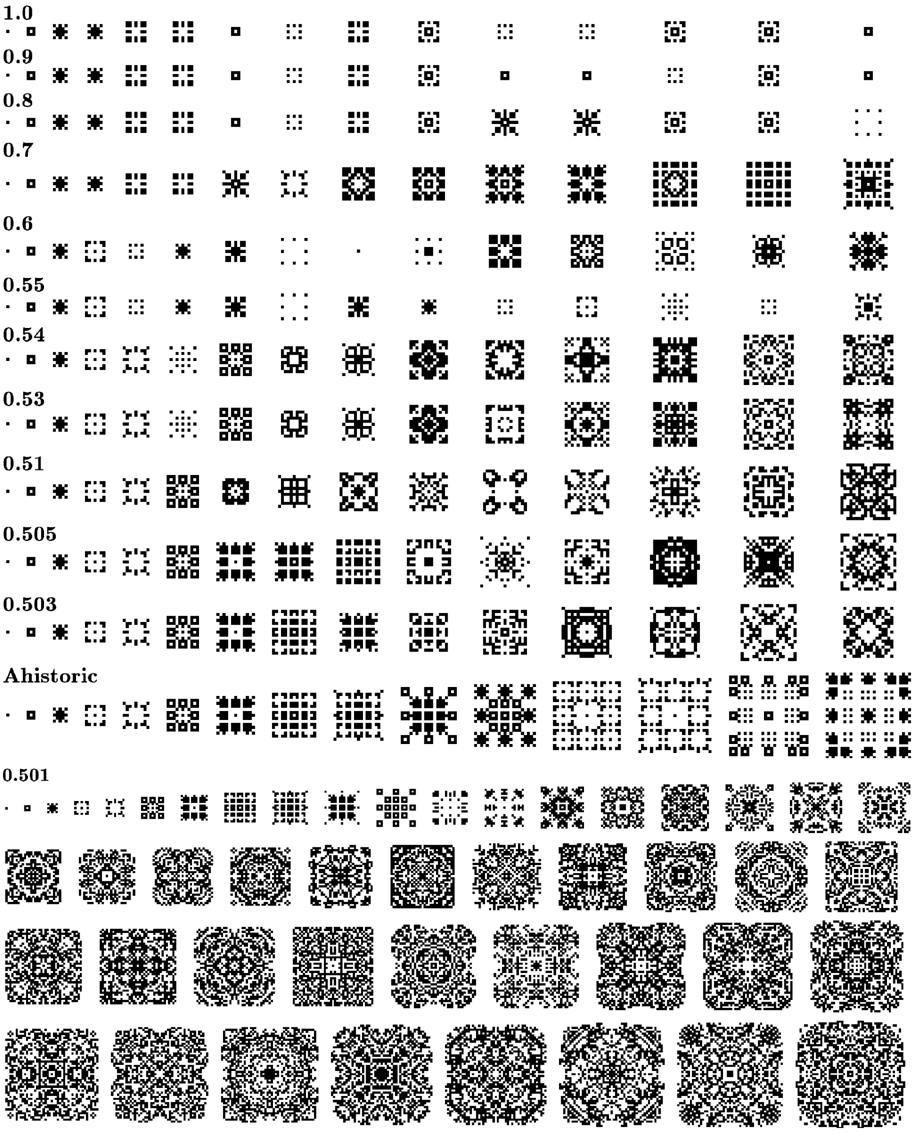
We have studied the effect of memory in the reversible formulation of CA in many scenarios, e. g., totalistic, $k = r = 2$ rules [7], or rules with three states [21].

Reversible systems are of interest since they preserve information and energy and allow unambiguous backtracking. They are studied in computer science in order to design computers which would consume less energy [51]. Reversibility is also an important issue in fundamental physics [31,41,52,53]. Geraldt 't Hooft, in a speculative paper [34], suggests that a suitably defined deterministic, local reversible CA might provide a viable formalism for constructing field theories on a Planck scale. Svozil [50] also asks for changes in the underlying assumptions of current field theories in order to make their discretization appear more CA-like. Applications of reversible CA with memory in cryptography are being scrutinized [30,42].

Heterogeneous CA

CA on networks have arbitrary connections, but, as proper CA, the transition rule is identical for all cells. This generalization of the CA paradigm addresses the intermediate class between CA and Boolean networks (BN, considered in the following section) in which, rules may be different at each site.

In networks two topological ends exist, random and regular networks, both display totally opposite geometric properties. Random networks have lower clustering coefficients and shorter average path length between nodes commonly known as *small world* property. On the other

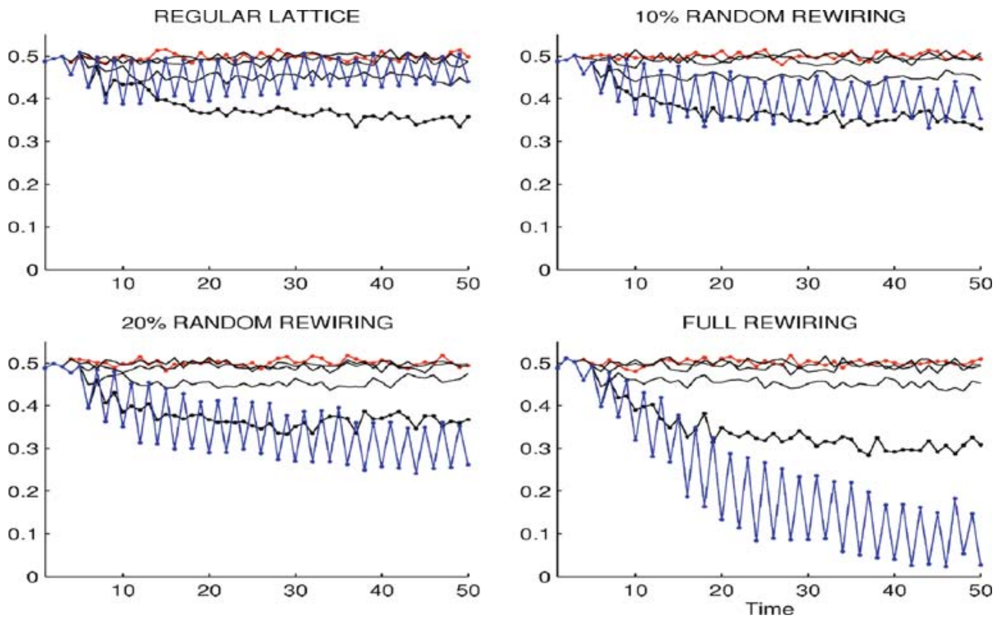


Cellular Automata with Memory, Figure 13
The reversible parity rule with memory

hand, regular graphs, have a large average path length between nodes and high clustering coefficients.

In an attempt to build a network with characteristics observed in real networks, a large clustering coefficient and a *small world* property, Watts and Strogatz (WS, [54]) proposed a model built by randomly rewiring a regular lattice. Thus, the WS model interpolates between regular and random networks, taking a single new parameter, the random rewiring degree, i. e.: the probability that any node redirects a connection, randomly, to any other. The WS model displays the high clustering coefficient common to regular lattices as well as the *small world* property (the *small world* property has been related to faster flow in the information transmission). The long-range links introduced by the randomization procedure dramatically reduce the diameter of the network, even when very few links are rewired.

Figure 14 shows the effect of memory and topology on the parity rule with four inputs in a lattice of size 65 × 65 with periodic boundary conditions, starting at random. As expected, memory depletes the Hamming distance between two consecutive patterns in relation to the *ahistoric*



Cellular Automata with Memory, Figure 14

The parity rule with four inputs: effect of memory and random rewiring. Distance between two consecutive patterns in the ahistoric model (*red*) and memory models of α levels: 0.6,0.7.0.8, 0.9 (*dotted*) and 1.0 (*blue*)

model, particularly when the degree of rewiring is high. With full memory, quasi-oscillators tend to appear. As a rule, the higher the curve the lower the memory factor α, but in the particular case of a regular lattice (and lattice with 10% of rewiring), the evolution of the distance in the full memory model turns out rather atypical, as it is maintained over some memory models with lower α parameters.

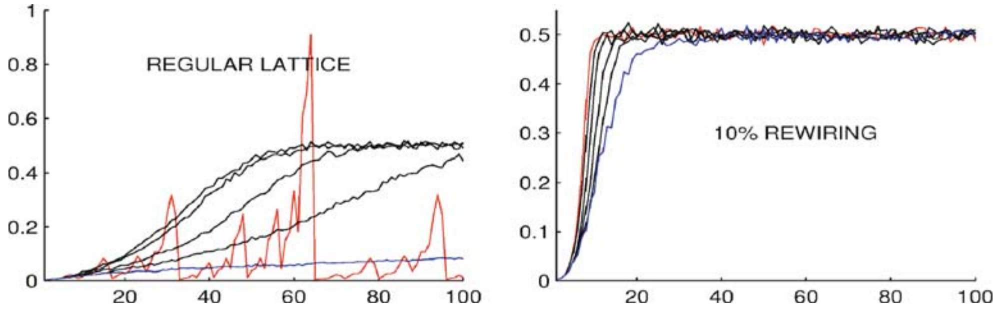
Figure 15 shows the evolution of the damage spread when reversing the initial state of the 3×3 central cells in the initial scenario of Fig. 14. The fraction of cells with the state reversed is plotted in the regular and 10% of rewiring scenarios. The plots corresponding to higher rates of rewiring are very similar to that of the 10% case in Fig. 15. Damage spreads fast very soon as rewiring is present, even in a short extent.

Boolean Networks

In Boolean Networks (BN,[38]), instead of what happens in canonical CA, cells may have arbitrary connections and rules may be different at each site. Working with totalistic rules: $\sigma_i^{(T+1)} = \phi_i(\sum_{j\in\mathcal{N}_i} s_j^{(T)})$.

The main features on the effect of memory in Fig. 14 are preserved in Fig. 16: (*i*) the ordering of the *historic* networks tends to be stronger with a high memory factor, (*ii*) with full memory, quasi-oscillators appear (it seems that full memory tends to induce *oscillation*), (*iii*) in the particular case of the regular graph (and a lesser extent in the networks with low rewiring), the evolution of the full memory model turns out rather atypical, as it is maintained over some of those memory models with lower α parameters. The relative Hamming distance between the *ahistoric* patterns and those of *historic* rewiring tends to be fairly constant around 0.3, after a very short initial transition period.

Figure 17 shows the evolution of the damage when reversing the initial state of the 3×3 central cells. As a rule in every frame, corresponding to increasing rates of random rewiring, the higher the curve the lower the memory factor α. The *damage vanishing* effect induced by memory does result apparently in the regular scenario of Fig. 17, but only full memory controls the damage spreading when the rewiring degree is not high, the dynamics with the remaining α levels tend to the damage propagation that characterizes the *ahistoric* model. Thus, with up to 10% of connections rewired, full memory notably controls the spreading, but this control capacity tends to disappear with a higher percentage of rewiring connections. In fact, with rewiring of 50% or higher, neither full memory seems to be very effective in altering the final rate of damage, which tends to reach a plateau around 30% regardless of



Cellular Automata with Memory, Figure 15
Damage up to $T = 100$ in the parity CA of Fig. 14

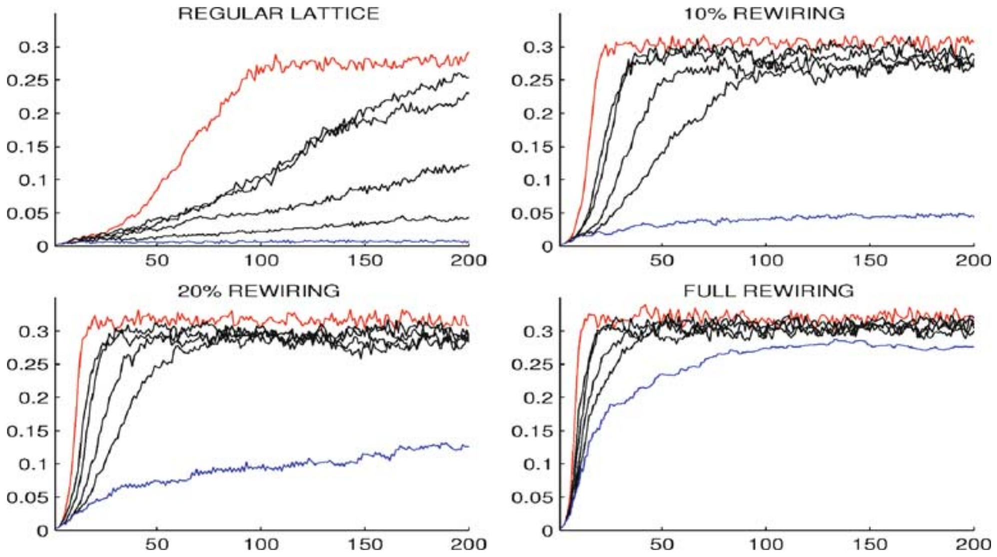
scenario. A level notably coincident with the percolation threshold in site percolation in the simple cubic lattice, and the critical point for the nearest neighbor Kaufmann model on the square lattice [49]: 0.31.

Structurally Dynamic CA

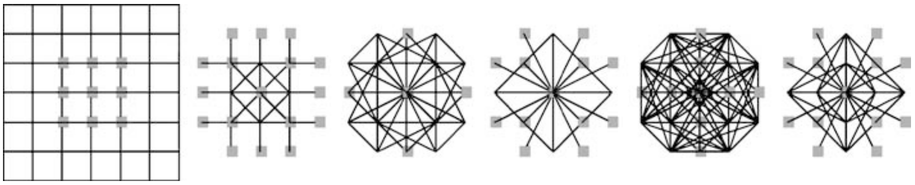
Structurally dynamic cellular automata (SDCA) were suggested by Ilachinski and Halpern [36]. The essential new feature of this model was that the connections between the cells are allowed to change according to rules similar in nature to the state transition rules associated with the conventional CA. This means that given certain conditions, specified by the *link transition rules*, links between rules may be created and destroyed; the neighborhood of each cell is dynamic, so, state and link configurations of an SDCA are both dynamic and continually interacting.

If cells are numbered 1 to N, their connectivity is specified by an $N \times N$ connectivity matrix in which $\lambda_i j = 1$ if cells i and j are connected; 0 otherwise. So, now: $\mathcal{N}_i^{(T)} = \{j/\lambda_{ij}^{(T)} = 1\}$ and $\sigma_i^{(T+1)} = \phi(\sigma_j^{(T)} \in \mathcal{N}_i^{(T)})$. The geodesic *distance* between two cells i and j, δ_{ij}, is defined as the number of links in the shortest path between i and j. Thus, i and j are *direct* neighbors if $\delta_{ij} = 1$, and are *next-nearest* neighbors if $\delta_i j = 2$, so $\mathcal{N}\mathcal{N}_i^{(T)} = \{j/\delta_{ij}^{(T)} = 2\}$. There are two types of link transition functions in an SDCA: *couplers* and *decouplers*, the former add new links, the latter remove links. The coupler and decoupler set determines the link transition rule: $\lambda_{ij}^{(T+1)} = \psi(l_{ij}^{(T)}, \sigma_i^{(T)}, \sigma_j^{(T)})$.

Instead of introducing the formalism of the SDCA, we deal here with just one example in which the decoupler rule removes all links connected to cells in which both values are zero ($\lambda_{ij}^{(T)} = 1 \to \lambda_{ij}^{(T+1)} = 0$ iff $\sigma_i^{(T)} + \sigma_j^{(T)} = 0$)



Cellular Automata with Memory, Figure 17
Evolution of the damage when reversing the initial state of the 3 × 3 central cells in the scenario of Fig. 16



Cellular Automata with Memory, Figure 18
The SDCA described in text up to $T = 6$

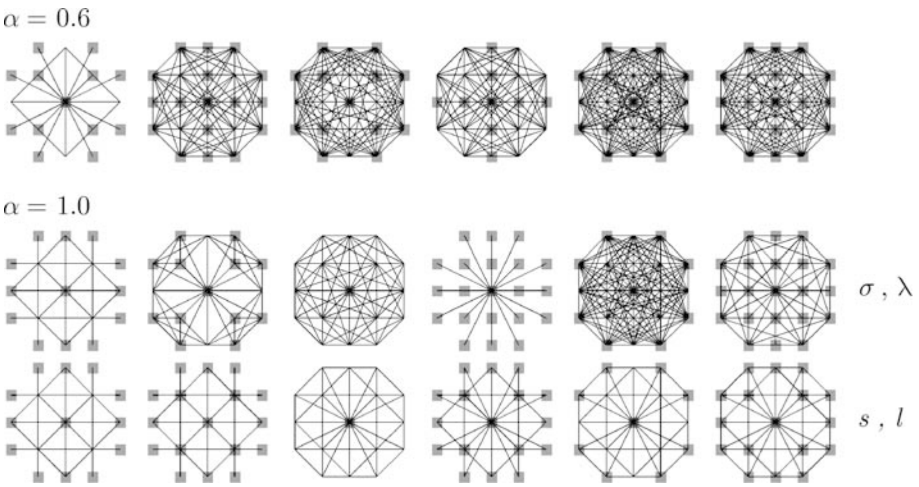
and the coupler rule adds links between all next-nearest neighbor sites in which both values are one ($\lambda_{ij}^{(T)} = 0 \to \lambda_i^{(T+1)} j = 1$ iff $\sigma_i^{(T)} + \sigma_j^{(T)} = 2$ and $j \in \mathcal{N}\mathcal{N}_i^{(T)}$). The SDCA with these transition rules for connections, together with the *parity* rule for mass states, is implemented in Fig. 18, in which the initial Euclidean lattice with four neighbors (so the generic cell □ has eight next-nearest neighbors: ⁘) is seeded with a 3 × 3 block of ones. After the first iteration, most of the lattice structure has decayed as an effect of the decoupler rule, so that the active value cells and links are confined to a small region. After $T = 6$, the link and value structures become periodic, with a periodicity of two.

Memory can be embedded in links in a similar manner as in state values, so the link between any two cells is featured by a mapping of its previous link values: $l_{ij}^{(T)} = l(\lambda_{ij}^{(1)}, \ldots, \lambda_{ij}^{(T)})$. The *distance* between two cells in the historic model (d_{ij}), is defined in terms of l instead of λ values, so that i and j are *direct* neighbors if $d_{ij} = 1$, and are *next-nearest* neighbors if $d_{ij} = 2$. Now: $N_i^{(T)} = \{j/d_{ij}^{(T)} = 1\}$, and $NN_i^{(T)} = \{j/d_{ij}^{(T)} = 2\}$. Generalizing the approach to embedded memory applied to states, the unchanged transition rules (ϕ and ψ) operate on the featured link and cell state values: $\sigma_i^{(T+1)} = \phi(s_j^{(T)} \in N_i)$, $\lambda_{ij}^{(T+1)} = \psi(l_i^{(T)} j, s_i^{(T)}, s_j^{(T)})$.

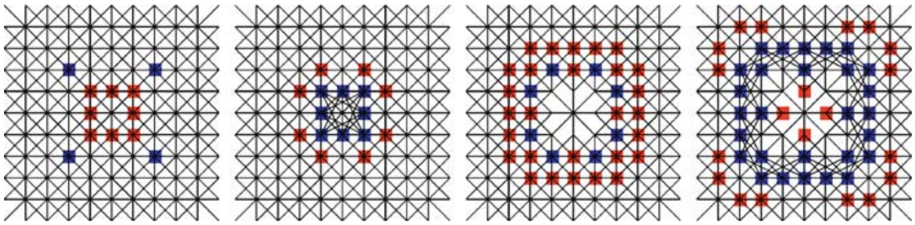
Figure 19 shows the effect of α-memory on the cellular automaton above introduced starting as in Fig. 18. The effect of memory on SDCA in the hexagonal and triangular tessellations is scrutinized in [11].

A plausible wiring dynamics when dealing with excitable CA is that in which the decoupler rule removes all links connected to cells in which both values are at refractory state ($\lambda_{ij}^{(T)} = 1 \to \lambda_{ij}^{(T+1)} = 0$ iff $\sigma_i^{(T)} = \sigma_j^{(T)}$=2) and the coupler rule adds links between all next-nearest neighbor sites in which both values are excited ($\lambda_{ij}^{(T)} = 0 \to \lambda_{ij}^{(T+1)} = 1$ iff $\sigma_i^{(T)} = \sigma_j^{(T)} = 1$ and $j \in \mathcal{N}\mathcal{N}_i^{(T)}$).

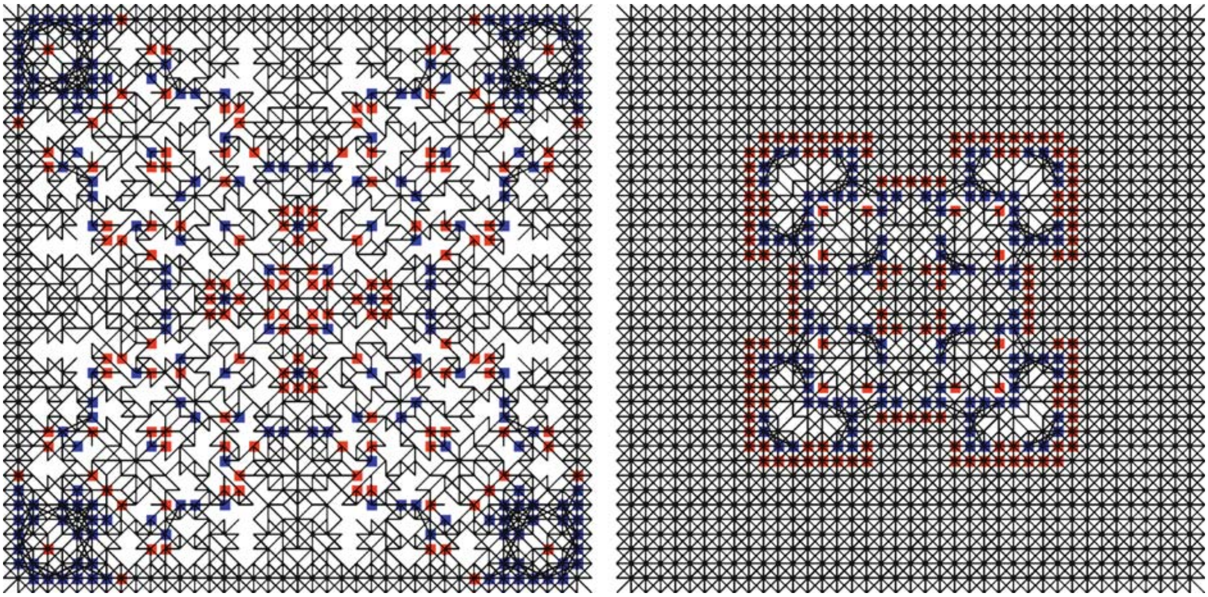
In the SDCA in Fig. 20, the transition rule for cell states is that of the generalized defensive inhibition rule: resting cell is excited if its ratio of excited and connected to the cell neighbors to total number of connected neighbors lies in



Cellular Automata with Memory, Figure 19
The SD cellular automaton introduced in text with weighted memory of factor α. Evolution from $T = 4$ up to $T = 9$ starting as in Fig. 18



Cellular Automata with Memory, Figure 20
The $k = 3$ SD cellular automaton described in text, up to $T = 4$



Cellular Automata with Memory, Figure 21
The SD cellular automaton starting as in Fig. 20 at $T = 20$, with no memory (*left*) and mode memory in both cell states and links

the interval [1/8,2/8]. The initial scenario of Fig. 20 is that of Fig. 12 with the wiring network revealed, that of an Euclidean lattice with eight neighbors, in which, the generic cell □ has 16 next-nearest neighbors: ▣. No decoupling is verified at the first iteration in Fig. 20, but the excited cells generate new connections, most of them lost, together with some of the initial ones, at $T = 3$. The excited cells at $T = 3$ generate a *crown* of new connections at $T = 4$. Figure 21 shows the ahistoric and mode memory patterns at $T = 20$. The figure makes apparent the preserving effect of memory.

The Fredkin's reversible construction is feasible in the SDCA scenario extending the $\ominus$ operation also to links: $\lambda_{ij}^{(T+1)} = \psi(\lambda_{ij}^{(T)}, \sigma_i^{(T)}, \sigma_j^{(T)}) \ominus \lambda_{ij}^{(T-1)}$. These automata may be endowed with memory as: $\sigma_i^{(T+1)} = \phi\big(s_j^{(T)} \in N_i^{(T)}\big) \ominus \sigma_i^{(T-1)}, \lambda_{ij}^{(T+1)} = \psi\big(l_{ij}^{(T)}, s_i^{(T)}, s_j^{(T)}\big) \ominus \lambda_{ij}^{(T-1)}$ [12].

The SDCA seems to be particularly appropriate for modeling the human brain function—updating links between cells imitates variation of synaptic connections between neurons represented by the cells—in which the relevant role of memory is apparent. Models similar to SDCA have been adopted to build a dynamical network approach to quantum space-time physics [45,46]. Reversibility is an important issue at such a fundamental physics level. Technical applications of SDCA may also be traced [47]. Anyway, besides their potential applications, SDCA with memory have an aesthetic and mathematical interest on their own [1,35]. Nevertheless, it seems plausible that further study on SDCA (and Lattice Gas Automata with dynamical geometry [40]) with memory should turn out to be profitable.

Memory in Other Discrete Time Contexts

Continuous-Valued CA

The mechanism of implementation of memory adopted here, keeping the transition rule unaltered but applying it to a function of previous states, can be adopted in any spatialized dynamical system. Thus, historic memory can be embedded in:

- *Continuous–valued* CA (or *Coupled Map Lattices* in which the state variable ranges in $\mathcal{R}$, and the transition rule φ is a continuous function [37]), just by considering m instead of σ in the application of the updating rule: $\sigma_i^{(T+1)} = \varphi\big(m_j^{(T)} \in \mathcal{N}_i^{(T)}\big)$. An elementary CA of this kind with memory would be [20]: $\sigma_i^{(T+1)} = \frac{1}{3}\big(m_{i-1}^{(T)} + m_i^{(T)} + m_{i+1}^{(T)}\big)$.
- *Fuzzy* CA, a sort of continuous CA with states ranging in the real [0,1] interval. An illustration of the effect of memory in fuzzy CA is given in [17]. The illustration operates on the elementary rule 90 : $\sigma_i^{(T+1)} = \big(\sigma_{i-1}^{(T)} \wedge (\neg\sigma_{i+1}^{(T)})\big) \vee \big((\neg\sigma_{i-1}^{(T)}) \wedge \sigma_{i+1}^{(T)}\big)$, which after fuzzification $(a \vee b \to \min(1, a+b), a \wedge b \to ab, \neg a \to 1-a)$ yields: $\sigma_i^{(T+1)} = \sigma_{i-1}^{(T)} + \sigma_{i+1}^{(T)} - 2\sigma_{i-1}^{(T)}\sigma_{i+1}^{(T)}$; thus incorporating memory: $\sigma_i^{(T+1)} = m_{i-1}^{(T)} + m_{i+1}^{(T)} - 2m_{i-1}^{(T)}m_{i+1}^{(T)}$.
- *Quantum* CA, such, for example, as the simple 1D quantum CA models introduced in [32]:

  $$\sigma_j^{(T+1)} = \frac{1}{N^{1/2}}\left(i\delta\sigma_{j-1}^{(T)} + \sigma_j^{(T)} + i\delta^*\sigma_{j+1}^{(T)}\right) ,$$

  which would become with memory [20]:

  $$\sigma_j^{(T+1)} = \frac{1}{N^{1/2}}\left(i\delta m_{j-1}^{(T)} + m_j^{(T)} + i\delta^* m_{j+1}^{(T)}\right) .$$

Spatial Prisoner's Dilemma

The Prisoner's Dilemma (PD) is a game played by two players (A and B), who may choose either to cooperate (C or 1) or to defect (D or 0). Mutual cooperators each score the *reward* R, mutual defectors score the *punishment* P ; D scores the *temptation* $\mathcal{T}$ against C, who scores S (*sucker's* payoff) in such an encounter. Provided that $\mathcal{T} > R > P > S$, mutual defection is the only equilibrium strategy pair. Thus, in a single round both players are to be *penalized* instead of both *rewarded*, but cooperation may be rewarded in an iterated (or spatial) formulation. The game is simplified (while preserving its essentials) if $P = S = 0$. Choosing $R = 1$, the model will have only one parameter: the *temptation* $\mathcal{T}$=b.

In the spatial version of the PD, each player occupies at a site (i,j) in a 2D lattice. In each generation the payoff of a given individual ($p_{i,j}^{(T)}$), is the sum over all interactions with the eight nearest neighbors and with its own site. In the next generation, an individual cell is assigned the decision ($d_{i,j}^{(T)}$) that received the highest payoff among all the cells of its Moore's neighborhood. In case of a tie, the cell retains its choice. The spatialized PD (SPD for short) has proved to be a promising tool to explain how cooperation can hold out against the ever-present threat of exploitation [43]. This is a task that presents problems in the classic *struggle for survival* Darwinian framework.

When dealing with the SPD, memory can be embedded not only in choices but also in rewards. Thus, in the *historic* model we dealt with, at T: (i) the payoffs coming from previous rounds are accumulated ($\pi_{i,j}^{(T)}$), and (ii) players are featured by a summary of past decisions ($\delta_{i,j}^{(T)}$). Again, in each round or generation, a given cell plays with each of the eight neighbors and itself, the decision δ in the cell of the neighborhood with the highest π being adopted. This approach to modeling memory

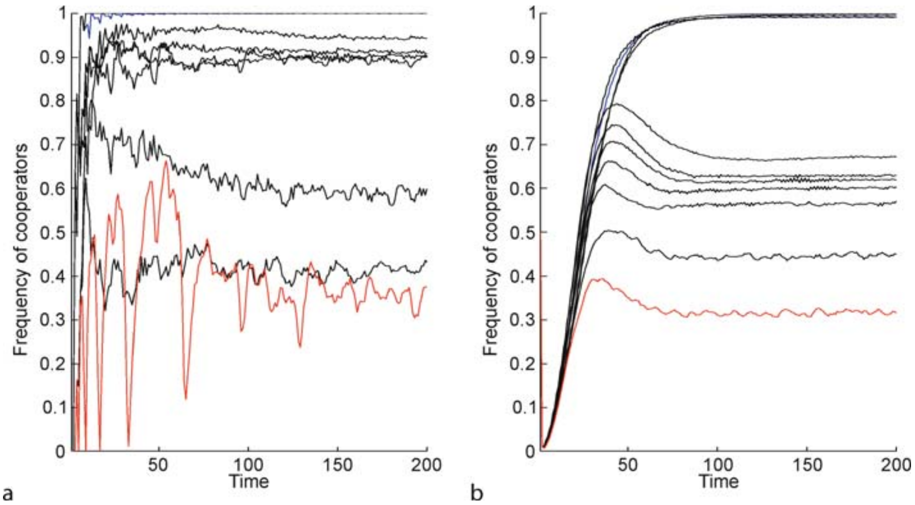
has been rather neglected, the usual being that of designing strategies that specify the choice for every possible outcome in the sequence of historic choices recalled [33,39].

Table 1 shows the initial scenario starting from a single defector if $8b > 9 \Leftrightarrow b > 1.125$, which means that neighbors of the initial defector become defectors at $T = 2$.

Nowak and May paid particular attention in their seminal papers to $b = 1.85$, a high but not excessive temptation value which leads to complex dynamics. After $T = 2$, defection can advance to a 5×5 square or be restrained as a 3×3 square, depending on the comparison of $8\alpha + 5 \times 1.85$ (the maximum π value of the recent defectors) with $9\alpha + 9$ (the π value of the non-affected players). As $8\alpha + 5 \times 1.85 = 9\alpha + 9 \rightarrow \alpha = 0.25$, i. e., if $\alpha > 0.25$, defection remains confined to a 3×3 square at $T = 3$. Here we see the paradigmatic effect of memory: it tends to avoid the spread of defection.

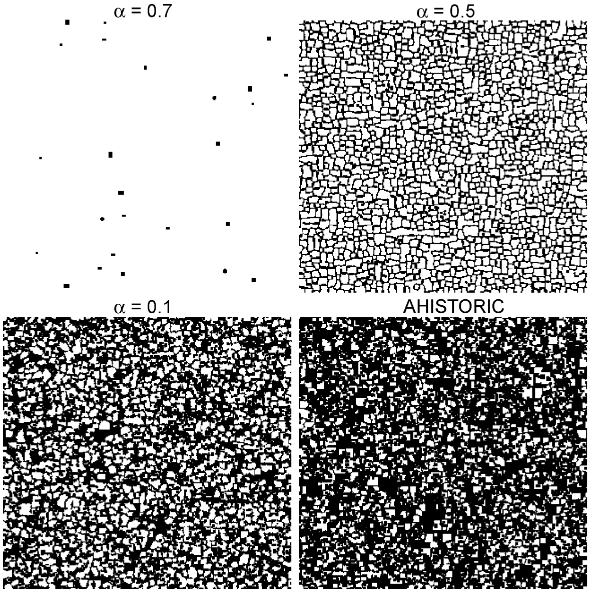
If memory is limited to the last three iterations: $\pi_{i,j}^{(T)} = \alpha^2 p_{i,j}^{(T-2)} + \alpha p_{i,j}^{(T-1)} + p_{i,j}^{(T)}$, $m_{i,j}^{(T)} = \left(\alpha^2 d_{i,j}^{(T-2)} + \alpha d_{i,j}^{(T-1)} + d_{i,j}^{(T)}\right)/(\alpha^2 + \alpha + 1)$, $\Rightarrow \delta_{i,j}^{(T)} = \text{round}(m_{i,j}^{(T)})$, with assignations at $T = 2$: $\pi_{i,j}^{(2)} = \alpha\pi_{i,j}^{(1)} + \pi_{i,j}^{(2)}$, $\delta_{i,j}^{(2)} = d_{i,j}^{(2)}$.

Memory has a dramatic restrictive effect on the advance of defection as shown in Fig. 22. This figure shows the frequency of cooperators (f) starting from a single defector and from a random configuration of defectors in a lattice of size 400×400 with periodic boundary conditions when $b = 1.85$. When starting from a single defector, f at time step T is computed as the frequency of cooperators within the square of size $(2(T - 1) + 1)^2$ centered on the initial D site. The ahistoric plot reveals the convergence of f to 0.318, (*which seems to be the same value regardless of the initial conditions* [43]). Starting from a single defector (*a*), the model with small memory ($\alpha = 0.1$) seems to reach a similar f value, but sooner and in a smoother way. The plot corresponding to $\alpha = 0.2$ still shows an early decay in f that leads it to about 0.6, but higher memory factor values lead f close to or over 0.9 very



Cellular Automata with Memory, Figure 22

Frequency of cooperators (f) with memory of the last three iterations. a starting from a single defector, b starting at random ($f(1) = 0.5$). The *red curves* correspond to the ahistoric model, the *blue ones* to the full memory model, the remaining curves to values of α from 0.1 to 0.9 by 0.1 intervals, in which, as a rule, the higher the α the higher the f for any given T



Cellular Automata with Memory, Figure 23
Patterns at $T = 200$ starting at random in the scenario of Fig. 22b

soon. Starting at random (b), the curves corresponding to $0.1 \leq \alpha \leq 0.6$ (thus with no memory of choices) do mimic the ahistoric curve but with higher f, as $\alpha \geq 0.7$ (also memory of choices) the frequency of cooperators grows monotonically to reach almost full cooperation: D persists as scattered unconnected small oscillators (*D-blinkers*), as shown in Fig. 23. Similar results are found for any temptation value in the parameter region $0.8 < b < 2.0$, in which spatial chaos is characteristic in the ahistoric model. It is then concluded that short-type memory supports cooperation.

As a natural extension of the described binary model, the 0-1 assumption underlying the model can be relaxed by allowing for *degrees* of cooperation in a continuous-valued scenario. Denoting by x the degree of cooperation of player A and by y the degree of cooperation of the player B, a consistent way to specify the pay-off for values of x and y other than zero or one is to simply interpolate between the extreme payoffs of the binary case. Thus, the payoff that the player A receives is:

$$G_A(x,y) = (x, 1-x)\begin{pmatrix} R & S \\ \mathcal{T} & P \end{pmatrix}\begin{pmatrix} y \\ 1-y \end{pmatrix} .$$

In the continuous-valued historic formulation it is $\delta \equiv m$, including $\delta^{(2)}_{i,j} = \left(\alpha d^{(1)}_{i,j} + d^{(2)}_{i,j}\right)/(\alpha+1)$. Table 2 illustrates the initial scenario starting from a single (full) defector. Unlike in the binary model, in which the initial defector never becomes a cooperator, the initial defector cooperates with degree $\alpha/(1+\alpha)$ at $T = 3$: its neighbors which received the highest accumulated payoff (those in the corners with $\pi^{(2)} = 8\alpha + 5b > 8b\alpha$), achieved this mean degree of cooperation after $T = 2$. Memory dramatically constrains the advance of defection in a smooth way, even for the low level $\alpha = 0.1$. The effect appears much more homogeneous compared to the binary model, with no special case for high values of α, as memory on decisions is always operative in the continuous-valued model [24]. The effect of unlimited trailing memory on the SPD has been studied in [5,6,7,8,9,10].

Discrete-Time Dynamical Systems

Memory can be embedded in any model in which time plays a dynamical role. Thus, Markov chains $\mathbf{p}'_{T+1} = \mathbf{p}'_T\mathbf{M}$ become with memory: $\mathbf{p}'_{T+1} = \boldsymbol{\imath}'_T\mathbf{M}$ with $\boldsymbol{\imath}_T$ being a weighted mean of the probability distributions up to T: $\boldsymbol{\imath}_T = \pi(\mathbf{p}_1, \ldots, \mathbf{p_T})$. In such scenery, even a minimal incorporation of memory notably alters the evolution of $\mathbf{p}$ [23]. Last but not least, conventional, non-spatialized, *discrete dynamical systems* become with memory: $x_{T+1} = f(m_T)$ with m_T being an average of past values. As an overall rule, memory leads the dynamics a fixed point of the map f [4].

We will introduce an example of this in the context of the PD game in which players follow the so-called Paulov strategy: a Paulov player cooperates if and only if both players opted for the same alternative in the previous move. The name Paulov stems from the fact that this strategy embodies an almost reflex-like response to the payoff: it repeats its former move if it was rewarded by $\mathcal{T}$ or R, but switches behavior if it was punished by receiving only P or S. By coding cooperation as 1 and defection as 0, this strategy can be formulated in terms of the choices x of Player A (Paulov) and y of Player B as: $x^{(T+1)} = 1- \mid x^{(T)} - y^{(T)} \mid$. The Paulov strategy has proved to be very successful in its contests with other strategies [44]. Let us give a simple example of this: suppose that Player B adopts an Anti-Paulov strategy (which cooperates to the extent Paulov defects) with $y^{(T+1)} = 1- \mid 1 - x^{(T)} - y^{(T)} \mid$. Thus, in an iterated Paulov-Anti-Paulov (PAP) contest, with $T(x,y) = \big(1 - |x-y|\,, 1 - |1-x-y|\big)$, it is $T(0,0) = T(1,1) = (1,0)$, $T(1,0) = (0,1)$, and $T(0,1) = (0,1)$, so that (0,1) turns out to be immutable. Therefore, in an iterated PAP contest, Paulov will always defect, and Anti-Paulov will always cooperate. Relaxing the 0-1 assumption in the standard formulation of the PAP contest, *degrees* of cooperation can be considered in a continuous-valued scenario. Now x and

Cellular Automata with Memory, Figure 24

Dynamics of the mean values of *x* (*red*) and *y* (*blue*) starting from any of the points of the 1 × 1 square

y will denote the degrees of cooperation of players A and B respectively, with both x and y lying in [0,1].

In this scenario, not only (0,1) is a fixed point, but also $T(0.8, 0.6) = (0.8, 0.6)$. Computer implementation of the iterated PAP tournament turns out to be fully disrupting of the theoretical dynamics. The errors caused by the finite precision of the computer floating point arithmetics (a common problem in dynamical systems working modulo 1) make the final fate of every point to be (0,1). With no exceptions: even the *theoretically* fixed point (0.8,0.6) ends up as (0,1) in the computerized implementation.

A natural way to incorporate older choices in the strategies of decision is to feature players by a summary (m) of their own choices farther back in time. The PAP contest becomes in this way: $x^{(T+1)} = 1- \mid m_x^{(T)} - m_y^{(T)} \mid$, $y^{(T+1)} = 1- \mid 1 - m_x^{(T)} - m_y^{(T)} \mid$. The simplest historic extension results in considering only the two last choices: $m(z^{(T-1)}, z^{(T)}) = (\alpha z^{(T-1)} + z^{(T)})/(\alpha + 1)$ (z stands for both x and y) [10].

Figure 24 shows the dynamics of the mean values of x and y starting from any of the 101×101 lattice points of the 1×1 square with sides divided by 0.01 intervals. The dynamics in the ahistoric context are rather striking: immediately, at $T = 2$, both $\overline{x}$ and $\overline{y}$ increase from 0.5 up to app. $0.66(\simeq 2/3)$, a value which remains stable up to app. $T = 100$, but soon after Paulov cooperation plummets, with the corresponding firing of cooperation of Anti-Paulov: finite precision arithmetics leads every point to (0,1). With memory, Paulov not only keeps a permanent mean degree cooperation but it is higher than that of Anti-Paulov; memory tends to lead the overall dynamics to the ahistoric (theoretically) fixed point (0.8, 0.6).

Future Directions

Embedding memory in states (and in links if wiring is also dynamic) broadens the spectrum of CA as a tool for modeling, in a fairly natural way of easy computer implementation. It is likely that in some contexts, a transition rule with memory could match the *correct* behavior of the CA system of a given complex system (physical, biological, social and so on). A major impediment in modeling with CA stems from the difficulty of utilizing the CA complex behavior to exhibit a particular behavior or perform a particular function. Average memory in CA tends to inhibit *complexity*, inhibition that can be modulated by varying the depth of memory, but memory not of average type opens a notable new perspective in CA. This could mean a potential advantage of CA with memory over standard CA as a tool for modeling. Anyway, besides their potential applications, CA with memory (CAM) have an aesthetic and mathematical interest on their own.

Thus, it seems plausible that further study on CA with memory should turn out profitable, and, maybe that as a result of a further rigorous study of CAM it will be possible to paraphrase T. Toffoli in presenting CAM—as an alternative to (rather than an approximation of) integro-differential equations in modeling— phenomena with memory.

Article Outline

Glossary

Agents Ingredients under study occupying the cells in the grid.

Asynchronous Each cell in turn, at random responds to a rule.

Cells Sections of the grid in which the agents exist.

Gravity The relative relationship of two agents within the frame of a grid with opposite bound edges.

Grid The frame containing the cells and the agents.

Movement The simulation of agent movement between cells accomplished by the disappearance of an agent in a cell and the appearance of that agent in an adjacent cell.

Neighborhood The cells immediately touching a given cell in the grid.

Rules Statements of actions to be taken by an agent under certain conditions. They may take the form of a probability of such an action.

Synchronous All cells in a grid exercise a simultaneous response to a rule.

Definition of the Subject

Cellular automata are discrete, agent-based models that can be used for the simulation of complex systems [1]. They are composed of:

- A grid of cells.
- A set of ingredients called agents that can occupy the cells.
- A set of local rules governing the behaviors of the agents.
- Specified initial conditions.

Once these components are defined, a simulation can be carried out. During the simulation the system evolves via a series of discrete time-steps, or iterations, in which the rules are applied to all of the ingredients of the system and the configuration of the system is regularly updated. A striking feature of the cellular automata (CA) models is that they treat not only the ingredients, or agents, of the model as discrete entities, as do the traditional models of physics and chemistry, but in the CA models time (iterations) and space (the cells) are also regarded as discrete, in contrast to the continuous forms assumed for these variables in the traditional, equation-based physical models. In practice, this distinction usually makes little difference, since the traditional continuous results appear naturally as limiting cases of the discrete CA analysis.

Introduction

Cellular automata (CA) were first proposed by the mathematical physicist John von Neumann [2] and the mathematician Stanislaw Ulam [3,4] more than a half century ago, and similar ideas were suggested at about the same time, in the 1940s, by the German engineer Konrad Zuse. Von Neumann's interest was in the construction of "self-reproducing automata". His original idea was to construct a series of mechanical devices or "automata" that would gather and assemble the parts necessary to reproduce themselves. A suggestion by Ulam led him to consider more abstract systems consisting of grids with moving agents, operating under sets of rules. The first such system proposed by von Neumann consisted of a two-dimensional grid of square cells, each having a set of possible states, along with a set of rules. With the development of modern digital computers, it has became increasingly clear that these very abstract ideas could in fact be usefully applied to the examination of real physical and biological systems, with interesting and informative results.

A number of research groups have developed different realizations of the CA paradigm for the study of a broad range of physical [5,6], chemical [7], biological [8,9], medical [10,11] and even sociological [12,13,14] phenomena. These models have contributed important new insights regarding the deeper, often hidden, factors underlying a host of complex phenomena. These diverse CA studies have been especially important in treating the often-surprising behaviors of systems where large numbers of diverse interactions between the system agents serve to hide the general patterns involved and, in addition, render the conventional, differential-equation-based methods difficult to implement or ineffective—i. e., complex systems.

Models and Simulations with Cellular Automata

Cellular automata can be used to both model and to simulate real systems. A model is a substitute, usually greatly simplified, for what is the real thing. A model should capture from the real system and display in some revealing way its most important or interesting features. Where possible it should capture the essence of the system without being overly cumbersome or complicated. Many models in the physical sciences take the form of mathematical relationships, equations connecting some property with other parameters of the system. Some of these relationships are quite simple, while many mathematical relationships are more complicated, and rely on the techniques of calculus to describe the rates of change of the quantities involved. Overall, mathematical models have been exceedingly successful in depicting the broad outlines of an enormously diverse variety of phenomena in nature.

Simulations are active imitations of real things, and there are generally two different types of simulations, with different aims. In one approach a simulation is merely designed to match a certain behavior, often in a very limited context. Thus a mechanical noisemaker may simulate a desired sound, and does so through a very different mechanism than the real sound-maker. Such a simulation reveals little or nothing about the features of the original system, and is not intended to do so. Only the outcome, to some extent, matches reality. A hologram may look like a real object, but it is constructed from interfering light waves. A second type of simulation is more ambitious. It attempts to mimic at least some of the key features of the system under study, with the intent of gaining insight into how the system operates.

The Grid

The grid in a CA model may contain a single cell, or more commonly a larger collection. The grid might be one-, two-, or three-dimensional in form, although most studies have used two-dimensional grids. A moving agent may encounter an edge or boundary during its response to the rules. Three general types of two-dimensional grids are considered relating to the boundaries: (i) a box, (ii) a cylinder, and (iii) a torus. In the box grid moving agents encounter boundaries on all four sides; in the cylinder they encounter only top and bottom boundaries; and in the torus no boundaries restrict the agent movements. An illustration of a $7 \times 7 = 49$-cell grid of square cells occupied by two different types of agents, A and B, is shown in Fig. 1.

The nature of the grid type employed will normally depend on the boundary characteristics of the system of interest. For some systems, e. g., when the agents are either stationary or confined, a box grid is perfectly suitable. In other cases, one may need only a constraining top and bottom (or right and left sides), and a cylindrical grid will be used. The torus effectively simulates a small segment of a larger, unrestricted system by allowing cells to move off the top edge and appear at the bottom, or move off the bottom edge and appear at the top.

The Cells

Structure

The cells can take a variety of shapes; they can be triangles, squares, hexagons or other shapes on the two-dimensional grid, with square cells being most common. Each cell in the grid can normally exist in a number of distinct states which define the occupancy of the cell. The cell can be empty or contain a specific agent, representing a particle, a type of molecule or isomer, a molecular electronic state, or some other entity pertinent to the study in question. The choice of the cell shape is based on the objective of the study. In the case of studies of water-related phenomena, for example, square cells are especially advantageous since water molecules, are quadravalent with respect to their participation in intermolecular hydrogen bonding. An individual water molecule can employ two hydrogen atoms and two lone pairs of electrons to form hydrogen bonds with its neighbors. This leads to the tetrahedral configuration found in ice, a structure that is retained to some extent in the liquid state. The four faces of a square cell thus correspond to the four hydrogen-bonding opportunities of a water molecule.

The interactions of an agent with other agents take place at the cell edges. Originally, cellular automata models routinely assumed that all of the edges of a given agent should obey the same rules. More recently, the idea of a variegated cell, in which each edge can have its own independent rules for interaction with other agents, has been introduced and shown to have considerable value in modeling. Examples of some types of variegated cells are shown in Fig. 2.

Cell Neighborhoods

The movements and other actions of an agent on the grid are governed by rules, that depend only on the nature of the cells in close proximity to the agent. This proximate environment of a cell is called its neighborhood. The most common neighborhood used in two-dimensional cellular automata studies is called the von Neumann neighborhood, after the pioneer of the CA method. This neighborhood for a cell A refers to the four B cells adjoining its four faces (see Fig. 3). Another common neighborhood is the Moore neighborhood referring to the eight cells completely surrounding cell A, including those cells on the diagonals.

The Rules

Several different types of rules govern the behaviors of the agents on the grid and thereby the subsequent evolutions of the CA systems. The key features of all these rules are that they are local, involving only an agent itself and possibly those agents in its immediate neighborhood, and that they are uniformly applied throughout a CA study.

Movement Rules

Much of the dynamic character of cellular automata models is developed through the movements of the agents about the grid. During each time-step interval, or iteration, in the CA simulation an agent on the grid has the possibility of moving vertically or horizontally to an adjacent, unoccupied cell. In the absence of further restrictions, a free agent would therefore, over time, perform a random walk about the grid. Normally, however, there are other agents on the grid and their presence will influence the motion of the first agent. During each iteration the movement of every agent on the grid is computed based on rules that involve the status of its neighboring cells, i. e., whether these cells are empty or occupied, and, if occupied, by what types of agents. Deterministic cellular automata use a fixed set of rules, the values of which are immutable and uniformly applied to the agents. In probabilistic, or stochastic, cellular automata, the movements of the agent are based on probabilistic rules, embodied as probabilities of moving or not moving during each iteration.

Free Moving Probability P_m

The free moving probability $P_m(A)$ defines the probability that an agent A in a cell *i* will move to one of the four adjacent cells, *j*, in its von Neumann neighborhood if that space is unoccupied. An example would be the agent in cell A which might move to any of the unoccupied neighboring B cells. This probability is usually set at $P_m = 1.0$, which means that a movement in one of the allowed directions always happens. However, in some cases P_m can be set to lower values if certain species in the CA simulation are to be regarded as moving more slowly than others.

Joining Parameter *J*

The first of the two trajectory or interaction rules is the joining trajectory parameter, $J(AB)$, which defines the propensity of movement of an agent A toward or away from a second agent B when the two are separated by a vacant cell. It thus involves the extended von Neumann neighborhood of agent A, and has the effect of adding a short-range attraction or repulsion component to the interaction between agents A and B. J is a non-negative real number. When $J = 1$, species A has the same probability of movement toward or away from B as when the B cell is not present. When J is greater than 1, agent A has a greater probability of movement toward a B agent than when agent B is absent, simulating, in effect, a degree of short-range attraction. When J lies between 0 and 1, agent A has a lower probability of such movement, and this can be considered as a degree of mutual repulsion. When $J = 0$, agent A cannot move toward B at all.

Breaking Probability P_B

The second trajectory or interaction rule is the breaking probability, P_B. This parameter, in effect, assigns a persistence to the encounter between two agents that are in contact, i. e., adjacent to each other on the grid. The breaking rule assigns the probability $P_B(AB)$ that an agent A, adjacent to an agent B, will break apart from B. The value for P_B necessarily lies within the range 0 to 1. Low values of P_B imply a strong cohesion between A and B, whereas high values indicate little cohesion. Thus if $P_B = 0$, the agents will not separate from each other, and if $P_B = 1$ they have no tendency to adhere to one another. If P_B lies between these values there is an intermediate tendency to break apart. When molecule A is bordered two agents, B and C, the simultaneous probability of A breaking away is given by the product $P_B(AB) * P_B(AC)$. If agent A has three adjacent agents (B, C, and D), the simultaneous breaking probability of agent A, the probability that it will move to the remaining adjacent empty cell, is $P_B(AB) * P_B(AC) * P_B(AD)$. If agent A is surrounded by four agents, it cannot move.

Transition Rules

Transitions occur constantly in nature; molecules change from one tautomeric form to another, radioactive nuclei decay to form other nuclei, acids dissociate, proteins alter their shapes, molecules undergo transitions between electronic states, chemicals react to form new species, and so forth. Transition rules allow the simulation of these changes. They govern the probability that during each iteration of the simulation an agent will transform to a different type of agent. If $P_{\mathrm{T}}(\mathrm{AB}) = 1.0$ the transition A → B is certain to occur; if $P_{\mathrm{T}}(\mathrm{AB}) = 0.0$, it will never occur. But if, for example, $P_{\mathrm{T}}(\mathrm{AB}) = 0.5$, then during each iteration there will be a 50% chance that the transition A → B will occur. The first two cases can be considered deterministic, since they do not allow for different outcomes. The third case is stochastic, however, since it allows different outcomes, the agent might remain unchanged or it might transform to a different state. The transition probabilities may, in some cases, depend on the conditions prevailing in neighboring cells. For example, the transformation probability $P_{\mathrm{T}}(\mathrm{AB})$ might depend on the occupancies of neighboring cells. In reaction simulations two agents A and B that come in contact on the grid will have a probability $P_{\mathrm{R}}(\mathrm{AB})$ of reacting, or transforming, to other species, say, C and D, during such an encounter. In this case the reaction probability $P_{\mathrm{R}}(\mathrm{AB})$ defines the probability that the reaction $\mathrm{A} + \mathrm{B} \rightarrow \mathrm{C} + \mathrm{D}$ will occur when A and B encounter one another in the course of their motions. If $P_{\mathrm{R}}(\mathrm{AB}) = 1$ the reaction will take place on every encounter, but if $P_{\mathrm{R}}(\mathrm{AB}) = 0.1$, for example, only 10% of such encounters will lead to reaction.

Relative Gravity Rules

The simulation of a gravity effect can be introduced into a cellular automaton model in two different ways. Separation phenomena like the de-mixing of immiscible liquids can be simulated using a relative gravity rule. For this, a boundary condition is first imposed at the upper and lower edges of the grid to apply vertical limits on the motions of the agents (a cylindrical grid). The differential effect of gravity on different agents A and B is simulated by introducing reciprocal rules governing their tendencies to exchange positions when they come together. When one agent moves to a position on top of the other the rules are applied. The first rule, $G_{\mathrm{R}}(\mathrm{AB})$, applies when A is above B and is the probability that agent A will exchange places with agent B, so that A will appear below, and B above. The complementary rule is $G_{\mathrm{R}}(\mathrm{BA})$, which expresses the probability that molecule B, originally above A, will exchange positions with A and end up below.

When $G_{\mathrm{R}}(\mathrm{AB})$ is greater than $G_{\mathrm{R}}(\mathrm{BA})$ there will be an overall tendency for the A agents to congregate below the B agents, and when $G_{\mathrm{R}}(\mathrm{AB})$ is less than $G_{\mathrm{R}}(\mathrm{BA})$ the A agents will tend toward the upper part of the grid. In the first case the A's can be thought of as forming a more dense liquid than the B's, and in the latter case, a less dense liquid. The G_{R} rules are probabilities that the events will occur.

Absolute Gravity Rule

In other simulations an absolute gravity rule, denoted by $G_{\mathrm{A}}(\mathrm{A})$, is more appropriate. This rule favors motion in a preferred direction. For example, one might wish to simulate the motions of different gas molecules, some heavier than others, in a gravitational field. The value $G_{\mathrm{A}}(\mathrm{A}) = 0$ is the neutral value, so that the movement probabilities are equal in all four directions. Values greater than $G_{\mathrm{A}}(\mathrm{A}) = 0$ increase the likelihood of downward movements. Thus a value of $G_{\mathrm{A}}(\mathrm{A}) = 0.2$ would impose a slight tendency of the agents of species A to move downward on the grid, and $G_{\mathrm{A}}(\mathrm{A}) = 0.5$ would impose a much stronger tendency.

Cell Rotation Rules

In those cases where variegated agents are used it is necessary to insure that there exists a balanced representation of the possible rotational states of these agents on the grid. To accomplish this, the variegated cells are rotated randomly, by 90°, −90°, +180°, or −180°, during every iteration of the run. Only free cells rotate; when a variegated agent has a neighboring agent in its von Neumann neighborhood it does not rotate.

Application of the Rules

A complete time-step (iteration) in a CA model involves the application of all of the applicable rules to all of the agents on the grid. During an iteration the movement rules can be applied either simultaneously (synchronously) or sequentially (asynchronously). Synchronous application of the governing movement rules for a CA simulation, as outlined above, can lead in some instances to conflicts, e. g., the assigning of two agents to move to the same empty cell. As a result, synchronous rule application may not be practical for cellular automata studies of some kinds. In asynchronous application of the rules, in contrast, agents are selected in random order for application of the movement rules, and such potential conflicts are avoided.

Examples

Structure of Bulk Water

The physical properties of water, such as its viscosity, heat capacity, heat of vaporization, surface tension, dielectric constant, etc., are commonly related to temperature under normal pressure. It is accepted that underlying changes in the structure of water are responsible for the changes in the properties, although the precise physical basis for this relationship has not been established. Cellular automata models of bulk water in the liquid state at different temperatures produce a series of structural patterns, differing in the extent of binding between the individual water molecules. The fractions of water molecules unbound, bound to one, two, three or four neighbors, designated, f_0, f_1, f_2, f_3, and f_4, can be employed as structural descriptors of bulk liquid water at various temperatures. The significance of these descriptors can be evaluated by examining the correlations of these descriptors with these physical properties. A linkage between the J and P_B rules for water models has been postulated and tested leading to the relationship [15]:

$$\mathrm{Log}\, J = -1.5 P_B + 0.6\,. \tag{1}$$

The temperature of the water has been found to relate with the P_B value as

$$\mathrm{T}\left({}^\circ\mathrm{C}\right) = 100 P_B\,. \tag{2}$$

Using the f_x parameters as structure parameters in regression analysis, correlations arise between them and a variety of physical properties. Several relationships are given in Table 1, where r^2 is the coefficient of determination and s is the standard error of the fit. The observed relationships suggest that the bulk water f_x descriptors encode information allowing them to be used in correlations with a variety of physical properties. This reveals possibilities of using these descriptors in analyzing properties and behavior entirely on the basis of structure rather than using an inter-connected web of physical properties. The relationship between the f_x descriptors and the temperature (P_B value) is shown in Fig. 4.

Solution Phenomena

Solute Rules The solubility of a compound in a particular solvent reflects the intermolecular interactions between the molecular species involved. Thus the breaking and joining rules pertaining to solute-solute and solute-solvent interactions may be assigned on the basis of some anticipation of the magnitude of these intermolecular terms. For the solute (S), a large value of J(SS) encodes a high tendency for its molecules to be attracted to one another.

Cellular Automata Modeling of Complex Biochemical Systems, Table 1
Equations relating f_x values to properties of water

Property	Equation	r^2	s
Temperature	$T\,(^\circ\mathrm{C}) = -490.28 f_0 + 622.60 f_1 + 4.46$	0.996	1.90
Heat capacity	$C_p\,[\mathrm{Cal/g/^\circ C}] = 1.0478 - 0.0488 f_2 - 0.0620 f_3 - 0.0446 f_4$	0.995	0.0002
Surface tension	$\gamma\,(\mathrm{dynes/cm}) = -93.72 f_1 + 75.33$	0.996	1.90
Vapor pressure	$\mathrm{Log}\,P_v\,(\mathrm{mm\,Hg}) = -24.30 f_0 + 15.64 f_1 + 0.90$	0.997	0.035
Compressibility	$\kappa\,(10^6/\mathrm{Bar}) = 79.60 - 43.61 f_2 - 39,57 f_3 - 30.32 f_4$	0.991	0.190
Dielectric constant	$\varepsilon = -178.88 f_1 + 55.84$	0.994	0.735
Viscosity	$\eta\,(\mathrm{centipoises}) = 1.439 f_4 + 0.202$	0.965	0.045

The companion rule, $P_B(SS)$, encodes the ease or difficulty of a pair of joined solute molecules to break apart. To illustrate the cooperativity of these two rules for a solute, a molecule with rules $J(SS) = 2.0$ and $P_B(SS) = 0.2$ would be expected to have a strong tendency to remain as an insoluble aggregate or crystal. Such a solute would likely have a high melting point. In contrast, a solute with $J(SS) = 0.5$ and $P_B(SS) = 0.8$ would be expected to have a lower melting point and be more soluble. The choice of these rules govern the general behavior of solute molecules toward themselves [16].

The Hydrophobic Effect The hydrophobic effect refers to the action of relatively non-polar (hydrophobic) substances on the organization of the water molecules in their vicinity. A common expression is that water becomes "more structured" or organized in the neighborhood of a hydrophobic solute. This phenomenon has been simulated using a cellular automata model [17]. In this model the breaking probability of water-solute molecule pairs, $P_B(WS)$, was systematically increased, thus encoding an increasing hydrophobicity of the solute and a decreasing probability that the solute molecules would associate with the water molecules.

It was observed that low $P_B(WS)$ values, representing strong water-solute attractions, produced solution configurations in which the solute molecules were heavily surrounded by water molecules. Conversely, at high $P_B(WS)$ values most of the solute molecules were found outside of the water clusters and within the solution cavities. These configurations leave the water clusters relatively free of solute and hence more internally structured or organized. These models thus reflect the molecular system level conditions present in the hydrophobic effect. These results agree with molecular dynamics simulations and the interpretation presented agrees with recent experimental evidence and models proposed for the hydrophobic effect.

Solute Dissolution Dissolution refers to the breaking apart of a solute aggregate within a solvent to form a solution. Cellular automata simulations of the dissolution process have been carried out in which the solute aggregates started as solid blocks surrounded by water [18]. The solute species were endowed with specific $P_B(SS)$, $J(SS)$, $P_B(WS)$ and $J(WS)$ rules. The system attributes recorded during the ensuing system evolutions were the fraction $f_0(S)$ of solutes unbound to other solute molecules, the average number of solute-solute joined faces $T(S)$, and the average distance $D(S)$ that solute molecules traveled from the center of the block at a specific iteration. The $f_0(S)$ values were interpreted as representing the extent of dissolution of the solute, the decrease in the $T(S)$ values were used to characterize the extent of disruption of the solute block, and the $D(S)$ values quantified the extent of diffusion of the solutes into the surrounding water.

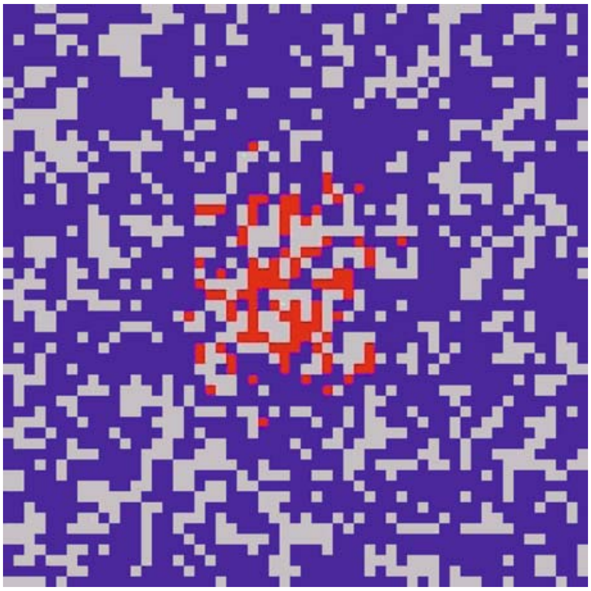
The extent and rate of the solute block disruption, $T(S)$, is primarily a function of the $P_B(S)$ rule, with secondary influence from the $P_B(WS)$ rule. A high value of $P_B(S)$ implies a high probability of solute molecules separating from each other, and hence a strong tendency toward crystal disruption. The f_0 fraction serves as a measure of the extent of solute solubility. The extent of dissolution depends upon both the $P_B(S)$ and the $P_B(WS)$ rules. High values of $P_B(S)$ and low values of $P_B(WS)$ promote an extensive degree of dissolution. A low value of $P_B(WS)$ characterizes a solute that is relatively hydrophilic. The simulations also implied that solutes with high $P_B(WS)$ values should diffuse more rapidly than those with low values of equal size. It was also observed that simulations of higher temperatures led to faster disruption of the block of solute, and more extensive diffusion of the solute molecules through the bulk water, in accord with the normal expectations.

An unexpected observation arises from the graphical display of the disintegration of the solute block of cells. The early stages of the disruption occurred as a series of intrusions of cavities, rather than water molecules, into the block. The cavities roamed throughout the block, behaving as "particles". The entrance of water into the block structure appeared much later, after significant disruption and loss of solute molecules from the block. This behavior is shown in Fig. 5.

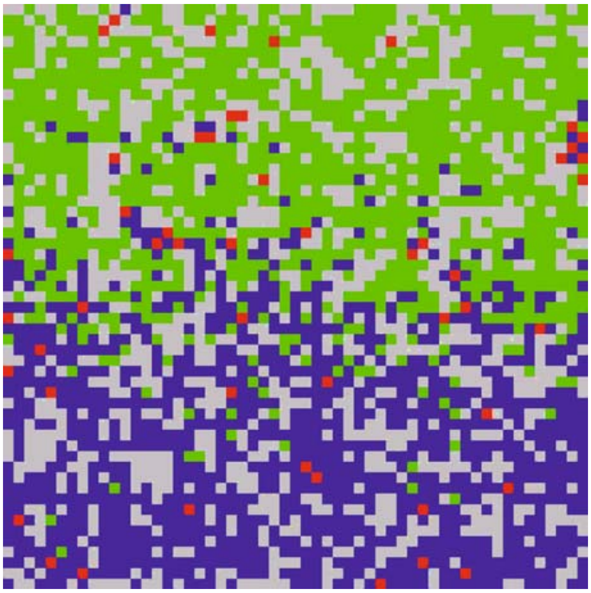
Diffusion in Water

Models of the diffusion process in water have been reported. One study revealed that hydrophobic solutes diffuse faster than hydrophilic ones, comparing molecules of similar size [19]. A model of diffusion as a function of water temperature produced the expected result of greater diffusion with higher temperature. A series of dilute solutions were modeled where the relative polarity of a solute S_1, was varied. A second solute, S_2, was introduced at the center of the grid. The dynamics showed that the solute, S_2, diffused faster when there is no co-solute and when the polarity of S_2 is low. The presence of the co-solute revealed that the diffusion of S_2 was fastest when the co-solvent, S_1 was hydrophobic.

In another study, the grid was divided into two halves, the upper half, containing a solution of a non-polar solute while the lower half contained a solution of a polar solute [20]. Between these two halves, a thin layer of cells



Cellular Automata Modeling of Complex Biochemical Systems, Figure 5
A model of the dissolution of a crystal in water



Cellular Automata Modeling of Complex Biochemical Systems, Figure 6
A model of the de-mixing of immiscible liquids

simulated a solution made up of a solute of intermediate polarity. The dynamics created a model in which the solute in the middle layer preferentially diffused into the upper layer containing the non-polar solute. A second study simulated an aqueous solution of intermediate polarity in the middle of the grid. Surrounding this solution were regions with highly polar, intermediately polar and non-polar solutes in solution. A fourth region around the center was pure water. The solute in the central section of the grid was allowed to freely diffuse. It diffused more rapidly into the pure water, however it secondarily preferred the more non-polar solution quadrant. The diffusion of a solute is modeled to be faster when it is hydrophobic and when co-solutes are also hydrophobic. The rate of diffusion of a solute in water was studied as a function of the water temperature and the hydropathic state of the solute.

Oil-Water Demixing

Models of the separation of two immiscible liquids and the partitioning of a solute between them have been reported [21]. The emerging configuration is an immiscible, two phase system. An interface formed with a greater concentration of water in the lower half while the second liquid dominated the upper half. The interface was unorganized with large "fingers" of cells from each half projecting into the other half of the grid. Figure 6 shows the interface in this model. This interface structure and behavior has been observed using other modeling paradigms. The simulated events of the demixing process present an intriguing model of a phenomenon that might be difficult to examine experimentally.

Another study tested the ability of this model to simulate the partitioning of solute molecules between the two phases, governed by their relative hydrophobicity. The addition of a small number of solute molecules was made to the initial, random mixture. As the dynamics proceeded, it was observed that the solute was associating with the patches of solvent to which it had the closest parameter-governed affinity. As a relatively stable configuration developed, the ratio of the solute molecules among the two phases became relatively constant. This ratio is the partition coefficient of the solute between the two phases. The dominant rules influencing the partition coefficient were the $P_B(WS_2)$ and $P_B(S_1S_2)$, the affinity of the solute for the two liquids, where S_2 is the solute molecule.

Observing the course of the dynamics there is a constantly changing pattern from the random configuration at the outset to the eventual formation of a disturbed interface and separated compartments of the two solvents. The solute molecules move rapidly to the patches in which the rules have ordained an affinity. The solute molecules have essentially partitioned themselves among the patches long before the two phases and the interface have formed.

Chemical Kinetics

Acid Dissociation The dissociation of an acid and the influence of the environment on this process was the subject of a recent study [22]. A cell modeling an organic acid molecule was divided into two parts, one face representing the carboxyl group, Y, and the other three faces, X, representing the non-dissociating, non-polar parts of the acid molecule. The strength of the acid, i. e. its propensity to dissociate, was governed by the probability rule, P_D. The hydronium ion was endowed with greater mobility since it is known to move very rapidly from one oxygen to another within the hydrogen bonded system of water. This was accomplished by allowing any of the four possible neighboring water molecules, relative to H to exchange positions with the hydronium cell, H.

An initial test of the model was to vary the P_D value and monitor the concentration of products. As expected, an increase in the P_D rule produced an increase in the calculated acid dissociation constant, K_a. A second study examined the influence of acid concentration on the observed properties. As expected, the K_a was approximately constant over a modest concentration range. A study on solution environment influences modeled the presence of another molecule in the solution. This co-solute was endowed with an attribute of non-dissociation. It's hydrophobicity was varied in a series of studies. The dissociation of the acid decreased when the hydrophobicity of the co-solute decreased. The interaction of two acids of different strength was also simulated using the same basic model. The observed dissociations revealed a strong and unequal influence of the two acids on each other. Both acids exhibit a suppression in their dissociations relative to their behavior in pure solution. The weaker acid is significantly more suppressed than the stronger acid. The decrease in dissociation of the two acids in a mixture cannot be readily calculated from the acid concentrations and their individual dissociation constants because of the complicating influences of ionic solvation effects on the water structure plus temperature factors.

First-Order Kinetics Many important natural processes ranging from nuclear decay to unimolecular chemical reactions, are first-order, or can be approximated as first-order [23]. This means that these processes depend only on the concentration to the first power of the transforming species itself. A cellular automaton model for such a system takes on an especially simple form, since rules for the movements of the ingredients are unnecessary and only transition rules for the inter-converting species need to be specified. Recent work described such a general cellular automaton model for first-order kinetics and tested its ability to simulate a number of classic first-order phenomena.

The prototype first-order transition is radioactive decay A → B, in which the concentration [A] of a species A decreases according to the rule that each A ingredient has a probability $P_t(\mathrm{AB})$ per unit time (here, per iteration) of converting to some other form B. For small numbers of A ingredients the actual decay curve observed for [A] is rather jagged and only roughly exponential, as a result of the irregular decays expected in this very finite, stochastic system. However, as the number of decaying ingredients is increased the decay curve approaches the smooth exponential fall-off expected for a deterministic system obeying the rate equation

$$\frac{\mathrm{d}[A]}{\mathrm{d}t} = -k[A] \,. \tag{3}$$

When a reverse transition probability $P_t(\mathrm{BA})$ for the transition B → A is included the model simulates the first-order equilibrium:

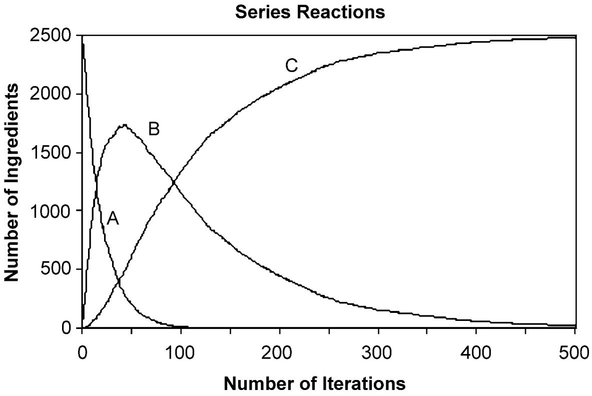
$$\mathrm{A} \leftrightarrow \mathrm{B} \,.$$

Here too, the finite size of the system causes notable fluctuations, in this case in the value of the equilibrium constant K, which fluctuates with time about the deterministic value

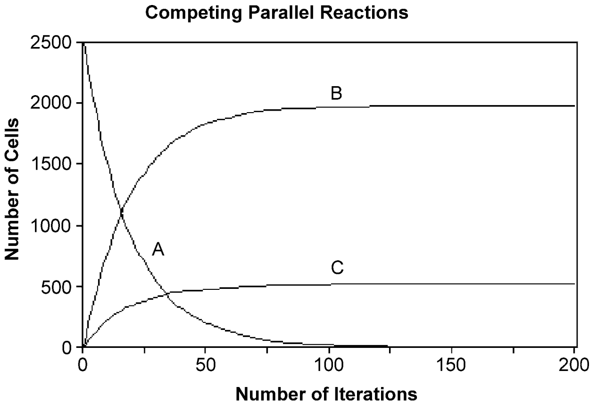
$$\mathrm{K} = \frac{P_t(\mathrm{AB})}{P_t(\mathrm{BA})} \,. \tag{4}$$

As an example, for 10 trials with 400 ingredients taking $P_t(\mathrm{AB}) = 0.05$ and $P_t(\mathrm{BA}) = 0.04$, we found K= 1.27 with a standard deviation of 0.13, compared to the deterministic value of 1.25. As a further test of the model one can ask whether it is ergodic in the sense that the average of K over time, i. e., for a single system observed for a long time after reaching equilibrium, is equal to the average K for identical systems taken at a particular time in a large number of trials. When this was tested for 1000 time steps (separated by 100 iterations) vs. 1000 trials the results were statistically identical, indicating that the first-order cellular automaton model is sensibly ergodic [2].

The first-order model can also be used to examine sequences of transformations of the form A → B → C . . .. For the simple example A → B → C the concentration of the initial reactant A falls exponentially, that of the intermediate species B rises then falls, and that of C builds up as it is fed from B. These time-dependent changes are illustrated in Fig. 7 using specific transformation probabilities.



Cellular Automata Modeling of Complex Biochemical Systems, Figure 7
Typical time-dependent variations of the ingredient populations for a two-step reaction A → B → C



Cellular Automata Modeling of Complex Biochemical Systems, Figure 8
Typical variations in the ingredient populations for competing reaction A → B → C

Kinetic and Thermodynamic Reaction Control Parallel competing reactions

$$\begin{array}{l} A \rightarrow B \\ \downarrow \\ C \end{array}$$

can also be simulated. An especially interesting example occurs when the reactions are reversible [24]:

$$A \leftrightarrow B \quad \text{and} \quad A \leftrightarrow C\,.$$

With properly chosen transformation probabilities, this model can be utilized to examine the conditions governing thermodynamic and kinetic control of reactions. An illustration is shown in Fig. 8 for the conditions $P_t(AB) = 0.01$, $P_t(AC) = 0.001$, $P_t(BA) = 0.02$, and $P_t(CA) = 0.0005$, using a set of 10 000 ingredients. Starting with all species A, in the initial stages of the reaction the kinetically-favored product B is produced in excess, whereas at later times the thermodynamically-favored product C gains dominance. The cellular automata model is in good agreement with those found in a deterministic, numerical solution for the same conditions. For example, the cellular automata model yields final equilibrium concentrations for species B and C of $[B] = 0.1439 \pm 0.0038$ and $[C] = 0.5695 \pm 0.0048$ compared to reported deterministic values of 0.14 and 0.571, respectively.

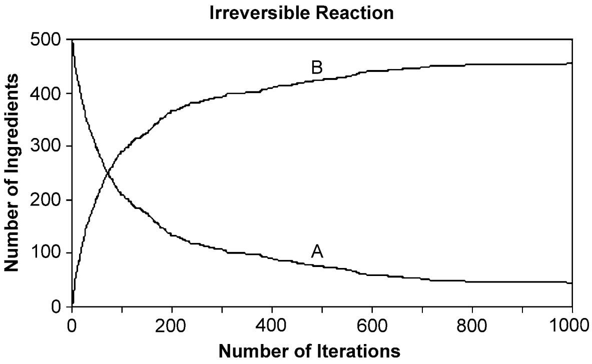
Excited-State Kinetics Another important application of the first-order model is to the examination of the ground and excited state kinetics of atoms and molecules [25]. One illustration of the excited-state cellular automata model is the dynamics of the excited-state transitions of oxygen atoms [26]. The oxygen atom has a ^3P ground state and ^1S and ^1D excited states. Emissions from the latter two excited states play an important role in the dramatic light displays—the *Aurora Borealis*, or "Northern lights"—seen under certain conditions in the northern polar skies, and similar emissions have been detected in the atmospheres of Mars and Venus. The excited states are believed to be mainly produced by dissociative recombinations of ionized oxygen molecules and electrons generated in the atmosphere by ultraviolet bombardment during the daylight hours:

$$O_2^+ + e^- \rightarrow O^* + O^{**}\,.$$

In this, the species O^* and O^{**} are unspecified atomic oxygen states, which may be any of the species ^3P, ^1S, or ^1D. The most prominent feature in the atmospheric displays is normally the green spin-allowed $^1S \rightarrow {}^1D$ transition appearing at 5577 angstroms.

Using transition probabilities taken from the compilation of Okabe [27] we have simulated the dynamics associated with these atomic transitions under both pulse and steady-state conditions. For the pulse simulations two starting conditions were examined: the first in which all ingredients started in the upper ^1S excited state, and the second in which the ingredients started in a distribution believed characteristic of that produced by the dissociative recombination process shown above. The simulations yield excited state lifetimes and luminescence quantum yields consistent with the experimental observations for these properties.

Second-Order Kinetics Several groups have developed cellular automata models for particular reaction-diffusion



Cellular Automata Modeling of Complex Biochemical Systems, Figure 9
Illustration of the variation with time of the ingredient populations for an irreversible reaction A → B

systems. In particular, the Belousov–Zhabotinsky oscillating reaction has been examined in a number of studies. Attention has also been directed to the simpler $A + B \rightarrow C$ reaction, using both lattice-gas models and a generalized Margolus diffusion approach. We have recently developed a simple, direct cellular automaton model [28] for hard-sphere bimolecular chemical reactions of the form

$$A + B \rightarrow C + D\,.$$

As before, the different species are assigned different colors in the visualization. In this model the reactant and product species diffuse about the grid in random walks. When the species A and B encounter each other (come to adjacent cells) on the grid the probability that these species transform to C and D is determined by an assigned reaction probability $P_r(AB)$. The simulations take place on a toroidal space such that ingredients leaving the grid on one side appear at the opposite edge. Initially the ingredients are placed randomly on the grid.

The production of species C over time for starting counts of 100 A and 200 B ingredients on a $100 \times 100 = 10\,000$ cell grid provides an example shown in Fig. 9. The expected second-order rate law

$$\frac{d[C]}{dt} = k[A][B] \tag{5}$$

is found to be obeyed in the simulations, subject to fluctuations expected for a system containing a finite number of reacting ingredients. When the results from a number of trials are combined to mimic, in effect, the results for a much larger system, the fluctuations become relatively small and the results approach the deterministic forms.

When a back reaction $C + D \rightarrow A + B$ with probability $P_r(CD)$ is included in the automaton rules the equilibrium

$$A + B \equiv C + D$$

can be simulated. Once the system has stabilized from its initial non-equilibrium concentrations, fluctuations about the equilibrium concentrations occur over time, and the relative size of these fluctuations decreases as the number of ingredients increases. A variation of this theme occurs in a pseudo first-order reaction. This type of reaction involves an actual second-order reaction $A + B \rightarrow C + D$ in which one of the reactants, say B, is present in sufficient excess that its variation becomes effectively unnoticeable. Simulations with 50 A ingredients and 1000 B ingredients bear out the expectation that the reaction kinetics are such that the rate of production of C and D appears to depend only on the concentration of A.

Enzyme Reactions

A recent study on the kinetics of an enzyme reaction considered the Michaelis–Menten model [29]. The rules selected for this reaction included a probability of the conversion, P_c, of an enzyme-substrate pair, ES, to an enzyme-product pair, EP. The Michaelis–Menten model was observed and characteristic Lineweaver–Burk plots were found from the model. The systematic variation of the hydrophobicity of substrates and products showed that a lower affinity between a substrate and water leads to a greater extent of the reaction at a common point along the reaction progress curve. This influence is greater than the influence of the affinity between the substrate and the enzyme. The water-substrate affinity appears to primarily influence the concentration of the ES complex at the observed point along the reaction progress curve. A low affinity between water and substrate favors a high ES concentration at this point. A hydrophilic substrate appears to be more entrapped in the water continuum, hence to be less available to the enzyme. It was also observed that an accumulation of product molecules around the enzymes coincides with a decline in the reaction rate. A biochemical network was reported to be modeled using cellular automata [30]. A protein kinase was modeled and studied using various concentrations of substrates and changes in enzyme competence.

An Anticipatory Model

An anticipatory enzyme system has been modeled using the dynamic characteristics of cellular automata [31]. A concentration of an intermediate product influences the competence of an enzyme down stream. This anticipation of the future event creates a condition in which the concentration of a later substrate is suppressed, a property characteristic of the system. The dynamics revealed concentrations over time, influenced by the presence or absence of a feed-forward or pre-adaptation state in the system. The concentration of A steadily diminishes as successive concentrations of B, C and D rise and fall at the same levels. The concentration of E rises at the end of the run, eventually becoming the only ingredient in the system. The concentration of D is approximately 0.25 in a non-anticipatory model. In contrast, with an anticipatory or feed-forward step in the system there is created an additional amount of enzyme specific for substrate D. This enzyme, $e_{2,4}$, is available at a future time to catalyze the conversion of D to E. This creates a property of the system in which the concentration of ingredient, D, is not allowed to accumulate to its normal level. The concentration of D in an anticipatory model is approximately 0.13, about one half of the D concentrations for the non-anticipatory models. The concentration of B therefore serves as a predictor of the concentration of D at a later time.

Micelle Formation

A micelle is a structure formed from the close interaction of hydrophobic fragments of amphiphiles plus the electrostatic encounters with the surrounding water. Typically they often assume a spherical structure with the non-polar fragments in the interior and the polar fragments on the periphery, in aqueous solution. The formation of these structures is a dynamic process which has been modeled using cellular automata. The model of an amphiphile was created by treating each face of a square automaton cell as an independent structure [32]. Each face of this variegated cell can have its own set of $P_{\mathrm{B}}(\mathrm{X})$ and $J(\mathrm{X})$ values. For the micelle study three of the faces were considered as equivalent and were endowed with rules modeling a hydrophobic or non-polar part of the amphiphile. The other face was treated as a polar fragment of the molecule and assigned characteristic rules. The outcome of the dynamics was the creation of structures in which the non-polar fragments were in the interior of an aggregation of cells while the polar fragment lay on the periphery. The interpretation of these organized clusters is that they model a micelle. The dominant influence on the formation of these structures is the extent of non-polar character of the designated three sides of the cell. Of secondary influence is the polarity of the remaining face of the cell. If this is too polar, the micelle formation is retarded. Both of these influences produce models that agree with experiment. Other studies on these variegated cells depicting an amphiphile revealed a temperature effect on the critical micelle concentration (cmc) which was minimal at about $P_{\mathrm{B}}(\mathrm{W}) = 0.25$, corresponding to experiment. The onset of the cmc was modeled and shown to be dependent upon a modestly polar fragment of the amphiphile.

Membrane Permeability

An extension of the micelle and diffusion models was a simulation of the diffusion of a solute through a layer of hydrophobic cells simulating a membrane separating two water compartments [33]. A membrane layer five cells wide membrane was positioned on a grid between two water compartments. The membrane cells were endowed with a $P_{\mathrm{B}}(\mathrm{WS})$ rule making them hydrophobic. The membrane cells could only move about within the layer according to their rule response. The two water cell compartments on either side were assigned identical rules but were colored differently in order to monitor their origins after some movement into and through the membrane layer. The dynamics revealed that water molecules from both compartments pass into and through the membrane as expected. To model the behavior of a solute in this environment, a few cells simulating solute molecules were positioned randomly near the lower edge of the membrane surface. These cells were endowed with rules making them hydrophilic. As the dynamics proceeded, it was observed that more water molecules from the upper compartment passed into and through the membrane than water from the lower compartment. Since the solute molecules were hydrophilic, the membrane was relatively impervious to their passage. The behavior of this model is in agreement with experimental observations collectively referred to as an osmotic effect. This model of diffusion was solute concentration dependent.

As the hydrophobicity of the solute increased, it was observed that an increasing number of solute particles passed through the membrane from the lower aqueous compartment. There was no accumulation of solute molecules within the membrane. At a level of hydrophobicity midway on the scale, i. e. about $P_{\mathrm{B}}(\mathrm{WS}) = 0.5$, there was a very abrupt change in this behavior. At this critical hydrophobicity the number of solute molecules passing through the membrane dropped sharply. At higher $P_{\mathrm{B}}(\mathrm{WS})$ values the number of cells passing through the membrane fell to nearly zero. At this critical hydrophobicity, the accumulation of solute molecules in the membrane increased sharply.

Chromatographic Separation

Models of chromatographic separation have been reported, derived from cellular automata [34]. The solvent cells were randomly distributed over the grid at the initiation of each run. The stationary phase, designated B is simulated by the presence of cells randomly distributed over the grid, replacing W cells. These B cells are immobile and are positioned at least 3 cells from another B cell. The solute cells, usually simulating two different compounds are represented by a few cells each. The movements of the solutes and mobile phase in the grid were governed by rules denoting the joining and breaking of like or unlike cells. The position of each solute cell was recorded at a row in the column after a certain number of iterations. The position of the peak maximum was determined by summing the number of cells found in groups of ten rows on the column then plotting these averages against the iteration time.

The gravity parameter for each ingredient in the simulation defines the flow rate. The polarity of the solvent, W, is encoded in the relative self-association experienced. This is governed by the rules, P_{B}(WW) and J(WW). The migration of the solutes was found to be faster when the solvent was non-polar. Another study modeled the influence of the relative affinities of solutes for the stationary phase, B. This affinity is encoded in the parameters, P_{B}(SB) and J(SB). High values of P_{B}(SB) and low values of J(SB) denote a weak affinity. A single solute was used in this study with five different sets of parameters. These studies revealed that solutes with a greater affinity for the stationary phase migrated at a slower rate. These parameters characterize the structural differences among solutes that give rise to different migratory rates and separations in chromatography.

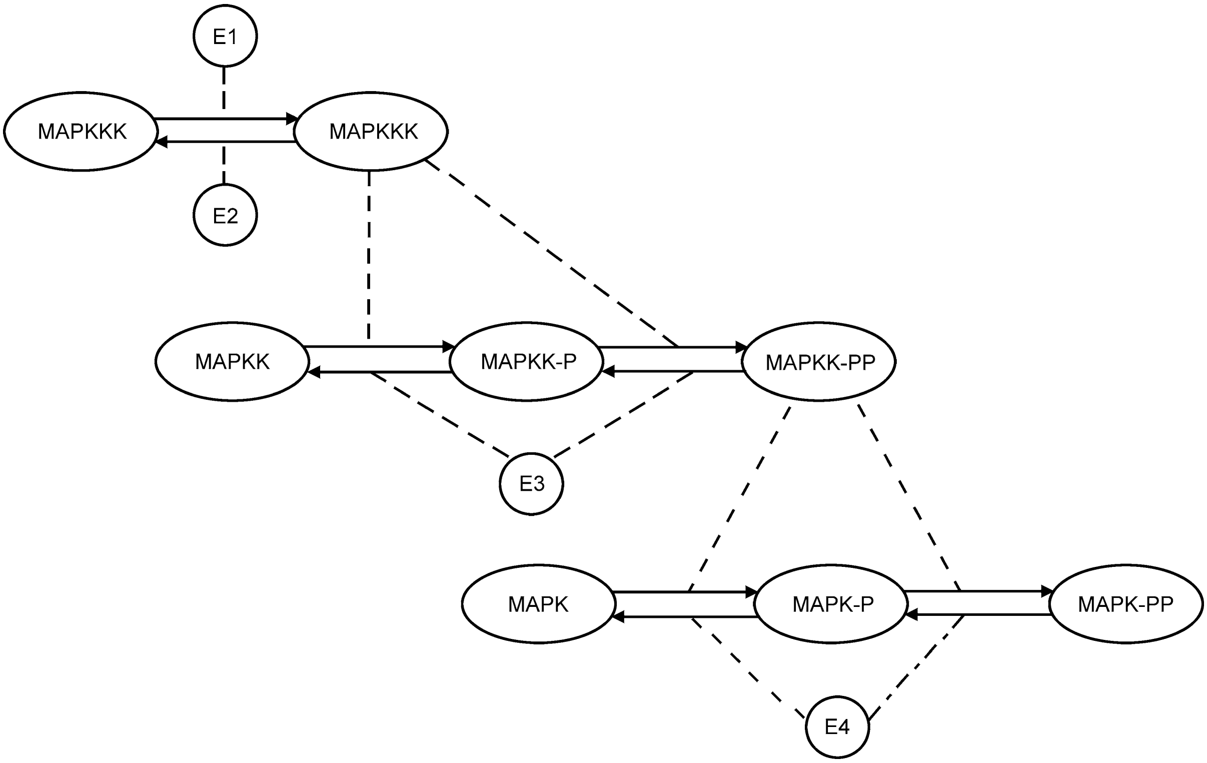
Modeling Biochemical Networks

The Network Dynamic evolutionary networks have recently been recognized as a universal approach to complex systems including biochemical systems. Network topology is generally used in characterizing these, focusing on their connectivity, neighborhood and distance relationships. Network complexity has also been recently quantitatively characterized [35]. The large size of the metabolic, protein, and gene regulatory networks makes impractical many of the traditional methods for dynamic modeling. A study on the MAPK signaling cascade has recently introduced the potential of cellular automata as a basic method for the dynamic modeling of networks for biological and medical applications [30].

The CA Modeling Design Each molecule involved in the MAPK pathway, Fig. 10, was represented by a number of cells in the CA grid. The numbers chosen reflect the relative concentration of that protein. Each of the cells representing all other proteins move about freely in the grid. They may encounter each other but this has no consequence. The only encounters that have a consequence are those between a specific protein (substrate) and a specific enzyme, as shown in the network. When such an encounter occurs, there is modeled a complex (enzyme-substrate). This complex has an assigned probability of converging to a new complex (enzyme-product). Following this there is a probability assigned for the separation of these two species.

The studies of the MAPK cascade were performed using a CA grid of 100 by 100 cells. Each model was obtained as the average of 50 runs, each of which included 5000 iterations. A network to be studied was represented by groups of CA cells, each group representing one of the network species. The number of cells in each group reflects the relative concentrations of each network ingredient. We have systematically altered the initial concentrations of several proteins (MAPKKK, MAPKK, and MAPK) and the competencies of several enzymes (MAPKK- and MAPK-proteases, and the hypothetical enzymes E1 and E2 that affect the forward and reverse reactions of activation and deactivation of MAPKKK). The basic variable was the concentration of MAPKKK, which was varied within a 25-fold range from 20 to 500 cells. The concentrations of MAPKK and MAPK were kept constant (500 or 250 cells) in most of the models. The four enzymes, denoted by E1, E2, E3, and E4, were represented in the CA grid by 50 cells each. In one series of models, we kept the transition probabilities of three of the enzymes the same, ($P = 0.1$), and varied the probability of the fourth enzyme within the 0 to 1 range. In another series, *all* enzyme probabilities were kept constant, whereas the concentrations of substrates were varied. The last series varied both substrate concentrations and enzyme propensities. Recorded were the variations in the concentrations of the three substrates MAPKKK, MAPKK, and MAPK, and the products MAPKKK*, MAPKK-P, MAPKK-PP, MAPK-P, and MAPK-PP.

Modeling Enzymes Network Activity Upgrading or downgrading enzymes activity is one of the typical ways the cell reacts to stress and interactions with pathogens. A systematic study was made of the variations of one of the four enzymes E1 to E4 at constant concentrations of the substrates MAPKKK, MAPKK and MAPK, and constant propensity of the other three enzymes. This is illustrated in Fig. 11 with the variation of the MAPKK-protease (E3 enzyme in Fig. 10), which reverses the two-step reaction of MAPKK phosphorilation. It is shown that the concentration of the MAPKK- and MAPK-diphos-



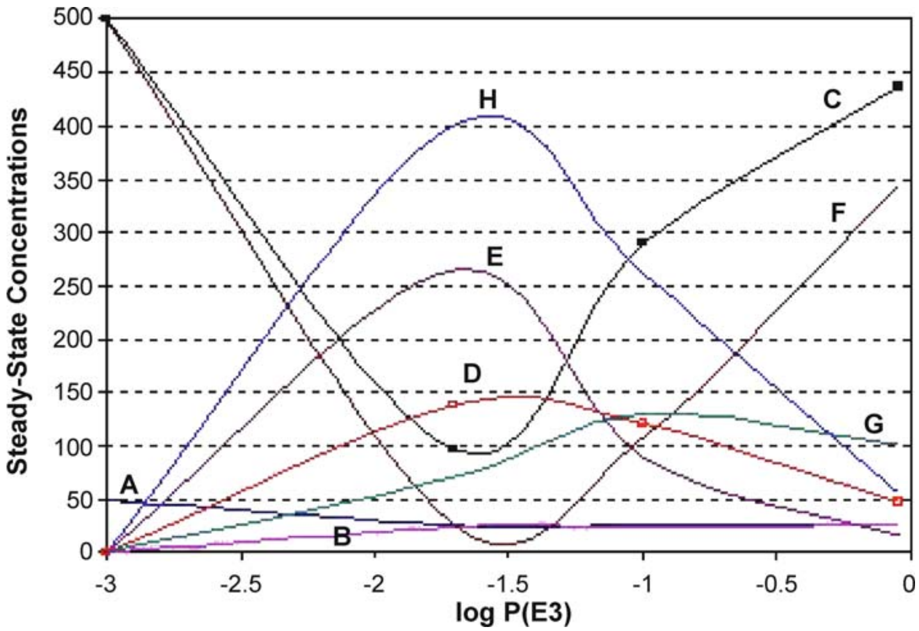
Cellular Automata Modeling of Complex Biochemical Systems, Figure 10
The MAPK signaling cascade. The substrates and products are represented by *oval contours*, reactions by *arrows*, and the catalysts action by *dashed lines*. E3 and E4 are MAPKK-protease and MAPK-protease, respectively. P stands for phosphate, PP for diphosphate

phates (marked as E and H respectively) passes through a maximum near relatively low enzyme transition probability ($P \approx 0.02$). At the point of its maximum, the concentration of MAPK-PP reaches over 80% of its maximum, whereas that of MAPKK-PP is slightly over 50%. This shows the potential for a strong influence on the concentrations of the two diphosphates in the MAPK cascade by inhibiting the MAPKK-protease. In contrast, the level of steady-state concentrations of the two monophosphates (marked by D and G in Fig. 11) is not sensitive to the activity of the enzyme modeled, except for the extreme case of very strong inhibition ($P \to 0.001$).

Future Directions

Applications of cellular automata as a modeling paradigm in chemistry is in its infancy. Literature searches show little attention to the use of this method to study chemical phenomena. Chemistry is about dynamic systems, thus a rich harvest of information is possible using this paradigm. This potential is illustrated here where primarily solution systems are modeled. A broader use is clearly on the horizon.

The study of bulk water structure is one example of this potential. It points to a way of encoding the structure of an evanescent substance with some degree of validity. A recent example of this potential is a series of studies of the influence of protein surface amino acid side chains on the structure of nearby water [36]. Because of the varying hydropathic states of the surface side chains, a series of passageways (chreodes) was postulated to exist through the water. These chreodes were invoked in the facilitated 2-D diffusion of ligands and substrates to receptors and enzyme active sites. The interference of these chreodes was proposed in a theory of the action of general anesthetics. As an extension of this theory, the induction of sleep was proposed to arise from the interference of these chreodes by elemental nitrogen accumulated through respiration over several hours. The remarkable correspondence of kinetic and enzyme CA models with reality is excellent and foretells the use of these in many applications. The treatment of networks, foretells of another area of great



Cellular Automata Modeling of Complex Biochemical Systems, Figure 11
Influence of the MAPKK-protease propensity *P*(E3) on the steady-state concentrations of the MAPK cascade species (A = MAPKKK, B = MAPKKK*, C = MAPKK, D = MAPKK-P, E = MAPKK-PP, F = MAPK, F = MAPK-P, H = MAPK-PP). Enzyme propensities *P*(E1) = *P*(E2) = *P*(E4) = 0.1, substrate initial concentrations $[A_o] = 50$, $[C_o] = [F_o] = 500$

possibilities of models with CA. The beginning of this approach is shown above with the MAPK mode. There is success here that is not achievable with classical differential equations.

A noteable advantage and a golden opportunity exists for any CA chemical model. That is the didactic value of any CA model. You can see the dissolution of a crystal, the changes of concentration in a CA enzyme model, the changes in structure as the temperature changes, and many more. A student will never forget a CA model of these while an equation is quietly forgotten.

New aspects of CA models are on the horizon. Multidimensional models, nested hierarchies, multi-grid assemblies, all are being explored and will soon surface as viable methods rich in information.

Selected Bibliography of Works on Cellular Automata

At this time thousands of scientific articles have been published describing cellular automata studies of topics ranging from applications dealing with physical and biological systems to investigations of traffic control and topics in the social sciences. It would be impossible to describe all of these studies within a limited space, but it may be useful to provide a short list of representative investigations on a limited variety of topics, permitting starting points for readers who might wish to further examine applications in these more narrow subjects. Below we give a short selection of publications, some of which, although not explicitly referring to CA, cover the same approach or a related approach.

Article Outline

Cellular automata offer a powerful modeling framework to describe and study physical systems composed of interacting components. The potential of this approach is demonstrated in the case of applications taken from various fields of physics, such as reaction-diffusion systems, pattern formation phenomena, fluid flows and road traffic models.

Glossary

BGK models Lattice Boltzmann models where the collision term Ω is expressed as a deviation from a given local equilibrium distribution $f^{(0)}$, namely $\Omega = (f^{(0)} - f)/\tau$, where f is the unknown particle distribution and τ a relaxation time (which is a parameter of the model). BGK stands for Bhatnager, Gross and Krook who first considered such a collision term, but not specifically in the context of lattice systems.

CA Abbreviation for cellular automata or cellular automaton.

Cell The elementary spatial component of a CA. The cell is characterized by a state whose value evolves in time according to the CA rule.

Cellular automaton System composed of adjacent cells or sites (usually organized as a regular lattice) which evolves in discrete time steps. Each cell is characterized by an internal state whose value belongs to a finite set. The updating of these states is made in parallel according to a local rule involving only a neighborhood of each cell.

Conservation law A property of a physical system in which some quantity (such as mass, momentum or energy) is locally conserved during the time evolution. These conservation laws should be included in the microdynamics of a CA model because they are essential ingredients governing the macroscopic behavior of any physical system.

Collision The process by which the particles of a LGA change their direction of motion.

Continuity equation An equation of the form $\partial_t \rho + \operatorname{div} \rho \mathbf{u} = 0$ expressing the mass (or particle number) conservation law. The quantity ρ is the local density of particles and $\mathbf{u}$ the local velocity field.

Critical phenomena The phenomena which occur in the vicinity of a continuous phase transition, and are characterized by very long correlation length.

Diffusion A physical process described by the equation $\partial_t \rho = D\nabla^2 \rho$, where ρ is the density of a diffusing substance. Microscopically, diffusion can be viewed as a random motion of particles.

DLA Abbreviation of Diffusion Limited Aggregation. Model of a physical growth process in which diffusing particles stick on an existing cluster when they hit it. Initially, the cluster is reduced to a single seed particle and grows as more and more particles arrive. A DLA cluster is a fractal object whose dimension is typically 1.72 if the experiment is conducted in a two-dimensional space.

Dynamical system A system of equations (differential equations or discretized equations) modeling the dynamical behavior of a physical system.

Equilibrium states States characterizing a closed system or a system in thermal equilibrium with a heat bath.

Ergodicity Property of a system or process for which the time-averages of the observables converge, in a probabilistic sense, to their ensemble averages.

Exclusion principle A restriction which is imposed on LGA or CA models to limit the number of particles per site and/or lattice directions. This ensures that the dynamics can be described with a cellular automata rule with a given maximum number of bits. The consequence of this exclusion principle is that the equilibrium distribution of the particle numbers follows a Fermi–Dirac-like distribution in LGA dynamics.

FHP model Abbreviation for the Frisch, Hasslacher and Pomeau lattice gas model which was the first serious candidate to simulate two-dimensional hydrodynamics on a hexagonal lattice.

Fractal Mathematical object usually having a geometrical representation and whose spatial dimension is not an integer. The relation between the size of the object and its "mass" does not obey that of usual geometrical objects. A DLA cluster is an example of a fractal.

Front The region where some physical process occurs. Usually the front includes the locations in space that are first affected by the phenomena. For instance, in a reaction process between two spatially separated reactants, the front describes the region where the reaction takes place.

HPP model Abbreviation for the Hardy, de Pazzis and Pomeau model. The first two-dimensional LGA aimed at modeling the behavior of particles colliding on a square lattice with mass and momentum conservation. The HPP model has several physical drawbacks that have been overcome with the FHP model.

Invariant A quantity which is conserved during the evolution of a dynamical system. Some invariants are imposed by the physical laws (mass, momentum, energy) and others result from the model used to describe physical situations (spurious, staggered invariants). Collisional invariants are constant vectors in the space where the Chapman–Enskog expansion is performed, associated to each quantity conserved by the collision term.

Ising model Hamiltonian model describing the ferromagnetic paramagnetic transition. Each local classical spin variables $s_i = \pm 1$ interacts with its neighbors.

Isotropy The property of continuous systems to be invariant under any rotations of the spatial coordinate system. Physical quantities defined on a lattice and obtained by an averaging procedure may or may not be isotropic, in the continuous limit. It depends on the type of lattice and the nature of the quantity. Second-order tensors are isotropic on a 2D square lattice but fourth-order tensors need a hexagonal lattice.

Lattice The set of cells (or sites) making up the spatial area covered by a CA.

Lattice Boltzmann model A physical model defined on a lattice where the variables associated to each site represent an average number of particles or the probability of the presence of a particle with a given velocity. Lattice Boltzmann models can be derived from cellular automata dynamics by an averaging and factorization procedure, or be defined per se, independently of a specific realization.

Lattice gas A system defined on a lattice where particles are present and follow given dynamics. Lattice gas automata (LGA) are a particular class of such a system where the dynamics are performed in parallel over all the sites and can be decomposed in two stages: (i) propagation: the particles jump to a nearest-neighbor site, according to their direction of motion and (ii) collision: the particles entering the same site at the same iteration interact so as to produce a new particle distribution. HPP and FHP are well-known LGA.

Lattice spacing The separation between two adjacent sites of a regular lattice. Throughout this book, it is denoted by the symbol Δ_r.

LB Abbreviation for Lattice Boltzmann.

LGA Abbreviation for Lattice Gas Automaton. See lattice gas model for a definition.

Local equilibrium Situation in which a large system can be decomposed into subsystems, very small on a macroscopic scale but large on a microscopic scale such that each sub-system can be assumed to be in thermal equilibrium. The local equilibrium distribution is the function which makes the collision term of a Boltzmann equation vanish.

Lookup table A table in which all possible outcomes of a cellular automata rule are pre-computed. The use of a lookup table yields a fast implementation of a cellular automata dynamics since however complicated a rule is, the evolution of any configuration of a site and its neighbors is directly obtained through a memory access. The size of a lookup table grows exponentially with the number of bits involved in the rule.

Margolus neighborhood A neighborhood made of two-by-two blocks of cells, typically in a two-dimensional square lattice. Each cell is updated according to the values of the other cells in the same block. A different rule may possibly be assigned dependent on whether the cell is at the upper left, upper right, lower left or lower right location. After each iteration, the lattice partition defining the Margolus blocs is shifted one cell right and one cell down so that at every other step, information can be exchanged across the lattice. Can be generalized to higher dimensions.

Microdynamics The Boolean equation governing the time evolution of a LGA model or a cellular automata system.

Moore neighborhood A neighborhood composed of the central cell and all eight nearest and next-nearest neighbors in a two-dimensional square lattice. Can be generalized to higher dimensions.

Multiparticle models Discrete dynamics modeling a physical system in which an arbitrary number of particles is allowed at each site. This is an extension of an LGA where no exclusion principle is imposed.

Navier–Stokes equation The equation describing the velocity field **u** in a fluid flow. For an incompressible fluid ($\partial_t \rho = 0$), it reads

$$\partial_t \mathbf{u} + (\mathbf{u} \cdot \nabla)\mathbf{u} = -\frac{1}{\rho}\nabla P + \nu \nabla^2 \mathbf{u}$$

where ρ is the density and P the pressure. The Navier–Stokes equation expresses the local momentum conservation in the fluid and, as opposed to the Euler equation, includes the dissipative effects with a viscosity term $\nu \nabla^2 \mathbf{u}$. Together with the continuity equation, this is the fundamental equation of fluid dynamics.

Neighborhood The set of all cells necessary to compute a cellular automaton rule. A neighborhood is usually composed of several adjacent cells organized in a simple geometrical structure. Moore, von Neumann and Margolus neighborhoods are typical examples.

Occupation numbers Boolean quantities indicating the presence or absence of a particle in a given physical state.

Open system A system communicating with the environment by exchange of energy or matter.

Parallel Refers to an action which is performed simultaneously at several places. A parallel updating rule corresponds to the updating of all cells at the same time as if resulting from the computations of several independent processors.

Partitioning A technique consisting of dividing space in adjacent domains (through a partition) so that the evolution of each block is uniquely determined by the states of the elements within the block.

Phase transition Change of state obtained when varying a control parameter such as the one occurring in the boiling or freezing of a liquid, or in the change between ferromagnetic and paramagnetic states of a magnetic solid.

Propagation This is the process by which the particles of a LGA are moved to a nearest neighbor, according to the direction of their velocity vector $\mathbf{v_i}$. In one time step Δ_t the particle travel from cell $\mathbf{r}$ to cell $\mathbf{r} + \mathbf{v_i}\Delta_t$ where $\mathbf{r} + \mathbf{v_i}\Delta_t$ is the nearest neighbor in lattice direction i.

Random walk A series of uncorrelated steps of length unity describing a random path with zero average displacement but characteristic size proportional to the square root of the number of steps.

Reaction-diffusion systems Systems made of one or several species of particles which diffuse and react among themselves to produce some new species.

Scaling hypothesis A hypothesis concerning the analytical properties of the thermodynamic potentials and the correlation functions in a problem invariant under a change of scale.

Scaling law Relations among the critical exponents describing the power law behaviors of physical quantities in systems invariant under a change of scale.

Self-organized criticality Concept aimed at describing a class of dynamical systems which naturally drive themselves to a state where interesting physics occurs at all scales.

Site Same as a cell, but preferred terminology in LGA and LB models.

Spatially extended systems Physical systems involving many spatial degrees of freedom and which, usually, have rich dynamics and show complex behaviors. Coupled map lattices and cellular automata provides a way to model spatially extended systems.

Spin Internal degree of freedom associated to particles in order to describe their magnetic state. A widely used case is the one of classical Ising spins. To each particle, one associates an "arrow" which is allowed to take only two different orientations, up or down.

Time step Interval of time separating two consecutive iterations in the evolution of a discrete time process, like a CA or a LB model. Throughout this work the time step is denoted by the symbol Δ_t.

Universality The phenomenon whereby many microscopically different systems exhibit a critical behavior with quantitatively identical properties such as the critical exponents.

Updating operation consisting of assigning a new value to a set of variables, for instance those describing the states of a cellular automata system. The updating can be done in parallel and synchronously as is the case in CA dynamics or sequentially, one variable after another, as is usually the case for Monte–Carlo dynamics. Parallel, asynchronous updating is less common but can be envisaged too. Sequential and parallel updating schemes may yield different results since the interdependencies between variables are treated differently.

Viscosity A property of a fluid indicating how much momentum "diffuses" through the fluid in a inhomogeneous flow pattern. Equivalently, it describes the stress occurring between two fluid layers moving with different velocities. A high viscosity means that the resulting drag force is important and low viscosity means that this force is weak. Kinematic viscosity is usually denoted by ν and dynamic viscosity is denoted by $\eta = \nu\rho$ where ρ is the fluid density.

von Neumann neighborhood On a two-dimensional square lattice, the neighborhood including a central cell and its nearest neighbors north, south, east and west.

Ziff model A simple model describing adsorption–dissociation–desorption on a catalytic surface. This model is based upon some of the known steps of the reaction A–B_2 on a catalyst surface (for example CO–O_2).

Definition of the Subject

The computational science community has always been faced with the challenge of bringing efficient numerical tools to solve problems of increasing difficulty. Nowadays, the investigation and understanding of the so-called complex systems, and the simulation of all kinds of phenomena originating from the interaction of many components are of central importance in many area of science.

Cellular automata turn out to be a very fruitful approach to address many scientific problems by providing an efficient way to model and simulate specific phenomena for which more traditional computational techniques are hardly applicable.

The goal of this article is to provide the reader with the foundation of this approach, as well as a selection of simple applications of the cellular automata approach to the modeling of physical systems. We invite the reader to consult the web site http://cui.unige.ch/~chopard/CA/Animations/img-root.html in order to view short movies about several of the models discussed in this article.

Introduction

Cellular automata (hereafter termed CA) are an idealization of the physical world in which space and time are of discrete nature. In addition to space and time, the physical quantities also take only a finite set of values. Since it has been proposed by von Neumann in the late 1940s, the cellular automata approach has been applied to a large range of scientific problems (see for instance [4,10,16,35,42,51]). International conferences (e. g. ACRI) and dedicated journals (J. of Cellular Automata) also describe current developments.

When von Neumann developed the concept of CA, its motivation was to extract the abstract (or algorithmic) mechanisms leading to self-reproduction of biological organisms [6].

Following the suggestions of S. Ulam, von Neumann addressed this question in the framework of a fully discrete universe made up of simple cells. Each cell was characterized by an internal state, which typically consists of a finite number of information bits. Von Neumann suggested that this system of cells evolves, in discrete time steps, like simple automata which only know of a simple recipe to compute their new internal state. The rule determining the evolution of this system is the same for all cells and is a function of the states of the cell itself and its neighbors.

Similarly to what happens in any biological system, the activity of the cells takes place simultaneously. The same clock is assumed to drive the evolution of every cell and the updating of their internal state occurs synchronously.

Such a fully discrete dynamical system (cellular space), as invented by von Neumann, is now referred to as a cellular automaton.

Among the early applications of CA, the *game of life* [19] is famous. In 1970, the mathematician John Conway proposed a simple model leading to complex behaviors. He imagined a two-dimensional square lattice, like a checkerboard, in which each cell can be either alive (state one) or dead (state zero). The updating rule of the game of life is as follows: a dead cell surrounded by exactly three living cells gets back to life; a living cell surrounded by less than two or more than three neighbors dies of isolation or overcrowdness. Here, the surrounding cells correspond to the neighborhood composed of the four nearest cells (North, South, East and West), plus the four second nearest neighbors, along the diagonals. It turns out that the game of life automaton has an unexpectedly rich behavior. Complex structures emerge out of a primitive "soup" and evolve so as to develop some skills that are absent of the elementary cells (see Fig. 1).

The game of life is a cellular automata capable of universal computations: it is always possible to find an initial configuration of the cellular space reproducing the behavior of any electronic gate and, thus, to mimic any computation process. Although this observation has little practical interest, it is very important from a theoretical point of view since it assesses the ability of CAs to be a nonrestrictive computational technique.

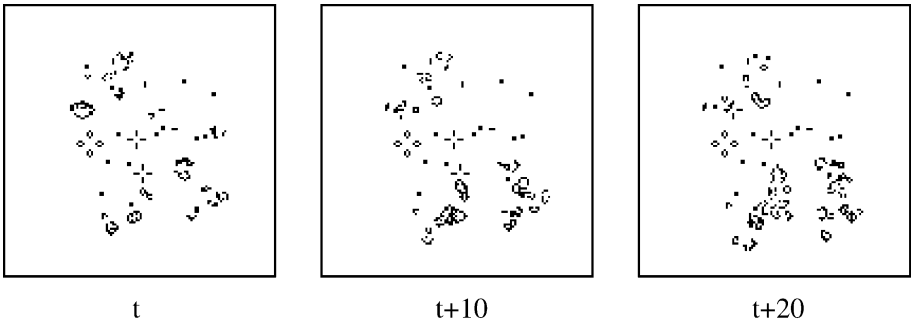
A very important feature of CAs is that they provide simple models of complex systems. They exemplify the fact that a collective behavior can emerge out of the sum of many, simply interacting, components. Even if the basic and local interactions are perfectly known, it is possible that the global behavior obeys new laws that are not obviously extrapolated from the individual properties, as if the whole were more than the sum of all the parts. These properties make cellular automata a very interesting approach to model physical systems and in particular to simulate complex and nonequilibrium phenomena.

The studies undertaken by S. Wolfram in the 1980s [50,51] clearly establishes that a CA may exhibit many of the behaviors encountered in continuous systems, yet in a much simpler mathematical framework. A further step is to recognize that CAs are not only behaving similarly to some dynamical processes, they can also represent an actual model of a given physical system, leading to macroscopic predictions that could be checked experimentally.

This fact follows from statistical mechanics which tells us that the macroscopic behavior of many systems is often only weakly related to the details of its microscopic reality. Only symmetries and conservation laws survive to the change of observation level: it is well known that the flows of a fluid, a gas or even a granular media are very similar at a macroscopic scale, in spite of their different microscopic nature.

When one is interested in the global or macroscopic properties of a system, it is therefore a clear advantage to invent a much simpler microscopic reality, which is more appropriate to the available numerical means of investigation.

An interesting example is the FHP fluid model proposed by Frisch, Hasslacher and Pomeau in 1986 [18] which can be viewed as a fully discrete molecular dynamic and yet behaves as predicted by the Navier–Stokes equation when the observation time and length scales are much larger than the lattice and automaton time step.



Cellular Automata Modeling of Physical Systems, Figure 1

The game of life automaton. *Black dots* represent living cells whereas dead cells are *white*. The figure shows the evolution of a random initial configuration and the formation of spatial structures, with possibly some emerging functionalities. The figure shows the evolution of some random initial configurations

A cellular automata model can then be seen as an idealized universe with its own microscopic reality but, nevertheless, with the same macroscopic behavior as given in the real system.

The cellular automata paradigm presents nevertheless some weaknesses inherent to its discrete nature. In the early 1990s, Lattice Boltzmann (LB) models were proposed to remedy some of these problems, using real-valued states instead of Boolean variables. It turns out that LB models are indeed a very powerful approach which combines numerical efficiency with the advantage of having a model whose microscopic components are intuitive. LB-fluids are more and more used to solve complex flows such as multi-component fluids or complicated geometries problems. See for instance [10,40,41,49] for an introduction to LB models.

Definition of a Cellular Automata

In order to give a definition of a cellular automaton, we first present a simple example, the so-called parity rule. Although it is very basic, the rule we discuss here exhibits a surprisingly rich behavior. It was proposed initially by Edward Fredkin in the 1970s [3] and is defined on a two-dimensional square lattice.

Each site of the lattice is a cell which is labeled by its position $\mathbf{r} = (i, j)$ where i and j are the row and column indices. A function $\psi(\mathbf{r}, t)$ is associated with the lattice to describe the state of each cell $\mathbf{r}$ at iteration t. This quantity can be either 0 or 1.

The cellular automata rule specifies how the states $\psi(\mathbf{r}, t+1)$ are to be computed from the states at iteration t. We start from an initial condition at time $t = 0$ with a given configuration of the values $\psi(\mathbf{r}, t = 0)$ on the lattice. The state at time $t = 1$ will be obtained as follows

(1) Each site $\mathbf{r}$ computes the sum of the values $\psi(\mathbf{r}', 0)$ on the four nearest neighbor sites $\mathbf{r}'$ at north, west, south, and east. The system is supposed to be periodic in both i and j directions (like on a torus) so that this calculation is well defined for all sites.

(2) If this sum is even, the new state $\psi(\mathbf{r}, t = 1)$ is 0 (white) and, else, it is 1 (black).

The same rule (steps 1 and 2) is repeated over to find the states at time $t = 2, 3, 4, \ldots$.

From a mathematical point of view, this cellular automata parity rule can be expressed by the following relation

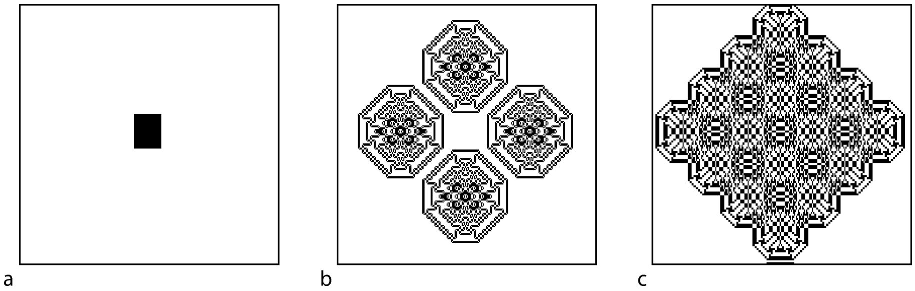
$$\begin{aligned}\psi(i, j, t+1) = &\psi(i+1, j, t) \oplus \psi(i-1, j, t)\\ &\oplus \psi(i, j+1, t) \oplus \psi(i, j-1, t)\end{aligned} \quad (1)$$

where the symbol $\oplus$ stands for the exclusive OR logical operation. It is also the sum modulo 2: $1 \oplus 1 = 0 \oplus 0 = 0$ and $1 \oplus 0 = 0 \oplus 1 = 1$.

When this rule is iterated, very nice geometric patterns are observed, as shown in Fig. 2. This property of generating complex patterns starting from a simple rule is generic of many cellular automata rules. Here, complexity results from some spatial organization which builds up as the rule is iterated. The various contributions of successive iterations combine together in a specific way. The spatial patterns that are observed reflect how the terms are combined algebraically.

A computer implementation of this CA can be given. In Fig. 3 we propose as, an illustration, a Matlab program (the reader can also consider Octave which is a free version of Matlab).

On the basis of this example we now give a definition of a cellular automata. Formally, a cellular automata is a tuple $(A, \Psi, R, \mathcal{N})$ where



Cellular Automata Modeling of Physical Systems, Figure 2
The ⊕ rule (or parity rule) on a 256 × 256 periodic lattice. a Initial configuration; b and c configurations after $t_b = 93$ and $t_c = 110$ iterations, respectively

```
nx=128; ny=128;  % size of the domain: 128x128
a=zeros(nx,ny);  % the states are first initialized to 0

north=[ 2:nx,1];    % vectors to access the neighbors
south=[nx, 1:nx-1]; % corresponding to a cyclic permutation
east=[2:ny,1];      % of 1:nx  or 1:ny
west=[ny,1:ny-1];

% a central patch  is initialized with 1's
a(nx/2-3:nx/2+2, ny/2-4:ny/2+3)=1;

for t=1:65   % let us do 65 iterations
     pcolor(a)       % build a graphical representation
     axis off
     axis square
     shading flat
     drawnow         % display it
     somme=a(north,:) + a(south,:) + a(:,west) + a(:,east);
     a=mod(somme,2);
end
```

Cellular Automata Modeling of Physical Systems, Figure 3
A example of a Matlab program for the parity rule

(i) A is a regular lattice of cells covering a portion of a d-dimensional space.

(ii) A set $\Psi(\mathbf{r},t) = \{\Psi^{(1)}(\mathbf{r},t), \Psi^{(2)}(\mathbf{r},t), \ldots, \Psi^{(m)}(\mathbf{r},t)\}$ of m Boolean variables attached to each site $\mathbf{r}$ of the lattice and giving the local state of the cells at time t.

(iii) A set R of rules, $R = \{R^{(1)}, R^{(2)}, \ldots, R^{(m)}\}$, which specifies the time evolution of the states $\Psi(\mathbf{r},t)$ in the following way

$$\Psi^{(j)}(\mathbf{r}, t+\Delta_t) = R^{(j)}(\Psi(\mathbf{r},t), \Psi(\mathbf{r}+\mathbf{v_1},t), \\ \Psi(\mathbf{r}+\mathbf{v_2},t), \ldots, \Psi(\mathbf{r}+\mathbf{v_q},t)) \tag{2}$$

where $\mathbf{r}+\mathbf{v_k}$ designate the cells belonging to the neighborhood $\mathcal{N}$ of cell $\mathbf{r}$.

In the above definition, the rule R is identical for all sites and is applied simultaneously to each of them, leading to synchronous dynamics. As the number of configurations of the neighborhood is finite, it is common to precompute all the values of R in a lookup table. Otherwise, an algebraic expression can be used and evaluated at each iteration, for each cell, as in Eq. (1).

It is important to notice that the rule is *homogeneous*, that is it cannot not depend explicitly on the cell position $\mathbf{r}$. However, spatial (or even temporal) inhomogeneities can be introduced anyway by having some $\Psi_j(\mathbf{r})$ systematically

1 in some given locations of the lattice to mark particular cells on which a different rule applies. Boundary cells are a typical example of spatial inhomogeneities. Similarly, it is easy to alternate between two rules by having a bit which is 1 at even time steps and 0 at odd time steps.

The neighborhood $\mathcal{N}$ of each cell (i. e. the spatial region around each cell used to compute the next state) is usually made of its adjacent cells. It is often restricted to the nearest or next to nearest neighbors, otherwise the complexity of the rule is too large. For a two-dimensional cellular automaton, two neighborhoods are often considered: the von Neumann neighborhood which consists of a central cell (the one which is to be updated) and its four geographical neighbors North, West, South, and East. The Moore neighborhood contains, in addition, the second nearest neighbor North-East, North-West, South-West, and South-East, that is a total of nine cells. Another interesting neighborhood is the Margolus neighborhood briefly described in the glossary.

According to the above definition, a cellular automaton is deterministic. The rule **R** is some well-defined function and a given initial configuration will always evolve identically. However, it may be very convenient for some applications to have a certain degree of randomness in the rule. For instance, it may be desirable that a rule selects one outcome among several possible states, with a probability p. Cellular automata whose updating rule is driven by some external probabilities are called *probabilistic* cellular automata. On the other hand, those which strictly comply with the definition given above, are referred to as *deterministic* cellular automata.

Probabilistic cellular automata are a very useful generalization because they offer a way to adjust the parameters of a rule in a continuous range of values, despite the discrete nature of the cellular automata world. This is very convenient when modeling physical systems in which, for instance, particles are annihilated or created at some given rate.

Limitations, Advantages, Drawbacks, and Extensions

The interpretation of the cellular automata dynamics in terms of simple "microscopic" rules offers a very intuitive and powerful approach to model phenomena that are very difficult to include in more traditional approaches (such as differential equations). For instance, boundary conditions are often naturally implemented in a cellular automata model because they have a natural interpretation at this level of description (e. g. particles bouncing back on an obstacle).

Numerically, an advantage of the CA approach is its simplicity and its adequation to computer architectures and parallel machines. In addition, working with Boolean quantities prevent numerical instabilities since an exact computation is made. There is no truncation or approximation in the dynamics itself. Finally, a CA model is an implementation of an N-body system where all correlations are taken into account, as well as all spontaneous fluctuations arising in a system made up of many particles.

On the other hand, cellular automata models have several drawbacks related to their fully discrete nature. An important one is the statistical noise requiring systematic averaging processes. Another one is the little flexibility to adjust parameters of a rule in order to describe a wider range of physical situations.

The Lattice Boltzmann approach solves several of the above problems. On the other hand, it may be numerically unstable and, also, requires some hypotheses of molecular chaos which reduces the some of the richness of the original CA dynamics [10].

Finally, we should remark that the CA approach is not a rigid framework but should allow for many extensions according to the problem at hand. The CA methodology is a philosophy of modeling where one seeks a description in terms of simple but essential mechanisms. Its richness and interest comes from the microscopic contents of its rule for which there is, in general, a clear physical or intuitive interpretation of the dynamics directly at the level of the cell.

Einstein's quote "Everything should be made as simple as possible, but not simpler" is a good illustration of the CA methodology to the modeling of physical systems.

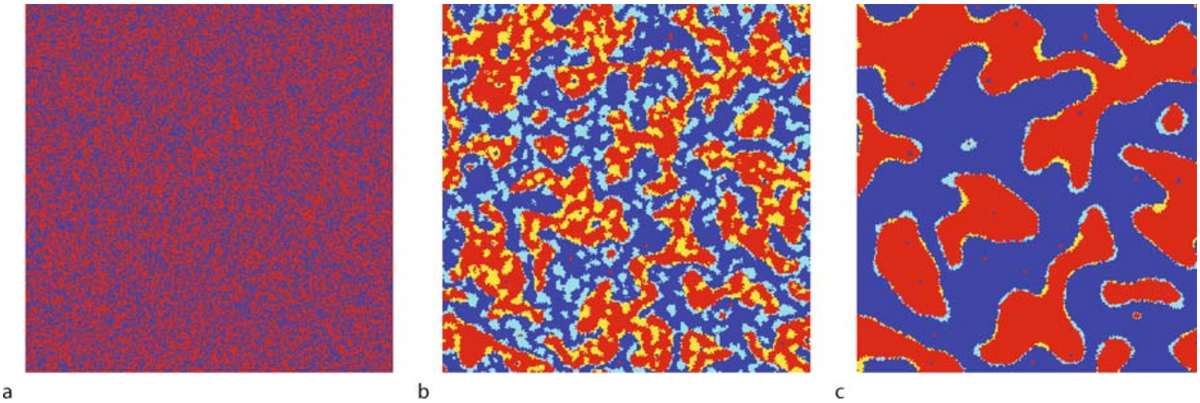
Applications

Many physical situations, like fluid flows, pattern formation, reaction-diffusion processes, nucleation-aggregation growth phenomena, phase transition, population dynamics, or traffic processes are very well suited to the cellular automata approach because both space and time play a central role in the behavior of these systems.

Below we describe several applications which illustrate the potential of the approach and that can be extended in order to address a wide class of scientific problems.

A Growth Model

A simple class of cellular automata rules consists of the so-called *majority rules*. The updating selects the new state of each cell so as to conform to the value currently held by the majority of the neighbors. Typically, in these majority rules, the state is either 0 or 1.



Cellular Automata Modeling of Physical Systems, Figure 4
Evolution of the twisted majority. The inherent "surface tension" present in the rule tends to separate the *red phases* $s = 1$ from the blue phase $s = 0$. The snapshots a, b and c correspond to $t = 0$, $t = 72$, and $t = 270$ iterations, respectively. The other colors indicate how "capes" have been eroded and "bays" filled: *light blue* shows the blue regions that have been eroded during the last few iterations and *yellow* marks the red regions that have been filled

A very interesting behavior is observed with the twisted majority rule proposed by G. Vichniac [44]: in two-dimensions, each cell considers its Moore neighborhood (i. e. itself plus its eight nearest neighbors) and computes the sum of the cells having a value 1. This sum can be any value between 0 and 9. The new state $s(t+1)$ of each cell is then determined from this local sum, according to the following table

$$\begin{array}{ccccccccccc} \text{sum}(t) & 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ s(t+1) & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 & 1 \end{array} \tag{3}$$

As opposed to the plain majority rule, here, the two middle entries of the table have been swapped. Therefore, when there is a slight majority of 1 around a cell, it turns to 0. Conversely, if there is a slight majority of 0, the cell becomes 1.

Surprisingly enough this rule describes the interface motion between two phases, as illustrated in Fig. 4. Vichniac has observed that the normal velocity of the interface is proportional to its local curvature, as required by the Allen–Cahn [21] equation. Of course, due to its local nature, the rule cannot detect the curvature of the interface directly. However, as the rule is iterated, local information is propagated to the nearest neighbors and the radius of curvature emerges as a collective effect.

This rule is particularly interesting when the initial configuration is a random mixture of the two phases, with equal concentration. Otherwise, some pathological behaviors may occur. For instance, an initial square of 1's surrounded by zero's will not evolve: 90-degree angles are not eroded and remain stable structures.

Ising-Like Dynamics

The Ising model is extensively used in physics. Its basic constituents are spins s_i which can be in one of two states: $s_i \in \{-1, 1\}$. These spins are organized on a regular lattice in d-dimensions and coupled in the sense that each pair (s_i, s_j) of neighbor spins contributes an amount $-Js_is_j$ to the energy of the system. Intuitively, the dynamics of such a system is that a spin flips ($s_i \to -s_i$) if this is favorable in view of the energy of the local configuration.

Vichniac [44], in the 1980s, proposed a CA rule, called Q2R, simulating the behavior of Ising spin dynamics. The model is as follows:

We consider a two-dimensional square lattice such that each site holds a spin s_i which is either up ($s_i = 1$) or down ($s_i = 0$) (instead of ±1). The coupling between spins is assumed to come from the von Neumann neighborhood (i. e. north, west, south, and east neighbors).

In this simple model, the spins will flip (or not flip) during their discrete time evolution according to a local energy conservation principle. This means we are considering a system which cannot exchange energy with its surroundings. The model will be a microcanonical cellular automata simulation of Ising spin dynamics, without a temperature but with a critical energy.

A spin s_i can flip at time t to become $1 - s_i$ at time $t+1$ if and only if this move does not cause any energy change. Accordingly, spin s_i will flip if the number of its neighbors with spin up is the same as the number of its neighbors with spin down. However, one has to remember that the motion of all spins is simultaneous in a cellular automata. The decision to flip is based on the assumption that the neighbors are not changing. If they are allowed to flip too, (because they obey the same rule), then energy may not be conserved.

A way to cure this problem is to split the updating in two phases and consider a partition of the lattice in odd and even sites (e. g. the white and black squares of a chessboard in 2D): first, one flips the spins located at odd positions, according to the configuration of the even spins. In the second phase, the even sublattice is updated according to the odd one. The spatial structure (defining the two sublattices) is obtained by adding an extra bit b to each lattice site, whose value is 0 for the odd sublattice and 1 for the even sublattice. The flipping rule described earlier is then regulated by the value of b. It takes place only for those sites for which $b = 1$. Of course, the value of b is also updated at each iteration according to $b(t + 1) = 1 - b(t)$, so that at the next iteration, the other sublattice is considered. In two-dimensions, the Q2R rule can be then expressed by the following expressions

$$s_{ij}(t{+}1) = \begin{cases} 1 - s_{ij}(t) & \text{if } b_{ij} = 1 \text{ and } s_{i-1,j} \\ & +s_{i+1,j} + s_{i,j-1} + s_{i,j+1} = 2 \\ s_{ij}(t) & \text{otherwise} \end{cases} \tag{4}$$

and

$$b_{ij}(t + 1) = 1 - b_{ij}(t) \tag{5}$$

where the indices (i, j) label the Cartesian coordinates and $s_{ij}(t = 0)$ is either one or zero.

The question is now how well does this cellular automata rule perform to describe an Ising model? Figure 5 shows a computer simulation of the Q2R rule, starting from an initial configuration with approximately 11% of spins $s_{ij} = 1$ (Fig. 5a). After a transient phase (figures b and c), the system reaches a stationary state where domains with "up" magnetization (white regions) are surrounded by domains of "down" magnetization (black regions).

In this dynamics, energy is exactly conserved because that is the way the rule is built. However, the number of spins down and up may vary. In the present experiment, the fraction of spins up increases from 11% in the initial state to about 40% in the stationary state. Since there is an excess of spins down in this system, there is a resulting macroscopic magnetization.

It is interesting to study this model with various initial fractions ρ_s of spins up. When starting with a random initial condition, similar to that of Fig. 5a, it is observed that, for many values of ρ_s, the system evolves to a state where there is, in the average, the same amount of spin down and up, that is no macroscopic magnetization. However, if the initial configuration presents a sufficiently large excess of one kind of spins, then a macroscopic magnetization builds up as time goes on. This means there is a phase transition between a situation of zero magnetization and a situation of positive or negative magnetization.

It turns out that this transition occurs when the total energy E of the system is low enough (a low energy means that most of the spins are aligned and that there is an excess of one species over the other), or more precisely when E is smaller than a critical energy E_c. In that sense, the Q2R rule captures an important aspect of a real magnetic system, namely a non-zero magnetization at low energy (which can be related to a low temperature situation) and a transition to a nonmagnetic phase at high energy.

However, Q2R also exhibits unexpected behavior that is difficult to detect from a simple observation. There is a breaking of ergodicity: a given initial configuration of energy E_0 evolves without visiting completely the region of the phase space characterized by $E = E_0$.

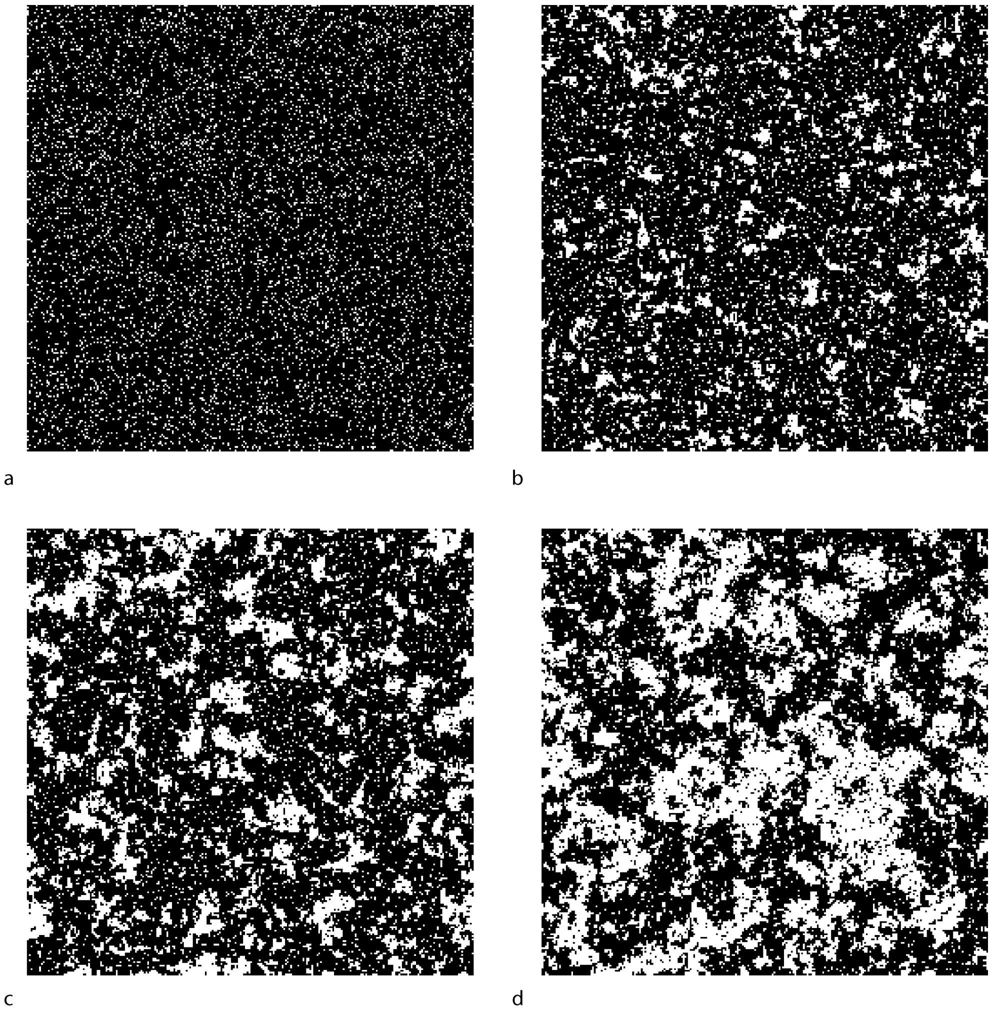
This is illustrated by the following simple 1D example, where a ring of four spins with periodic boundary condition are considered.

$$\begin{aligned} t&: \ 1001 \\ t+1&: \ 1100 \\ t+2&: \ 0110 \\ t+3&: \ 0011 \\ t+4&: \ 1001 \end{aligned} \tag{6}$$

After four iterations, the system cycles back to its original state. The configuration of this example has $E_0 = 0$. As we observed, it never evolves to 0111, which is also a configuration of zero energy. This nonergodicity means that not only energy is conserved during the evolution of the automaton, but also another quantity which partitions the energy surface in independent regions.

Competition Models and Cell Differentiation

In Sect. "A Growth Model" we have discussed a majority rule in which the cells imitate their neighbors. In some sense, this corresponds to a cooperative behavior between the cells. A quite different situation can be obtained if the cells obey competitive dynamics. For instance, we may imagine that the cells compete for some resources at the expense of their nearest neighbors. A winner is a cell of state 1 and a loser a cell of state 0. No two winner cells can be neighbors and any loser cell must have at least one winner neighbor (otherwise nothing would have prevented it to also win).

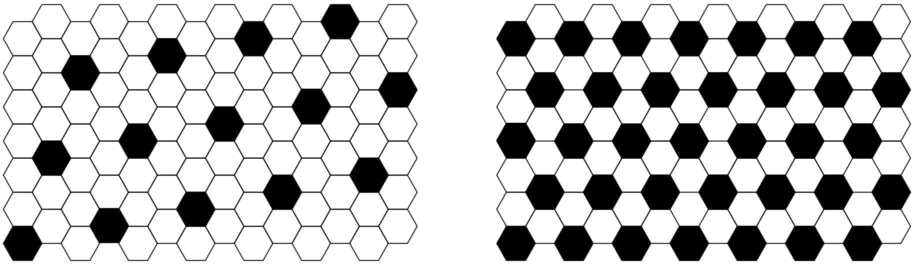


Cellular Automata Modeling of Physical Systems, Figure 5
Evolution of a system of spins with the Q2R rule. *Black* represents the spins down $s_{ij} = 0$ and *white* the spins up $s_{ij} = 1$. The four images a, b, c, and d show the system at four different times $t_a = 0 < t_b \ll t_{cd}$

It is interesting to note that this problem has a direct application in biology, to study cell differentiation. It has been observed in the development of Drosophila that about 25% of the cells forming the embryo evolve to the state of neuroblast, while the remaining 75% do not. How can we explain this differentiation and the observed fraction since, at the beginning of the process all cells can be assumed equivalent? A possible mechanism [28] is that some competition takes place between the adjacent biological cells. In other words, each cell produces some substance *S* but the production rate is inhibited by the amount of *S* already present in the neighboring cells. Differentiation occurs when a cell reaches a level of *S* above a given threshold.

The competition CA model we propose to describe this situation is the following. Because of the analogy with the biological system, we shall consider a hexagonal lattice, which is a reasonable approximation of the cell arrangement observed in the Drosophila embryo (see Fig. 6). We assume that the values of *S* can be 0 (inhibited) or 1 (active) in each lattice cell.

- A $S = 0$ cell will grow (i. e. turn to $S = 1$) with probability p_{grow} provided that all its neighbors are 0. Otherwise, it stays inhibited.
- A cell in state $S = 1$ will decay (i. e. turn to $S = 0$) with probability p_{decay} if it is surrounded by at least one active cell. If the active cell is isolated (all the neighbors are in state 0) it remains in state 1.



Cellular Automata Modeling of Physical Systems, Figure 6
The hexagonal lattice used for the competition-inhibition CA rule. *Black cells* are cells of state 1 (winners) and *white cells* are cells of state 0 (losers). The two possible final states with a fully regular structure are illustrated with density 1/3 and 1/7 of a winner, respectively

The evolution stops (stationary process) when no $S=1$ cell feels any more inhibition from its neighbors and when all $S=0$ cells are inhibited by their neighborhood. Then, with our biological interpretation, cells with $S=1$ are those which will differentiate.

What is the expected fraction of these $S=1$ cells in the final configuration? Clearly, from Fig. 6, the maximum value is 1/3. According to the inhibition condition we imposed, this is the close-packed situation on the hexagonal lattice. On the other hand, the minimal value is 1/7, corresponding to a situation where the lattice is partitioned in blocks with one active cell surrounded by six inhibited cells. In practice we do not expect any of these two limits to occur spontaneously after the automaton evolution. On the contrary, we should observe clusters of close-packed active cells surrounded by defects, i. e. regions of low density of active cells.

CA simulations show indeed that the final fraction s of active cells is a mix of the two limiting situations of Fig. 6

$$.23 \le s \le .24$$

almost irrespectively of the values chosen for p_{anihil} and p_{growth}.

This is exactly the value expected from the biological observations made on the Drosophila embryo. Thus, cell differentiation can be explained by a geometrical competition without having to specify the inhibitory couplings between adjacent cell and the production rate (i. e. the values of p_{anihil} and p_{growth}): the result is quite robust against any possible choices.

Traffic Models

Cellular automata models for road traffic have received a great deal of interest during the past few years (see [13,32,33,36,37,47,48,52] for instance).

One-dimensional models for single lane car motions are quite simple and elegant. The road is represented as a line of cells, each of them being occupied or not by a vehicle. All cars travel in the same direction (say to the right). Their positions are updated synchronously. During the motion, each car can be at rest or jump to the nearest neighbor site, along the direction of motion. The rule is simply that a car moves only if its destination cell is empty. This means that the drivers do not know whether the car in front will move or will be blocked by another car. Therefore, the state of each cell s_i is entirely determined by the occupancy of the cell itself and its two nearest neighbors s_{i-1} and s_{i+1}. The motion rule can be summarized by the following table, where all eight possible configurations $(s_{i-1}s_is_{i+1})_t \to (s_i)_{t+1}$ are given

$$\underbrace{(111)}_{1}\;\underbrace{(110)}_{0}\;\underbrace{(101)}_{1}\;\underbrace{(100)}_{1}\;\underbrace{(011)}_{1}\;\underbrace{(010)}_{0}\;\underbrace{(001)}_{0}\;\underbrace{(000)}_{0}\,. \tag{7}$$

This cellular automaton rule turns out to be Wolfram rule 184 [50,52].

These simple dynamics capture an interesting feature of real car motion: traffic congestion. Suppose we have a low car density ρ in the system, for instance something like

$$\ldots 0010000010010000010\ldots\,. \tag{8}$$

This is a *free* traffic regime in which all the cars are able to move. The average velocity $\langle v \rangle$ defined as the number of motions divided by the number of cars is then

$$\langle v_{\text{f}} \rangle = 1 \tag{9}$$

where the subscript f indicates a free state. On the other hand, in a high density configuration such as

$$\ldots 110101110101101110\ldots\,. \tag{10}$$

only six cars over 12 will move and $\langle v \rangle = 1/2$. This is a partially jammed regime.

If the car positions were uncorrelated, the number of moving cars (i. e. the number of particle-hole pairs) would be given by $L\rho(1-\rho)$, where L is the system size. Since the number of cars is ρL, the average velocity would be

$$\langle v_{\text{uncorrel}} \rangle = 1 - \rho \,. \tag{11}$$

However, in this model, the car occupancy of adjacent sites is highly correlated and the vehicles cannot move until a hole has appeared in front of them. The car distribution tries to self-adjust to a situation where there is one spacing between consecutive cars. For densities less than one-half, this is easily realized and the system can organize to have one car every other site.

Therefore, due to these correlations, Eq. (11) is wrong in the high density regime. In this case, since a car needs a hole to move to, we expect that the number of moving cars simply equals the number of empty cells [52]. Thus, the number of motions is $L(1-\rho)$ and the average velocity in the jammed phase is

$$\langle v_j \rangle = \frac{1-\rho}{\rho} \,. \tag{12}$$

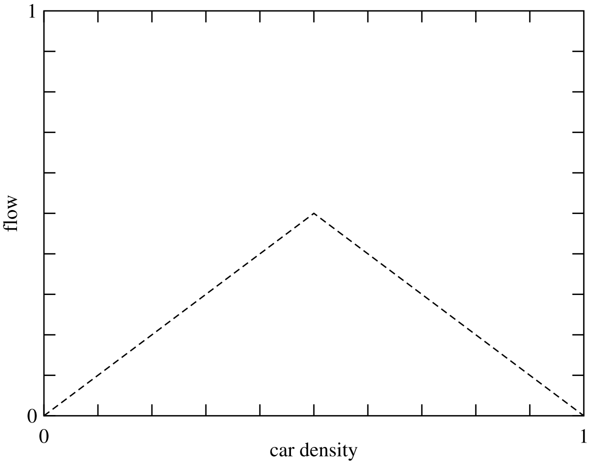
From the above relations we can compute the so-called fundamental flow diagram, i. e. the relation between the flow of cars $\rho\langle v \rangle$ as a function of the car density ρ: for $\rho \le 1/2$, we use the free regime expression and $\rho\langle v \rangle = \rho$. For densities $\rho > 1/2$, we use the jammed expression and $\rho\langle v \rangle = 1 - \rho$. The resulting diagram is shown in Fig. 7. As in real traffic, we observe that the flow of cars reaches a maximum value before decreasing.

A richer version of the above CA traffic model is due to Nagel and Schreckenberg [33,47,48]. The cars may have several possible velocities $u = 0, 1, 2, \ldots, u_{\max}$. Let u_i be the velocity of car i and d_i the distance, along the road, separating cars i and $i+1$. The updating rule is:

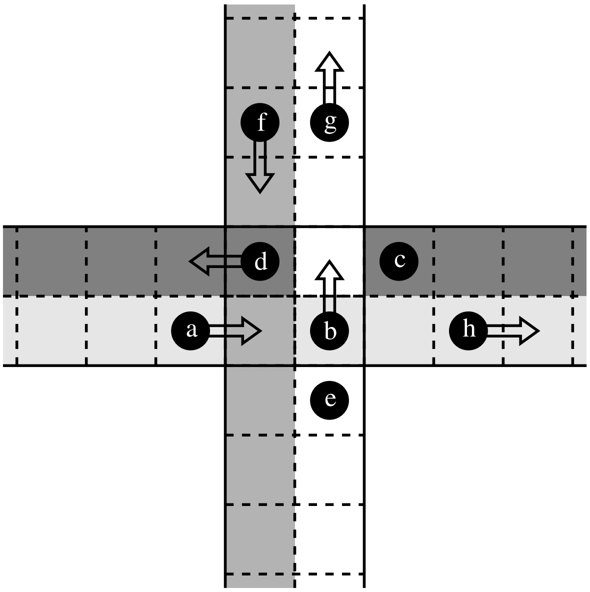
- The cars accelerate when possible: $u_i \to u_i' = u_i + 1$, if $u_i < u_{\max}$.
- The cars slow down when required: $u_i' \to u_i'' = d_i - 1$, if $u_i' \ge d_i$.
- The cars have a random behavior: $u_i'' \to u_i''' = u_i'' - 1$, with probability p_i if $u_i'' > 0$.
- Finally, the cars move u_i''' sites ahead.

This rule captures some important behaviors of real traffic on a highway: velocity fluctuations due to a nondeterministic behavior of the drivers, and “stop-and-go” waves observed in a high-density traffic regime.

We refer the reader to recent literature for the new developments of this topic. See for instance [24,25].

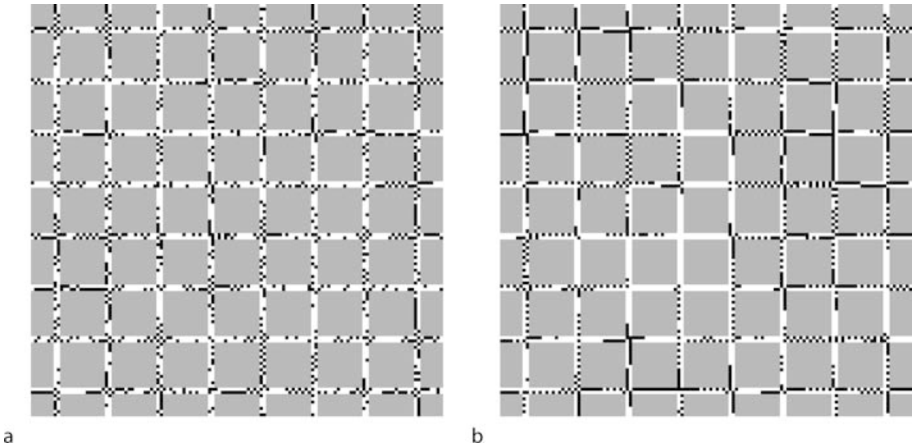


Cellular Automata Modeling of Physical Systems, Figure 7
Traffic flow diagram for the simple CA traffic rule

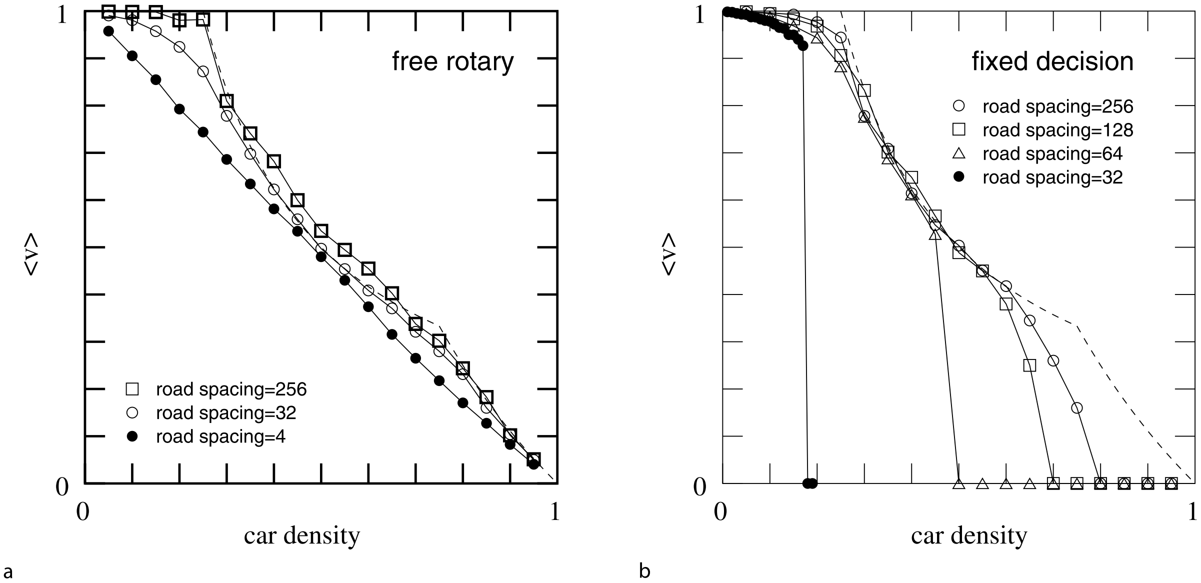


Cellular Automata Modeling of Physical Systems, Figure 8
The four central cells represent a roundabout which is traveled counterclockwise. The gray levels indicate the different traffic lanes: *white* is a northbound lane, *light gray* an eastbound lane, *gray* a southbound lane and, finally, *dark gray* is a westbound lane. The *dots* labeled *a*, *b*, *c*, *d*, *e*, *f*, *g*, and *h* are cars which will move to the destination cell indicated by the arrows, as determined by some local decision rule. Cars without an arrow are forbidden to move

Note that a street network can also be described using a CA. A possible approach is to model a road intersection as a roundabout. Cars in the roundabout have priority over those willing to enter. Figure 8 illustrates a simple four-way road junction.



Cellular Automata Modeling of Physical Systems, Figure 9
Traffic configuration after 600 iterations, for a car density of 30%. Streets are *white*, buildings *gray* and the *black pixels* represent the cars. Situation a corresponds to the roundabout junctions, whereas image b mimics the presence of traffic lights. In the second case, queues are more likely to form and the global mobility is less than in the first case



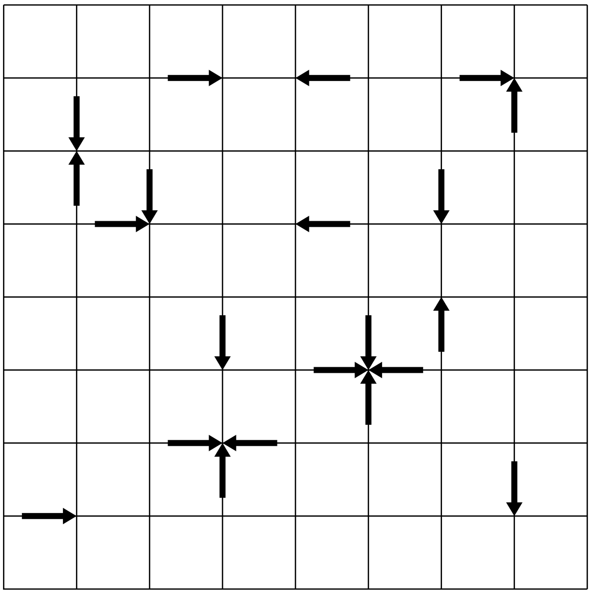
Cellular Automata Modeling of Physical Systems, Figure 10
Average velocity versus average density for the cellular automata street network, for a time-uncorrelated turning strategies and b a fixed driver decision. The different curves correspond to different distances *L* between successive road junctions. The *dashed line* is the analytical prediction (see [13]). Junction deadlock is likely to occur in b, resulting in a completely jammed state

Traffic lights can also be modeled in a CA by stopping, during a given number of iterations, the car reaching a given cell. Figure 9 illustrates CA simulation of a Manhattan-like city in which junctions are either controlled by a roundabout or by a traffic light. In both cases, the destination of a car reaching the junction is randomly chosen.

Figure 10 shows the fundamental flow diagram obtained with the CA model, for a Manhattan-like city governed by roundabouts separated by a distance *L*.

CA modeling of urban traffic has been used for real situations by many authors (see for instance [11]) and some cities in Europe and USA use the CA approach as a way to manage traffic.

Note finally that crowd motion is also addressed within the CA framework. Recent results [7,29] show that the approach is quite promising to plan evacuation strategies and reproduce several of the motion patterns observed in real crowds.



Cellular Automata Modeling of Physical Systems, Figure 11
Example of a configuration of HPP particles

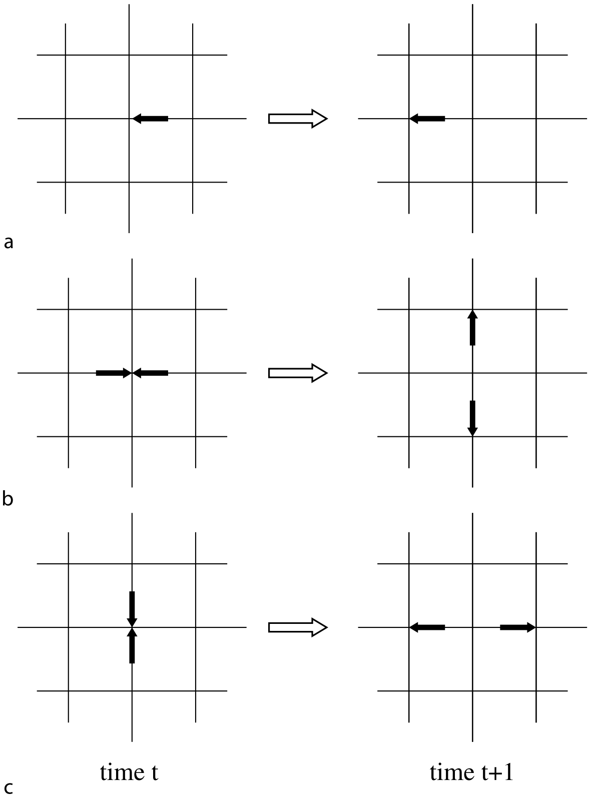
A Simple Gas: The HPP Model

The HPP rule is a simple example of an important class of cellular automata models: lattice gas automata (LGA). The basic ingredient of such models are point particles that move on a lattice, according to appropriate rules so as to mimic fully discrete "molecular dynamics."

The HPP lattice gas automata is traditionally defined on a two-dimensional square lattice. Particles can move along the main directions of the lattice, as shown in Fig. 11. The model limits to 1 the number of particles entering a given site with a given direction of motion. This is the exclusion principle which is common in most LGA (LGA models without the exclusion principle are called multi-particle models [10]).

With at most one particle per site and direction, four bits of information at each site are enough to describe the system during its evolution. For instance, if at iteration t site $\mathbf{r}$ has the following state $s(\mathbf{r}, t) = (1011)$, it means that three particles are entering the site along direction 1, 3, and 4, respectively.

The cellular automata rule describing the evolution of $s(\mathbf{r}, t)$ is often split into two steps: collision and motion (or propagation). The collision phase specifies how the particles entering the same site will interact and change their trajectories. During the propagation phase, the particles actually move to the nearest neighbor site they are traveling to. This decomposition into two phases is a quite convenient way to partition the space so that the collision rule is purely local.



Cellular Automata Modeling of Physical Systems, Figure 12
The HPP rule: a a single particle has a ballistic motion until it experiences a collision; b and c the two nontrivial collisions of the HPP model: two particles experiencing a head on collision are deflected in the perpendicular direction. In the other situations, the motion is ballistic, that is the particles are transparent to each other when they cross the same site

Figure 12 illustrates the HPP rules. According to our Boolean representation of the particles at each site, the collision part for the two head on collisions are expressed as

$$(1010) \to (0101) \qquad (0101) \to (1010) \tag{13}$$

all the other configurations being unchanged. During the propagation phase, the first bit of the state variable is shifted to the east neighbor cell, the second bit to the north and so on.

The aim of this rule is to reproduce some aspect of the real interactions between particles, namely that momentum and particle number are conserved during a collision. From Fig. 12, it is easily checked that these properties are obeyed: a pair of zero momentum particles along a given direction is transformed into another pair of zero momentum along the perpendicular axis.

It is easy to express the HPP model in a mathematical form. For this purpose, the so-called occupation numbers $n_i(\mathbf{r}, t)$ are introduced for each lattice site $\mathbf{r}$ and each time step t. The index i labels the lattice directions (or the possible velocities of the particles). In the HPP model, the lattice has four directions (North, West, South, and East) and i runs from 1 to 4.

By definition and due to the exclusion principle, the n_i's are Boolean variables

$$n_i(\mathbf{r}, t) = \begin{cases} 1 & \text{if a particle is entering site } \mathbf{r} \text{ at time } t \\ & \text{along lattice direction } i \\ 0 & \text{otherwise .} \end{cases}$$

From this definition it is clear that, for HPP, the n_i's are simply the components of the state s introduced above

$$s = (n_1, n_2, n_3, n_4) .$$

In an LGA model, the microdynamics can be naturally expressed in terms of the occupation numbers n_i as

$$n_i(\mathbf{r} + \mathbf{v_i}\Delta_t, t + \Delta_t) = n_i(\mathbf{r}, t) + \Omega_i(n(\mathbf{r}, t)) \qquad (14)$$

where $\mathbf{v_i}$ is a vector denoting the speed of the particle in the ith lattice direction. The function Ω is called the collision term and it describes the interaction of the particles which meet at the same time and same location.

Note that another way to express Eq. (14) is through the so-called collision and propagation operators C and P

$$n(t + \Delta_t) = PCn(t) \qquad (15)$$

where $n(t)$ describe the set of values $n_i(\mathbf{r}, t)$ for all i and $\mathbf{r}$. The quantities C and P act over the entire lattice. They are defined as

$$(Pn)_i(\mathbf{r}) = n_i(\mathbf{r} - \mathbf{v_i}\Delta_t) \qquad (Cn)_i(\mathbf{r}) = n_i(\mathbf{r}) + \Omega_i .$$

More specifically, for the HPP model, it can be shown [10] that the collision and propagation phase can be expressed as

$$\begin{aligned} &n_i(\mathbf{r} + \mathbf{v_i}\Delta_t, t + \Delta_t) \\ &\quad = n_i - n_i n_{i+2}(1 - n_{i+1})(1 - n_{i+3}) \\ &\qquad + n_{i+1}n_{i+3}(1 - n_i)(1 - n_{i+2}) . \end{aligned} \qquad (16)$$

In this equation, the values $i + m$ are wrapped onto the values 1 to 4 and the right-hand term is computed at position $\mathbf{r}$ and time t.

The HPP rule captures another important ingredient of the microscopic nature of a real interaction: invariance under time reversal. Figure 12b and c show that, if at some given time, the directions of motion of all particles are reversed, the system will just trace back its own history. Since the dynamics of a deterministic cellular automaton is exact, this fact allows us to demonstrate the properties of physical systems to return to their original situation when all the particles reverse their velocity.

Figure 13 illustrates the time evolution of an HPP gas initially confined in the left compartment of a container. There is an aperture on the wall of the compartment and the gas particles will flow so as to fill the entire space available to them. In order to include a solid boundary in the system, the HPP rule is modified as follows: when a site is a wall (indicated by an extra bit), the particles no longer experience the HPP collision but bounce back from where they came. Therefore, particles cannot escape a region delimited by such a reflecting boundary.

If the system of Fig. 13 is evolved, it reaches an equilibrium after a long enough time and no macroscopic trace of its initial state is visible any longer. However, no information has been lost during the process (no numerical dissipation) and the system has the memory of where it comes from. Reversing all the velocities and iterating the HPP rule makes all particles go back to the compartment in which they were initially located.

Reversing the particle velocity can be described by an operator R which swaps occupation numbers with opposite velocities

$$(Rn)_i = n_{i+2} .$$

The reversibility of HPP stem from the fact that the collision and propagation operators obey

$$PRP = R \qquad CRC = R .$$

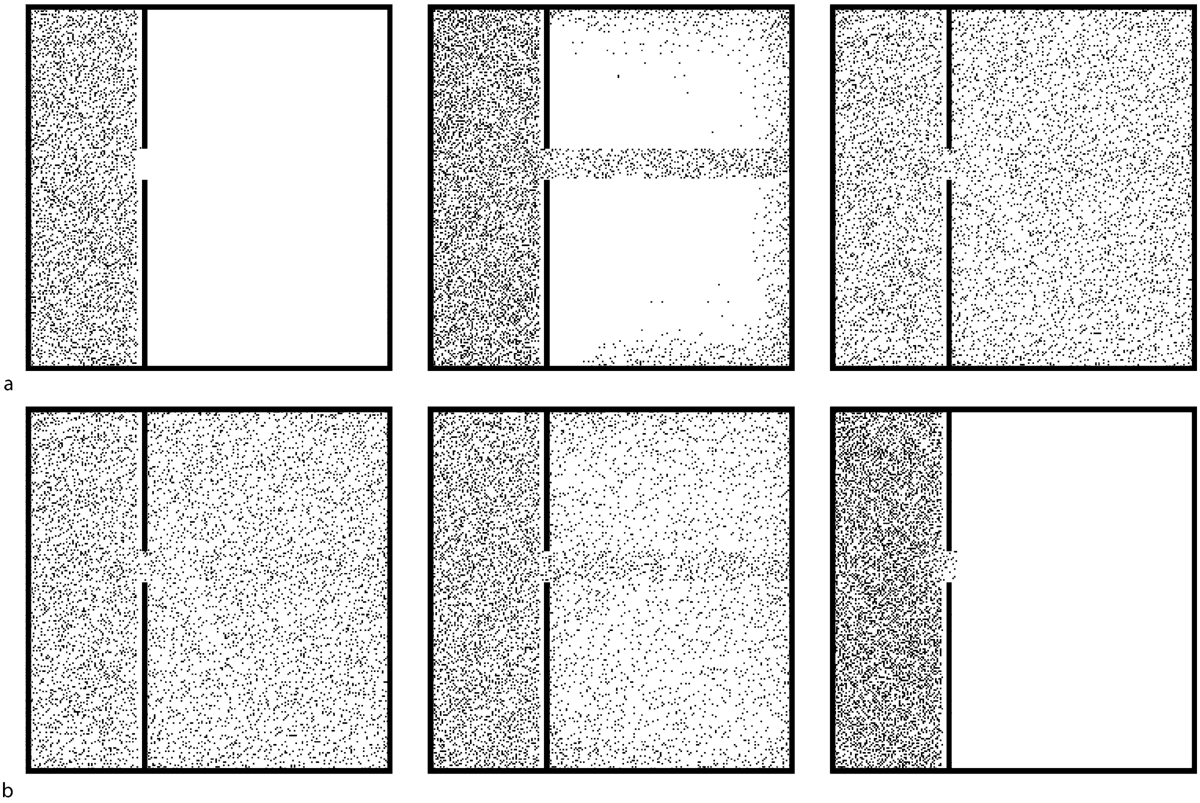
Thus

$$(PC)^n PR(PC)^n = R$$

which shows that the system will return to its initial state (though with opposite velocities) if the first n iterations are followed by a velocity change $\mathbf{v_i} \to -\mathbf{v_i}$, a propagation and again n iterations.

This time-reversal behavior is only possible because the dynamics are perfectly exact and no numerical errors are present in the numerical scheme. If one introduces externally some errors (for instance, one can add an extra particle in the system) before the direction of motion of each particle is reversed, then reversibility is lost.

Note that this property has inspired a new symmetric cryptography algorithm called Crystal [30], which exploits and develops the existing analogy between discrete physical models of particles and the standard diffusion-confusion paradigm of cryptography proposed by Shannon [39].



Cellular Automata Modeling of Physical Systems, Figure 13
Time evolution of an HPP gas. a From the initial state to equilibrium. b Illustration of time reversal invariance: in the rightmost image of a, the velocity of each particle is reversed and the particles naturally return to their initial position

The FHP Model

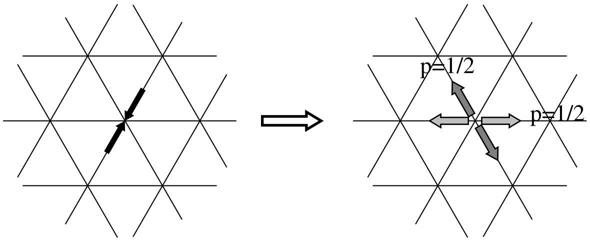
The HPP rule is interesting because it illustrates the basic ingredients of LGA models. However, the capability of this rule to model a real gas of particles is poor, due to a lack of isotropy and spurious invariants. A remedy to this problem is to use a different lattice and a different collision model.

The FHP rule (proposed by Frisch, Hasslacher, and Pomeau [18] in 1986) was the first CA whose behavior was shown to reproduce, within some limits, a two-dimensional fluid.

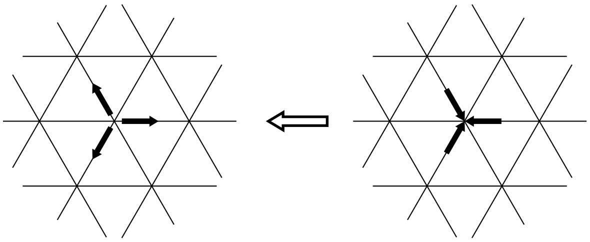
The FHP model is an abstraction, at a microscopic scale, of a fluid. It is expected to contain all the salient features of a real fluid. It is well known that the continuity and Navier–Stokes equations of hydrodynamics express the local conservation of mass and momentum in a fluid. The detailed nature of the microscopic interactions does not affect the form of these equations but only the values of the coefficients (such as the viscosity) appearing in them. Therefore, the basic ingredients one has to include in the microdynamics of the FHP model is the conservation of particles and momentum after each updating step. In addition, some symmetries are required so that, in the macroscopic limit, where time and space can be considered as continuous variables, the system be isotropic.

As in the case of the HPP model, the microdynamics of FHP is given in terms of Boolean variables describing the occupation numbers at each site of the lattice and at each time step (i. e. the presence or the absence of a fluid particle). The FHP particles move in discrete time steps, with a velocity of constant modulus, pointing along one of the six directions of the lattice.

Interactions take place among particles entering the same site at the same time and result in a new local distribution of particle velocities. In order to conserve the number of particles and the momentum during each interaction, only a few configurations lead to a nontrivial collision (i. e. a collision in which the directions of motion have changed). For instance, when exactly two particles enter the same site with opposite velocities, both of them are deflected by 60 degrees so that the output of the collision is



Cellular Automata Modeling of Physical Systems, Figure 14
The two-body collision in the FHP model. On the *right part of the figure*, the two possible outcomes of the collision are shown in *dark* and *light gray*, respectively. They both occur with probability one-half



Cellular Automata Modeling of Physical Systems, Figure 15
The three-body collision in the FHP model

still a zero momentum configuration with two particles. As shown in Fig. 14, the deflection can occur to the right or to the left, indifferently. For symmetry reasons, the two possibilities are chosen randomly, with equal probability.

Another type of collision is considered: when exactly three particles collide with an angle of 120 degrees between each other, they bounce back (so that the momentum after collision is zero, as it was before collision). Figure 15 illustrates this rule.

For the simplest case we are considering here, all interactions come from the two collision processes described above. For all other configurations (i. e. those which are not obtained by rotations of the situations given in Figs. 14 and 15) no collision occurs and the particles go through as if they were transparent to each other.

Both two- and three-body collisions are necessary to avoid extra conservation laws. The two-particle collision removes a pair of particles with a zero total momentum and moves it to another lattice direction. Therefore, it conserves momentum along each line of the lattice. On the other hand, three-body interactions deflect particles by 180 degrees and cause the net momentum of each lattice line to change. However, three-body collisions conserve the number of particles within each lattice line.

The FHP model has played a central role in computational physics because it can be shown (see for instance [10]) that the density ρ, defined as the average number of particles at a given lattice site and $\mathbf{u}$ the average velocity of these particles, obey Navier–Stokes equation

$$\partial_t \mathbf{u} + (\mathbf{u}\cdot\nabla)\mathbf{u} = -\frac{1}{\rho}\nabla p + \nu\nabla^2\mathbf{u} \tag{17}$$

where $p = c_s^2\rho$ is the scalar pressure, with c_s the speed of sound and ν is the kinematic viscosity. Note that here both ν and c_s are quantities that emerge from the FHP dynamics. The speed of sound reflects the lattice topology whereas the viscosity reflects the details of the collision process.

As an illustration, Fig. 16 shows the propagation of a density wave in a FHP model. Figure 17 shows the eddies that form when a FHP-fluid flow against an obstacle.

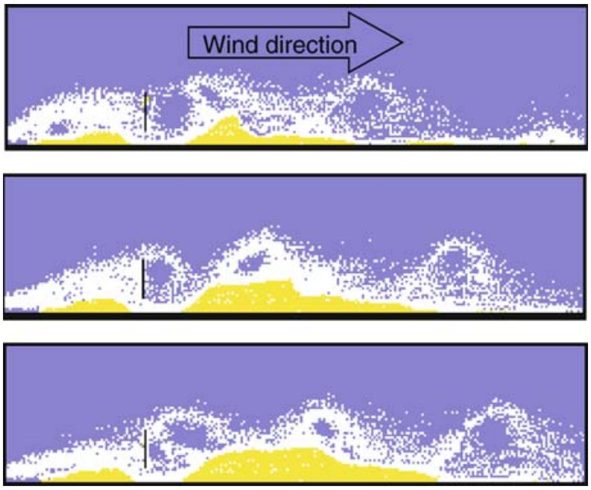
A CA snow transport and deposition model



Cellular Automata Modeling of Physical Systems, Figure 19
A lattice Boltzmann snow transport and deposition model. The three panels show the time evolution of the snow deposit (*yellow*) past a fence. Airborne snowflakes are shown as *white dots*

More complex models can be built by adding new processes on top of a FHP-fluid. For instance, Fig. 18 shows the result of a model of snow transport and deposition by wind. In addition to the wind flow, obtained from a FHP model, snow particles are traveling due to the combined effect of wind and gravity. Upon reaching the ground, they pile up (possible after toppling) so as to form a new boundary condition for the wind. In Fig. 19 an extension of the model (using the lattice Boltzmann approach described in Sect. "Lattice Boltzmann Models") shows how a fence with ground clearance creates a snow deposit.

Lattice Boltzmann Models

Lattice Boltzmann models (LBM) are an extension of the CA-fluid described in the previous section. The main conceptual difference is that in LBM, the CA state is no longer Boolean numbers n_i but real-valued quantity f_i for each lattice directions i. Instead of describing the presence or absence of a particle, the interpretation of f_i is the density distribution function of particles traveling in lattice directions i.

As with LGA (see Eq. (16)), the dynamics of LBM can be expressed in terms of an equation for the f_i's. The fluid quantities such as the density ρ and velocity field $\mathbf{u}$ are obtained by summing the contributions from all lattice directions

$$\rho = \sum_i f_i \qquad \rho\mathbf{u} = \sum_i f_i \mathbf{v_i}$$

where $\mathbf{v_i}$ denotes the possible particle velocities in the lattice.

From a numerical point of view, the advantages of suppressing the Boolean constraint are several: less statistical noise, more numerical accuracy and, importantly, more flexibility to choose the lattice topology, the collision operator and boundary conditions. Thus, for many practical applications, the LBM approach is preferred to the LGA one.

The so-called BGK (or "single-time relaxation") LBM

$$f_i(\mathbf{r} + \Delta_t \mathbf{v_i}, t + \Delta_t) = f_i(\mathbf{r}, t) + \frac{1}{\tau}\left(f_i^{\mathrm{eq}}(\rho, \mathbf{u}) - f_i\right) \quad (18)$$

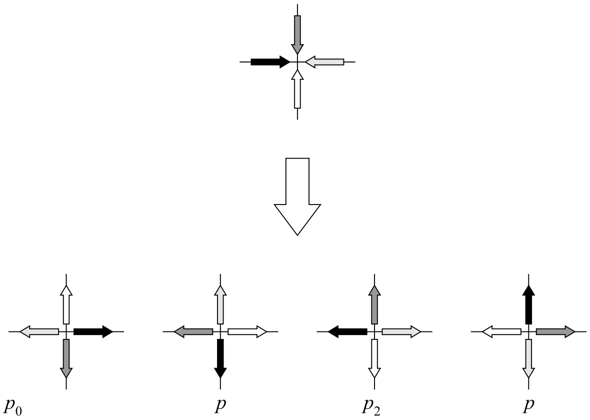
where f^{eq} is a given function, has been used extensively in the literature to simulate complex flows. The method is now recognized as a serious competitor of the more traditional approach based on the computer solution of the Navier–Stokes partial differential equation.

It is beyond the scope of this article to discuss the LBM approach in more detail. We refer the reader to several textbooks on this topic [8,10,40,41,49]. In addition to some rather technical aspects, one advantage of the LBM over the Navier–Stokes equation is its extended range of validity when the Knudsen number is not negligible (e. g. in microflows) [2].

Note finally that the LBM approach is also applicable to reaction-diffusion processes [1] or wave equation [10] by simply choosing an appropriate expression for f_i^{eq}.

Diffusion Processes

Diffusive phenomena and reaction processes play an important role in many areas of physics, chemistry, and biology and still constitute an active field of research. Systems in which reactive particles are brought into contact by a diffusion process and transform, often give rise to very complex behaviors. Pattern formation [31,34], is a typical example of such a behavior. CA provide an interesting framework to describe reaction-diffusion phenomena.



Cellular Automata Modeling of Physical Systems, Figure 20
How the entering particles are deflected at a typical site, as a result of the diffusion rule. The four possible outcomes occur with respective probabilities p_0, p_1, p_2, and p_3. The figure shows four particles, but the mechanism is data-blind and any one of the arrows can be removed when fewer entering particles are present

The HPP rule we discussed in the Sect. "A Simple Gas: The HPP Model" can be easily modified to produce many synchronous random walks. Random walk is well known to be the microscopic origin of a diffusion process.

Thus, instead of experiencing a mass and momentum conserving collision, each particle now selects, at random, a new direction of motion among the possible values permitted by the lattice. Since several particles may enter the same site (up to four, on a two-dimensional square lattice), the random change of directions should be such that there are never two or more particles exiting a site in the same direction. This would otherwise violate the exclusion principle.

The solution is to shuffle the directions of motion or, more precisely, to perform a random permutation of the velocity vectors, independently at each lattice site and each time step. Figure 20 illustrates this probabilistic evolution rule for a 2D square lattice.

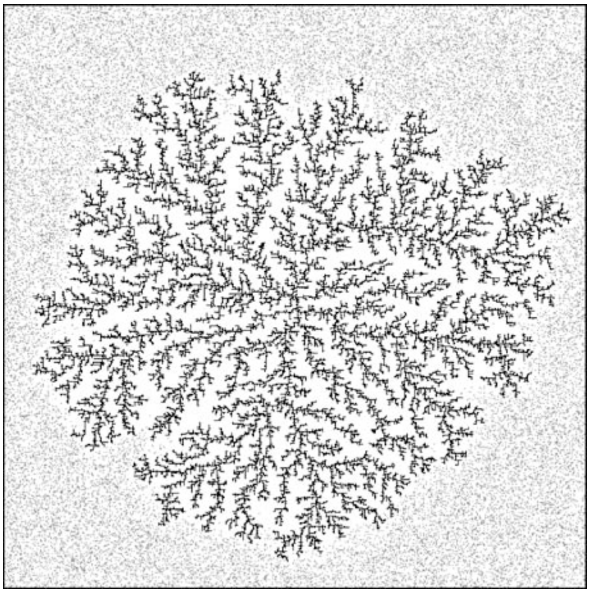
It can be shown that the quantity ρ defined as the average number of particle at site $\mathbf{r}$ and time t obeys the diffusion equation [10]

$$\partial_t \rho + \operatorname{div}\left[-D \operatorname{grad} \rho\right] = 0$$

where D is the diffusion constant whose expression is

$$D = \frac{\Delta_\mathrm{r}^2}{\Delta_t}\left(\frac{1}{4(p+p_2)} - \frac{1}{4}\right) = \frac{\Delta_\mathrm{r}^2}{\Delta_t}\left(\frac{p+p_0}{4[1-(p+p_0)]}\right) \tag{19}$$

where Δ_t and Δ_r are the time step and lattice spacing, respectively. For the one- and three-dimensional cases, a similar approach can be developed [10].



Cellular Automata Modeling of Physical Systems, Figure 21
Two-dimensional cellular automata DLA-like cluster (*black*), obtained with $p_\mathrm{s} = 1$, an aggregation threshold of 1 particle and a density of diffusing particle of 0.06 per lattice direction. The gray dots represent the diffusing particles not yet aggregated. The fractal dimension is found to be $d_\mathrm{f} = 1.78$

As an example of the use of the present random walk cellular automata rule, we discuss an application to growth processes. In many cases, growth is governed by an aggregation mechanism: like particles stick to each other as they meet and, as a result, form a complicated pattern with a branching structure.

A prototype model of aggregation is the so-called DLA model (diffusion-limited aggregation), introduced by Witten and Sander [46] in the early 1980s. Since its introduction, the DLA model has been investigated in great detail. However, diffusion-limited aggregation is a far from equilibrium process which is not described theoretically by first principle only. Spatial fluctuations that are typical of the DLA growth are difficult to take into account and a numerical approach is necessary to complete the analysis.

DLA-like processes can be readily modeled by our diffusion cellular automata, provided that an appropriate rule is added to take into account the particle-particle aggregation. The first step is to introduce a rest particle to represent the particles of the aggregate. Therefore, in a two-dimensional system, a lattice site can be occupied by up to four diffusing particles, or by one "solid" particle.

Figure 21 shows a two-dimensional DLA-like cluster grown by the cellular automata dynamics. At the beginning of the simulation, one or more rest particles are intro-

duced in the system to act as aggregation seeds. The rest of the system is filled with particles with average concentration ρ. When a diffusing particle becomes nearest neighbor to a rest particle, it stops and sticks to it by transforming into a rest particle. Since several particles can enter the same site, we may choose to aggregate all of them at once (i. e. a rest particle is actually composed of several moving particles), or to accept the aggregation only when a single particle is present.

In addition to this question, the sticking condition is important. If any diffusing particle always sticks to the DLA cluster, the growth is very fast and can be influenced by the underlying lattice anisotropy. It is therefore more appropriate to stick with some probability p_s.

Reaction-Diffusion Processes

A reaction term can be added on top of the CA diffusion rule. For the sake of illustration let us consider a process such as

$$A + B \overset{K}{\rightarrow} C \tag{20}$$

where A, B, and C are different chemical species, all diffusing in the same solvent, and K is the reaction constant. To account for this reaction, one can consider the following mechanism: at the "microscopic" level of the discrete lattice dynamics, all the three species are first governed by a diffusion rule. When an A and a B particle enter the same site at the same time, they disappear and form a C particle.

Of course, there are several ways to select the events that will produce a C when more than one A or one B are simultaneously present at a given site. Also, when Cs already exist at this site, the exclusion principle may prevent the formation of new ones. A simple choice is to have A and B react only when they perform a head-on collision and when no Cs are present in the perpendicular directions. Figure 22 displays such a process.

Other rules can be considered if we want to enhance the reaction (make it more likely) or to deal with more complex situations ($2A + B \rightarrow C$, for instance).

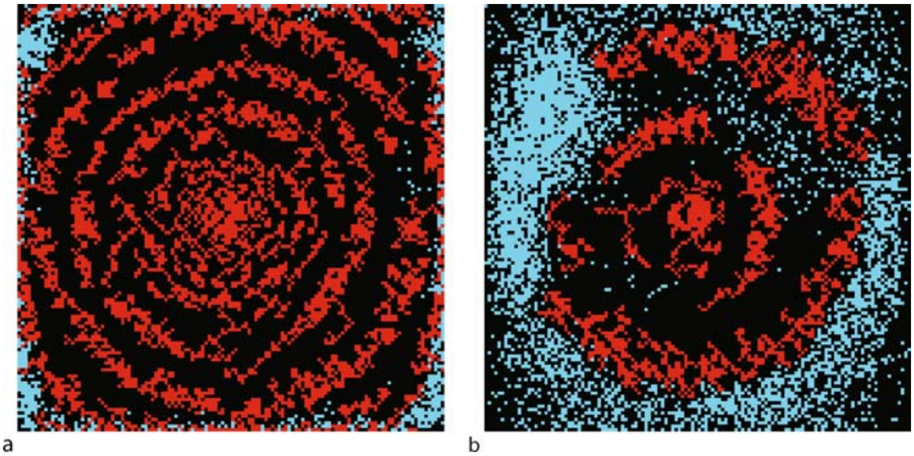
A parameter k can be introduced to tune the reaction rate K by controlling the probability of a reaction taking place. Using an appropriate mathematical tool [10], one can show that the idealized microscopic reaction-diffusion behavior implemented by the CA rule obeys the expected partial differential equation

$$\partial_t \rho_A = D\nabla^2 \rho_A - K\rho_A\rho_B \tag{21}$$

provided k is correctly chosen [10].

As an example of a CA reaction-diffusion model, we show in Fig. 23 the formation of the so-called Liesegang patterns [22].

Liesegang patterns are produced by precipitation and aggregation in the wake of a moving reaction front. Typ-



Cellular Automata Modeling of Physical Systems, Figure 24
Formation of Liesegang rings in a cellular automata simulation. The *red spots* correspond to the precipitate created by the $A + B$ reaction front (in *blue*)

ically, they are observed in a test tube containing a gel in which a chemical species B (for example $AgNO_3$) reacts with another species A (for example HCl). At the beginning of the experiment, B is uniformly distributed in the gel with concentration b_0. The other species A, with concentration a_0 is allowed to diffuse into the tube from its open extremity. Provided that the concentration a_0 is larger than b_0, a reaction front propagates in the tube. As this $A + B$ reaction goes on, formation of consecutive bands of precipitate (AgCl in our example) is observed in the tube, as shown in Fig. 23. Although this figure is from a computer simulation [12], it is very close to the picture of a real experiment.

Figure 24 shows the same process but in a different geometry. Species A is added in the middle of a 2D gel and diffuses radially. Rings (a) or spirals (b) result from the interplay between the reaction front and the solidification.

Excitable Media

Excitable media are other examples of reaction processes where unexpected space-time patterns are created. As opposed to the reaction-diffusion models discussed above, diffusion is not considered here explicitly. It is assumed that reaction occurs between nearest neighbor cells, making the transport of species unnecessary. The main focus is on the description of chemical waves propagating in the system much faster and differently than any diffusion process would produce.

An excitable medium is basically characterized by three states [5]: the resting state, the excited state, and the refractory state. The resting state is a stable state of the system. But a resting state can respond to a local perturbation and become excited. Then, the excited state evolves to a refractory state where it no longer influences its neighbors and, finally, returns to the resting state.

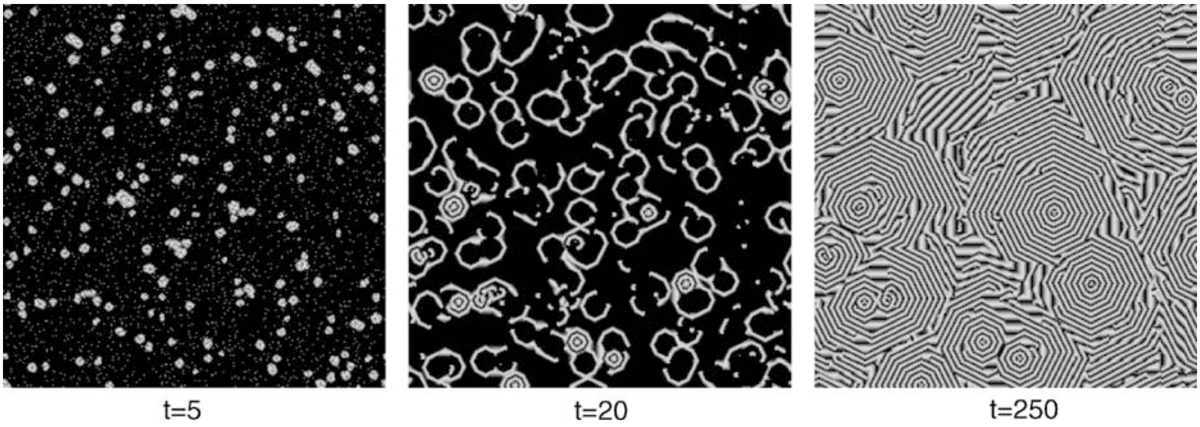
A generic behavior of excitable media is to produce chemical waves of various geometries [26,27]. Ring and spiral waves are a typical pattern of excitations. Many chemical systems exhibit an excitable behavior. The Selkov model [38] and the Belousov–Zhabotinsky reaction are examples. Chemical waves play an important role in many biological processes (nervous systems, muscles) since they can mediate the transport of information from one place to another.

The Greenberg–Hasting model is an example of a cellular automata model of an excitable media. This rule, and its generalization, have been extensively studied [17,20].

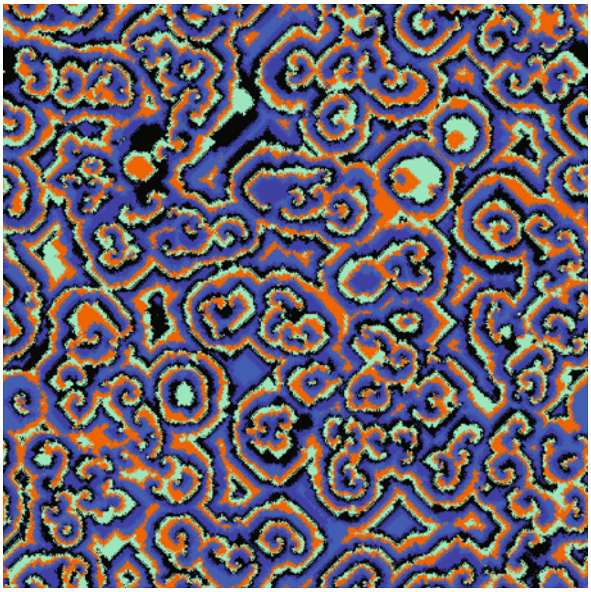
The implementation we propose here for the Greenberg–Hasting model is the following: the state $\psi(\mathbf{r}, t)$ of site $\mathbf{r}$ at time t takes its value in the set $\{0, 1, 2, \dots, n-1\}$. The state $\psi = 0$ is the resting state. The states $\psi = 1, \dots, n/2$ (n is assumed to be even) correspond to excited states. The rest, $\psi = n/2 + 1, \dots, n-1$ are the refractory states. The cellular automata evolution rule is the following:

1. If $\psi(\mathbf{r}, t)$ is excited or refractory, then $\psi(\mathbf{r}, t + 1) = \psi(\mathbf{r}, t) + 1 \mod n$.
2. If $\psi(\mathbf{r}, t) = 0$ (resting state) it remains so, unless there are at least k excited sites in the Moore neighborhood of site $\mathbf{r}$. In this case $\Psi(\mathbf{r}, t + 1) = 1$.

The n states play the role of a clock: an excited state evolves



Cellular Automata Modeling of Physical Systems, Figure 25
Excitable medium: evolution of a configuration with 5% of excited states $\Psi = 1$, and 95% of resting states (*black*), for $n = 8$ and $k = 3$



Cellular Automata Modeling of Physical Systems, Figure 26
The tube-worms rule for an excitable media

through the sequence of all possible states until it returns to 0, which corresponds to a stable situation.

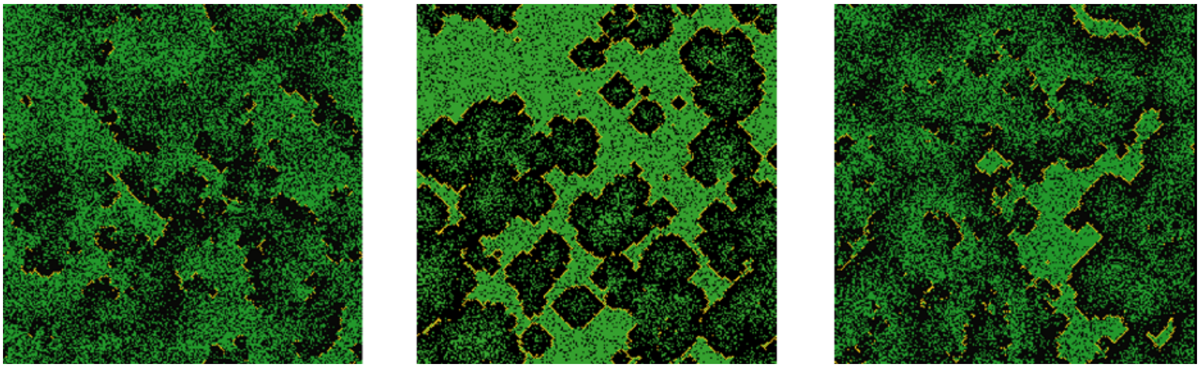
The behavior of this rule is quite sensitive to the value of *n* and the excitation threshold *k*. Figure 25 shows the evolution of this automaton for a given set of the parameters *n* and *k*. The simulation is started with a uniform configuration of resting states, perturbed by some excited sites randomly distributed over the system. Note that if the concentration of perturbation is low enough, excitation dies out rapidly and the system returns to the rest state. Increasing the number of perturbed states leads to the formation of traveling waves and self-sustained oscillations may appear in the form of ring or spiral waves.

The Greenberg–Hasting model has some similarity with the "tube-worms" rule proposed by Toffoli and Margolus [42]. This rule is intended to model the Belousov–Zhabotinsky reaction and is as follows. The state of each site is either 0 (refractory) or 1 (excited) and a local timer (whose value is 3, 2, 1, or 0) controls the refractory period. Each iteration of the rule can be expressed by the following sequence of operations: (i) where the timer is zero, the state is excited; (ii) the timer is decreased by 1 unless it is 0; (iii) a site becomes refractory whenever the timer is equal to 2; (iv) the timer is reset to 3 for the excited sites which have two, or more than four, excited sites in their Moore neighborhood.

Figure 26 shows a simulation of this automaton, starting from a random initial configuration of the timers and the excited states. We observe the formation of spiral pairs of excitations. Note that this rule is very sensitive to small modifications (in particular to the order of operations (i) to (iv)).

Another rule which is also similar to Greenberg–Hasting and Margolus–Toffoli tube-worm models is the so-called forest-fire model. This rule describes the propagation of a fire or, in a different context, may also be used to mimic contagion in the case of an epidemic. Here we describe the case of a forest-fire rule.

The forest-fire rule is a probabilistic CA defined on a *d*-dimensional cubic lattice. Initially, each site is occupied by either a tree, a burning tree, or is empty. The state of the system is parallel updated according to the following rule: (1) a burning tree becomes an empty site; (2) a green



Cellular Automata Modeling of Physical Systems, Figure 27

The forest fire rule: *green sites* correspond to a grown tree, *black pixels* represent burned sites and the *yellow color* indicates a burning tree. The snapshots given here represent three situations after a few hundred iterations. The parameters of the rule are $p = 0.3$ and $f = 6 \times 10^{-5}$

tree becomes a burning tree if at least one of its nearest neighbors is burning; (3) at an empty site, a tree grows with probability p; (4) A tree without a burning neighbor becomes a burning tree with probability f (so as to mimic an effect of lightning).

Figure 27 illustrates the behavior of this rule, in a two-dimensional situation. Provided that the time scales of tree growth and burning down of forest clusters are well separated (i. e. in the limit $f/p \to 0$), this model has self-organized critical states [15]. This means that in the steady state, several physical quantities characterizing the system have a power law behavior.

Surface Reaction Models

Other important reaction models that can be described by a CA are surface-reaction models where nonequilibrium phase transitions can be observed. Nonequilibrium phase transitions are an important topic in physics because no general theory is available to describe such systems and most of the known results are based on numerical simulations.

The so-called Ziff model [54] gives an example of the reaction A–B_2 on a catalyst surface (for example CO–O$_2$).

The system is out of equilibrium because it is an open system in which material continuously flows in and out. However, after a while, it reaches a stationary state and, depending on some control parameters, may be in different phases.

The basic steps are

- A gas mixture with concentrations X_{B_2} of B_2 and X_A of A sits above a surface on which it can be adsorbed. The surface is divided into elementary cells and each cell can adsorb one atom only.
- The B species can be adsorbed only in the atomic form. A molecule B_2 dissociates into two B atoms only if two adjacent cells are empty. Otherwise the B_2 molecule is rejected.
- If two nearest neighbor cells are occupied by different species they chemically react and the product of the reaction is desorbed. In the example of the CO–O$_2$ reaction, the desorbed product is a CO$_2$ molecule.

This final desorption step is necessary for the product to be recovered and for the catalyst to be regenerated. However, the gas above the surface is assumed to be continually replenished by fresh material so that its composition remains constant during the whole evolution.

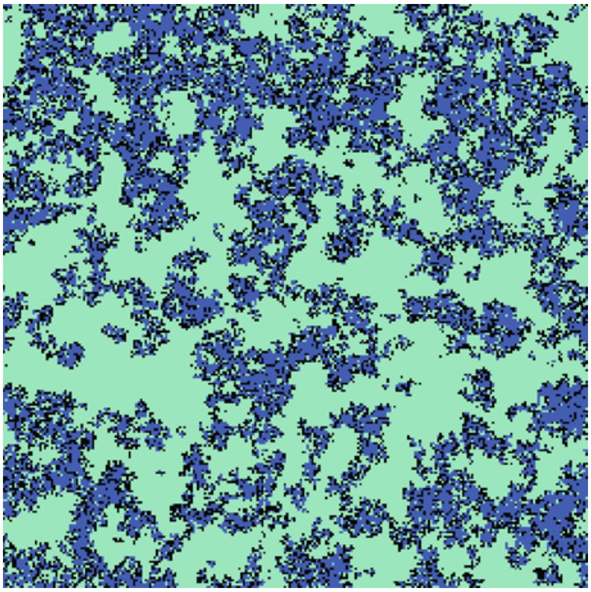
It is found by *sequential* numerical simulation [54] that a reactive steady state occurs only in a window defined by

$$X_1 < X_A < X_2$$

where $X_1 = 0.389 \pm 0.005$ and $X_2 = 0.525 \pm 0.001$ (provided that $X_{B_2} = 1 - X_A$). This situation is illustrated in Fig. 28, though for the corresponding cellular automata dynamics and $X_{B_2} \neq 1 - X_A$.

Outside this window of parameter, the steady state is a "poisoned" catalyst of pure A (when $X_A > X_2$) or pure B (when $X_A < X_1$). For $X_1 < X_A < X_2$, the coverage fraction varies continuously with X_A and one speaks of a continuous (or second-order) nonequilibrium phase transition. At $X_A = X_2$, the coverage fraction varies discontinuously with X_A and one speaks of a discontinuous (or first-order) nonequilibrium phase transition. Figure 30 displays this behavior.

The asymmetry of behavior at X_1 and X_2 comes from the fact that A and B atoms have a different adsorption rule: two vacant adjacent sites are necessary for B to stick on the surface, whereas one empty site is enough for A.



Cellular Automata Modeling of Physical Systems, Figure 28
Typical microscopic configuration in the stationary state of the CA Ziff model, where there is coexistence of the two species over time. The simulation corresponds to the generalized model described by rules R1, R2, R3, and R4 below. The *blue* and *green dots* represent, respectively, the *A* and *B* particles, whereas the empty sites are *black*

In a CA approach the elementary cells of the catalyst are mapped onto the cells of the automaton. In order to model the different processes, each cell j can be in one of four different states, denoted $|\psi_j\rangle = |0\rangle, |A\rangle, |B\rangle$ or $|C\rangle$.

The state $|0\rangle$ corresponds to an empty cell, $|A\rangle$ to a cell occupied by an atom A, and $|B\rangle$ to a cell occupied by an atom B. The state $|C\rangle$ is artificial and represents a precursor state describing the conditional occupation of the cell by an atom B. Conditional means that during the next evolution step of the automaton, $|C\rangle$ will become $|B\rangle$ or $|0\rangle$ depending upon the fact that a nearest neighbor cell is empty and ready to receive the second B atom of the molecule B_2. This conditional state is necessary to describe the dissociation of B_2 molecules on the surface.

The main difficulty when implementing the Ziff model with a fully synchronous updating scheme is to ensure that the correct stoichiometry is obeyed. Indeed, since all atoms take a decision at the same time, the same atom could well take part in a reaction with several different neighbors, unless some care is taken.

The solution to this problem is to add a vector field to every site in the lattice [53], as shown in Fig. 29. A vector field is a collection of arrows, one at each lattice site, that can point in any of the four directions of the lattice. The directions of the arrows at each time step are assigned randomly. Thus, a two-site process is carried out only on those pairs of sites in which the arrows point toward each other (matching nearest-neighbor pairs (MNN)). This concept of *reacting matching pairs* is a general way to partition the parallel computation in local parts.

In the present implementation, the following generalization of the dynamics is included: an empty site remains empty with some probability. One has then two control parameters to play with: X_A and X_{B_2} that are the arrival probability of an A and a B_2 molecule, respectively.

Thus, the time evolution of the CA is given by the following set of rules, fixing the state of the cell j at time $t+1$, $|\psi_j\rangle(t+1)$, as a function of the state of the cell j and its nearest neighbors (von Neumann neighborhood) at time t. Rules R1, R4 describe the adsorption–dissociation mechanism while rules R2, R3 (illustrated in Fig. 29) describe the reaction–desorption process.

<u>R1</u>: If $|\psi_j\rangle(t) = |0\rangle$ then

$$|\psi_j\rangle(t+1) = \begin{cases} |A\rangle & \text{with probability } X_A \\ |C\rangle & \text{with probability } X_{B_2} \\ |0\rangle & \text{with probability } 1 - X_A - X_{B_2} \end{cases} \tag{22}$$

<u>R2</u>: If $|\psi_j\rangle(t) = |A\rangle$ then

$$|\psi_j\rangle(t+1) = \begin{cases} |0\rangle & \text{if the MNN of } j \\ & \text{was in the state } |B\rangle \text{ at time } t \\ |A\rangle & \text{otherwise} \end{cases} \tag{23}$$

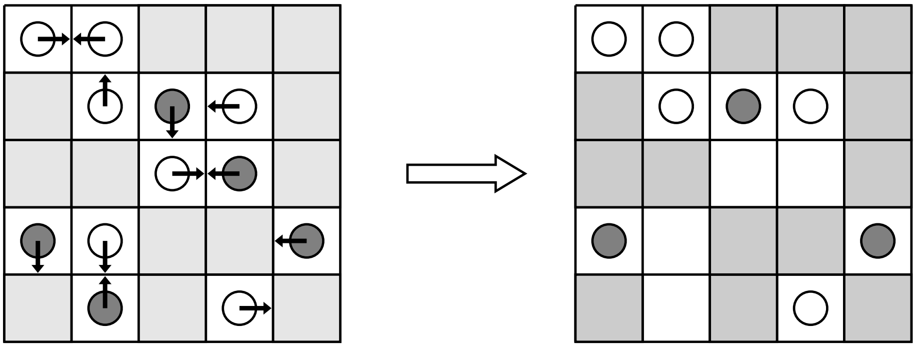
<u>R3</u>: If $|\psi_j\rangle(t) = |B\rangle$ then

$$|\psi_j\rangle(t+1) = \begin{cases} |0\rangle & \text{if the MNN of } j \\ & \text{was in the state } |A\rangle \text{ at time } t \\ |B\rangle & \text{otherwise} \end{cases} \tag{24}$$

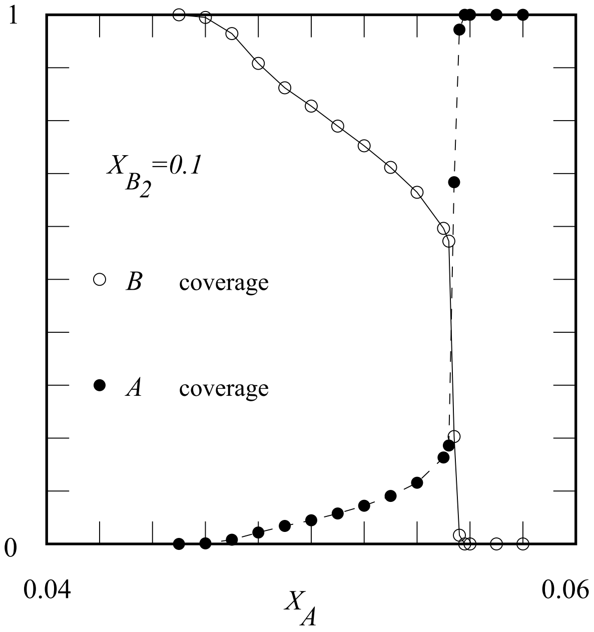
<u>R4</u>: If $|\psi_j\rangle(t) = |C\rangle$ then

$$|\psi_j\rangle(t+1) = \begin{cases} |B\rangle & \text{if MNN is in the state } |C\rangle \\ & \text{at time } t \\ |0\rangle & \text{otherwise} \end{cases} \tag{25}$$

Figure 28 shows typical stationary configurations obtained with a cellular automata version of the Ziff model. At time $t = 0$, all the cells are empty and a randomly prepared mixture of gases with fixed concentrations X_A and X_{B_2} sits on top of the surface. The rules are iterated until



Cellular Automata Modeling of Physical Systems, Figure 29
Illustration of rules R2 and R3. The *arrows* select which neighbor is considered for a reaction. *Dark* and *white particles* represent the *A* and *B* species, respectively. The *shaded region* corresponds to cells that are not relevant to the present discussion such as, for instance, cells occupied by the intermediate *C* species



Cellular Automata Modeling of Physical Systems, Figure 30
Stationary state phase diagram corresponding to the CA Ziff model

a stationary state is reached. The stationary state is a state for which the mean coverage fractions X_A^a and X_B^a of atoms of type A or B does not change in time, although microscopically the configurations of the surface changes.

The phase diagram obtained for this generalized CA Ziff model is given in Fig. 30, with the value $X_{B_2} = 0.1$. This phase diagram is topologically similar to the sequential updating case (with $X_{B_2} = 1 - X_A$) since we observe a first and a second order transition surrounding a region of coexistence of both species. However, the locations of the critical points are different, illustrating the nonuniversal character of these quantities.

Future Directions

Cellular Automata are clearly an active field of research. CA are easy to implement on personal computers or on large-scale parallel machines. They are very well suited to discuss many complex systems and dynamical phenomena with space inhomogeneities. Thus, CA provide a very interesting framework for modeling and simulating various processes, for a wide range of application domains where space and time are playing a central role. One can expect that such developments will continue in the future.

In addition, to provide numerical predictions, CA also offer a very intuitive and efficient language to describe various processes or systems. In a period where interdisciplinary applications are very important, it is crucial to be able to communicate between different scientific communities and to develop models that incorporate the knowledge of different fields. Partial differential equations are often an obstacle for several researchers outside Mathematics or Physics. CA then provide a different tool to describe new systems, for instance in ecology, social behavior or in many fields for which a standard mathematical framework is still missing.

The concept of CA can certainly be extended to correspond better to the future scientific challenges. The Lattice Boltzmann method is a well-known example where the Boolean nature of the CA state has been removed. As a result, powerful flow solvers have been obtained.

The nature of the cellular space can also be extended. Graphs are more and more studied for their ability to describe many organizations, whether social, economical, or biological. Therefore, a natural evolution of CA is to be able to include irregular and/or dynamic lattices of cells, so as to capture the behaviors that come from specificities of the space topology.

Another important direction in computational science are the so-called multiscale and multiscience simulations, aiming at coupling several processes spanning very different spatial or temporal scales. Such a combination of processes is for instance quite common in the simulation of biomedical problems. Recently, the concept of Complex Automaton [23] was proposed as a way to integrate in one single simulation many different components, each described by a different CA.

Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations

Carter Bays
Department of Computer Science and Engineering,
University of South Carolina, Columbia, USA

Article Outline

Typically, cellular automata ("CA") are defined in Cartesian space (e. g. a square grid). Here we explore characteristics of CA in triangular and other non-cartesian grids. Methods for programming CA for these non-cartesian grids are briefly discussed.

Glossary

Cellular automaton (CA) a structure comprising a grid with individual cells that can have two or more states; these cells evolve in discrete time units and are governed by a rule, which usually involves neighbors of each cell.

Game of life a particular cellular automaton discovered by John Conway in 1968.

Neighbor a neighbor of cell "x" is typically a cell that is in close proximity to (frequently touching) cell "x".

Oscillator a periodic shape within a specific cellular automaton rule.

Glider a translating oscillator that moves across the grid of a CA.

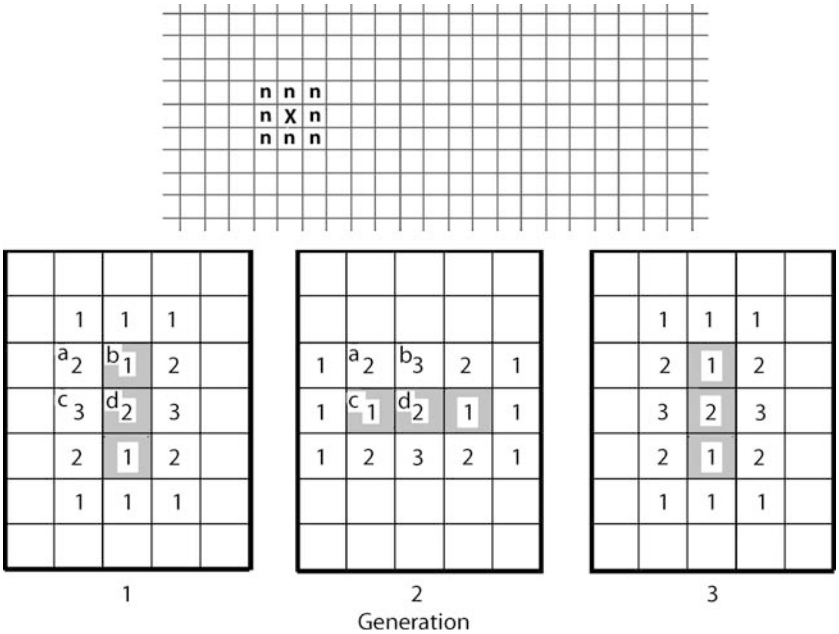
Generation the discrete time unit which depicts the evolution of a cellular automaton.

Rule determines how each individual cell within a cellular automaton evolves.

Definition of the Subject

A tessellation or tiling is composed of a specific shape that is repeated endlessly in a plane, with no gaps or overlaps. Examples of simple tessellations are the square grid, the triangular grid (a plane completely covered by identical triangles), etc. Hereafter, we shall also use "grid" when refering to tessellations.

Cellular automata (CA) can be explained most effectively with an example. Start with an infinite grid of squares; each square represents a cell, which is either "alive" or "dead". Time progresses in discrete units called "generations"; at every generation we evaluate simultane-



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 1
Top: Each cell in a grid has 8 "neighbors". The cells containing "n" are neighbors of the cell containing the "X". Any cell in the grid can be either "dead" or "alive". *Bottom*: Here we have outlined a specific area of what is presumably a much larger grid. At the *left* we have installed an initial shape. *Shaded* cells are alive; all others are dead. The number within each cell gives the quantity of live neighbors for that cell. (Cells containing no numbers have zero live neighbors.) Depicted are three generations, starting with the configuration at generation 1. Generations 2 then 3 show the result when we apply the following cellular automata rule: "Live cells with exactly 2 or 3 live neighbors remain alive (otherwise they die); dead cells with exactly 3 live neighbors come to life (otherwise they remain dead)". Let us now evaluate the transition from generation 1 to generation 2. In our diagram, cell "a" is dead. Since it does not have exactly 3 live neighbors, it remains dead. Cell "b" is alive, but it needs exactly 2 or 3 live neighbors to remain alive; since it only has 1, it dies. Cell "c" is dead; since it has exactly 3 live neighbors, it comes to life. And cell "d" has 2 live neighbors; hence it will remain alive. And so on. Notice that the form repeats every two generations. Such forms are called oscillators

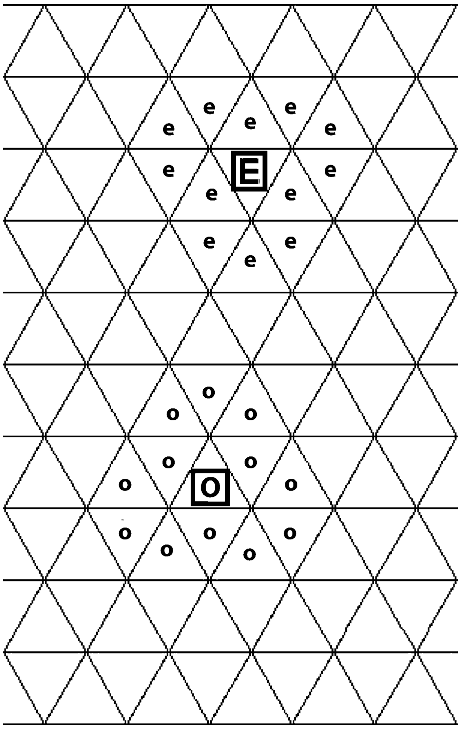
ously the fate for each cell at the next generation by examining neighboring cells (called "neighbors") – in this case, we shall consider as neighbors any cell touching the candidate cell (eight neighbors in all). This is sometimes called the Moore neighborhood. We apply a "rule" to determine the next generation status of our candidate cell. For example, our rule might state, (a) "If our candidate cell is currently alive, then it will remain alive next generation if it touches either two or three live neighbors, otherwise it dies", and (b) "If our candidate cell is not alive then it will come to life next generation if and only if it is touching exactly three live neighbors."

Figure 1 illustrates a simple configuration to which this CA rule has been applied. Notice that this particular object repeats itself indefinitely. Such an object is called an "oscillator"; this particular oscillator has a "period" of two. Other configurations can have much larger periods, or can behave in a more chaotic fashion. Motionless patterns can be thought of as oscillators whose period is one.

Needless to say, there are a huge number of rules that can be applied, and each rule will cause a distinct action. The rule given above – the most famous cellular automaton of all – specifies the "Game of Life", discovered by John Horton Conway in 1968. Game of Life (GL) rules must satisfy the following informal criteria.

1. All neighbors must be touching the candidate cell and all are treated the same.
2. There must exist at least one translating oscillator (called a "glider").
3. Random configurations must eventually stabilize into zero or more oscillators..

For a more formal description of GL rule requirements see [1]. It is important to note that CA can be represented in one, two, three or higher dimensions, but most work has been done in one or two. Furthermore, neighbors can be defined in many ways; for example we might only consider as neighbors those cells touching the sides of



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 2

The neighborhoods for cells in the triangular grid. Note that the candidate cells can have two orientations – "E" and "O". The neighbors are indicated by "e" and "o" respectively

a candidate cell and not the corners. Or we might expand our neighborhood to include cells within a given distance of a candidate cell. This is typically done for one-dimensional CA.

Some Convenient Notation for Describing CA Rules

We shall write CA rules using the following notation,

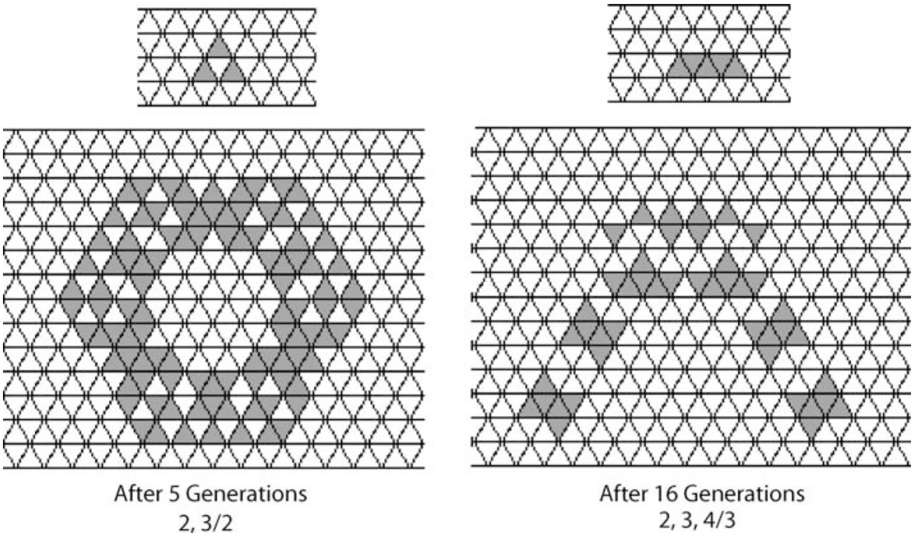
$$E_1, E_2, \ldots / F_1, F_2, \ldots$$

where the E_i specify the number of live neighbors required to keep a living cell alive, and the F_i give the number required to bring a non-living cell to life. The E_i and F_i will be listed in ascending order; hence if $i > j$ then $E_i > E_j$ etc. Thus the rule for Conway's Game of Life is written 2,3/3.

We shall also use a convenient shorthand when appropriate: E_i–E_j denotes $E_i, E_{i+1}, \ldots, E_{i+j-i}$ etc. Thus, 2,3,4,5,6/2,3,4 can also be written 2–6/2–4.

Introduction

Almost all CA research in two dimensions has been done using rectangular (Cartesian) coordinates, and hence typically utilizes the square grid. But there is no reason to limit ourselves to this tessellation; the number of different possible grids is almost endless. Here we shall briefly investigate CA behavior in only three – triangular, hexagonal and pentagonal.



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 3

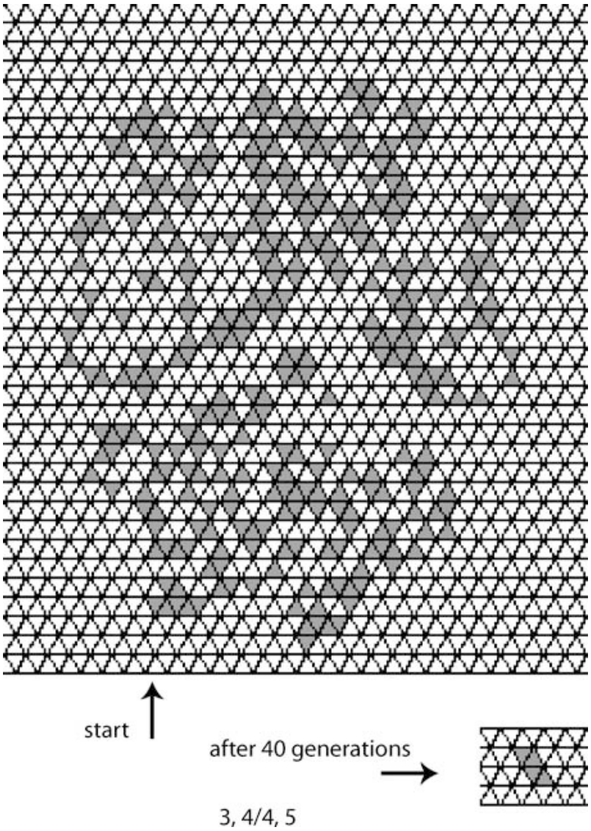
Examples of expanding rules. The starting configurations are at the top

Two Dimensional Cellular Automata in the Triangular Grid

Throughout this article we shall consider as neighbors only those cells that touch the candidate cell; hence for a grid composed of triangles, each cell would have 12 neighbors (Fig. 2). These non-cartesian grids for CA have been investigated from time to time; most notably by Preston [3] and Bays [1,2]. Recently work relating to hexagonal CA has appeared on the internet occasionally.

With 12 touching neighbors instead of 8 (as in the square grid), we can write more than 16 million distinct rules, most of which are probably of only marginal interest. Many however exhibit behavior worthy of investigation.

Some rules will generate a continually expanding collection of live cells – we shall call such rules "expanding" or "unstable" rules. Thus 2,3/2; 2,3/3,4; 2,3,4/3 each produce an ever increasing area of live cells – even with extremely small starting configurations (Fig. 3). A few expanding rules "barely" expand; i. e. several generations are required and the initial live configuration must be fairly large in order to observe instability. For example 2,3,6/4,5 can produce unbounded growth, while 2,3,8/4,5 always eventually stabilizes. The fate of configurations under 2,3,7/4,5 is uncertain, but the rule appears to produce unbounded growth. Many rules will ultimately lead to a stable pattern (Fig. 4), or no live cells at all.



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 4
An example of a stable rule. The starting random configuration eventually stabilizes into the shape shown at the *lower right*; interestingly this shape happens to be an oscillator with a period of two

For some rules we can start with bounded forms whose innards churn endlessly forever; these rules can, for example, be used to generate random numbers (Fig. 5). Such rules differ somewhat from expanding rules in that all finite patterns are bounded and will not expand indefinitely, but an infinite grid of random live cells will never stabilize.

Game of Life Rules in the Triangular Grid

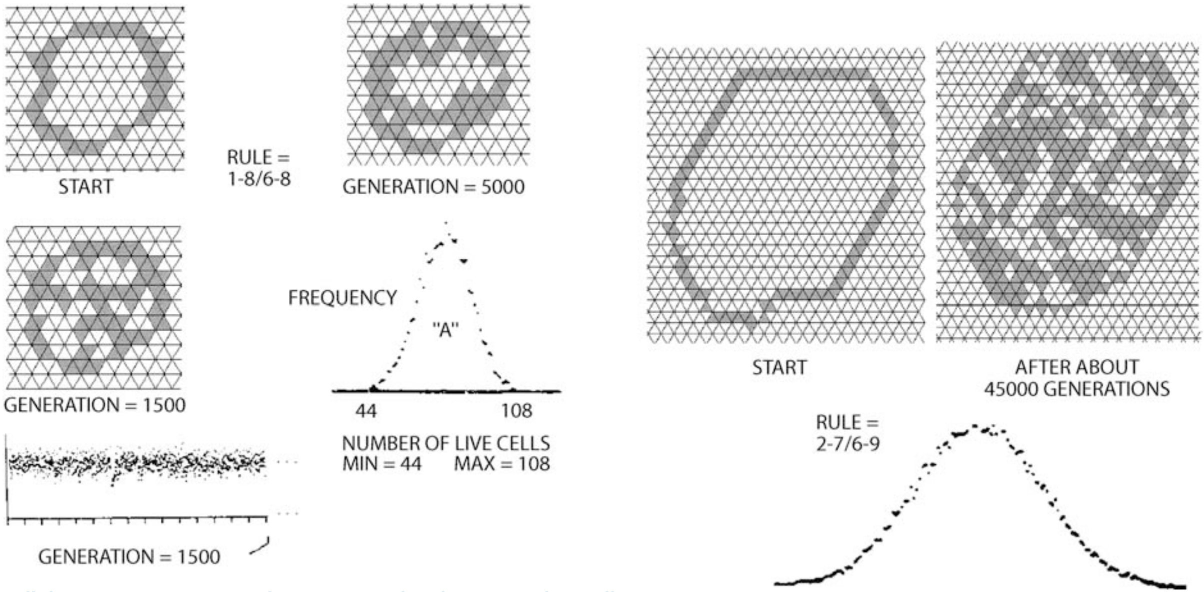
As mentioned above, the most famous GL rule is Conway's game, which utilizes a square grid. But GL rules are not limited to squares; quite a few exist in the triangular grid. Among these are 4,5,6/4; 3,4/4,5; 4,5/4,5,6; 2,3/4,5; 3,4/4,5,6; 2/3; 2,4/4,6; 3,5/4; 2,4,6/4,6; 2,7/3; 2,7,8/3. Further information about these and other rules can be found in [1] and [2].

The Hexagonal Grid

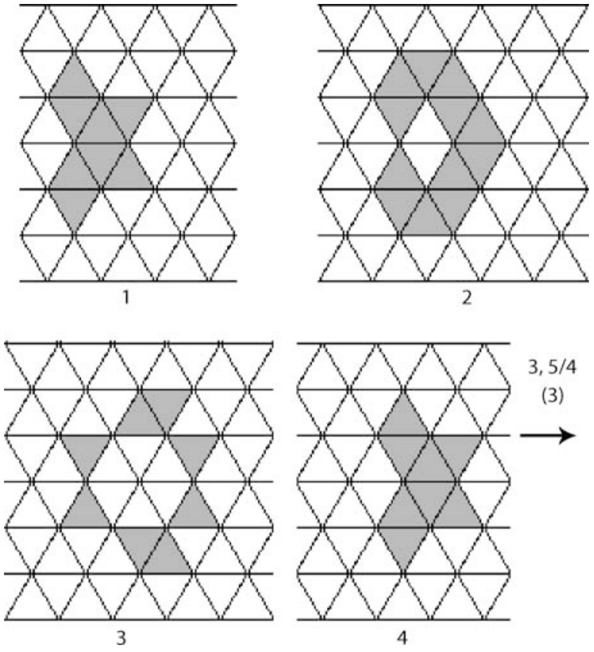
The neighborhood for the hexagonal grid is only half the size of that for the triangular grid and is symmetric – each neighbor is identical in the manner of contact with the cell in question. This symmetry can be important for some applications. Unfortunately, the hexagonal grid has a limited number of possible rules – there are only about 4000, many of which are of little interest. For many years past attempts to find a GL rule in the hexagonal grid have failed, although gliders were discovered by defining rules where the spatial relationship between neighbors was a factor [3]. Recently however the GL rule 3/2 was discovered. It supports the glider shown in Fig. 12. Another glider has also turned up; its rule is 3/2,4,5. Unfortunately this rule is not a GL rule, as it will very slowly exhibit unbounded growth, given a sufficiently large starting pattern.

The Pentagonal Grid

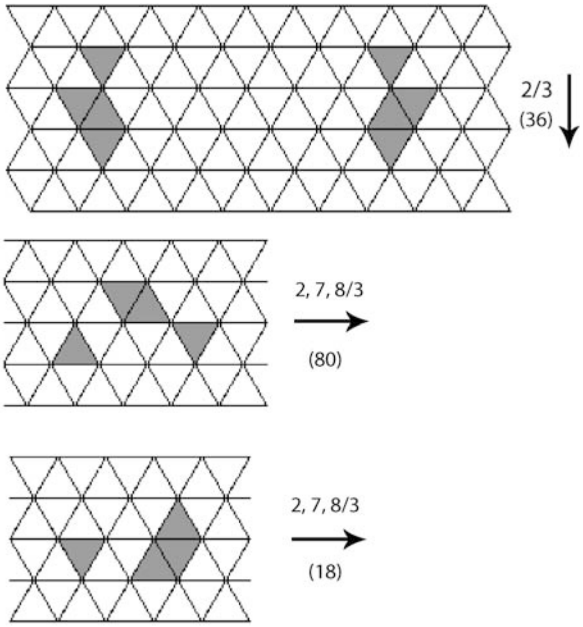
Regular pentagons cannot be formed into a grid, but by varying the angles and side lengths, we can create several tessellations from identical convex pentagons. A classification system has been devised, wherein 14 different types of tilings have been identified (Fig. 14). Of these, 12 are



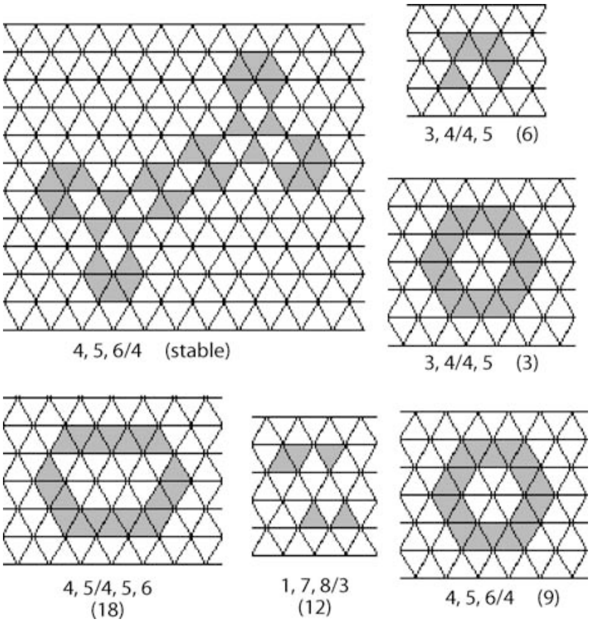
Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 5
Examples of bounded rules that churn endlessly. The total number of live cells can be employed as pseudorandom numbers that approximate a normal distribution. Many candidate rules can be used. Naturally the randomlike patterns eventually repeat, but with a sufficiently large initial shape, the period will be quite large. The plot at the *lower left* gives the number of live cells at each generation. These values exhibit a normal distribution (plot "A"). Note however that there are some gaps. This is because the rule 1-8/6-8 tends to have "clumps" of living (and fairly large "holes" of non-living) cells. Hence, before using this technique for generating random numbers, the candidate rule should be carefully investigated



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 6
A simple glider for the GL rule 3,5/4. It has a period of three (indicated in parentheses) after which it will have moved one cell to the right. Many gliders are not this well behaved, with much longer periods and irregular structure (see next figure)



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 7
Some gliders exhibit rather spectacular evolution. The period 80 2,7,8/3 glider, swells to 60 live cells during its swaggering trip across the grid, and at the 81st generation, will have moved 12 cells to the right. The gliders move in the direction given by the arrows. It should be noted that gliders have also been found for non-GL rules but since these rules are unstable they have not been investigated



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 8

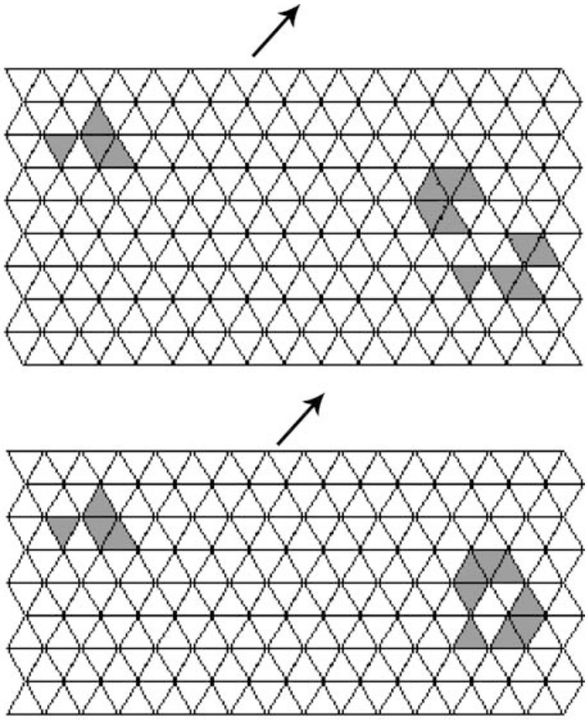
Hundreds of oscillators exist for the GL (and other) rules in the triangular grid. A few interesting ones are illustrated here. The stationary 4,5,6/4 form is representative of an infinite number of such objects that can be created for this rule by the careful positioning of live cells. The different oscillators at the lower right happen to share one identical shape. The oscillator at the *upper right* "rotates" clockwise, as does the period 12 oscillator at the bottom. Unfortunately rule 1,7,8/3 is not a GL rule

topologically distinct; these twelve varieties will behave in different ways under CA rules. We have chosen to investigate one of the most pleasing, the "Cairo tiling", so named because of its alleged use in parts of that city. It's appeal derives from the fact that the pentagons are both equilateral and isoseles.

Under the Cairo grid, there are rules that behave in the manner already described for the triangular grid – some rules expand, some stabilize, others contain a bounded, churning mass, etc. Interestingly, a GL rule has been discovered; its glider is depicted in Fig. 15. There is much opportunity for discovery in this and other pentagonal grids, as very little work has been done.

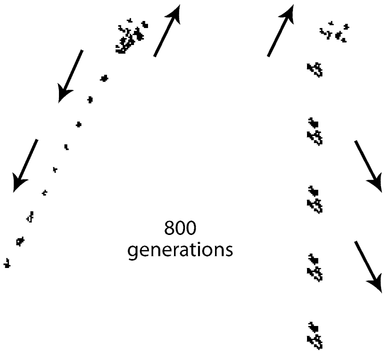
Programming Tips

We can speed up the scan of any grid by storing within each cell its current number of live neighbors along with a tag that indicates whether it is alive or not. Thus when we scan the entire grid for the next generation, we update



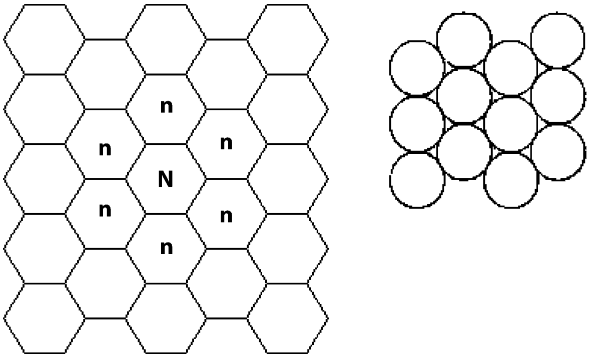
Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 9

The GL rule 2,7,8/3 is of special interest. It is the only known GL rule besides Conway's rule that supports a "glider gun" – a configuration that spews out an endless stream of gliders. In fact, there are probably several such patterns under that rule. Here we illustrate two guns; the top one generates period 18 gliders and the bottom one creates period 80 gliders. These configurations move in the direction shown, sending a stream of gliders out behind them (see next figure)

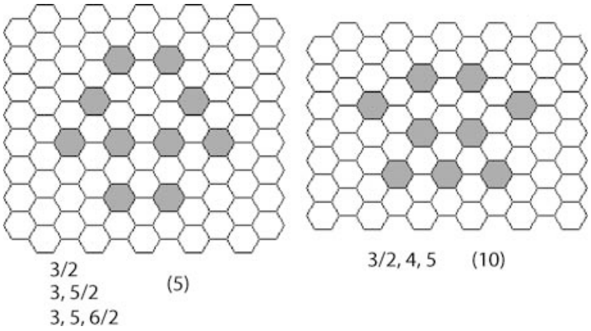


Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 10

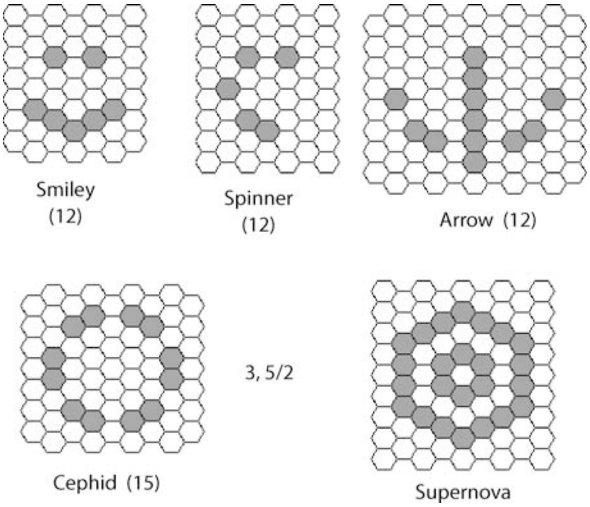
After 800 generations, the two guns will have produced the output shown. Motion is in the direction given by the arrows. The gun at the left yields period 18 gliders, one every 80 generations, and the gun at the right produces a period 80 glider every 160 generations



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 11
The symmetric hexagonal neighborhood. This rather "natural" grid can also be illustrated with *circles* (*upper right*) and, just as the square grid can be expanded to cubes in 3 dimensions, the hexagonal grid lends itself to "densely packed spheres" in three dimensions, where each sphere has exactly 12 touching neighbors



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 12
At least two gliders have been found. The GL rule 3/2 supports a period 5 glider and the non-GL rule 3/2,4,5 supports a period 10 glider. Note that the 3/2 glider also works for GL rules 3,5/2 and 3,5,6/2



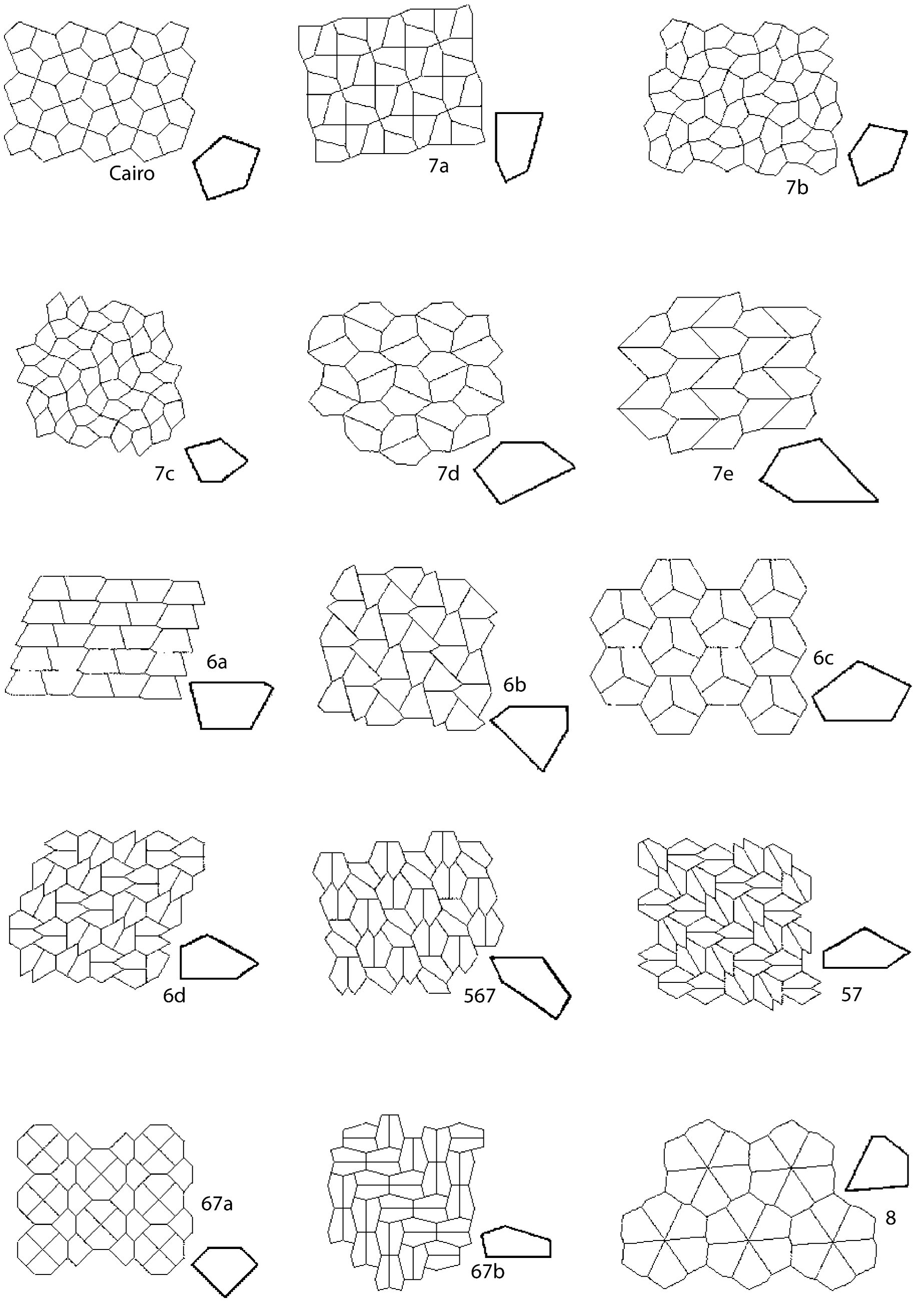
Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 13
Several interesting oscillators have been discovered for GL rule 3/2. They have been given rather whimsical names, a custom dating back to the early days of Conway's rule. After 65 generations the "supernova" pattern leaves a period 3 "neutron star" remnant. These patterns also work under rules 3,5/2 and 3,5,6/2

the status of cells that have changed since last generation (by examining their new neighbor counts) and, for each cell whose status has changed, we fix the neighbor counts for its neighbors; these cells are candidates for updating at the next generation iteration. This method employs two arrays – a "current" array, *A*, and a "next" array, *B*. And, rather than moving *B* back to *A* for the next iteration, we switch between the two; i. e. if array *A* is the array we are examining, then we copy it into array *B*, changing the status and neighbor counts of cells as needed. Array *B* then becomes array *A* for the next generation, etc. This trick allows us to rapidly scan over all non-changed cells. For further speed we can utilize hashing techniques and only store cells whose status is going to change. For this method, the speed of evaluation will depend only upon the number of cells that change between generations, and not the size of the grid, nor the total number of live cells. Furthermore, with a clever plotting algorithm, we can get away with replotting only those changed cells and not the entire grid.

We can program practically any grid or tiling in rectangular (square) coordinates by using templates to locate the neighbor cells as depicted in Fig. 16. The operation of finding the correct neighbors via templates adds a very small amount of time to the overall "next generation" evaluation; hence we would expect calculations on any type of grid to execute almost as fast as on the standard square grid.

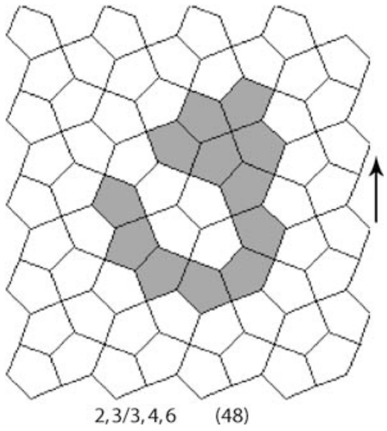
Future Directions

The triangular grid yields 12 touching neighbors and hence an ample supply of rules to investigate – many more than the 8 neighbor square grid. The hexagonal grid affords a more natural approach to CA than does the traditional 8 neighbor square grid, since neighbors all touch in the same way. Furthermore, when we expand this grid into three dimensions, we obtain a universe of dense packed spheres, which probably gives the best methodology for emulating 3D applications, as each cell has 12 touching neighbors and all touch in the same way. The fact that



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 14

The 14 distinct convex pentagonal tilings [see 1,5]. They are based upon certain relationships between the angles and lengths of the sides of the particular pentagon that constitutes the tiling. A sample of the pentagon for that tiling is displayed at the right of each. The tilings have been arranged to depict the number of touching neighbors for each cell. Where more than one number is given, there are some cells with each of those neighbor counts. For example the "67b" tiling is the second tiling where some cells have 6 neighbors and others 7. The Cairo tiling is at the *upper left* and is topologically equivalent to 7a and 7b. Note that 7c and 7d are also topologically equivalent



Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 15
The GL rule 2,3/3,4,6 supports the period 48 glider shown. It is asymmetric, though the second half of its period is a mirror image of the first. This characteristic is common amongst many gliders

GL rules have been found in a pentagonal grid undoubtedly means that other such rules can probably be found in many different tessellations – pentagonal and otherwise. The ultimate conclusion is that there is room for much work in the area of non-cartesian CA.

Cellular Automata in Triangular, Pentagonal and Hexagonal Tessellations, Figure 16
Templates can be used to simulate any grid with rectangular coordinates. For example, if we are evaluating the neighbors for a hexagonal cell at (i, j) (see "X") they would be found at $(i-1, j)$; $(i-1, j+1)$; $(i, j+1)$; etc. We can even simulate grids made up of different types of polygons. Here, we determine the polygon type by examining the subscripts of the cell in question. Of course, appropriate graphics procedures must be employed in order to view our grid

Article Outline

Glossary

Cellular automata They are dynamical systems that are continuous, local, parallel, synchronous and space and time uniform. Cellular automata are used to model phenomena where the space can be regularly partitioned and where the same rules are used everywhere, for example: flow dynamics or percolation in physics, systolic arrays in computer science, epidemics in biology...

The configurations are infinite arrays of cells. Each cell has a state chosen inside a finite set. The dynamics is given by replacing the state of each cell according to it and the states of the cells at a bounded distance. Since there are finitely many neighboring cells, there are finitely many state patterns/inputs. The mapping to the new state is called the local function. The same local function is used for all the cells. They are all updated simultaneously.

Computational universality Computability is defined by Turing machine, μ-recursive functions or λ-calculus. All these approaches (and many more) end up defining the same set of functions over $\mathbb{N}$ (or on words, i. e. finite sequences over a finite alphabet): the computable functions. They defined, according to the Church–Turing thesis, what can be computed by any reasonable device.

A machine is computation universal if it is able to compute any computable function (indicated as a part of the entry). This corresponds also to the common approach of computer, the hardware is universal and the program to be executed is stored in main memory (like the data to process) and is part of the input as far as the hardware / operating system is concerned.

Intrinsic universality It is the capability to simulate any machine in a class of machine. If one think of Turing machines or an equivalent model of computation, this folds back to the classical computational universality. The interest of this notion lays with machines that are not equivalent to Turing machines. This is the case of cellular automata: they update infinite configurations, there are uncountably many possible configurations thus they cannot be encoded in a countable set, say $\mathbb{N}$.

An intrinsically universal CA "represents" all the CA since it can exhibit any phenomenon any other one can.

Definition of the Subject

Cellular automata (CA) and the subject are briefly defined before two kinds of universality are considered: computational universality and intrinsic universality. A more involving section on advanced topics ends this chapter.

Computational universality deals with the capability to carry out any computation as defined by Turing machines (in computability Theory) while *intrinsic universality* deals with the capability to simulate any other machine of the same class (here cellular automata). This distinction is fundamental here because while computational universality refers to finite inputs and relates to our understanding of computing with computers, intrinsic universality encompasses infinite configurations and relates to our understanding of the physical world. These universalities are presented as simply as possible and an example of universal CA is presented in each case. The last section is devoted to the history and advanced topics such as various definitions of simulation between CA, restriction to reversible CA and different underlying lattices.

Introduction

A cellular automaton is a discrete dynamical system composed of regularly displayed cells which satisfies the following properties:

1. *Local finiteness*: the set of states available for any cell is finite and there is finitely many cells in any bounded region of space;
2. *Locality of computation*: the next state of a cell only depends on the cells around it. There is no global data nor unbounded effect;
3. *Uniformity* in both space and time: the dynamics of the cells are identical (space) and never change (time);
4. *Parallelism*: all cells are updated at each iteration; and
5. *Synchrony*: all cells are iterated at the same instant.

Local finiteness and locality of computation ensure that the next state of any cell can be computed with finite information. This and uniformity ensure that a finite description exists. Parallelism and synchrony ensure that the system is deterministic.

Locality of computation also means that a finite part of a configuration can be isolated in order to see how its central part evolves. It also means that the system is continuous according to the product topology [21,48]. Uniformity also means that the date is not relevant and that if, starting from some local pattern, a phenomenon appends, when the same pattern appears again, the same phenomenon appends, whatever the iteration and location.

Universality. Being universal is somehow to represent all, to be capable to achieve anything possible. This notion is twofold: on the one hand it can be *absolute*, not related to anything in particular, and on the other hand, it can be *relative* to a specific domain. In the case of cellular automata, these two cases are: computational universality and intrinsic universality.

The first one deals with the capability to compute any computable function and relates to simulating Turing machines. Computability Theory and the Church–Turing thesis tell that the set of computable functions does not rely on one specific computing system. On the many textbooks on the subject, (see Part 2 in [51]) is among the best ones for a computer scientist approach.

The second one deals with the capability to simulate any other CA starting from any initial configuration. The distinction is real because since CA do not halt, the notion of the result of a computation is quite meaningless and because CA handle infinite configurations. Even if Turing machines with infinite entries are considered, they only update a limited part of the tape in finite time while CA update the whole (infinite) configuration at each iteration! Since there are computation universal CA in dimension one and simulation is expected to preserve this property, all intrinsically universal CA are also computation universal.

For more information on cellular automata and universality, the reader might be interested in the following surveys and books: [11,20,24,26,58,61].

Outline of this chapter. Section "Computational Universality" deals with computational universality and Sect. "Intrinsic Universality" deals with intrinsic universality. In each of these sections, definition and results as well as the construction of an example of a universal CA are provided.

Section "Advanced Topics" starts with some history on the subject and then presents advanced and more involving results on existing definitions of simulations between CA, results on the restriction to the reversible CA and on variations on different underlying lattices. Section "Future Directions" presents some insight on future researches.

Formal Definition of a Cellular Automaton

A configuration is a made of cells regularly displayed on $\mathbb{Z}^d$; d is called the *dimension*. Each cell is in a state chosen among a finite set of states Q. A *configuration* is then an element of the set:

$$C = Q^{\mathbb{Z}^d} ,$$

which is referred to as the *set of configurations*. The computation is local, each cell evolves according to the states of the cells whose coordinates differ by at most r (*radius*) on any coordinate. The local evolution is given by a *local transition function* f that maps the states of the cell and the neighboring ones to the new state of the cell. The *global transition function*, $\mathcal{G}$, maps configurations into configurations; each state is replaced by the image of the states of the cell and the neighboring ones by the local transition function. The subset of $\mathbb{Z}^d$, $\mathcal{N} = [\![-r, r]\!]^d$ is called the *(complete) neighborhood*. It represents the relative positions of neighboring cells. The neighborhood is not necessarily of this form, in fact it can be any finite subset of $\mathbb{Z}^d$. The local and global functions are defined by:

$$\begin{array}{rcl} Q^{\mathcal{N}} & \xrightarrow{f} & Q \end{array} \qquad \begin{array}{rcl} C & \xrightarrow{\mathcal{G}} & C \\ c & \mapsto & \mathcal{G}(c) \ \text{ s.t. } \ \forall x \in \mathbb{Z}^d , \\ & & (\mathcal{G}(c))_x = f(c|_{x+\mathcal{N}}) , \end{array} \tag{1}$$

where $c|_{x+\mathcal{N}}$ denotes the restriction of the configuration c to the positions in $x + \mathcal{N}$.

Definition 1 A *cellular automaton* (CA) is designated by: (d, Q, r, f). When the (finite) neighborhood does not correspond to some $[\![-r, r]\!]^d$, this is emphasized by using $\mathcal{N}$ instead of r. The *space-time diagram*, $\mathcal{D}\colon \mathbb{Z}^d \times \mathbb{N} \to Q$, or orbit of a CA is just the infinite sequence of the configurations as the CA is iterated.

Examples of space-time diagrams are provided on Figs. 2 (left) and 4. For 1-dimensional CA, the space-time diagram can be seen as a tiling of the plane. In dimension 2, each configuration can be considered as a tiling. This approach leads to many undecidability results. It is developed in the ▶ Tiling Problem and Undecidability in Cellular Automata.

Definition 2 If any, the *quiescent state* of a CA, $q_\#$, is a distinguished state such that the uniform configuration $\overline{q_\#}$ is map onto itself (which is equivalent to $f(q_\#, q_\#, \ldots, q_\#) = q_\#$). A configuration is *finite* if only finitely many cells are not in the quiescent state.

Computational Universality

In this section, cellular automaton are proved to be able to perform any computation in the acceptation of computability Theory and thus that there exist computation universal CA. Only useful concepts and definitions are presented.

The computable functions can be defined by μ-recursion, λ-calculus, Turing machines or any other equivalent model. The Church–Turing thesis asserts that one gets the same functions up to some encoding/representation with any reasonable mean of computation. This is important since, for example, recursive functions address functions over natural integers while Turing machines deal with computations over words (finite sequences over a finite set of symbols). A model of computation is *computation universal* if any computable function can be computed by an instance/machine of the model. A machine is *computation universal* if it can compute any computable function as long as it is provided with the description of the function to compute along with the corresponding input. Computability Theory guarantees that such a universal machine exists.

The typical techniques to prove that a model of computation, here cellular automata, is computation universal are by:

Induction like recursion Theory. This would be proving that some functions over integer (e. g. $n \mapsto n+1$) are computable and then that the functions computable in the model are closed under some operations (e. g. composition);

Simulation of a generic instance of a computation universal model of computation. This would be to prove that any, say, Turing machine could be simulated by a cellular automata; and

Simulation of a computation universal instance of a computation universal model of computation.

These approaches are very different. The first one relies on defining functions but is not concerned by the way they are computed. The second one deals with effective means of computation (allowing the implementation of algorithms and the measure of complexity). The third one is the modern vision of the all-purposes computer: a laptop can do anything from picture manipulation to music playing going through text edition and programming. There is only one hardware and according to the need, one uses a program or another. This is the duality of data and code in modern computers.

Generally, the second case is more simple to tackle. There are mainly two cases when a specific universal machine is transformed:

- When the situation is so complex that using a specific machine with few instructions becomes easier; and
- To get a computation universal CA with specific properties or qualities, typically as few states as possible.

The latter is done by designing a special simulation with a good property and then applying it to a particularly well chosen instance.

The term "computation universal" is not synonymous of "Turing equivalent" which means that whatever computes the model can be computed by, say, a Turing machine. In the case of cellular automata, this is meaningless for two reasons:

- The output is not defined since as a dynamical system, a CA never stops; and
- When considering infinite configurations, there is just no way to manipulate them with Turing machines (uncountably many configurations for countably many words).

The first reason leads to a notion of simulation in an not-ending computation rather than an input-output function definition approach. The second reason can be bypassed when considering restrictions of configurations: finite or periodic. Another canonical thing is to consider models of computation able to handle uncountably many different inputs… like cellular automata. This idea leads to intrinsic universality presented in Sect. "Intrinsic Universality".

A Computation Universal Cellular Automaton

Here Turing machines and their executions are defined and a simulation by cellular automata is provided.

A Turing machine is a very simple device: a finite automaton that can read and write on an unbounded memory (indexed by $\mathbb{N}$). The memory is organized as an infinite sequence of cells called the *tape*. Each cell has a value from a finite set of *symbols* (the alphabet). Only a finite part of the tape is not empty at any step of the computation. The automaton is equipped with a head that can read or write a single cell of the tape and move the head one position forward of backward on the tape.

Definition 3 A *Turing machine* is defined by $(\Sigma, \#, Q, q_i, \delta)$, where

- Σ is a finite *alphabet*;
- $\# \in \Sigma$ is a special symbol use to indicate *empty* part of the tape;
- Q is the *set of states* of the automaton;
- $q_i \in Q$ is the *initial state*, and
- $\delta\colon Q \times \Sigma \to Q \times \Sigma \times \{\leftarrow, \rightarrow\}$ is the *transition function*.

δ	a	b	#
q_i	q_i, b, $\rightarrow$	q_i, a, $\rightarrow$	r, #, $\leftarrow$
r	r, a, $\leftarrow$	r, b, $\leftarrow$	r, #, $\leftarrow$

x	y	z	$f(x,y,z)$
α	q_i, a	β	b
α	q_i, b	β	a
q_i, a	α	β	q_i, α
q_i, b	α	β	q_i, α
α	q_i, #	β	#
α	β	q_i, #	r, β
α	r, β	γ	β
α	β	r, γ	r, β

$\alpha, \beta, \gamma \in \{\mathtt{a}, \mathtt{b}, \#\}$

	b	
α	q_i, a	β

Cellular Automata, Universality of, Figure 1
Transition function of a Turing machine and the simulating CA

The transition function works as follows: in a state q, reading a symbol a, if $\delta(q, \mathtt{a}) = (r, \mathtt{b}, \rightarrow)$ then the new state is r, the symbol b is written instead of a and the head moves one step on the right/forward.

Definition 4 A *computation* of a TM starts with the input written on the tape (completed by #s) and the automaton in state q_i. The computation goes on as defined by the transition function δ. The computation ends when the head tries to leave the tape on the left. The result is what is written on the tape.

This is not the usual definition which involves an halting state, although it is correct. This formalization stresses that stopping is somehow an incident from the dynamical system point of view. As far as cellular automata are concerned, they do not stop; an operator might stop a CA when some condition is fulfilled but this is external to the CA.

The Turing machine considered as an example is very simple: starting on a word on $\{\mathtt{a}, \mathtt{b}\}$, it replaces each a by a b and vice-versa. The only symbols on the tape are a, b and #. There are only two states: q_i and r. The transition function is given on the left of Fig. 1.

This Turing machine is simulated by a CA of radius 1 (i. e. only cells at distance at most 1 are taken into account for computing the next state of a cell). The set of states of the CA is $\Sigma \cup \Sigma \times Q$, that is, a tape symbol alone or together with a state of the TM. The CA has 9 states, the table of its local function has $729 (= 9^3)$ entries! In the table on the right of Fig. 1 only the cases where the state of the central cell changes are indicated. On the far right, the first transition rule is represented as it appears on space-time diagrams: the bottom line represents the cell and its two closest neighbors and on top the next state of the cell (at the next iteration). In all the space-time diagrams, time is evolving upward.

The dynamics is presented on Fig. 2. On the left the whole computation of the Turing machine on the entry aab is given; the output of the function is bba as written on the tape when the machine stops. On the right, the corresponding iterations of the simulating CA are displayed. Since the CA works on a bi-infinite lattice, the configuration is completed with # on the left. As mentioned, a CA never stops so that at some point the computation has been carried out but the system goes on.

A "halting" condition has to be provided, especially when one remembers that the halting of a Turing machine (the famous *Halting problem*) is not decidable. Usually, something very simple to test is chosen, for example that some state appears somewhere. Here this would be the first time the closest #-cell on the left is not in state #.

This example can easily be extended to a general method to simulate any Turing machine or specifically a computation universal one. Starting from a computation universal TM, a computation universal CA is generated.

Other Ways to Achieve Computational Universality

Among the various systems achieving computational universality that have been used to prove computational universality of CA, a brief classification can be made.

Machines. (Turing machines, counter automata and random access machines) These systems are very simple, an automaton together with a memory. In general, the whole evolution/orbit of the Turing machine is encoded inside the space-time diagram of the cellular automata like in the example. For counter automata [36], there are finitely many counters but they can hold any natural integer, any counter can be accessed at any time. Random access machines are like counter automata but with infinitely many register and an indirect access mode which allows to access any register. The random access machines model is the closest to modern computer architecture, but to sim-

Cellular Automata, Universality of, Figure 2
Iterations of a Turing machine and of the simulating CA

ulate it, one has to consider indirect addressing and infinitely many register. Counter automata are more simple to simulate: since there exists a computation universal 2-counter automaton, only 6 instructions have to be implemented.

Boolean circuits. The idea is to encode Boolean logic and then to say that any value can be encoded in binary and any function can then be computed with the binary encoding. For example, the transition function of a TM (resp. 2-counter automata) can be encoded and the value of the tape (resp. the counters) stored in an infinite memories. This is generally done by providing a way to encode bits, then logical gates and finally wiring to connect them. It is usually done in dimension 2, since ensuring a correct wire crossing is more complicated in dimension 1. A typical example of this is the computational universality of the Game of Life [6,19]. This is developed in the ▶ Gliders in Cellular Automata.

Rewriting systems. These systems work on words by removing some sub-word and adding some other sub-word. Starting with a word encoding an entry, the system is expected to stop with the output encoded in the final word. Here are some examples of computation universal systems:

- Type-0 grammar in Chomsky's hierarchy: one may replace sub-words by others according to rewriting rules; and
- Tag-systems: a prefix of the word is removed and according to it and some rules, a suffix is added.

The proof of the universality of the 2-states 3-neighbors 1-dimension CA referred as the elementary cellular automaton 110 by Cook [9] is done with some tag-system. The construction relies on an intermediate level of simulation that ensures signal transmission and updating. It is too involving and lengthy to be presented here. Signals and particles/solitons [1,53] are often used to carry bits/information around.

Consequences of Computational Universality

To have computation universality provides two things. On the positive side:

- Any computation can be carried out, so that if something has to be computed, whether as a final result or to use in a broader scheme, it can be done;
- Since any computation may take place, complex and interesting behaviors may appear;

and on negative side: many questions one may ask about the system become undecidable. The second point comes from the undecidability of the *Halting problem* (whether a given computation of a TM halts). Here are a few examples of this – many more can be found in, for example the ▶ Tiling Problem and Undecidability in Cellular Automata –, given a CA and a finite initial configuration:

- Will some state ever appear?
- Will the CA ever enter a stable configuration?
- Will the configuration grow infinitely?
- Will some given configuration be reached?

"Quality" of a Computation Universal Cellular Automata

Computability Theory is rather disappointing: one the one side what is computing and computable becomes clear but on the other side it mostly provides negative results like this and that are not computable. In this subsection slight differences on computability/simulation are addressed as well as complexity (of computing) issues.

For Turing machines, the written part of the tape is always finite. The tape is *potentially infinite*, it is extended by # as much as needed, it is never infinite. For computing with a CA, it can be assumed that only a finite part of the space is used for computing since otherwise it would take an infinite time for states to interact (it takes $l/2r$ for cells at distance l to interact). There is a definition of finiteness for CA (Def. 2): outside a finite part is it the quiescent state $q_{\#}$ (which plays the same role as #). When an infinite configuration (even if it is periodic after some point) is used to achieve computational universality, one talks about *weak computational universality*; more insights on the weakness notion on Turing machines can be found in [62].

Another important criterion is the one of the efficiency of computation. For example, the simulating a Turing machine by a 2-counter automaton suffers an exponential slowdown so that one may not be interested in such a computing device or any device where computational universality derives from a 2-counter automaton. For example, the proof of the computational universality of rule 110 by Cook [9] has an exponential slowdown but Neary and Wood [42] proved that in fact that it can be done with a polynomial slowdown. Polynomial slowdown is the classic simulation mode between reasonable models of computation (and this one of the key to the definition – and stability – of the complexity class P –polynomial time solvable problems).

Another thing worth mentioning is that CA are inherently parallel, the universality proofs more or less directly leads to the Turing machines which is the canonical sequential model. Various approaches have been made to consider CA as a computing system on its own, independently of any other model of computation, for example:

- *Iterative automaton* where the input is given symbol by symbol to a distinguished cell;
- As word recognizers with only one cell per symbol [55] (this cannot be computation universal because the memory is bounded);
- If finitely many cells are considered but they are all equipped with a stack, then any computation can be made [27];
- A algorithmic on CA based on signals has been developed [12,32,35]; and
- Martin devised an intrinsically universal CA together $S-m-n$ theorem for CA (as computing devices over infinite configurations) to provide a *acceptable programming system* point of view [31].

This directly links to the notion of universality developed in the next section.

Intrinsic Universality

Definition

Previous section deals with universality as the capability to perform any computation as defined in computability Theory. This theory deals with numbers/words and there exist only countably many configurations. But there are uncountably many configurations for any CA (unless, of course, if there is only one state). It is worth inquiring about another kind of universality that would take this into account and not involve any other model of computation. (It can thus be used for any class of dynamical systems.) It is some kind of *inner-universality*. The idea behind *intrinsic universality* is somehow the counterpart of universality for a Turing machine: being able to simulate any other CA (of the same dimension) on any (infinite) configuration.

Definition 5 A cellular automaton $\mathcal{A}$ *simulates* another CA $\mathcal{B}$ if there is an injective (one-to-one) function, ι, from the configurations of $\mathcal{B}$ to the ones of $\mathcal{A}$ and an integer, τ, such that the following diagram commutes:

$$\begin{tikzcd}
C_{\mathcal{B}} \arrow[r, "\iota"] \arrow[d, "\mathcal{G}_{\mathcal{B}}"'] & C_{\mathcal{A}} \arrow[d, "\mathcal{G}_{\mathcal{A}}^{\tau}"] \\
C_{\mathcal{B}} \arrow[r, "\iota"] & C_{\mathcal{B}}
\end{tikzcd}$$

A cellular automaton is *intrinsically universal* if it can simulate any other CA (of the same dimension).

The injectivity ensures that $\mathcal{B}$-configurations can be distinguished when mapped into $\mathcal{A}$-configurations. From this definition, it directly comes that:

$$\forall n \in \mathbb{N}\,, \quad \iota \circ \mathcal{G}_{\mathcal{B}}^{n} = \mathcal{G}_{\mathcal{A}}^{n.\tau} \circ \iota\,.$$

In an infinite run, $\mathcal{A}$ generates one iteration of $\mathcal{B}$ every τ iterations. Since the composition of injective functions is injective, the simulation relation is transitive. The definition is illustrated by the construction of an example in the rest of this section.

Other definitions of simulation can be found in Subsect. "Defining Simulation Among CA (For Intrinsic Universality)". In every case, a different intrinsic universality is generated.

The Way It Usually Works

It is assumed that the simulated CA has radius 1 and is 1-dimensional (how to deal with higher dimension is explained at the end of this section). If it is not the case, it is easy to simulate it by one of radius 1 (and then to use transitivity). Let $\mathcal{A} = (1, Q, r, f)$ be such that the radius is greater than 1. The idea is to group cells r by r and define $\mathcal{B} = (1, Q^r, 1, f_{\mathcal{B}})$ such that $f_{\mathcal{B}}$ is:

$$\begin{aligned}
&\forall (c_1, c_2, \ldots, c_r), (c_{r+1}, c_{r+2}, \ldots, c_{2r}),\\
&(c_{2r+1}, c_{2r+2}, \ldots, c_{3r}) \in (Q^r)^3,\\
&f_{\mathcal{B}}((c_1, c_2, \ldots, c_r), (c_{r+1}, c_{r+2}, \ldots, c_{2r}),\\
&(c_{2r+1}, c_{2r+2}, \ldots, c_{3r}))\\
&\qquad = (f(c_1, c_2, \ldots, c_{2r+1}), f(c_2, c_3, \ldots, c_{2r+2}),\\
&\qquad\qquad \ldots, f(c_r, c_{r+1}, \ldots, c_{3r})) .
\end{aligned}$$

The injection ι is the canonical injection where states are grouped r by r:

$$\forall c \in C \, , \forall i \in \mathbb{Z} \, , (\iota(c))_i = (c_{ir}, c_{ir+1}, \ldots, c_{(i+1)r-1}) .$$

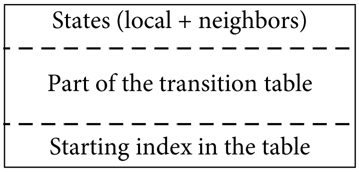
This simulation is just a rescaling of space. From now on, only radius 1 CA are considered. The construction of an intrinsically universal CA uses two scales:

- *Meta-cells scale* to manipulate the states and the transition function of the simulated CA; and
- *Bit scale* to implement the meta-cells.

A meta-cell gathers copies of the states of its two closest neighbors. Then it has to use the transition function to compute the new state. The transition function is tabulated in the form of a sequence of blocks $(\mathtt{a}, \mathtt{b}, \mathtt{c}, f(\mathtt{a}, \mathtt{b}, \mathtt{c}))$. (It could also have been be represented by, e. g., a boolean circuit with states binary encoded as in [45].)

Meta-Cells Scale Each meta-cell holds one block/entry of the transition table. The entries are infinitely repeating on both side and are endlessly shifting on the left so that in one period, the block corresponding to the update eventually appears. When one period has passed a new cycle starts. The architecture of meta-cells is presented on Fig. 3.

In the upper part of Fig. 4, a space-time diagram generated by some CA is given as well as the transition function of the CA in terms of a relation inside the space-time diagram between three states (at an iteration) and the state above (at the next iteration). In the lower part of Fig. 4, the simulation, at the meta-cell scale is presented. Each meta-cell corresponds to the presentation in Fig. 3. The transition table is set inside the initial configuration. The starting index is used by the meta-cell to detect the end of the cycle.



States (local + neighbors)
Part of the transition table
Starting index in the table

Cellular Automata, Universality of, Figure 3
Meta-cell

As it can be seen on Fig. 4, on the upper part of each cell; at start (lowest row) there are three copies of the state of the simulated cell then, copies are exchanged with the neighbors (first simulating iteration). Then the transition table starts moving. As soon as the entry is found in the table, the three states are replaced by three copies of the new state. The meta-cell then waits for its index to appear again to start this cycle again. The synchrony and uniformity of CA ensures that all meta-cells stay synchronized.

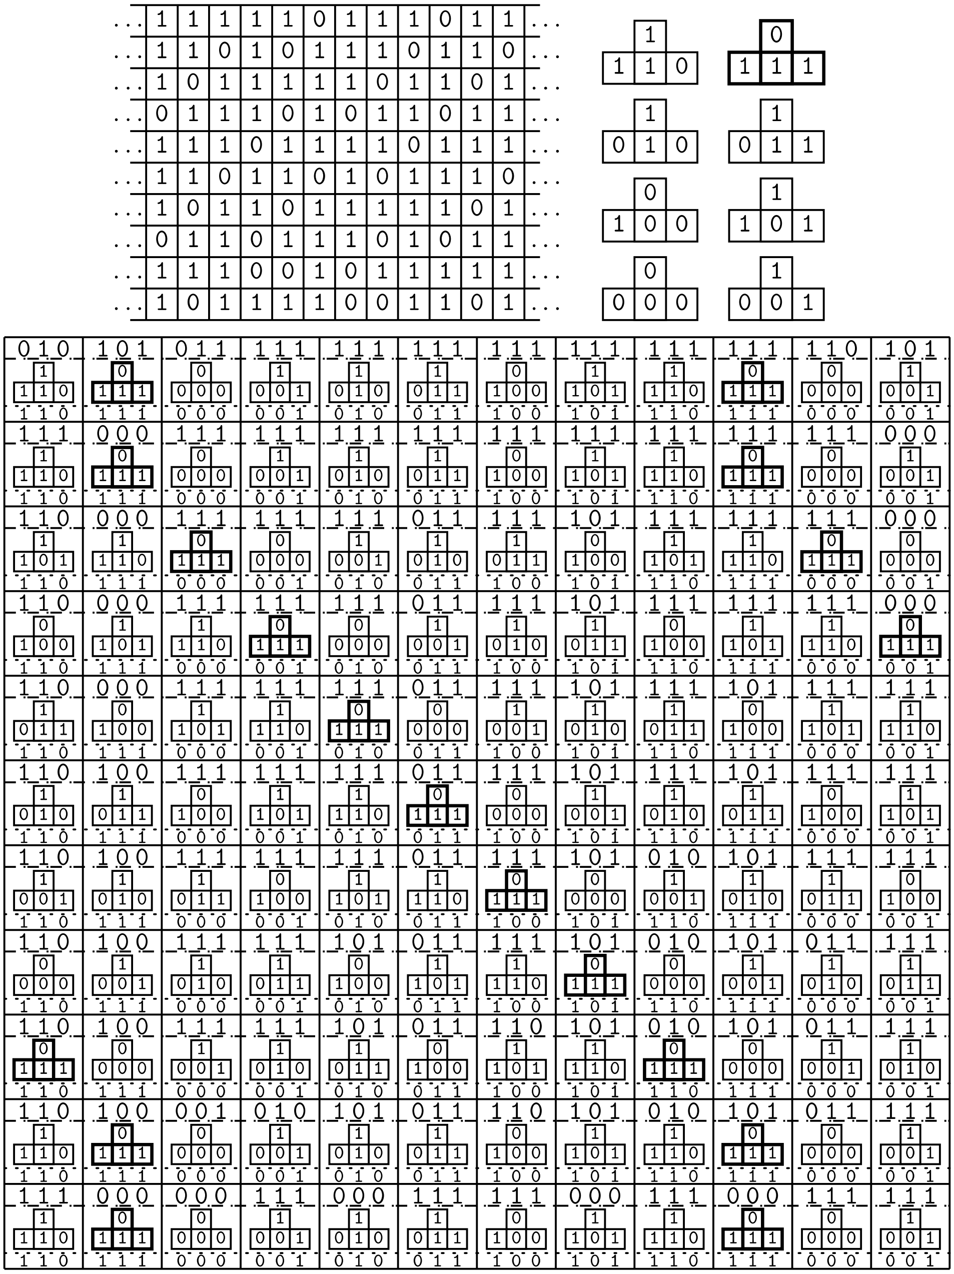
Bits Scale Since the encoding and simulation must work for any CA, it must be able to handle any set of states. The set of states of any CA if finite but unbounded, thus it is impossible to use a common set of states. A state a is thus binary encoded (denoted $(a)_2$). This way if the set of states is larger, then the meta-cell is larger, composed of more elementary cells.

On Fig. 5, a meta-cell is given and the layers named. The set of states on each layer for elementary cells are also given. Some layers are added:

- Structure: to delimit the different parts of the meta-cell,
- Control: to drive the movement, copy and test of bits, and
- Left and right: to carry bits around (to exchange states and to shift the transition table).

The left and right layers carry the bits very simply: unless noted otherwise the new value in left (resp. right) is the one that on the left (resp. right) layer of the right (resp. left) cell ensuring a left (resp. right) shift on the layer. When the simulation starts, s_{-1} and s_1 are equal to s_0 and (a, b, c) is equal to (a_0, b_0, c_0).

The meta-cell implementation works as follows: there is a single value in the control layer. It moves forth and back on the entire meta-cell like a signal. It manages bits from various layers and changes its state accordingly. The construction is only sketched; the states mentioned below are in an intermediate level between meta-cells and elementary cells. The universal CA is not detailed because although this is not complicated it would be quite lengthy and not very informative.



Cellular Automata, Universality of, Figure 4
Iteration of a CA and simulation at meta-cell scale of the first iteration

Starting in state q_0, a meta-cell first carries out the states exchange with the meta-cell on the left (the meta-cell on the right takes care of the other exchange) bit by bit using the left and right layers. In state q_1, the transition table is shifted by one entry. In state q_2, it moves through the entire meta-cell and checks whether the state and rule-in layers are identical. If the layers agree, the right transition is found and the state layer can be updated (the bits are copied) then it enters q_3 otherwise it restarts in q_1. In state q_3, the meta-cell has been updated; the transition

Cellular Automata, Universality of, Figure 5
Binary encoding of a meta-cell with elementary cells

table is still shifted until a full shift has been done. This is indicated by identical rule-in and index layers. In this the case it enters q_0 and the simulation of a new iteration starts.

Various technical things like delays are added to keep meta-cells synchronized. The number of iterations needed to simulate an iteration is roughly speaking the length of a cell multiplied by the length of the transition table: $\log(|Q|).|Q|^3$.

Higher dimension. It is treated exactly in the same way. One layer gathers the information, another one deals with the transition function. The transition table shifting is done on one dimension only. Extra dimensions can be used to accelerate the process or to design circuitry for a more efficient encoding of the transition function.

Intrinsically universal CA are computation universal by composition (as long as the definitions are robust enough). There is no notion of semi-weakly simulation since the whole configuration has to be used to encode an infinite configuration.

Advanced Topics

This section gathers a brief history of the subject and various results on specific approaches. It is more involving and targeted to a learned reader.

A Bit of History

Since there is a lot of places where the history of CA is presented (as well as other chapters of this encyclopedia, the reader might be interested in the following survey: [50]), only the universality part is developed here.

Cellular automaton were introduced in the 50's by Ulam and von Neumann [59] to study self-reproduction [3,7,60]. Computational universality was used just to prove that any pattern can be built. Universality was investigated and proved without any explicit distinction between computational and intrinsic universality before [5].

The most famous CA is certainly Conway's Game of Life [19] from the early 70s. This 2-dimensional CA is both computation universal [6] and intrinsically universal [14].

Quest for Small Universal CA There have been an ongoing search for more than four decades for universal CA as small as possible. The interest is to know whether "small" CA are more simple and thus can be handled or there is no gap in complexity. Table 1 sums up results in this quest. Intrinsically universal CA are also computation universal but the converse is not true.

These results were achieved with various constructions. Some use quite different definitions of CA for commodity (but there are indeed CA):

- As partitioned CA [38], and
- As CA with Margolus's neighborhood (or partitioning CA): [30,58] (billiards) and [10] (spin model in Physics).

Computing universality can also be defined by the computational complexity of the sets of orbits of a CA as well as the reachability relation, relating to the Turing degrees of undecidability [54].

Defining Simulation Among CA (For Intrinsic Universality)

The definition used in Sect. "Computational Universality" is not the only existing one. Many papers prove results on simulation without providing a formalized definition of it, but by considering the construction anyone would say that it is a simulation, in an empirical fashion. There is no absolute definition commonly accepted and none contradicts the intuition of simulation. In Table 1, no distinction on the simulation is made and most of the time the construction fits in more than one definition.

Most of the presented definitions can be amended in order to cover cases where not all iterations are covered,

say for example only the one out of 3. In the following, $\mathcal{A} = (Q_{\mathcal{A}}, r_{\mathcal{A}}, f_{\mathcal{A}})$ and $\mathcal{B} = (Q_{\mathcal{B}}, r_{\mathcal{B}}, f_{\mathcal{B}})$ denote cellular automata of the same dimension d.

Embedding of Hertling The term *embedding* is to be understood as simulation. It was introduced in order to prove that CA that are not onto cannot be simulated by onto (and specially reversible) ones of the same dimension.

Definition 6 (Embedding [23]) A mapping $\mu\colon Q_{\mathcal{A}}^{\mathbb{Z}^d} \to Q_{\mathcal{A}}^{\mathbb{Z}^d}$ is said to be a *morphism* if and only if for any shift of $\mathbb{Z}^d$, $\sigma_{\mathcal{A}}$, there exists a shift of $\mathbb{Z}^d$, $\sigma_{\mathcal{B}}$, such that: $\mu \circ \sigma_{\mathcal{A}} = \sigma_{\mathcal{B}} \circ \mu$.

$\mathcal{A}$ can be embedded in $\mathcal{B}$ if there are mapping $\mu\colon Q_{\mathcal{A}}^{\mathbb{Z}^d} \to Q_{\mathcal{A}}^{\mathbb{Z}^d}$ and $\nu\colon Q_{\mathcal{A}}^{\mathbb{Z}^d} \to Q_{\mathcal{A}}^{\mathbb{Z}^d}$ and an integer k such that:

$$\forall t \in \mathbb{N}\,, \quad G_{\mathcal{A}}^{t} = \nu \circ G_{\mathcal{B}}^{kt} \circ \mu\,. \tag{2}$$

The embedding is *strong* if μ is a continuous morphism, *weak* if it is a just a morphism and *set-theoretic* otherwise (i. e. not a morphism).

The interest of the morphism is to enforce the respect of the structure of $\mathbb{Z}^d$. Hertling proved, using the Axiom of Choice (hence the qualification) that any CA can be set-theoretically embedded in the one dimensional CA that does nothing but shift the value on the left. This is of course highly nonconstructive and contradict the intuition of what simulation could be.

Comparing to Def. 5, using ν to come back allows to have some garbage produced and discarded by ν.

Grouping Relation of Mazoyer and Rappaport This definition of a grouping relation was introduced to focus on the importance of space and time structure. It allows to consider iterations once in a while, periodically.

Definition 7 (Grouping [33,34]) A cellular automaton $\mathcal{A}$ is a *sub-automaton* of $\mathcal{B}$ (denoted $\mathcal{A} \subseteq \mathcal{B}$) if there is an injection $\phi\colon Q_{\mathcal{A}} \to Q_{\mathcal{B}}$ such that:

$$\overline{\phi} \circ G_{\mathcal{A}} = G_{\mathcal{B}} \circ \overline{\phi}\,,$$

where $\overline{\phi}$ is the component-wise extension of ϕ to $\mathcal{A}$-configurations. The nth grouping of an automaton is defined by grouping the cells n by n and consider only every nth iteration, $\mathcal{A}^n = (d, Q_{\mathcal{A}}^n, r_{\mathcal{A}}, f_{\mathcal{A}}^{(n)})$. The function $G_{\mathcal{A}^n}$ is the nth iterate of $G_{\mathcal{A}}$. Since the cells are grouped by n, the radius is not changed. The grouping relation is defined by:

$$\begin{aligned}&\mathcal{A} \leq_{\text{grouping}} \mathcal{B}\\ &\qquad \iff \exists n, m \in \mathbb{N}\,, \quad 0 < n, m\,, \quad \mathcal{A}^n \subseteq \mathcal{B}^m\,.\end{aligned}$$

This is a stronger form of simulation where the space-time diagrams should be included; up to some rescaling on both side, all the space-time diagrams of $\mathcal{A}$ should be exactly (up to an injection) generated. There is no shift involved and the space-time ratio should be preserved.

This relation is a pre-order. The authors proved that there is a bottom equivalence class for CA: the CA with only one state (and one configuration). The nilpotent ones (after a fixed number of iterations any configuration is turned into the same one: only quiescent state) are just above. They also proved that there is an unbounded infinite ascending chain, so that there is no top and thus no intrinsically universal CA for this definition.

Rescaling of Ollinger The previous definition is on the one hand interesting because it relays on space-time diagrams and a natural operation, grouping, over them, but on the other hand, there is no intrinsically universal CA, which have been provided for other definition. The following definition is a weakening of the first one that allows intrinsically universal CA.

Definition 8 (Rescaling [44]) For any k in $\mathbb{Z}^d$, let σ^k denotes the *shift* by k over configurations. For any m in $\mathbb{Z}^d$, let o^m denotes the *packing* of cells into packs of size m; it is a mapping from $Q^{\mathbb{Z}^d}$ into $(Q^m)^{\mathbb{Z}^d}$ (o^{-m} is the inverse, the unpacking function).

For $n, k \in \mathbb{Z}^d$ and $n \in \mathbb{N}$, $0 < n$, the $\langle m, n, k\rangle$-rescaling of $\mathcal{A}$ is the cellular automaton $\mathcal{A}^{\langle m,n,k\rangle}$ such that:

$$\mathcal{G}_{\mathcal{A}^{\langle m,n,k\rangle}} = \sigma^k \circ o^m \circ \mathcal{G}^n_{\mathcal{A}} \circ o^{-m} \; .$$

A cellular automaton $\mathcal{A}$ is simulated by $\mathcal{B}$ if there exists a rescaling of $\mathcal{A}$ which is a sub-automaton of a rescaling of $\mathcal{B}$. (The sub-automaton relation is defined as in Def. 7.)

This definition allows to include a shift and to treat independently the size of the blocks of cells and the iteration step. Comparing to the grouping definition (Def. 7), this allows to have enough time to locally mix information and compute the next state. Intrinsically universal CA exist (also with a meta-cell approach) and intrinsic universality of a 1-d CA is undecidable [46]. This result is still true on captive CA (the transition function may only output a state that is in the input) even though as the number of states grows larger, almost all captive CA is intrinsically universal [56,57].

Reversible Case

The reversible subset of cellular automaton (CA such that the global function is invertible, its inverse is then the one of a CA) also contains computation universal CA [13,38,40]. This topic is developed in the ▶ Reversible Cellular Automata.

There exist reversible CA that are intrinsically universal inside reversible CA [15,16,18]. This means able to simulate any other reversible CA (of the same dimension) and not just any CA. It is a strong embedding (Def. 6) and does not contradict Hertling's results [23] that non surjective CA cannot be simulated by reversible one.

Morita proved the any CA can be simulated over finite configurations by a reversible in [37,39] but garbage is produced in order to ensure reversibility and the simulation time varies as the simulation goes on.

There is also a particular result [17] including the simulation of the non-reversible CA, but the simulation goes by a different definition. It is centered (like the usual metric) and the simulated iterated configurations are displayed on parabolas. This twisting of space yields an infinite space to store the information for reversibility. It is not possible to recover a simulated iteration from finitely many simulating ones! The whole simulating space-time diagram is needed.

Variations on CA

Changing the Underlying Space Other 2-dimensional spaces have been considered. There exist reversible computation universal CA both on triangular lattices [25] and hexagonal lattice [41].

Róka studied simulation between CA on different lattices in a very general way: lattices are Cayley graph (it corresponds to a group, the arrows corresponds to generators). She proved the existence of simulations in the case of the existence of an homomorphism with a finite kernel and that all bi-dimensional planar structure are equivalent to $\mathbb{Z}^2$ [49].

There exist computation universal CA [22] and intrinsically universal CA [29] on the hyperbolic plane. This is more developed in the ▶ Cellular Automata in Hyperbolic Spaces.

Intrinsic Universality Among Quantum Cellular Automaton In the past decade, quantum computation theory has been tremendously developing. It relies on unitary gates which are of course reversible. The results on reversible CA has been "naturally" extended, for example, there is a 1-dimension Quantum CA which is intrinsically universal (among quantum CA) [4]. For more on the topic, please refer to the ▶ Quantum Cellular Automata.

Variable Neighborhood A new approach is to fix the states and the transition function and to have only the neighborhood (i. e. the relative localization of the entries of the transition function) varying. Somehow it can be considered that the neighborhood is not defined by the CA but by the configuration. Some simulation results exists [43,63]. The transition function of simulated CA is not given inside the simulating configuration but by the simulating neighborhood.

Future Directions

As mentioned just above, understanding the role played by the neighborhood in computing might be very enlightening.

It is known that 2 states and 2 neighbors is enough for computing with polynomial slowdown. It might be interesting to find constructions with limited slowdown and very concise encoding. Since CA are inherently parallel while Turing machines are sequential, a computing (and complexity) theory and algorithm that incorporate the parallelism of CA (local, uniform and synchronous) is worth enquiring.

As far as intrinsic universality is concerned, it relies on simulation between CA. The various definitions have to be linked and investigated.

Article Outline

Glossary

Cadherins Important class of transmembrane proteins. They play a significant role in cell-cell adhesion, ensuring that cells within tissues are bound together.

Chemotaxis Motion response to chemical concentration gradients of a diffusive chemical substance.

Extracellular matrix (ECM) Components that are extracellular and composed of secreted fibrous proteins (e. g. collagen) and gel-like polysaccharides (e. g. glycosaminoglycans) binding cells and tissues together.

Fiber tracts Bundle of nerve fibers having a common origin, termination, and function and especially one within the spinal cord or brain.

Haptotaxis Directed motion of cells along adhesion gradients of fixed substrates in the ECM, such as integrins.

"Slime trail motion" Cells secrete a non-diffusive substance; concentration gradients of the substance allow the cells to migrate towards already explored paths.

Somatic evolution Darwinian-type evolution that occurs on soma (as opposed to germ) cells and characterizes cancer progression [1].

Definition of the Subject

Cancer cells acquire characteristic traits in a step-wise manner during carcinogenesis. Some of these traits are autonomous growth, induction of angiogenesis, invasion and metastasis. In this chapter, the focus is on one of the late stages of tumor progression: tumor invasion. Tumor invasion has been recognized as a complex system, since its behavior emerges from the combined effect of tumor cell-cell and cell-microenvironment interactions. Cellular automata (CA) provide simple models of self-organizing complex systems in which collective behavior can emerge out of an ensemble of many interacting "simple" components. Recently, cellular automata have been used to gain a deeper insight in tumor invasion dynamics. In this chapter, we briefly introduce cellular automata as models of tumor invasion and we critically review the most prominent CA models of tumor invasion.

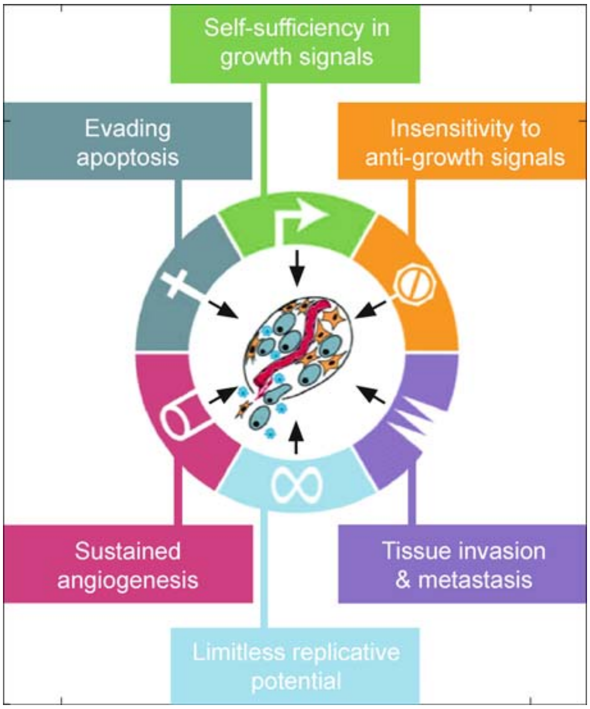
Introduction

Cancer describes a group of genetic and epigenetic diseases characterized by uncontrolled growth of cells, leading to a variety of pathological consequences and frequently death. Cancer has long been recognized as an evolutionary disease [2]. Cancer progression can be depicted as a sequence of traits or phenotypes that cells have to acquire if a neoplasm (benign tumor) is to become an invasive and malignant cancer. A phenotype refers to any kind of observed morphology, function or behavior of a living cell. Hanahan and Weinberg [3] have identified six cancer cell phenotypes: unlimited proliferative potential, environmental independence for growth, evasion of apoptosis, angiogenesis, invasion and metastasis.

In this chapter, we focus on the invasive phase of tumor growth. Invasion is the main feature that allows a tumor to be characterized as malignant. The progression of a benign tumor and delimited growth to a tumor that is invasive and potentially metastatic is the major cause of poor clinical outcome in cancer patients, in terms of therapy and prognosis. Understanding tumor invasion could potentially lead to the design of novel therapeutical strategies. However, despite the immense amounts of funds invested in cancer research, the intracellular and extracellular dynamics that govern tumor invasiveness in vivo remain poorly understood.

Biomedically, invasion involves the following tumor cell *processes*:

- Tumor cell migration, which is a result of down-regulation of cadherins, that is loss of cell-cell adhesion,
- Tumor cell-extracellular matrix (ECM) interactions, such as cell-ECM adhesion, and ECM degradation or remodeling, by means of proteolysis. These processes allow for the penetration of the migrating tumor cells into host tissue barriers, such as basement and interstitial stroma [4], and
- Tumor cell proliferation.



Self-sufficiency in growth signals
Evading apoptosis
Insensitivity to anti-growth signals
Sustained angiogenesis
Tissue invasion & metastasis
Limitless replicative potential

Cellular Automaton Modeling of Tumor Invasion, Figure 1
Hanahan and Weinberg have identified six possible types of cancer cell phenotypes: unlimited proliferative potential, environmental independence for growth, evasion of apoptosis, angiogenesis, invasion and metastasis (Reprinted from [3], with permission from the authors)

Tumor invasion facilitates the emergence of metastases, i. e. the spread of cancer cells to another part of the body and the formation of secondary tumors. Tumor invasion comprises a central aspect in cancer progression. However, invasive phenomena occur not only in pathological cases of malignant tumors but also during normal morphogenesis and wound healing.

Cancer research has been directed towards the understanding of tumor invasion dynamics and its implications in treatment design. In particular, research concentrates along the following *problems*:

Invasive tumor morphology: A wealth of empirical evidence links disease progression with tumor morphology [5]. The tumor morphology can indicate the degree of a tumor's malignancy. In particular, it is experimentally and clinically observed that a morphological instability is related to invasive solid tumors, producing finger-like spatial patterns. The question is which molecular and cellular mechanisms are responsible for this spatial pattern formation.

Cell migration and influence of the ECM: Important aspects of invading tumors are cell motion and the effect of the surrounding environment, especially the ECM [4].

Metabolism and acidosis: The multi-step process of carcinogenesis is often described by somatic evolution, wherein phenotypic properties are retained or lost depending on their contribution to the individual tumor cell survival and reproductive potential. One of the most prominent phenotypic changes involves the anaerobic glucose metabolism (glycolysis). A side-product of this metabolic activity is the production of H^+ ions that increase the pH of the tumor's microenvironment (acidosis). This gives rise to the questions: (i) Why does tumor evolution lead to this kind of metabolism, which is energetically deficient in comparison with the aerobic one? (ii) What are the advantages for the tumor? (iii) How do glycolytic tumor cells influence tumor invasion?

Emergence of invasion: Typically, tumor invasion appears during the late stages of carcinogenesis. Of ultimate importance is the question what are the mechanisms and the environmental conditions that trigger the progression from benign neoplasms to malignant invasive tumors.

Robustness: There are several questions concerning the stability and the resistance of tumor invasion such as: (i) Why are malignant tumor so robust (resistant) to perturbations (i. e. therapies)? (ii) Is it possible to design intelligent therapies (at the cellular level) that disturb the tumor's robustness? (iii) How can we investigate the tumor's robustness?

Mathematical modeling and analysis provide invaluable tools towards answering the above questions. Tumor invasion involves processes which occur at different spatio-temporal scales, including processes at the subcellular, cellular and tissue level. Mathematical models allow description and linking of these levels. One can distinguish *molecular*, *cellular* and *tissue* scales, respectively [6,7]:

- The molecular scale refers to phenomena at the subcellular level and concentrates on molecular interactions and resulting phenomena, such as alterations of signaling cascades and cell cycle control, gene mutations, etc. In tumor invasion, the down-regulation of cadherins provides an example of a molecular process.
- The cellular scale refers to cellular interactions and therefore to the most prominent dynamics of cell populations, e. g. adhesion, contact inhibition, chemotaxis etc.
- The tissue scale focuses on tissue level processes taking into account macroscopic quantities, such as volumes, flows etc. Continuum phenomena include cell convection and diffusion of nutrients and chemical factors, mechanical stress and the diffusion of metastases.

For example, genetic alterations may lead to invasive cells (molecular scale) that are able to migrate (cellular scale) and interact with diffusible or non-diffusible signals (tissue scale). Models that deal with phenomena at multiple scales are called multi-scaled.

Recently, a variety of mathematical models have been proposed to analyze different aspects of tumor invasion. Deterministic macroscopic models are used to model the spatio-temporal growth of tumors, usually assuming that tumor invasion is a wave propagation phenomenon [8,9,10,11,12]. Computational investigations of the invasiveness of glioma tumors illustrate that the ratio of tumor growth and spatial anisotropy in cell motility can quantify the degree of tumor invasiveness [13,14]. Whilst these models are able to capture the tumor structure at the tissue level, they fail to describe the tumor at the cellular and the sub-cellular levels. Lately, multi-scale approaches attempt to describe and predict invasive tumor morphologies, growth and phenotypical heterogeneity [15,16].

Cellular automata (CA), and more generally cell-based models, provide an alternative modeling approach, where a micro-scale investigation is allowed through a stochastic description of the dynamics at the cellular level [17]. In particular, CA define an appropriate modeling framework for tumor invasion since they allow for the following:

- CA rules can mimic the processes at the cellular level. This fact allows for the modeling of an abundance of experimental data that refer to cellular and sub-cellular processes related to tumor invasion.
- The discrete nature of CA can be exploited for investigations of the boundary layer of a tumor. Bru et al. [18] have analyzed the fractal properties of tumor surfaces (calculated by means of fractal scaling analysis) which can be compared with corresponding CA simulations to gain a better understanding of the tumor phenomenon. In addition, the discrete structure of CA facilitates the implementation of complicated environments without any of the computational problems characterizing the simulation of continuous models.
- Motion of tumor cells through heterogeneous media (e. g. ECM) involves phenomena at various spatial and temporal scales [19]. These cannot be captured in a purely macroscopic modeling approach. Alternatively, discrete microscopic models, such as CA, can in-

corporate different spatio-temporal scales and they are well-suited for simulating such phenomena.

- CA are paradigms of parallelizable algorithms. This fact makes them computationally efficient.

In the following section, we provide a definition of CA. In Sect. "Models of Tumor Invasion", we review the existing CA models for central processes of tumor invasion. Finally, the discussion, we critically discuss the use of CAs in tumor invasion modeling and we identify future research questions related to tumor invasion.

Cellular Automata

The notion of a *cellular automaton* originated in the works of John von Neumann (1903–1957) and Stanislaw Ulam (1909–1984). Cellular automata may be viewed as simple models of self-organizing complex systems in which collective behavior can emerge out of an ensemble of many interacting "simple" components. In complex systems, even if the basic and local interactions are perfectly known, it is possible that the global behavior obeys new laws that cannot be obviously extrapolated from the individual properties, as if the whole is more than the sum of the parts. This property makes cellular automata a very interesting approach to model complex systems in physics, chemistry and biology (examples are introduced in [17,20]). A CA can be defined as a 4-tuple $(\mathcal{L}, \mathcal{S}, \mathcal{N}, \mathcal{F})$, where:

- $\mathcal{L}$ is an infinite regular *lattice* of nodes (discrete space),
- $\mathcal{S}$ is a finite set of *states* (discrete states); each cell $i \in \mathcal{L}$ is assigned a state $s \in \mathcal{S}$,
- $\mathcal{N}$ is a finite set of *neighbors*,
- $\mathcal{F}$ is a deterministic or probabilistic map

$$\mathcal{F} : \mathcal{S}^{|\mathcal{N}|} \to \mathcal{S} \tag{1}$$

$$\{s_i\}_{i \in \mathcal{N}} \mapsto s \,, \tag{2}$$

which assigns a new state to a node depending on the state of all its neighbors indicated by $\mathcal{N}$ (*local rule*).

The evolution of a CA is defined by applying the function $\mathcal{F}$ synchronously to all nodes of the lattice $\mathcal{L}$ (*homogeneity* in space and time).

The above features can be extended, giving rise to several variants of the classical CA notion [21]. Some of these are:

Asynchronous CA: in such CA, the restriction of simultaneous update of all the nodes is revoked, allowing for asynchronous update.

Non-homogeneous CA: this variation allows the transition rules to depend on node position. Agent-based models are "relatives" of CA that lost the homogeneity property, i. e. each individual-particle may have its own set of rules.

Coupled-map lattices: in this case the constraint of discrete state space is withdrawn, i. e. the state variables are assumed to be continuous. An important type of coupled-map lattices are the so-called Lattice Boltzmann models [22].

Structurally dynamic CA: in these systems, the underlying lattice is no longer a passive static object but becomes a dynamic component. Therefore, the lattice, structure evolves depending on the values of the nodes state variables.

Models of Tumor Invasion

This section reviews the existing cellular automata models of tumor invasion. Categorizing these models is a nontrivial task. Moreover, existing CA models describe tumor invasion at more than one scale (sub-cellular, cellular and tissue). In this review, we distinguish models that analyze: (i) the invasive morphology, (ii) tumor cell migration and the influence of the ECM, (iii) metabolism and acidosis, and (iv) the emergence of tumor invasion.

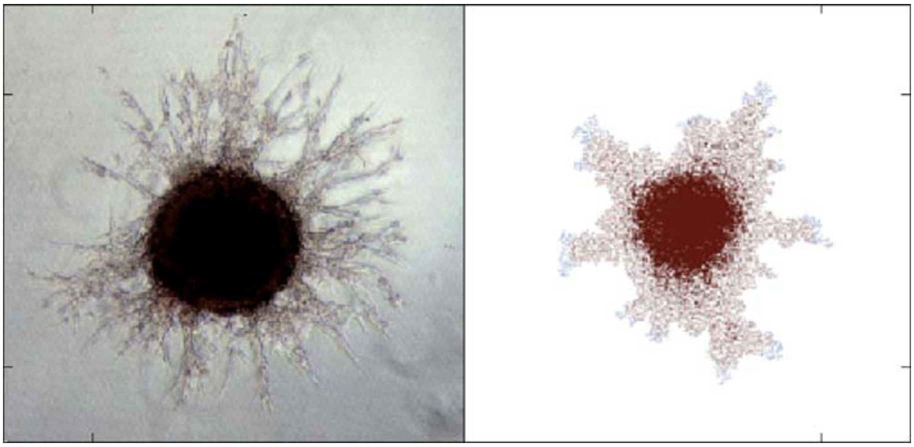
Invasive Tumor Morphology

The tumor morphology arising from the spatial pattern formation of the tumor cell population has been recognized as a very important aspect of tumor growth. Several researchers have attempted to reveal the mechanisms of spatial pattern formation of invasive tumors. Here, we present the most representative CA models for the invasive tumor morphology.

Effects of Directed Cell Motion Sander et al. [23] developed a CA model to investigate the branching morphology of invasive brain tumors. In the model tumor cell motion is influenced by two key processes: (i) chemotaxis, and (ii) "slime trail following". A typical example of a slime trail following mechanism is found in the motion of certain myxobacteria [24].

The authors show that the branching morphology of tumors can be explained as a result of chemotaxis and "slime trail following". In particular, simulations reproduce the branching pattern formation observed in vitro cultures of glioma cells. However, the assumption of slime trail following has not been proven biologically as yet.

Spatial Structure of Invasive Tumors Anderson [15,25] proposed a model to examine the effects of tumor cell heterogeneity (at the genetic level) on the spatial morphol-



Cellular Automaton Modeling of Tumor Invasion, Figure 2

***Left*: Microscopy image of a multicellular tumor spheroid, exhibiting an extensive branching system that rapidly expands into the surrounding extracellular matrix gel. These branches consist of multiple invasive cells. (Reprinted from [26] with permission). *Right*: Simulation of Anderson's model [15] reproducing the experimentally observed morphology of invasive tumors**

ogy and to analyze the importance of cell-cell and cell-ECM adhesion. The model assumes a non-diffusible, fixed configuration of ECM. The extracellular matrix can be degraded by diffusible enzymes, such as metallo-proteinases, produced by tumor cells. Moreover, cells are allowed to mutate and evolve their phenotype from proliferative to invasive. Finally, an oxygen concentration field plays the role of nutrients in the model.

Simulations of the model show that: (i) the ECM heterogeneity is mainly responsible for the tumor branching morphology (Fig. 2), (ii) cell-cell adhesion plays an important role only in the early stages of tumor development, (iii) invasive tumor cells are located at the boundary of the tumor, and (iv) the tumor is a phenotypically heterogeneous object.

Tumor Cell Migration and the Influence of the Extracellular Matrix

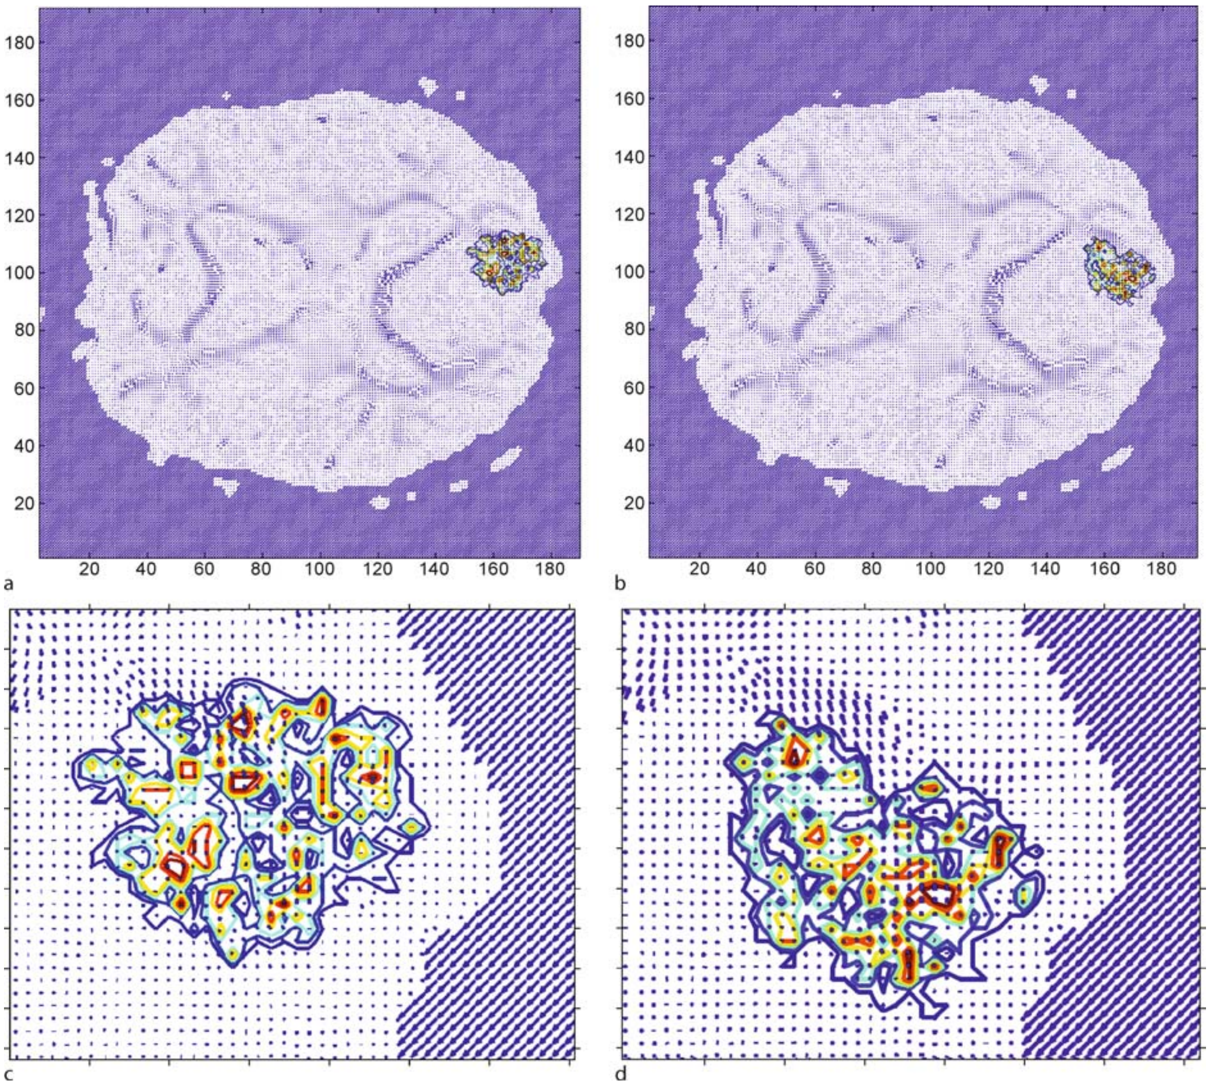
Cell migration and cell-ECM interactions are two of the most crucial invasion-related processes. Cellular automata provide an appropriate framework to model and analyze the effect of cell motility and cell-environment interactions of tumor cell migration.

The Role of Cell-Cell and Cell-ECM Adhesion Turner and Sheratt [27] proposed a cellular Potts model [28] to investigate how cell-cell and cell-ECM adhesion influence the tumor invasion depth and tumor morphology. A cellular Potts model can be viewed as an extension of the CA idea allowing to analyze phenomena that take into account specific cell shapes. Cells are assumed to move according to intercellular adhesive interactions and haptotactical gradients. Moreover, cells are allowed to proliferate, while mitotic probabilities depend on the strength of the adhesive interaction. Finally, cells are assumed to secrete proteolytic enzymes that degrade the ECM.

The authors show that adhesive dynamics can explain the "fingering" patterns observed in their simulations. Moreover, the authors demonstrate that the width of the invasion zone depends less on cell-cell adhesion and more on cell-ECM adhesion facilitated by haptotaxis and proteolysis.

Cellular Mechanisms of Glioma Cell Migration In the work of Aubert et al. [29], a CA model is introduced that allows for the investigation of tumor cell migration, based on experimentally observed density profiles of glioma cell cultures. The goal is to identify the mechanisms of tumor (glioma) cell motion, which play a crucial role in tumor invasion. The authors do not consider proliferation of tumor cells. Only the influence of tumor cell migration and intercellular interactions are studied. The authors introduce and test two distinct cell mechanisms: (i) cell-cell adhesion, and (ii) a kind of "inertia" in cell motion, i. e. the cells tend to maintain the direction of their motion.

The authors carefully scale the model according to the experimental setup and calibrate the corresponding model parameters. The simulation results indicate that cell-cell adhesion can explain the experimental results. It is concluded that cell-cell adhesion is an important process in glioma cell migration.



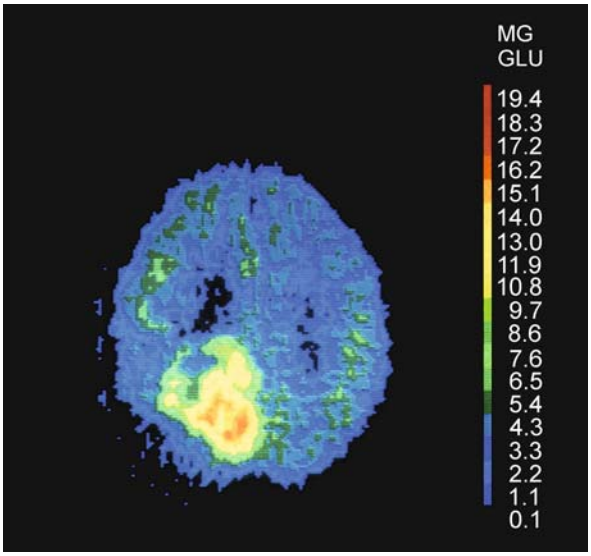
Cellular Automaton Modeling of Tumor Invasion, Figure 3

The effect of the brain's fiber tract on glioma growth. a A simulation is shown without taking into account the influence of fiber tracts. b The fiber tracts in the brain strongly drive the evolution of the tumor growth. c–d Figures display a close up of the tumor area of the top a–b simulations (Reprinted from [31])

Effects of Fiber Tracts on Glioma Invasion Wurzel et al. [30] model glioma tumor invasion with a lattice-gas cellular automaton (LGCA) [17]. The authors address the question of how fiber tracts found in the brain's white matter influence the spatio-temporal evolution and the invading front morphology of glioma tumors. Cells are assumed to move, proliferate and undergo apoptosis according to corresponding stochastic processes. Fiber tracts are represented as a local gradient field that enhances cell motion in a specific direction.

The authors develop and analyze different scenarios of fiber tract influence. A gradient field may increase the speed of the invading tumor front. For high field intensities the model predicts the formation of cancer islets at distances away from the main tumor bulk. The simulated invasion patterns qualitatively resemble clinical observations.

Effect of Heterogeneous Environments on Tumor Cell Migration Hatzikirou et al. [31] developed a LGCA model to investigate the influence of heterogeneous environments on tumor cell dispersal. This model is a simplified version of [30] which facilitates the mathematical analysis. In this study no proliferation or death of cells



Cellular Automaton Modeling of Tumor Invasion, Figure 4
Typically, tumors exhibit abnormal levels of glucose metabolism. Positron emission imaging (PET) techniques localize the regions of abnormal glycolytic activity and identify the tumor locus

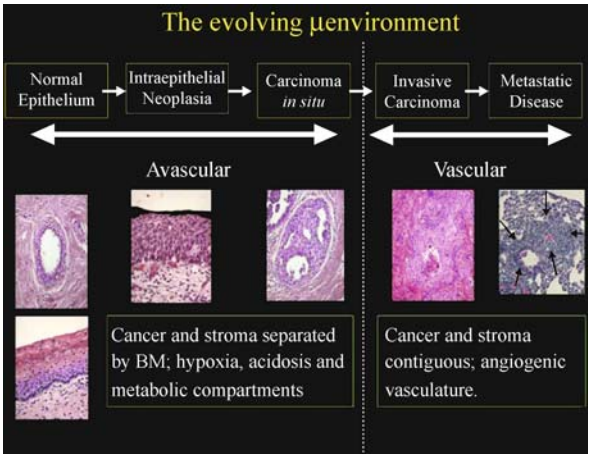
is considered. The authors distinguish two kinds of cell-ECM interactions (i) cell-ECM adhesion leading to haptotactical motion along integrin concentration gradients (environment with directional information) and (ii) contact guidance that promotes the alignment along ECM pores or fibres as seen in Fig. 3 (environment with orientational information).

In this study, it is investigated the impact of both types of cell-ECM interaction on tumor cell motion. In particular, macroscopic dispersal measures (such as mean cell flux) depending on cellular and environmental parameters are calculated. Accordingly, the models allow for prediction of cell motion in different environments.

Metabolism and Acidosis

In the course of cancer progression, tumor cells undergo several phenotypic changes in terms of motility, metabolism and proliferative rates. In particular, it is important to analyze the effect of the anaerobic metabolism of tumor cells and the acidification of the environment (as a side-product of glycolysis) on tumor invasion (Fig. 4).

Patel et al. [32] proposed a model of tumor growth to examine the roles of native tissue vascularity and anaerobic metabolism on the growth and invasion efficacy of tumors. The model assumes a vascularized host tissue. Anaerobic metabolism involves the consumption of glucose and the production of H^+ ions, leading to the acidification of the local tissue. The vascular network allows for the absorption of H^+ ions. Cells are assumed to be proliferative and non-motile. The pH level, i. e. is the H^+ concentration, and the glucose concentration determine the survival and death of the cells.



The evolving μenvironment

Normal Epithelium → Intraepithelial Neoplasia → Carcinoma *in situ* → Invasive Carcinoma → Metastatic Disease

Avascular

Vascular

Cancer and stroma separated by BM; hypoxia, acidosis and metabolic compartments

Cancer and stroma contiguous; angiogenic vasculature.

Cellular Automaton Modeling of Tumor Invasion, Figure 5
The evolving microenvironment of breast cancer. The multiple stages of breast carcinogenesis are shown progressing from left to right, along with histological representations of these stages. As indicated, the pre-invasive stages occur in an avascular environment, whereas cancer cells have direct access to vasculature following invasion. (Reprinted from [33])

Simulations of the model show: (i) high tumor H^+ ion production favors tumor invasion by the acidification of the neighboring host tissue, and (ii) there is an optimal density of microvessels that maximizes tumor growth and invasion, by minimizing the acidification effects on tumor cell proliferation (absorption of H^+ ions) and maximizing the negative effect of H^+ ions on the neighboring tissue.

Emergence of Tumor Invasion

Recently, several models have been proposed that concentrate on the evolutionary dynamics of tumors (Fig. 5). The main goal of these models is to understand under which environmental conditions particular phenotypes appear. Here, we review those models that focus on the mechanisms that allow the emergence of invasive behavior.

Influence of Metabolic Changes Smallbone et al. [34] developed an evolutionary CA model to investigate the cell-microenvironmental interactions that mediate somatic evolution of cancer cells. In particular, the authors investigate the sequence of tumor phenotypes that ultimately leads to invasive behavior. The model considers three phenotypes, (i) the hyperplastic phenotype that allows growth away from the basement membrane, (ii) the glycolytic phenotype that allows anaerobic metabolism (the "fuel" is glucose), and (iii) the acid-resistant phenotype that enables the cell to survive in low pH. Cells are allowed to proliferate, die or adapt (change their phenotype). No cell motion is explicitly considered.

The model predicts three phases of somatic evolution: (i) Initially, cell survival and proliferation are dependent on the oxygen concentration. (ii) When the oxygen becomes scarce, the glycolytic phenotype confers a significant proliferative advantage. (iii) The side-products of glycolysis, e. g. galactic acid, increase the microenvironmental pH and promote the selection of acid-resistant phenotypes. The latter cell type is able to invade the neighboring tissue since it takes advantage of the death of host cells, due to acidification, and proliferates using the available free space.

The Game of Invasion Recently, Basanta et al. [35] have developed a game theory inspired CA that addresses the question of how invasive behavior emerges during tumor progression (see also [36]). The authors study the circumstances under which mutations that confer increased motility to cells can spread through a tumor composed of rapidly proliferating cells. The model assumes the existence of only two phenotypes: "proliferative" (high division rate and no motility) and "migratory" (low division rate and high motility). Mutations are allowed for by the random change of phenotypes. Nutrients are assumed to be uniformly distributed over the lattice.

Simulations show that low nutrient conditions confer a reproductive advantage to motile cells over the proliferative ones. The model suggests novel ideas for therapeutic strategies, e. g. by increasing the oxygen supply around the tumor to favor the reproduction of proliferative cells over the migrating ones. This is not necessarily a therapy since there are benign tumors that are life threatening even if they do not become invasive. Despite that, in most cases a growing but non-aggressive tumor will have a much better prognosis than a smaller but invasive one.

Discussion

In this review, we have focused on one of the most important aspects of cancer progression: tumor invasion. The main processes involved in tumor invasion are related to tumor cell migration, cell-ECM interactions, especially ECM degradation/remodeling and tumor cell proliferation. These processes are evolving at different scales, e. g. cell-ECM adhesion is the response of tumor cells to ECM integrins (molecular level) leading to a haptotactical cell motion (cellular level) and influencing the tumor morphology (macroscopic level). Therefore, in order to understand tumor invasion dynamics, it is important to use mathematical tools that allow for modeling sub-cellular or cellular processes and to analyze the emergent macroscopic behavior. Individual-based models, especially CA, are well-suited for this task. Moreover, some types of CA models, such as lattice-gas cellular automata [17,31], facilitate analytical investigations allowing for deeper insight into the modeled phenomena.

In this chapter, we reviewed the existing CA models of tumor invasion. The presented models explore central aspects of tumor invasion. Some of the models are in good agreement with biomedical observations for in-vitro and in-vivo tumors. In the following, we list the most interesting biological insights that can be gained from the reviewed models:

- The significance of hypoxia in the process of tumor progression: Activation of glycolysis and acidification of the host tissue facilitate tumor invasion. Low nutrient conditions, such as hypoxia, may trigger invasive behaviors.
- Cell-cell adhesion: It is evident that intercellular adhesion has a great impact in the early stages of tumor growth. However, in tumor invasion the role of cell-cell adhesion is minor, since mainly the cell-ECM interactions appear to dictate the tumor cell behavior.
- Cell-ECM adhesion: This is an important process for tumor invasion. In particular, the heterogeneous structure of the ECM strongly influences the spatial morphology of invasive tumors.

Mathematical modeling offers potentially significant insight into tumor invasion. Several crucial questions have not been adequately addressed so far by modeling efforts:

Branching morphology: Several mechanisms have been proposed that lead to branching patterns, e. g. diffusion-limited aggregation, the interplay of cell-cell and cell-ECM adhesion, as well as chemotaxis or slime trail following motion. However, biologists and modelers have not yet identified a unique mechanism that drives the branching morphology of invasive tumors.

Go or grow: The mechanisms of invasive tumor cell migration are still not understood. Recently, Fedotov et al. [37] have analyzed the effect of a postulated migration/proliferation dichotomy on cell migration.

Emergence: Concerning the emergence of invasion in tumor progression little is known. Mechanisms related to tumor cell motion and other cell processes, such as proliferation (migration/proliferation dichotomy), may play an important role for the dominance of invasive phenotypes [35,38].

Angiogenesis: Another open issue is the influence of angiogenesis and vasculogenesis on tumor invasion. Despite significant efforts to describe the mechanisms of angio- and vasculogenesis, little is known about the effect of these processes on tumor invasion [32].

Robustness: The identification of cellular mechanisms that are responsible for tumor robustness remains significant challenge.

Finally, for clinical purposes, future models should be able to provide accurate and quantitative predictions. Simplified models considering only the essential ingredients for tumor growth, and especially tumor invasion, but validated with actual clinical data may be helpful in this regard. We sincerely hope that a more profound knowledge of important tumor characteristics, such as tumor invasion, will eventually lead to the design of more effective therapeutic strategies.

Acknowledgments

We are grateful to D. Basanta, L. Brusch, A. Chauviere, E. Flach and F. Peruani for the comments and the fruitful discussions. We acknowledge support from the systems biology network HepatoSys of the German Ministry for Education and Research through grant 0313082J. Andreas Deutsch is a member of the DFG Research Center for Regenerative Therapies Dresden – Cluster of Excellence – and gratefully acknowledges support by the Center. The research was supported in part by funds from the EU Marie Curie Network "Modeling, Mathematical Methods and Computer Simulation of Tumor Growth and Therapy" (EU-RTD IST-2001-38923). Finally, the authors would like to thank for the financial support of the Gottfried Daimler- and Karl Benz foundation through the project "Biologistics: From bio-inspired engineering of complex logistical systems until nanologistics" (25-02/07).

Article Outline

Glossary

Cell The biological cell is the smallest self-contained, self-maintaining, and self-reproducing unit of all living organisms. Various computing paradigms were inspired by the biological cell.

Molecular computing A subfield of cellular computing, where the molecules instead of the cell play a central functional role.

Computing The science that deals with the manipulation of symbols. Also refers to the processes carried out by real or abstract computers.

Computation Synonymous with information processing or also algorithm. Computations can for example be performed by abstract machines, real computer hardware, or biological systems. The abstract concept of the Turing machine separates the class of computable from the class of non-computable functions.

Parallel computing Parallel computing involves the execution of a task on multiple processors with the goal to speed-up the execution process by dividing up the task into smaller sub-tasks that can be executed simultaneously.

Definition of the Subject

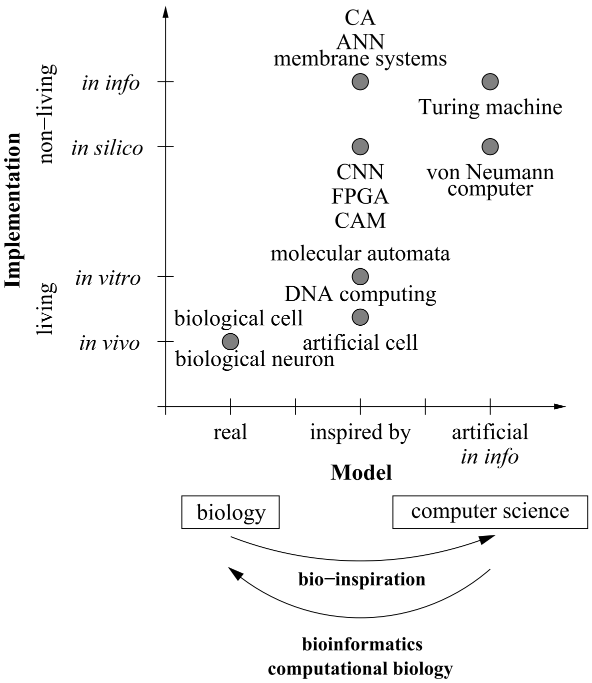
The field of *cellular computing* (abbreviated, CC) defines both a general computing framework and a discipline concerned with the analysis, modeling, and engineering of real cellular processes for the purpose of computation. The biological cell, discovered and coined by R. Hooke in 1665, is the smallest self-contained, self-maintaining, and self-reproducing unit of all living organisms. Its understanding and modeling is crucial both for the understanding of life and for the ability to use, control, and modify its complex bio-chemical processes to perform specific functions for the purpose of *in vivo* or *in vitro* computation. The cellular metaphor has inspired and influenced numerous, both abstract computing models and *in silico* implementations, such as *cellular automata* (abbreviated, CA), *membrane systems* (or P systems), or *Field Programmable Gate Arrays* (abbreviated, FPGAs), with the main purpose to solve algorithmic problems in alternative ways. The cellular computing approach is appealing because the cell provides a convenient level of abstraction and functionality, is reasonably simple with enough abstractions, and can be used as a building block to compose more complex systems. On the other hand, a wide range of computational approaches are used to model and understand the functioning of the inter- and intra-cellular processes of biological cells on its various levels of complexity. The cell's bio-chemical processes can either directly be interpreted as computations or they can be modified for the specific purposes of computations through bio-engineering methods. The hope in using biological cells as computing devices is to (1) ultimately go beyond complexity and fabrication limits currently encountered with traditional silicon circuits, (2) to embed computing capabilities into living organisms for autonomous therapeutic and diagnostic applications, and (3) to realize integrated biological sensing applications that use living organisms, such as for example plants and bacteria, as intelligent sensors.

Introduction

The English naturalist Robert Hooke is commonly accredited for the discovery of the cell [7] and the coining of its term, which he borrowed from the Latin word *cella*, that designates a small chamber. Hooke's work was published in 1665 in his book *Micrographia* [45], which contained observations he made with a very rudimentary microscope of dead cork cells. Since then, tremendous discoveries have been made around the cell, ranging from the pioneering work of German anatomist Walther Flemming [38,75] on cell division (mitosis) to the discovery of the DNA double helix structure by Watson and Crick in 1953 [117]. Nowadays, a sheer endless amount of knowledge and data on cells is available, originating from genetics, biochemistry, and molecular dynamics research. Nevertheless, the computational modeling at the molecular level of complete cells has been notoriously difficult because of the enormous complexity of the real cell, a lack of qualitative understanding, and the large number of unknowns in the models.

With the advent of modern computer science in the 1940s under pioneering fathers such as John von Neumann and Alan M. Turing, biology and computer science started to grow closer together. Biologists increasingly used computers to analyze experimental data and to model real biological organisms, while computer scientists began to draw inspiration from biology with the essential goal to engineer better and more "lifelike" machines. Using computer science, mathematics, statistics, machine learning, and artificial intelligence as tools to solve real problems in biology is commonly known under the term *bioinformatics* [11], while *computational biology* is more concerned with the exploration and discovery of new knowledge, for example by testing specific hypotheses by means of computer models. *Systems biology* [48], on the other hand, focuses on the system level and how the participating biological components interact. This is typically done in a combined approach, which involves theory, computational modeling, and experiments.

Living organisms are complex systems exhibiting a range of desirable characteristics, such as evolution, adaptation, and fault tolerance, that have proved difficult to realize using traditional engineering methodologies. Drawing inspiration from biology to design better and both more "lifelike" machines and algorithms is generally known under the term *biologically-inspired computer science* [39,59,90] (also *nature-inspired*, *bio-mimetic*, or *biologically-motivated*). Typically, this approach involves simulations, algorithms, and classical silicon-based circuits, but not living matter. The goal is not to copy nature, but to solely draw inspiration from it, while the field of *artificial life* [52] is more concerned with understanding life by building it. Figure 1 illustrates the various possibilities to implement cellular models that range from realistic to abstract.



Cellular Computing, Figure 1
Illustration of the various possibilities to implement cellular models that range from realistic to abstract. Drawing inspiration from biology to build better computing machines is known under the term *bio-inspiration*, while using machines to address problems in biology is known as *bioinformatics* and *computational biology*

The broad and very interdisciplinary field of *cellular computing*, in its natural and artificial dimension, defines both a

- General computing framework [89] and a
- Discipline concerned with the analysis, modeling, and engineering of real cellular processes for the purpose of computation [8].

As opposed to pure bio-inspired computing, cellular computing thus also includes the use of real biological cells for information processing. Cellular computing encompasses abstract theory, simulations, models, experiments, and includes both the paradigm of "the cell as a machine" and "the machine as a cell." Sometimes, cellular computing is used interchangeably with *molecular computing* [86], however, while molecular computing is concerned with the information processing in which molecules play a central functional role, cellular computing looks at the cell as the functional building block for more complex systems. Naturally, molecules are involved in cellular information processing as well, so we therefore consider molecular computing as a subset of cellular computing.

The birth hour of *connectionism* in the 1940s can be considered as the first occurrence of looking at cells as automata and modeling them by digital systems. The well known McCulloch–Pitts neuron [60] simulated a wealth of research in neural information processing and modeling that continues with increasing activity until today [9]. In 1948 (but first published in 1969, reprinted in [111]), Alan Turing proposed his own connectionist ideas [103,110], which were highly influenced by the digital systems paradigms. His neurons were simple NAND (not AND) logical gates, which would thus allow in principle to compute any logical function, provided enough neurons are available and that they can be interconnected in arbitrary ways.

The concept of molecular automata and of cells seen as information processing devices appeared around the 1960s. In their studies of the control of gene expression and the synthesis of proteins, Jacob and Monod [46,62], Davis [26], and others emphasized deterministic operations at the level of DNA, RNA, and ribosomes. Early work on protein synthesis, for example by Warner et al. [116], suggested that ribosomes move along the messenger RNA, not unlike the head reading the tape of a Turing machine. In 1961, Pattee [71] used the concept of the Turing machine computation to explain the generation of growing macromolecular sequences and rhetorically asked in the title of a section of his paper "Can molecules compute?" Stahl and Goheen [95] further pioneered the idea of seeing the cell as an information processor and Turing machine. They considered enzymes as computational primitives whose operations are simulated by a Turing machine, and are therefore computable in the formal sense of the term [27]. At about the same time, Sugita considered some aspects of molecular systems by using a logical circuit equivalent [98,99,100]. He states: "The mechanism of life shall be clarified by using electronic analogues, because the chemical system composing the living organism is nothing but a complicated network of rate processes from the chemical or physical point of view. Simulation of such a network may be done either by using an analogue computer or a digital differential analyzer, as has been done at the laboratory[…]. A digital system composed of some chemical reactions may play the role of a controlling computer of the living chemical plant, and the reactions having analogue behavior may be controlled by that computer as well as by analogue control systems which can be seen in primitive control" [98]. Schmitt [83] discussed the biological memory of macromolecular automata in his 1962 book, while Feynman [36] elaborated in his famous talk "There's plenty of room at the bottom" on the possibility to compute with atoms, molecules, and cells. Feynman was more focused on the miniaturization of the computer by storing and processing information at atomic levels, but his ideas were pursued by many others later (e. g. [14,21,86]), and ultimately led to what we know today as *nano-* and *molecular electronics* [24], but also greatly stimulated the earlier cellular computing research.

Michael Conrad, a pioneer in biologically-inspired, molecular, and cellular computing, as well as many others observed that living organisms process information in a very different way than digital computers [20]. Organisms typically exploit the inherent physical properties of the matter they are made of, while digital computers are based on multiple levels of abstractions, which are typically far away from the physical substrate and do not directly exploit any of its specific physical characteristics for the purpose of more efficient computation. Cellular computing, both in its natural and artificial dimension, tries to address these issues by drawing inspiration from real cells and by using them for the purpose of computation.

The principal reason for the increasing interest in cellular computing paradigms seem twofold. Firstly, Moore's Law [63] has dominated the progress of electronic circuits in the past decades, but fundamental limits of silicon-based technology now begin to become serious showstoppers [47]. The hope is that cellular computing will help to go beyond such limits by using alternative computing paradigms inspired by the cell or by using real cells, molecules, and atoms as information processing devices. Secondly, despite lots of progress, Turing's hope that "machines will eventually compete with men in all purely intellectual fields" [108] is far from accomplished. Biological systems outperform their silicon counterparts in various areas, such as for example with their ability to adapt, to recognize objects, or to self-repair. Again, by using cellular computing paradigms, the hope is that such bio-inspired approaches will ultimately allow to go beyond existing limits.

Computation and Computability

Both from the perspective of computer science and biological organisms, a central question is what kind of operations a given system can perform, what kind of problems it can solve, and how efficiently it can do this. Despite their ubiquitousness and seemingly endless power, there are clear and fundamental limitations – that are too often ignored unfortunately – to what computers can do [43,55]. Two fields of computer science are relevant in this context: *computability theory* [27,61] deals with what problems can be solved, while *computational complexity theory* [68] deals with how efficient they can be solved.

Since Alan M. Turing's seminal paper on the abstract concept of the *Turing machine* (abbreviated, TM) [107], *computability* is well defined and we generally know what classes of problems can be solved by which classes of machines. The *Chomsky hierarchy* [94], for example, partitions the formal languages into classes of different expressive power. Each class can be associated a class of abstract automaton, which is able to generate and recognize the corresponding language. At the top of this hierarchy sits the Turing machine, which is able to generate the most expressive class of languages. Along with other abstract formalisms and machines, a Turing machine is able to carry out any effective computation, i. e., it can simulate any other machine capable of performing a well-defined computational procedure. In this context, "effective" is synonymous with "mechanical" or "algorithmic." In its original form, the *Church–Turing thesis* states that there is an equivalence between Church's λ-calculus and Turing machines. Since then, numerous more general and stronger forms of the thesis have emerged. For example, David Deutsch wrote: "Every finitely realizable physical system can be perfectly simulated by a universal model computing machine operating by finite means" (p. 99 in [30]). Despite claims from "hypercomputationalists," (e. g., see [28,104] for an overview of this debate) the fact is that no physically realizable device, which thus necessarily operates on finite resources and time, was ever able to compute functions (in the formal sense of the definition) that a Turing machine could not compute, which means that the Church–Turing thesis has not been disproved as of today.

It is obviously an interesting question to ask how and what biological systems "compute," what their limits are, and how efficient they can solve problems. Biological organisms naturally process some information in some way, but how – if at all – can these processes be described in an algorithmic manner? What kind of abstract automata are useful to describe the many computational mechanisms of a biological cell? Paton describes four general types of computations in [70] under which the information processing capabilities of a cell can be seen:

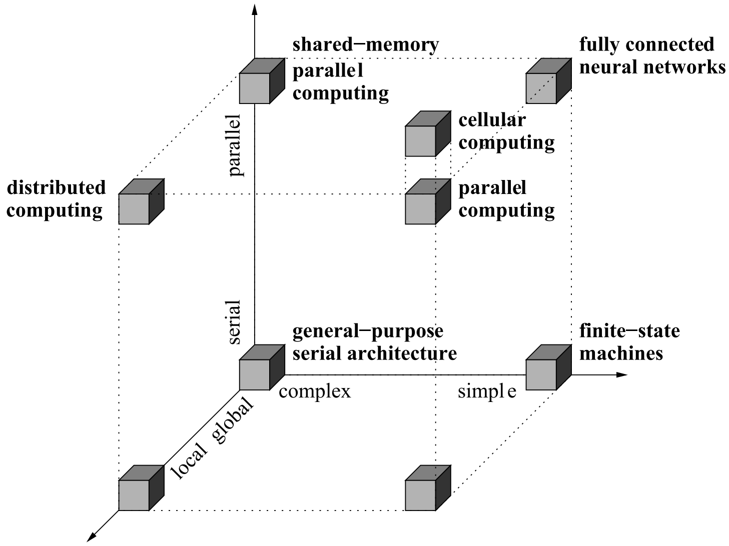
- *Sequential*. The most common form of machine, which usually has a central processor and a global memory. The instructions are carried out serially, such as for example by a Turing machine.
- *Parallel*. Several processors jointly execute a task. A wide range of parallel computing paradigms exist.
- *Distributed*. Similar to parallel computation, but the processors are usually located at larger distances.
- *Emergent*. The global behavior of such a computation emerges from the local interactions between the processors. This form is typical of self-organizing systems, cellular automata, and neural networks.

As he states, "[c]omputational models of the cell can utilize any of these views," however, most processes are best described as a parallel distributed computing paradigm with emergent properties. Paton also points out the risk of trying to force biological systems to "fit" into a certain computational model. Important details might be ignored and one is forced to think within the existing computing paradigms. We can conclude that abstract and formal models of computation have been very useful in describing the information processing capabilities of biological systems, however, not every formalism is well suited for such descriptions, even if his expressiveness matches that of the corresponding biological system. For example, modeling the highly parallel processes of a biological cell by a Turing machine is possible since parallel machines are not more expressive than sequential machines, however, the sequential paradigm does not offer a convenient and useful model in this context.

The Machine as a Cell

In 1999, Moshe Sipper, used the term "cellular computing" in a broad sense to introduce a general computing philosophy and framework. He hypothesized that "[t]his philosophy promises to provide new means for doing computation more efficiently – in terms of speed, cost, power dissipation, information storage, and solution quality. Simultaneously, cellular computing offers the potential to addressing much larger problem instances than previously possible, at least for some application domains" (p. 18 in [89]). Cellular computing consists of three essential and admittedly very general principles:

- Simplicity,



Cellular Computing, Figure 2

The "computing cube." Illustration of the cellular computing paradigm: simple + vastly parallel + local. Redrawn from Sipper [89] and extended. Cellular computing has been placed further along the parallelism axis to emphasize the "vastness" aspect

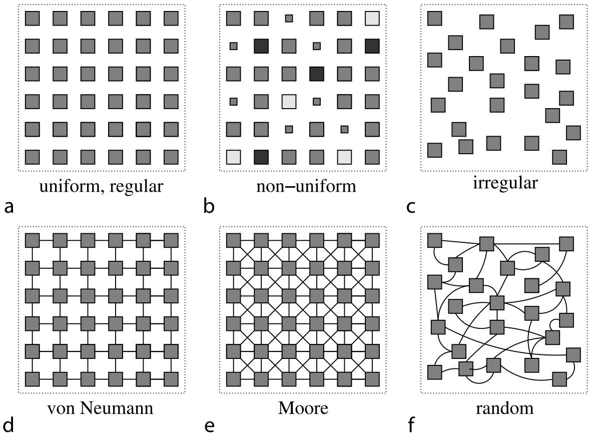
- Vast parallelism, and
- Locality.

Figure 2 illustrates these three principles. While most general-purpose processors are universal machines in the sense of a Turing machine, the concept of cellular computation expects the complexity of the basic unit, the cell, to be significantly lower, which is characterized by *simplicity*. While "simplicity" is not well or formally defined in this context, Sipper provides the example of an AND gate as being simple, while a Pentium processor is not. Most of today's computers are either based on a multi-core processor, which offers several cores that allow to process information in parallel. This trend – generally considered as an elegant way to keep up with Moore's law – is expected to continue in the next few years. As of November 2006, the Top500 supercomputing list [3] is headed by a BlueGene/L server with 131 072 processors. Cellular computing wants to be orders of magnitude above this level of complexity in terms of the number of cells (i. e., the processors) involved. Sipper uses the term *vast parallelism* to characterize systems where the number of cells is measured by the exponential notation 10^x. For example, an *Avogadro-scale system* would involve an Avogadro number of cells, i. e., 10^{23}. As we scale down electronic circuits to molecular and atomic dimensions and make use of self-assembling techniques, assemblies of this complexity become increasingly feasible. It is unlikely that systems of such complexity will ever be built on macroscopic levels. The last principle concerns the interactions among the cells: cellular computing is based on *local interactions* only, where no cell has a global view or control over the entire system. Obviously, the three principles are related and the cell's simplicity, for example, helps to achieve vast parallelism. Similarly, the vast parallelism makes it hard to implement non-local interactions. These interactions are illustrated in Fig. 2 by the "computing cube." Changing a single term in the "equation" simple + vastly parallel + local results in a different computing paradigm.

Compared to traditional parallel computing, which typically makes use of a rather small number of complex nodes, the cellular computing framework is based on a vast number of simple nodes. Also, parallel computers often have non-local interconnect topologies or even special nodes, which have some sort of global control over all other nodes, which cellular computing does not allow. Clearly, while it is already very challenging to find enough parallelism in applications to exploit the parallelism offered by traditional parallel computers, this problem will only be aggravated – and further moved to the programmer and the software – for fine-grained cellular computers. It is commonly accepted that such machines will likely only be more efficient for very specific problem domains which already offer plenty of inherent parallelism, such as for example image processing. Obviously, one can always implement some form of serial computing paradigm on a parallel machine (e. g., implementing a Turing machine on the *Game of Life* [81]), but that completely defeats the purpose of such a machine.

This very general framework naturally allows for considerable flexibility in the models. Besides the three basic principles, a number of other important properties play a role, such as for example the detailed local interconnect topology, the cell's arrangement in space, the mobility, the uniformity, and the cell's behavior [89].

- *Arrangement.* While a majority of abstract cellular models do not consider explicit physical locations and spatial dimensions (e. g., the cell dimension of a cellular automata is not generally considered), more biologically and physically plausible models do. Regular grids in 2D (Fig. 3a) or 3D with rectangular or other geometries are most common, but irregular (Fig. 3c) or even non-rigid grids are possible. In addition, one needs to specify the boundary conditions of the grid (e. g., fixed or wrapped around) and whether the grid has a finite or infinite dimension (open boundary).
- *Interconnect topology.* Cellular computing is based on local interactions only, but there are many possibilities to interconnect neighboring cells in a non-global way. In case of a regular rectangular grid, purely local four- (von Neumann, see Fig. 3d) and eight-cell neighborhoods (Moore, see Fig. 3e) are most common [105]. However, interconnect topologies that are completely random or that have the small-world [118] or power-law [6] property are also possible since no cell has a global view over the whole system.
- *Mobility.* Cells can either be physically mobile (e. g., for ant colony optimization [32]) or immobile. Alternatively, their "program" can also move from one cell to another (e. g., for self-replicating loops [58]) without a physical relocation of the cell.
- *Uniformity.* Both the cell type (i. e, its state and behavior) and it's interconnections with the neighboring cells can be uniform (Fig. 3a) or non-uniform (Fig. 3b) to some degree. Most cellular paradigms use uniform cells and interconnection schemes.
- *State and Behavior.* Cells can have internal states that are either discrete or analog. Based on its internal state and the internal states read from the neighboring cells, the cell changes it own state according to some algorithm. This can be as simple as a look-up-table (abbreviated, LUT) or a mathematical function, or as complicated as a small program. The cells are usually updated in discrete time steps, either in a synchronous or asynchronous way. A continuous behavior is also possible, for example if the cell's behavior is guided by differential equations or analog electronics. Finally, both the behavior and the cell's updating can be deterministic or non-deterministic.



Cellular Computing, Figure 3
Illustration of different cell arrangements and interconnect topologies. a regular and uniform; b regular and non-uniform, different shadings and sizes indicate different cell programs; c irregular and uniform; d regular, uniform, von Neumann neighborhood; e regular, uniform, Moore neighborhood; f irregular, uniform, random neighborhood

Cellular computing does not claim to be a faithful model of biological cells, however, the framework is general and flexible enough to allow for biologically-plausible models as well. As Toffoli and Margulus point out in their book [105] with regards to cellular automata, the generality and flexibility of cellular approaches also comes with a cost. Instead of only a few variables as typical in traditional computing models, the cellular computing paradigm uses at least one variable (or "program") per cell. With the vast number of cells involved, the challenging task is thus to find the right rule(s) which allow to solve a given task. As already stated above, the cellular computing paradigm is ideally suited for tasks that already contain a high degree of parallelism and require local interactions only.

A large number of computing models have drawn inspiration from real cells. While a very large part of the work is concerned with modeling neural cells, a number of researchers were also interested in developmental and other aspects. For example, Astor and Adami [10] used a developmental model for the growth of neural networks. Each neuron is an autonomous entity, which behavior is only determined by its genetic information contained within the cell. An artificial chemistry is also used to model chemicals and substrates. Fleischer and Barr [37] introduced a model of multicellular development that combines elements of the chemical, cell lineage, and mechanical models of morphogenesis pioneered by Turing [109], Lindenmayer [54], and Odell [65]. Cell migration is an important aspect of development, especially of the neural development. Compared to previous models, Fleischer's approach allows cells to move freely within the environment. Other pioneers of morphogenetic, developmental, and growing neural networks models, which necessarily involve cells in various forms, were for example Dellaert and Beer [29], Rust [82], Eggenberger [34], Gruau [42]. More abstract models that deal with the self-maintenance, the self-reproduction, and the self-replication came for example from Ono and Ikegami [66], Varela et al. [113], Langton [51], Mange et al. [58], and various others.

In the following, we will give three more detailed examples of cellular computing models.

Example: Cellular Automata

Cellular automata (abbreviated, CA) were originally conceived by Ulam and von Neumann in the 1940s to provide a formal framework for investigating the behavior of complex, extended systems [115]. CAs are dynamical systems in which space and time are discrete. In its basic version, a cellular automaton [105,120] consists of a regular grid of cells, each of which can be in one of a finite number of *k* possible states, updated synchronously (or asynchronously) in discrete time steps according to a local, usually identical (uniform, otherwise non-uniform) interaction rule. The state of a given cell is determined by the previous states of a specified neighborhood of cells. Figure 3d and e show two typical local CA neighborhoods, the von Neumann and the Moore neighborhood.

In CAs and many other cellular computing systems, there is a confound between the data and the computing devices, i. e., the structure, which process it. The abstract Turing machine and the von Neumann computer architecture make a clear distinction between these two. The Turing machine stores data on the tape, however, a CA cell can both store and process data and the machine can even extend or modify itself. Although it has been shown that elementary CAs are universal [22], this is more of theoretical than practical interest since most CAs that solve some real problem cannot – and do not need to – perform any universal computation.

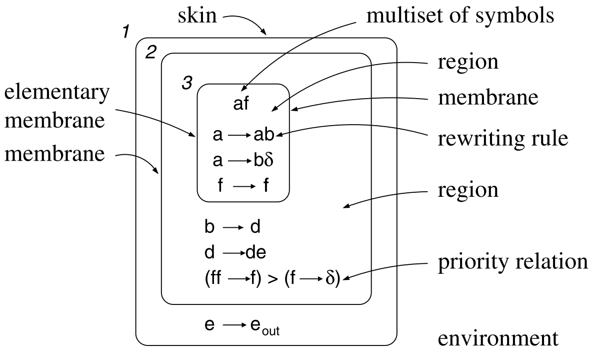
One of the main challenges with cellular automata is to find the cell's rule(s) which allow to obtain a global behavior from the local interactions only. For example, given a specific task, say, detecting the contours of an object in an image, what are the individual cell rules (either uniform or non-uniform) that allow to successfully solve that task for a wide range of inputs? The large – or even vast – number of cells involved and the local interactions make this problem very challenging. Thus, most cellular automata are either programmed by hand – which becomes infeasible for larger systems and complex problems – or the rules are for example found by means of an evolutionary algorithm [18,87,88,92].

Example: Membrane Computing

Artificial chemistries [31] are man-made systems that are a very general formulation of abstract systems of *objects* that follow arbitrary *rules of interaction*. More formally speaking, an artificial chemistry essentially consists of a set of *molecules S*, a set of *rules R*, and a definition of the *reactor algorithm A* that describes how the set of rules is applied to the set of molecules. This very broad paradigm, inspired by bio-chemical systems, allows to describe many complex natural and artificial systems by means of simple rules of decentralized, local, and parallel interactions. The chemical paradigm thus also fits in the bigger framework of cellular computing.

In 1998, George Paun initiated *membrane computing* (also *P systems*) [72,73] as an abstract computational model afar inspired by biochemistry and by some of the basic features of biological membranes. Membrane computing makes use of a hierarchical membrane structure that is similar to the structure used in the chemical abstract machine as proposed by Berry and Boudol [15]. The evolution rules that transform the multisets are inspired by *Gamma systems* as proposed by Banâtre et al. [12].

A typical membrane system consists of cell-like membranes placed inside a unique "skin" membrane. Multisets of *objects* – usually strings of symbols – and a set of *evolution rules* (or *reaction rules*) are then placed inside the regions delimited by the membranes. As an example, a simple membrane system is depicted in Fig. 4. The evolution between system configurations is done nondeterministically but synchronously by applying the rules in parallel for all objects able to evolve. A sequence of transitions in a membrane system is called a *computation*. A computation *halts* when a halting configuration is reached, i. e., when no rule can be applied in any region. In classical membrane systems, a computation is considered successful if and only if it halts, but other interpretations of inputs and outputs are possible. A great feature of membrane systems is their inherent parallelism, which allows to trade space for time, for example to solve computationally hard problems. Using membrane division, it has been shown that NP-complete problems can be solved in poly-



Cellular Computing, Figure 4
An example of a membrane system as given in [73]. The system generates $n^2, n \geq 1$, where *n* is the number of steps *before* the first application of the rule $a \rightarrow b\delta$. The rules are applied synchronously and in a maximum parallel manner, i. e., all rules that can be applied have to be applied. If multiple rules can be applied, one is picked nondeterministically

nomial and even linear time [73]. Most membrane systems are also Turing universal.

A wide variety of different membrane system flavors exist (see [2] for the latest publications), which have been applied to applications ranging from modeling spiking neural systems to economics.

Example: Amorphous Computing

In a 1996 white paper, Abelson et al. first described the *amorphous computing* (abbreviated, AC) framework [4]. Amorphous computing is the development of organizational principles and programming languages for obtaining coherent global behavior from the local cooperation of a myriad of unreliable parts that are interconnected in unknown, irregular, and time-varying ways. In biology, this question has been recognized as fundamental in the context of animals (such as ants and bees) that cooperate and form organizations. Amorphous computing asks this question in the field of computer science and engineering. Using the biological metaphor, the cells cooperate to form a multicellular organism (also called *programmable multitude*) under the direction of a genetic program shared by all members of the colony. Again, the cellular computing philosophy applies particularly well to the amorphous computing framework. The properties of an amorphous computer can be summarized under the following assumptions, where processor is used synonymous with cell:

- individual processors are identical and mass produced;
- processors possess no *a priori* knowledge of their location, orientation, or neighbors' identities;
- processors operate asynchronously although they have similar clock speeds;
- processors are distributed densely and randomly;
- processors are unreliable;
- processors communicate only locally and do not have a precision interconnect;
- the processors are arranged on a 2D surface or in 3D space;
- it is assumed that the number of particles is very large; and
- the communication model assumes that all processors have a circular broadcast of approximately the same fixed radius (large compared to the fixed size of a processor) and share a single channel.

The biggest challenge in amorphous computing – as with the majority of cellular computing paradigms – is how related to how to program the individual cells in order to obtain a consistent and robust global behavior. The amorphous computing research community came up with several automated approaches, which allow to compile a global system description into local interactions. Example are Nagpal's *origami shape language* [64], Coore's *growing point language* [23], and Butera's *process fragments* [16].

Cellular Computing Hardware

Cells have not only inspired abstract computing models but also real hardware, which is commonly called *biologically-inspired hardware* [93]. On the other hand, both specialized and non-specialized computers have been used for the acceleration and the faithful simulation of many biological processes related to the cell, particularly within the field of *bioinformatics* [11]. A biological cell is a massively parallel system, where thousands of highly complex processes run concurrently. Simulating these processes on a sequential von Neumann computer will obviously not be very efficient and will seriously limit the performance. Specialized hardware, which offers a high level of inherent parallelism, has thus attracted considerable attention in this field of cellular computing.

Cellular automata machines (abbreviated, CAMs) are specialized machines with the goal to very efficiently simulate cellular automata. For example, Hillis' connection machine [44] was the first milestone in that endeavor in the early 1980s. The processors were extremely simple and there was a strong emphasis on the interconnectivity, but not particularly on local topologies because the machines were targeted for supercomputer applications. Toffoli and Margolus' CAM machines [105] represent other examples of highly specialized machines. Nowadays, because of their inherent fine-grained parallelism, reconfigurable circuits, such as *Field Programmable Gate Arrays* (abbreviated, FPGAs) [41,114], are ideal candidates to simulate cellular systems. For example, Petreska and Teuscher [77] proposed a very first hardware realization of membrane systems using reconfigurable circuits, which was based on a universal and minimal membrane hardware component that allowed to very efficiently evolve membrane systems in hardware. Another example of cellular hardware are *cellular neural network* (abbreviated, CNN) [19] chips, which are massively parallel analog processor arrays. The CNN approach is extremely powerful for specific applications, such as real-time image and video processing.

In the following, we will provide three more detailed examples of typical and biologically-inspired hardware, which is based on cellular paradigms and metaphors.

Example: Embryonics

Biological systems grow, live, adapt, and reproduce, characteristics that are not truly encompassed by any existing computing system. Sipper et al. [93] proposed the *POE model* of bio-inspired hardware systems, which stands for *phylogeny* (abbreviated, P), *ontogeny* (abbreviated, O), and *epigenesis* (abbreviated, E). This model allows to partition the hardware space along three axes, which, in very simplified terms, correspond to evolution (P), development (O), and learning (E). Each axis thus represents a different form of adaption and organization on a different time scale. The ultimate goal are machines that combine all three forms of adaption, so called *POEtic machines* [112].

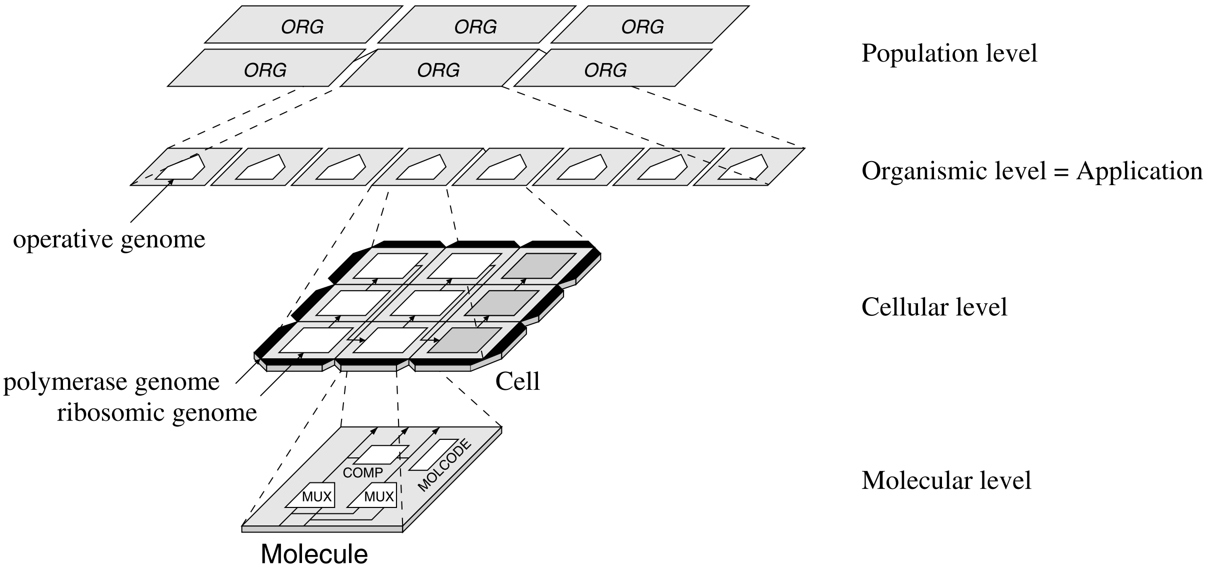
The *embryonics project* [57,59] (embryonics stands for embryonic electronics), is an attempt to design highly-robust integrated circuits, endowed with the properties usually associated with the living world: self-repair (cicatrization) and self-replication. In this context, self-replication allows for a complete reconstruction of an organism by making a copy of itself. The approach draws inspiration from the basic processes of molecular biology and from the embryonic development of living beings, which is represented by the ontogenetic axis in the POE model. An embryonic circuit is based on a finite but arbitrarily large two-dimensional surface of silicon. This surface is divided into rows and columns, whose intersections define the cells. Since such cells (i. e., a small processor and its memory) have an identical physical structure (i. e., an identical set of logic operators and connections), the cellular array is homogeneous. Embryonics largely draws inspiration from the following biological features, which the majority of living beings (at the exception of unicellular organisms) share: (1) multicellular organization, (2) cellular division, and (3) cellular differentiation. Similar to biological cells, each embryonic cell is "universal" in the sense that it contains the whole of the organism's genetic material, the genome. This feature allows to implement self-repair in an elegant way since each cell is potentially able to replace every other cell within an embryonic organism. The final embryonics architecture makes use of four hierarchical levels of organization:

- *Molecule.* The basic primitive of the system, which essentially consists of a multiplexer associated with a programmable connection network. The multiplexer is duplicated to allow the detection of faults. The logic function of each molecule is defined by its molecular code, the *MOLCODE.*
- *Cell.* A finite set of molecules makes up a cell, which is essentially a processor with an associated memory.
- *Organism* A finite set of cells makes up an organism (synonymous with application), an application-specific multiprocessor system.
- *Population.* The organism can itself self-replicate, given rise to a population of identical organisms.

Figure 5 illustrates these four hierarchical levels. As a showcase of bio-inspired systems and hardware, a complete embryonic machine and application has been implemented in real hardware by using *Field Programmable Gate Arrays* (abbreviated, FPGAs) [41] to implement the basic molecule [102]. The main application, which used several thousand molecules, was a fault-tolerant electronic watch, the BioWatch [96]. The project illustrates how biological organisms, and cells in particular, can help to build alternative computing machines with properties not truly encompassed by any existing architecture.

Example: Field Programmable Gate Arrays

A *Field Programmable Gate Array* (abbreviated, FPGA) [41] is a reconfigurable device [114] which is based on a set of *configurable logic blocks* (abbreviated, CLBs) that are interconnected by a programmable interconnect fabric. The logic blocks of most FPGAs are rather simple, consisting typically of some combinational logic (e. g., a 4-input look-up-table) and some sequential logic (e. g., a flip-flop). Some CLBs offer additional memory too. The interconnect fabric is typically organized in a hierarchical manner with mostly local interconnections between CLBs, but with the possibility to establish limited long(er)-distance connections as well. Sophisticated design tools, compilers, and hardware description languages allow to map essentially any digital circuit onto such a reconfigurable chip, provided enough CLBs are available.



Cellular Computing, Figure 5
The four-level hierarchy of the embryonics landscape. Each level is configured by a part of the genome, which in parallel into all cells once their cell membranes have been constructed by a mechanism similar to cellular division. After this process, the cells differentiate according to their spatial location in the organism [57]

In accordance with the cellular computing framework, FPGAs are based on simple basic building blocks (the CLBs), are locally interconnected (in the sense that no cell controls the entire system), and today's high-end circuits contain hundreds of thousands of CLBs. FPGAs tend to be slower than full-custom VLSI circuits, but offer more flexibility at a lower price. The application of FPGA is obviously most interesting where their massive parallelism can be fully exploited, for example for image processing, neural networks [67], DNA sequence matching, or cellular automata. Sipper et al., for example, used FPGAs for their firefly CA machine [91], which were also used to implement on-line evolution algorithms to automatically find solutions to the synchronization task for CAs [25,88].

Example: The Cell Matrix

The *Cell Matrix* [1,33,56] is an extremely fine-grained and universal hardware architecture, not unlike the structure of an FPGA. The reconfigurable device consists of a homogeneous collection of cells that are interconnected in a nearest-neighbor scheme (e. g., von Neumann or other neighborhoods). Each cell performs very basic operations only that are implemented by a simple look-up table. Unlike traditional reconfigurable devices that are controlled by external systems, the Cell Matrix is self-configurable, i. e., each cell within the matrix can reconfigure other cells. In order to accomplish this, each cell can operate independently in one of two modes: (1) the D mode or (2) the C mode. In the D mode (processing mode), incoming data is processed by the cell's internal look-up table and used to generate the output. In the C mode (configuration mode), on the other hand, incoming data is used to re-write the cell's look-up table. A cell can therefore modify one of its neighbors by placing it in the C mode and by writing the data into the look-up table. Since a cell's look-up table governs the ability to control a neighboring cell's mode, a cell X, for example, can configure a neighboring cell Y in such a way that Y will subsequently configure a third cell Z. By combining cells to so-called *supercells*, hierarchical designs of almost any complexity can be realized. The small groups of cells then interact with nearby groups to achieve higher functionalities, which are used to perform more complex functions, and so on. The Cell Matrix architecture was extended in 2004 by Petraglio in his Ph D thesis [76].

The Cell as a Machine

"The brain computes!" This is accepted as a truism by the majority of neuroscientists engaged in discovering the principles employed in the design and operation of nervous systems. What is meant here is that any brain takes the incoming sensory data, encodes them into various biophysical variables, such as the membrane potential or neural firing rates, and subsequently performs a very large number of ill-specified operations, frequently termed computations, on these variables to extract relevant features from the input" (p. 1 in [49]). Further on, Koch continues by elaborating that any physical process, which transforms variables, can in principle be thought of as computation, as long as it can be described by some mathematical formulation. As also noted by Conrad [20], living organisms process information in a very different way than digital computers and typically exploit the inherent physical properties of the matter they are made of. The direct, efficient, and sophisticated ways to process information in cells, molecules, and atoms are the results of billions of years of evolution.

In general, computation in living systems is more a question of what level is being analyzed and through which glasses the analyzer looks. A cell has thousands of information processing mechanisms, some are easy to map to existing computing paradigms, others are far away from any existing model and can therefore only be captured by new paradigms. If we want to use a biological cell as a computing device, we essentially have two possibilities:

- *Interpretation.* Interpret existing bio-chemical cellular mechanisms as computation.
- *Modification.* With the advances in bio-technology and bio-engineering in the last decade, bio-chemical processes at all organization levels of a cell can increasingly be modified for the specific purposes of computation.

For example, DNA can be described in computational terms rather easily and the DNA strand interpreted as data, which is being read by ribosomes is a fairly straightforward natural analog to the Turing machine [116]. But this undertaking becomes more interesting if the analogy can be reversed and the DNA is used to realize Boolean *in vivo* or *in vitro* logic gates in a well controlled manner.

As stated in the introduction, the concept of molecular automata and cells seen as information processing devices appeared around the 1960s and the field has seen impressive developments since then. The field is vast and we shall only give a very shallow taste here. The books by Amos [8], Calude and Paun [17], Paton et al. [69], and Sienko et al. [86] provide excellent overviews from the "cell as a machine" perspective on more recent work, while Paton [70], for example, deals with some of the earlier concepts.

Since Adelman's seminal work on *in vitro* DNA computation [5], this unconventional computing paradigm has played a very important role in cellular computation in both experiment and theory [74]. DNA computation clearly outperforms traditional silicon-based electronics in terms of speed, energy efficiency, and information density. However, while it is rather easy to explore huge search spaces, it is often non-trivial to find the correct answer within all the generated solutions, which has somehow limited the practical applications. Other work has focused on RNA editing as a computational process, which offers another interesting cellular paradigm for "biological software" [50]. Later, Winfree, Weiss, and various others, pioneered DNA-based and other *in vivo* logical circuits [13,84,85,119]. Based on deoxyribozymes, Stefanovic's group has developed molecular automata and logic [53,97]. Their circuits include an full adder, three-input logic gates, and an automaton that plays a version of the game tic-tac-toe. While such circuits serve as examples and proof-of-concepts, the group's long-term goal is to use engineered molecules to control autonomous therapeutic and diagnostic devices. These research areas are fast moving and lots of novel results are to be expected in the next few years.

Future Directions

"The simplest living cell is so complex that supercomputer models may never simulate its behavior perfectly. But even imperfect models could shake the foundations of biology" [40]. Gibbs further emphasizes that most attempts to create artificial life or to faithfully model biological systems suffered from a tremendous number of degrees of freedom. The high number of unconstrained system parameters can then lead to almost any desired behavior. Also, the models are often so complicated that they have a very limited ability to predict anything at all. Tomita believes that the study of the cell will never be complete unless its dynamic behavior on all levels is fully understood [106]. He suggests that the complex behavior can only be understood by means of sophisticated computer models that allow to undertake whole cell simulations. Endy and Brent [35] emphasize that "[p]ast efforts to model behavior of molecular and cellular systems over absolute time typically were qualitatively incomplete or oversimplified compared to available knowledge, and qualitatively incomplete in the sense that key numbers were unknown." It is estimated that complete E. coli simulations could run, perhaps, on a single processor system by 2020.

But the future not only lies in more faithful cellular models and in the ability to tweak cells for the purpose of computation. The construction of realistic living cells *in silico*, thought intractable for a long time, has now become within reach, and so does the possibility to build artificial living cells. Several efforts with this specific goal in mind are currently under way in both Europe and the United

States (see for example [78,79,101]). The question is, how and under which conditions simple life forms, which are able to self-maintain and self-replicate, can be synthesized artificially? Steen Rasmussen's team has taken one of the simpler and more artificial routes [79,80], but there is still a long way to go towards artificial cells that will be able to truly self-replicate and to hopefully perform some specific user-defined functions.

Cellular computing is still a very young field and lots of progress is to be expected in the next few decades, particularly in the areas of bio-technology, nano-technology, modeling, and computing. The main challenges in this interdisciplinary field are mostly related to the remaining wide-open gap between biological systems and machines [20]. On one hand, a much better understanding of cellular systems is required, on the other hand, we need to be able to apply this vast and growing body of knowledge to build better and more "lifelike" computing machines by either drawing inspiration from them or by using real cells and organisms for the purpose of computation.

The following research directions and challenges need to be addressed in the next few years:

1. Faithful qualitative and quantitative cellular models require a better understanding of the biological cell and its bio-chemical mechanism. For example, better non-invasive brain imaging techniques are required for a better understanding of neurons, populations of neurons, and brain regions.
2. Large-scale molecular simulations of cellular processes and large populations of cells. For example, by using specialized supercomputers, large-scale brain simulations only become possible now.
3. Novel computing paradigms are required to model and to understand biological systems. Boolean logic is appropriate for digital systems, where 0s and 1s can easily be represented by the presence and absence of electrical current, but alternative representations may be more appropriate for biological systems.
4. Novel programming paradigms for cellular systems made up from a vast number of cells. Traditional top-down design approaches do not typically scale up to such complexities. Nature-inspired bottom-up design approaches are required.

Article Outline

Glossary

Bifurcation Bifurcation is a qualitative change of the phase portrait. The term “bifurcation” was introduced by H. Poincaré.

Continuous and discrete dynamical systems A dynamical system is a mapping $X(t,x)$, $t \in R$ or $t \in Z$, $x \in E$ which satisfies the group property $X(t+s,x) = X(t, X(s,x))$. The dynamical system is continuous or discrete when t takes real or integer values, respectively. The continuous system is generated by an autonomous system of ordinary differential equations

$$\dot{x} \equiv \frac{\mathrm{d}x}{\mathrm{d}t} = F(x) \tag{1}$$

as the solution $X(t,x)$ with the initial condition $X(0,x) = x$. The discrete system generated by a system of difference equations

$$x_{m+1} = G(x_m) \tag{2}$$

as $X(n,x) = G^n(x)$. The phase space E is the Euclidean or Banach.

Critical part of the spectrum Critical part of the spectrum for a differential equation $\dot{x} = Ax$ is σ_c = {eigenvalues of A with zero real part}. Critical part of the spectrum for a diffeomorphism $x \to Ax$ is σ_c = {eigenvalues of A with modulus equal to 1}.

Eigenvalue and spectrum If for a matrix (linear mapping) A the equality $Av = \lambda v, v \neq 0$ holds then v and λ are called eigenvector and eigenvalue of A. The set of the eigenvalues is the spectrum of A. If there exists k such that $(A - \lambda I)^k v = 0$, v is said to be generating vector.

Equivalence of dynamical systems Two dynamical systems f and g are topologically equivalent if there is a continuous one-to-one correspondence (homeomorphism) that maps trajectories (orbits) of f on trajectories of g. It should be emphasized that the homeomorphism need not be differentiable.

Invariant manifold In applications an invariant manifold arises as a surface such that the trajectories starting on the surface remain on it under the system evolution.

Local properties If $F(p) = 0$, the point p is an equilibrium of (1). If $G(q) = q$, q is a fixed point of (2). We study dynamics near an equilibrium or a fixed point of the system. Thus we consider the system in a neighborhood of the origin which is supposed to be an equilibrium or a fixed point. In this connection we use terminology local invariant manifold or local topological equivalence.

Reduction principle In accordance with this principle a locally invariant (center) manifold corresponds to the critical part of the spectrum of the linearized system. The behavior of orbits on a center manifold determines the dynamics of the system in a neighborhood of its equilibrium or fixed point. The term "reduction principle" was introduced by V. Pliss [59].

Definition of the Subject

Let M be a subset of the Euclidean space R^n.

Definition 1 A set M is said to be smooth manifold of dimension $d \le n$ if for each point $p \in M$ there exists a neighborhood $U \subset M$ and a smooth mapping $g\colon U \to U_0 \subset R^d$ such that there is the inverse mapping g^{-1} and its differential Dg^{-1} (matrix of partial derivatives) is an injection i. e. its maximal rang is d.

For sphere in R^3 which is a two-dimensional smooth manifold the introduction of the described neighborhoods is demonstrated in [77]. A manifold M is C^k-smooth, $k \ge 1$ if the mappings g and g^{-1} have k continuous derivatives. Moreover, chosing the mappings g and g^{-1} as C^∞-smooth or analytical, we obtain the manifold with the same smoothness.

Consider a continuous dynamical system

$$\dot{x} = F(x) , \quad x \in R^n , \tag{3}$$

where $F\colon R^n \to R^n$ is a C^k-smooth vector field, $k \ge 1$, i. e. the mapping F has k continuous derivatives. Let us denote the solution of (3) passing through the point $p \in R^n$ at $t = 0$ by $X(t, p)$. Suppose that the solution is determined for all $t \in R$. By the fundamental theorems of the differential equations theory, the hypotheses imposed on F guarantee the existence, uniqueness, and smoothness of $X(t, p)$ for all $p \in R^n$. In this case the mapping $X_t(p) = X(t, p)$ under fixed t is a diffeomorphism of R^n. Thus, F generates the smooth flow $X_t\colon R^n \to R^n$, $X_t(p) = X(t, p)$. The differential $DX_t(0)$ is a fundamental matrix of the linearized system $\dot{v} = DF(0)v$. A trajectory (an orbit) of the system (3) through x_0 is the set $T(x_0) = \{x = X(t, x_0),\ t \in R\}$.

Definition 2 A manifold M is said to be invariant under (3) if for any $p \in M$ the trajectory through p lies in M. A manifold M is said to be locally invariant under (3) if for every $p \in M$ there exists, depending on p, an interval $T_1 < 0 < T_2$, such that $X_t(p) \in M$ as $t \in (T_1,\ T_2)$. It means that the invariant manifold is formed by trajectories of the system and the locally invariant manifold consists of arcs of trajectories. An equilibrium is 0-dimensional invariant manifold and a periodic orbit is 1-dimensional one. The concept of invariant manifold is a useful tool for simplification of dynamical systems.

Definition 3 A manifold M is said to be invariant in a neighborhood U if for any $p \in M \bigcap U$ the moving point $X_t(p)$ remains on M as long as $X_t(p) \in U$. In this case the manifold M is locally invariant.

Near an equilibrium point O the system (3) can be rewritten in the form

$$\dot{x} = Ax + f(x) , \tag{4}$$

where $O = \{x = 0\}$, $A = DF(O)$, f is second-order at the origin, i. e. $f(0) = 0$ and $Df(0) = 0$. Let us show that the system (4) near O can be considered as a perturbation of the linearized system

$$\dot{x} = Ax . \tag{5}$$

For this we construct a C^k-smooth mapping g which coincides with f in a sufficiently small neighborhood of the origin and is C^1-close to zero.

To construct the mapping g one uses the C^∞-smooth cut-off function $\alpha\colon R^+ \to R^+$

$$\alpha(r) = \begin{cases} 1, & r < 1/2 , \\ > 0, & 1/2 \le r \le 1 , \\ 0, & r > 1 . \end{cases}$$

Then set $g(x) = \alpha(|x|/\epsilon) f(x)$ where ε is a parameter. If $|x| > \epsilon$, $g(x) = 0$ and if $|x| < \epsilon/2$, $g(x) = f(x)$ and g is C^1-close to zero. Consider the system

$$\dot{x} = Ax + g(x) . \tag{6}$$

It is evident that the dynamics of (4) and (6) is the same on $U = \{|x| < \epsilon/2\}$. If the constructed system (6) has an invariant manifold M then $M \bigcap U$ is locally invariant manifold for the initial system (4) or, more precisely, the manifold M is invariant in U. It should be noted that for the case of infinite-dimensional phase space the described construction is more delicate (see details below).

Let us consider a C^k-smooth mapping $(k \ge 1)$ $G\colon R^n \to R^n$ which has the inverse C^k-smooth mapping G^{-1}. The mapping G generates the discrete dynamical system of the form

$$x_{m+1} = G(x_m) , \quad m = \ldots, -2, -1, 0, 1, 2, \ldots . \tag{7}$$

Each continuous system $X(t, p)$ gives rise to the discrete system $G(x) = X(1, x)$ which is the shift operator on unit time. Such a system preserves the orientation of the phase space,where as an arbitrary discrete system may change it.

Hence, the space of discrete systems is more rich than the space of continuous ones. Moreover, usually investigation of a discrete system is, as a rule, simpler than study of a differential equations one. In many instances the investigation of a differential equation may be reduced to study of a discrete system by Poincaré (first return) mapping. An orbit of (7) is the set $T = \{x = x_m,\ m \in \mathbb{Z}\}$, where x_m satisfies (7).

Near a fixed point O the mapping $x \to G(x)$ can be rewritten in the form

$$x \to Ax + f(x)\,, \tag{8}$$

where $O = \{x = 0\}$, $A = DG(O)$, f is second-order at the origin. It is shown above that near O (8) may be considered as a perturbation of the linearized system

$$x \to Ax\,. \tag{9}$$

Motivational Example

Consider the discrete dynamical system

$$\begin{pmatrix} x \\ y \end{pmatrix} \to \begin{pmatrix} X(x,y) = x + xy \\ Y(x,y) = \frac{1}{2}y + \frac{1}{2}x^2 + 2x^2y + y^3 \end{pmatrix}. \tag{10}$$

The origin $(0,0)$ is fixed point. Our task is to examine the stability of the fixed point. The linearized system at 0 is defined by the matrix

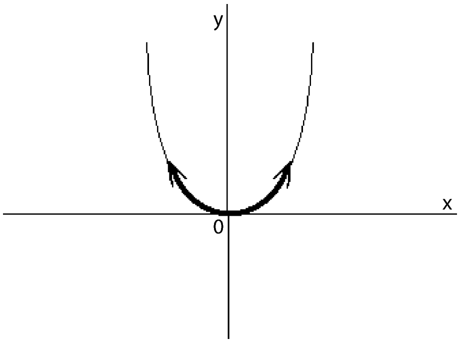
$$\begin{pmatrix} 1 & 0 \\ 0 & 1/2 \end{pmatrix}$$

which has two eigenvalues 1 and 1/2. Hence, the first approximation system contracts along y-axis, whereas its action along x-axis is neutral. So the stability of the fixed point depends on nonlinear terms. Let us show that the curve $y = x^2$ is invariant for the mapping (10). It is enough to check that if a point (x, y) is on the curve then the image (X, Y) is on the curve, i. e. $Y = X^2$ as $y = x^2$. We have

$$\begin{aligned} Y|_{y=x^2} &= \tfrac{1}{2}y + \tfrac{1}{2}x^2 + 2x^2y + y^3|_{y=x^2} \\ &= x^2 + 2x^4 + x^6\,, \\ X^2|_{y=x^2} &= (x + xy)^2|_{y=x^2} \\ &= x^2 + 2x^4 + x^6\,. \end{aligned} \tag{11}$$

Thus, the curve $y = x^2$ is an invariant one-dimensional manifold which is a center manifold W^c for the system (10), see Fig. 1. The fixed point O is on W^c. The restriction of the system on the manifold is

$$x \to x + xy|_{y=x^2} = x(1 + x^2)\,. \tag{12}$$



Center Manifolds, Figure 1
Dynamics on the invariant curve $y = x^2$

It follows that the fixed point 0 is unstable and $x_m \to \infty$ as $m \to \infty$, see Fig. 1. Hence, the origin is unstable fixed point for the discrete system (10). It turns out the system (10) near O is topologically equivalent to the system

$$\begin{aligned} x &\to x(1 + x^2)\,, \\ y &\to \tfrac{1}{2}y \end{aligned} \tag{13}$$

which is simpler than (10). The center manifold $y = x^2$ is tangent to the x-axis at the origin and W^c near 0 can be considered as a perturbed manifold of $\{y = 0\}$.

Introduction

In his famous dissertation “General Problem on Stability of Motion” [41] published at 1892 in Khar’kov (Ukraine) A.M. Lyapunov proved that the equilibrium O of the system (4) is stable if all eigenvalues of matrix A have negative real parts and O is unstable if there exists an eigenvalue with positive real part. He studied the case when some eigenvalues of A have negative real part and the rest of them have zero real one. Lyapunov proved that if the matrix A has a pair of pure imaginary eigenvalues and the other eigenvalues have negative real parts then there exists a two-dimensional invariant surface M through O, and the equilibrium O is stable if O is stable for the system restricted on M. Speaking in modern terms, Lyapunov proved the existence of “center manifold” and formulated “reduction principle” under the described conditions. Moreover, he found the stability condition by using power series expansions, which is an extension of his first method to evaluate stability of systems whose eigenvalues have zero real part. Now we use the same method to check stability [10,25,31,36,43,76]. The general reduction principle in stability theory was established by V. Pliss [59] in 1964, the term “center manifold” was introduced by A. Kelley at 1967 in the paper [38] where the existence of a family of invariant manifolds through equilibrium was proved in general case.

As we see the center manifold can be considered as a perturbation of the center subspace of linearized system. H. Poincaré [61] was probably the first who perceived the importance of the perturbation problem and began to study conditions ensuring the preservation of the equilibriums and periodic orbits under a perturbation of differential equations. Hadamard [26] and Perron [57] proved the existence of stable and unstable invariant manifolds for a hyperbolic equilibrium point and, in fact, showed their preservation. The conditions necessary and sufficient for the preservation of locally invariant manifolds passing through an equilibrium have been obtained in [51]. Many results on the center manifold follow from theory of normal hyperbolicity [77] which studies dynamics of a system near a compact invariant manifold. They will be considered below. The books by Carr [10], Guckenheimer and Holmes [25], Marsden and McCracken [43], Iooss [36], Hassard, Kazarinoff and Wan [31], and Wiggins [76] are popular sources of the information about center manifolds.

Center Manifold in Ordinary Differential Equations

Consider a linear system of differential equations

$$\dot{v} = Lv\,, \tag{14}$$

where $v \in R^n$ and L is a matrix. Divide the eigenvalues of the matrix L into three parts: stable $\sigma_s = \{$eigenvalues with negative real part$\}$, unstable $\sigma_u = \{$eigenvalues with positive real part$\}$ and central (neutral, critical) $\sigma_c = \{$eigenvalues with zero real part$\}$. If the matrix does not have the eigenvalues with zero real part, the system is called hyperbolic. The matrix L has three eigenspaces: the stable subspace E^s, the unstable subspace E^u, and the central subspace E^c correspond to these parts of spectrum. The subspaces E^s, E^u, and E^c are invariant under the system (14), that is, the solution starting on the subspace stays on it [33]. The solutions on E^s have exponential tending to 0, the solutions on E^u have exponential growth. The subspaces E^s, E^c, E^u meet in pairs only at the origin and $E^s + E^c + E^u = R^n$, i. e. we have the invariant decomposition $R^n = E^s \oplus E^c \oplus E^u$. There exists a linear change of coordinates (see [33]) transforming (14) to the form

$$\begin{aligned} \dot{x} &= Ax\,,\\ \dot{y} &= By\,,\\ \dot{z} &= Cz\,, \end{aligned} \tag{15}$$

where the matrix A has eigenvalues with zero real part, the matrix B has eigenvalues with negative real part, and the matrix C has eigenvalues with positive real part. So, (14) decomposes into three independent systems of differential equations. It is known [1,23,24] that the system (15) is topologically equivalent to the system

$$\begin{aligned} \dot{x} &= Ax\,,\\ \dot{y} &= -y\,,\\ \dot{z} &= z\,. \end{aligned} \tag{16}$$

Thus, the dynamics of the system (14) is determined by the system $\dot{x} = Ax$ which is the restriction of (14) on the center subspace E^c. Our goal is to justify a similar "reduction principle" for nonlinear systems of differential equations.

Summarizing the results of V. Pliss [59,60], A. Kelley [38], N. Fenichel [19], and M. Hirsch, C. Pugh, M. Shub [34] we obtain the following theorem.

Theorem 1 (Existence Theorem) *Consider a C^k-smooth ($1 \le k < \infty$) system of differential equations $\dot{v} = F(v)$, $F(O) = 0$ and $L = DF(O)$. Let E^s, E^u and E^c be the stable, unstable, and central eigenspaces of L.*

Then near the equilibrium O there exist the following five C^k-smooth invariant manifolds (see Fig. 2):

- *The center manifold W^c, tangent to E^c at O;*
- *The stable manifold W^s, tangent to E^s at O;*
- *The unstable manifold W^u, tangent to E^u at O;*
- *The center-stable manifold W^{cs}, tangent to $E^c + E^s$ at O;*
- *The center-unstable manifold W^{cu}, tangent to $E^c + E^u$ at O;*

The stable and unstable manifolds are unique, but center, center-stable, and center-unstable manifolds are not necessarily unique.

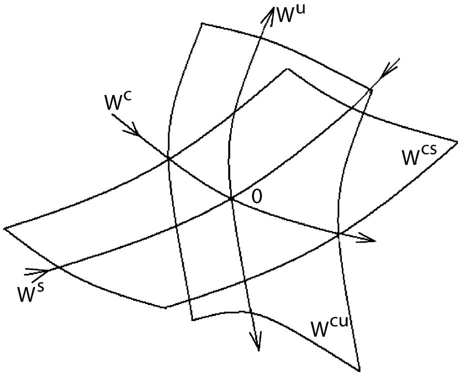
Solutions on W^s have exponential tending to O as $t \to \infty$. Solutions on W^u have exponential tending to O as $t \to -\infty$.

Remark 1 The expression "near the equilibrium O" means that there exists a neighborhood $U(O)$, depending on F and k, where the statements of the Existence Theorem hold.

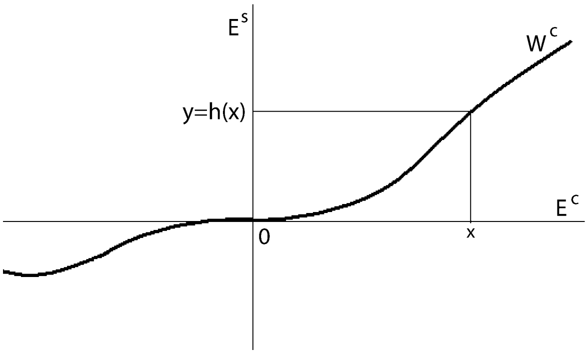
Remark 2 The linearized system $\dot{v} = DF(O)v$ has the invariant subspace $E^s + E^u$ whereas the complete system $\dot{v} = F(v)$ may not have any smooth invariant manifolds with the tangent space $E^s + E^u$ at O, see [5,30].

Representation of the Center Manifold

At first we suppose that our system does not have the unstable eigenspace and is transformed by the linear change



Center Manifolds, Figure 2
The classical five invariant manifolds



Center Manifolds, Figure 3
Representation of a center manifold

of coordinates mentioned above to the form

$$\begin{aligned} \dot{x} &= Ax + f(x, y)\,, \\ \dot{y} &= By + g(x, y)\,, \end{aligned} \tag{17}$$

where $E^c = \{(x, 0)\}$, $E^s = \{(0, y)\}$. Since the center manifold W^c is tangent to $E^c = \{(x, 0)\}$ at the origin $O = (0, 0)$, it can be represented near O in the form

$$W^c = \{(x, y) \mid |x| < \varepsilon,\ y = h(x)\}\,.$$

In other words the center manifold is represented as the graph of a smooth mapping $h\colon V \subset R^c \to R^s$, where c and s are dimensions of the center and stable subspaces, see Fig. 3. Since W^c goes through the origin and is tangent to E^s, we have the equalities

$$h(0) = 0\,, \quad Dh(0) = 0\,. \tag{18}$$

The invariance of W^c means that if an initial point (x, y) is in W^c, i. e. $y = h(x)$ then the solution $(X(t, x, y), Y(t, x, y))$ of (17) is in W^c, i. e. $Y(t, x, y)) = h(X(t, x, y))$. Thus, we get the invariance condition

$$Y(t, x, h(x))) = h(X(t, x, h(x)))\,. \tag{19}$$

Differentiating (19) with respect to t and putting $t = 0$ we get

$$Bh(x) + g(x, h(x)) = Dh(x)(Ax + f(x, h(x)))\,. \tag{20}$$

Thus, the mapping h have to be a solution of the partial differential equation (20) and satisfy (18).

Suppose that the system has the form

$$\begin{aligned} \dot{x} &= Ax + f(x, y, z)\,, \\ \dot{y} &= By + g_1(x, y, z)\,, \\ \dot{z} &= Cz + g_2(x, y, z)\,, \end{aligned} \tag{21}$$

where A has the eigenvalues with zero real part, B has the eigenvalues with negative real part, C has the eigenvalues with positive real part. Analogously to the previous case we can show that the center manifold is represented in the form

$$W^c = \{(x, y, z) \mid |x| < \epsilon,\ y = h_1(x),\ z = h_2(x)\}$$

where the mappings h_1 and h_2 satisfy the equations

$$\begin{aligned} &Bh_1(x) + g_1(x, h_1(x), h_2(x)) \\ &\qquad = Dh_1(x)(Ax + f(x, h_1(x), h_2(x))) \\ &Ch_2(x) + g_2(x, h_1(x), h_2(x)) \\ &\qquad = Dh_2(x)(Ax + f(x, h_1(x), h_2(x))) \end{aligned} \tag{22}$$

and the conditions

$$\begin{aligned} h_1(0) &= 0\,, \quad Dh_1(0) = 0 \\ h_2(0) &= 0\,, \quad Dh_2(0) = 0\,. \end{aligned} \tag{23}$$

Uniqueness and Nonuniqueness of the Center Manifold

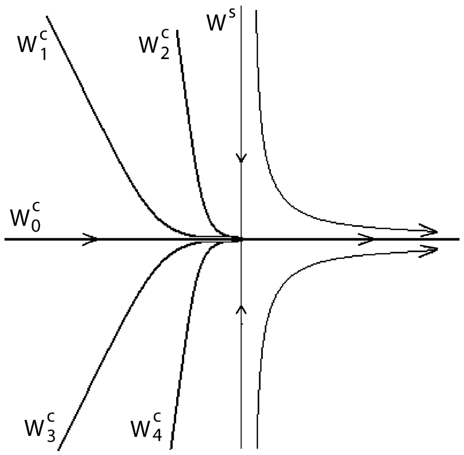
The center manifold is nonunique in general.

Let us consider the illustrating example from [38]. The system has the form

$$\begin{aligned} \dot{x} &= x^2\,, \\ \dot{y} &= -y\,, \end{aligned} \tag{24}$$

where $(x, y) \in R^2$. It is obviously that the origin $(0, 0)$ is the equilibrium with single stable manifold $W^s = \{(0, y)\}$. There is a center manifold of the form $W^c = \{(x, 0)\}$. Moreover, there are the center manifolds that can be obtained when solving the equation

$$\frac{\mathrm{d}y}{\mathrm{d}x} = \frac{-y}{x^2}\,. \tag{25}$$



Center Manifolds, Figure 4
Nonuniqueness of the center manifold

The solution of (24) has the form

$$y(x) = a \exp\left(\frac{1}{x}\right) \tag{26}$$

for $x \neq 0$ and any constant $a \in R$. It follows that

$$W^c(a) = \{(x, y) | y = a \exp\left(\frac{1}{x}\right) \\ \text{as } x < 0 \text{ and } y = 0 \text{ as } x \geq 0\}$$

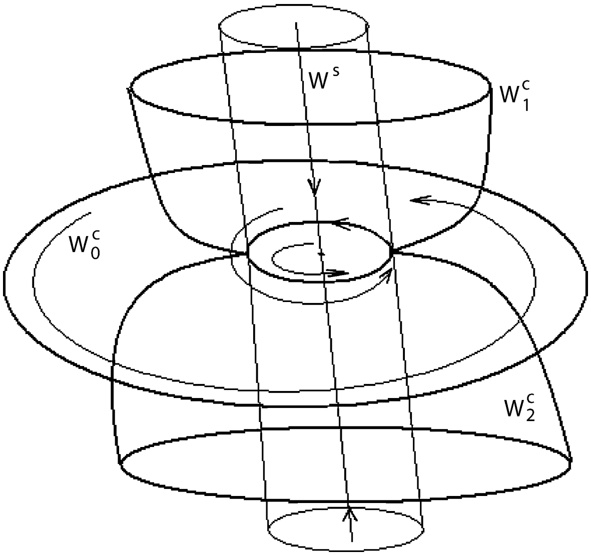
is center manifold for each a, being C^∞-smooth and pasting together the curve $\{y = a \exp(1/x)\}$ as $x < 0$ and the straight line $\{y = 0\}$ as $x \geq 0$., see Fig. 4.

However, the center manifolds possess the following weak uniqueness property. Let U be a neighborhood of the W^c. It turns out that the maximal invariant set I in U must be in W^c, that follows from the Reduction Theorem, see below. Consequently, all center manifolds contact on I. In this case the center manifold is called locally maximal. Thus, the center manifolds may differ on the trajectories leaving the neighborhood as $t \to \infty$ or $-\infty$.

For example, suppose that a center manifold is two-dimensional and a limit cycle is generated from the equilibrium through the Hopf bifurcation [31,35]. In this case the invariant set I is a disk bounded by the limit cycle and all center manifolds will contain this disk, see Fig. 5.

Smoothness

M. Hirsch, C. Pugh, M. Shub [34] proved that the center manifold is C^k-smooth if the system is C^k-smooth and $k < \infty$. Moreover if the kth derivative of the vector field is α-Hölder or Lipschitz mapping, the center manifold is the same.



Center Manifolds, Figure 5
Weak uniqueness of the center manifold

However, if the system is C^∞ or analytic then the center manifold is not necessary the same. First consider the analytic case. It is clear that if the analytic center manifold exists then it is uniquely determined by applying the Taylor power series expansion. Consider the illustrating example [31]

$$\begin{aligned} \dot{x} &= -x^2 , \\ \dot{y} &= -y + x^2 \end{aligned} \tag{27}$$

which does not have an analytic center manifold. In fact, applying the Taylor power series expansions we obtain that the center manifold has to be given by the series $y = \sum_{n=2}^{\infty}(n-1)!x^n$ which diverges when $x \neq 0$.

If the system is C^∞-smooth then the Existence Theorem guaranties the existence of a C^k-smooth center manifold for any $k < \infty$. However, the center manifold may not be C^∞-smooth. Van Strien S.J. [71] showed that the system

$$\begin{aligned} \dot{x} &= -x^2 + \mu^2 , \\ \dot{y} &= -y - (x^2 - \mu^2) , \\ \dot{\mu} &= 0 . \end{aligned} \tag{28}$$

does not have a C^∞-smooth center manifold. In fact if the system is C^∞-smooth then for each k there is a neighborhood $U_k(O)$ of a C^k-smooth central manifold W^c. There are the systems for which the sequence $\{U_k\}$ can shrink to O as $k \to \infty$ [25,71]. The results of the papers [19,34] show that the smoothness of the invariant manifold depends on the relation between Lyapunov exponents on the center manifold and on the normal subspace (stable plus unstable subspaces). This relation σ is included in the concept of the normal hyperbolicity. At an equilibrium $\sigma = \min(\mathrm{Re}\lambda_n/\mathrm{Re}\lambda_c)$, where $\mathrm{Re}\lambda_n/\mathrm{Re}\lambda_c > 0$, λ_c is the eigenvalue on the center subspace and λ_n is the eigenvalue on the normal subspace. The condition $\sigma > 1$ is necessary for a persistence of smooth invariant manifold. One can guarantee degree of smoothness k of the manifold provided $k < \sigma$. Moreover, there exists examples showing that the condition $k < \sigma$ is essential. It means that the system has to contract (expand) along $E^s(E^u)k$-times stronger than along the center manifold.

If a center manifold to the equilibrium O exists then $\mathrm{Re}\,\lambda_c = 0$ and $\sigma = \infty$ at O, but near O may be other equilibrium (or other orbits) on the center manifold where $\sigma < \infty$, and as a consequence, the center manifold may not be C^∞-smooth. Let us consider the illustrating example [25]

$$\begin{aligned} \dot{x} &= \mu x - x^3\,, \\ \dot{y} &= y + x^4\,, \\ \dot{\mu} &= 0\,. \end{aligned} \tag{29}$$

The point $O = (0, 0, 0)$ is equilibrium, the system linearized at O has the form

$$\begin{aligned} \dot{x} &= 0\,, \\ \dot{y} &= y\,, \\ \dot{\mu} &= 0\,. \end{aligned} \tag{30}$$

The system (30) has the following invariant subspace: $E^s = \{0, 0, 0\}$, $E^c = \{x, 0, \mu\}$, $E^u = \{0, y, 0\}$. The μ-axis consists of the equilibriums $(0, 0, \mu_0)$ for the system (29). The system linearized at $(0, \mu_0, 0)$ is the following

$$\begin{aligned} \dot{x} &= \mu_0 x\,, \\ \dot{y} &= y\,, \\ \dot{\mu} &= 0\,. \end{aligned} \tag{31}$$

The eigenvalues on the center subspace are 0 and μ_0, the eigenvalue on the normal (unstable) subspace is 1. Therefore the degree of smoothness is bounded by $\sigma = 1/\mu_0$. Detailed information and examples are given in [10,25,31,36,43,76].

Reduction Principle

As we saw above, a smooth system of differential equations near an equilibrium point O can be written in the form

$$\begin{aligned} \dot{x} &= Ax + f(x, y, z)\,, \\ \dot{y} &= By + g(x, y, z)\,, \\ \dot{z} &= Cz + q(x, y, z)\,, \end{aligned} \tag{32}$$

where $O = (0, 0, 0)$, A has eigenvalues with zero real part, B has eigenvalues with negative real part and C has eigenvalues with positive real part; $f(0, 0, 0) = g(0, 0, 0) = q(0, 0, 0) = 0$ and $Df(0, 0, 0) = Dg(0, 0, 0) = Dq(0, 0, 0) = 0$. In this case the invariant subspaces at O are $E^c = \{(x, 0, 0)\}$, $E^s = \{(0, y, 0)\}$, and $E^u = \{(0, 0, z)\}$. The center manifold has the form

$$W^c = \{(x, y, z) | x \in V \subset R^c,\ y = h_1(x),\ z = h_2(x)\}\,, \tag{33}$$

where c is the dimension of the center subspace E^c, the mappings $h_1(x)$ and $h_2(x)$ are C^k-smooth, $k \geq 1$, $h_1(0) = h_2(0) = 0$ and $Dh_1(0) = Dh_2(0) = 0$. The last equalities mean that the manifold W^c goes through O and is tangent to E^c at O.

Summarizing the results of V. Pliss [59,60], A. Shoshitaishvili [68,69], A. Reinfelds [63], K. Palmer [55], Pugh C.C., Shub M. [62], Carr J. [10], Grobman D.M. [24], and F. Hartman [29] we obtain the following theorem.

Theorem 2 (Reduction Theorem) *The system of differential Equations (32) near the origin is topologically equivalent to the system*

$$\begin{aligned} \dot{x} &= Ax + f(x, h_1(x), h_2(x))\,, \\ \dot{y} &= -y\,, \\ \dot{z} &= z\,. \end{aligned} \tag{34}$$

The first equation is the restriction of the system on the center manifold. The theorem allows to reduce the investigation of the dynamics near a nonhyperbolic fixed point to the study of the system on the center manifold.

Construction of the Center Manifold

The center manifold may be calculated by using simple iterations [10]. However, this method does not have wide application and we consider a method based on the Taylor power series expansion. First it was proposed by A. Lyapunov in [41]. Suppose that the unstable subspace is 0, that is the last equation of the system (32) is absent. Such systems have a lot of applications in stability theory. So we consider a system

$$\begin{aligned} \dot{x} &= Ax + f(x, y)\,, \\ \dot{y} &= By + g(x, y)\,, \end{aligned} \tag{35}$$

The center manifold is the graph of the mapping $y = h(x)$ which satisfies the equation

$$Dh(x)(Ax + f(x, h(x))) - Bh(x) - g(x, h(x)) = 0 \quad (36)$$

and the conditions $h(0) = 0$ and $Dh(0) = 0$. Let us try to solve the equation by applying the Taylor power series expansion. Denote the left part of (36) by N(h(x)). J. Carr [10] and D. Henry [32] proved the following theorem.

Theorem 3 *Let $\phi\colon V(0) \subset R^c \to R^s$ be a smooth mapping, $\phi(0)=0$ and $D\phi(0)=0$ such that $N(\phi(x))=o(|x|^m)$ for some $m > 0$ as $|x| \to 0$ then*

$$h(x) - \phi(x) = o(|x|^m) \text{ as } |x| \to 0$$

where $r(x)=o(|x|^m)$ means that $r(x)/|x|^m \to 0$ as $|x| \to 0$.

Thus, if we solve the Eq. (36) with a desired accuracy we construct h with the same accuracy. Theorem 3 substantiates the application of the described method. Let us consider a simple example from [76]

$$\begin{aligned} \dot{x} &= x^2 y - x^5 , \\ \dot{y} &= -y + x^2 , \end{aligned} \quad (37)$$

$(x, y) \in R^2$, the equilibrium is at the origin $(0, 0)$. The eigenvalues of the linearized system are 0 and -1. According to the Existence Theorem the center manifold is locally represented in the form

$$W^c = \{(x, y) \mid y = h(x),\ |x| < \delta, \\ h(0) = 0, Dh(0) = 0)\} ,$$

where δ is sufficiently small. It follows that h has the form

$$h = ax^2 + bx^3 + \cdots . \quad (38)$$

The equation for the center manifold is given by

$$Dh(x)(Ax + f(x, h(x))) - Bh(x) - g(x, h(x)) = 0 , \quad (39)$$

where $A = 0$, $B = -1$, $f(x, y) = x^2 y - x^5$, $g(x, y) = x^2$. Substituting (38) in (39) we obtain the equality

$$(2ax + 3bx^2 + \cdots)(ax^4 + bx^5 - x^5 + \cdots) \\ + ax^2 + bx^3 - x^2 + \cdots = 0 . \quad (40)$$

Equating coefficients on each power of x to zero we obtain

$$\begin{aligned} x^2 &\ :\ a - 1 = 0,\ \Rightarrow\ a = 1 \\ x^3 &\ :\ b = 0, \\ \vdots &\quad\ \ \vdots . \end{aligned} \quad (41)$$

Therefore we have

$$h(x) = x^2 + 0x^3 + \cdots . \quad (42)$$

In this connection we have to decide how many terms (powers of x) have be computed? The solution depends on our goal. For example, suppose that we study the Lyapunov stability of the equilibrium $(0, 0)$ for (37). According to the Reduction Theorem the system (37) is topologically equivalent to the system

$$\begin{aligned} \dot{x} &= x^2 h(x) - x^5 , \\ \dot{y} &= -y , \end{aligned} \quad (43)$$

where $h(x) = x^2 + 0x^3 + \cdots$. Substituting h we obtain the equation

$$\dot{x} = x^4 + \dots . \quad (44)$$

Hence the equilibrium is unstable. It should be noted that the calculation of bx^3 is unnecessary, since substituting $h(x) = x^2 + bx^3 + \cdots$ in the first equation of the system (43), we also obtain (44). Thus, it is enough to compute the first term ax^2 of the mapping h.

This example brings up the following question. The system (37) is topologically equivalent to the system

$$\begin{aligned} \dot{x} &= x^4 + \cdots , \\ \dot{y} &= -y , \end{aligned} \quad (45)$$

which has many center manifolds. From this it follows that the initial system has a lot of center manifolds. Which of center manifolds is actually being found when approximating the center manifold via power series expansion?

It turns out [10,70,74] that any two center manifolds differ by transcendentally small terms, i. e. the terms of their Taylor expansions coincide up to all existing orders. For example, the system (24) has the center manifolds of the form

$$W^c(a) = \left\{(x, y) | y = a \exp\left(\tfrac{1}{x}\right) \\ \text{as } x < 0 \text{ and } y = 0 \text{ as } x \geq 0\right\}$$

for any a. However, each manifold has null-expansion at 0.

Center Manifold in Discrete Dynamical Systems

Consider a dynamical system generated by the mapping

$$v \to Lv + G(v) , \quad (46)$$

where $v \in R^n$, L is a matrix and G is second-order at the origin. Without loss of generality we consider the system (46) as a perturbation of the linear system

$$x \to Lx . \quad (47)$$

Divide the eigenvalues of L into three parts:
stable $\sigma_s = \{$eigenvalues with modulus less than $1\}$,
unstable $\sigma_u = \{$eigenvalues with modulus greater than $1\}$,
critical $\sigma_c = \{$eigenvalues with modulus equal to $1\}$.
The matrix L has three eigenspaces: the stable subspace E^s, the unstable subspace E^u, and the central subspace E^c, which correspond to the mentioned spectrum parts respectively, being $E^s \oplus E^u \oplus E^c = R^n$. The next theorem follows from the theorem on perturbation of ρ-hyperbolic endomorphism on a Banach space [34].

Theorem 4 (Existence Theorem) *Consider a C^k-smooth $(1 \leq k < \infty)$ discrete system*

$$v \to Lv + G(v)\,,$$

$G(0) = 0$ and G is C^1-close to zero. Let E^s, E^u and E^c be the stable, unstable, and central eigenspaces of the linear mapping L.

Then near the fixed point O there exist the following C^k-smooth invariant manifolds:

- *The center manifold W^c tangent to E^c at O,*
- *The stable manifold W^s tangent to E^s at O,*
- *The unstable manifold W^u tangent to E^u at O,*
- *The center-stable manifold W^{cs} tangent to $E^c + E^s$ at O,*
- *The center-unstable manifold W^{cu} tangent to $E^c + E^u$ at O.*

The stable and unstable manifolds are unique, but center, center-stable, and center-unstable manifolds may not be unique.

The orbits on W^s have exponential tending to O as $m \to \infty$. The orbits on W^u have exponential tending to O as $m \to -\infty$.

There exists a linear change of coordinates transforming (46) to the form

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} \to \begin{pmatrix} Ax + f(x,y,z) \\ By + g_1(x,y,z) \\ Cz + g_2(x,y,z) \end{pmatrix}\,, \tag{48}$$

where A has eigenvalues with modulus equal 1, B has eigenvalues with modulus less than 1, C has eigenvalues with modulus greater than 1. The system (48) at the origin has the following invariant eigenspaces: $E^c = \{(x,0,0)\}$, $E^s = \{(0,y,0)\}$, and $E^u = \{(0,0,z)\}$. Since the center manifold W^c is tangent to E^c at the origin $O = (0,0)$, it can be represented near O in the form

$$W^c = \{(x,y,z) \,|\, |x| < \epsilon,\; y = h_1(x), z = h_2(x)\}\,,$$

where h_1 and h_2 are second-order at the origin, i. e. $h_{1,2}(0) = 0$, $Dh_{1,2}(0) = 0$. The invariance of W^c means that if a point $(x,y,z) \in W^c$, i. e. $y = h_1(x)$, $z = h_2(x)$, then $(Ax + f(x,y,z), By + g_1(x,y,z), Cz + g_2(x,y,z)) \in W^c$, i. e. $By + g_1(x,y,z) = h_1(Ax + f(x,y,z))$, $Cz + g_2(x,y,z) = h_2(Ax + f(x,y,z))$. Thus, we get the invariance property

$$\begin{aligned} &Bh_1(x) + g_1(x,h_1(x),h_2(x)) \\ &\qquad = h_1(Ax + f(x,h_1(x),h_2(x)))\,, \\ &Ch_2(x) + g_2(x,h_1(x),h_2(x)) \\ &\qquad = h_2(Ax + f(x,h_1(x),h_2(x)))\,. \end{aligned} \tag{49}$$

Results on smoothness and uniqueness of center manifold for discrete systems are the same as for continuous systems.

Theorem 5 (Reduction Theorem [55,62,63,64]) *The discrete system (48) near the origin is topologically equivalent to the system*

$$\begin{aligned} x &\to Ax + f(x,h_1(x),h_2(x))\,, \\ y &\to By\,, \\ z &\to Cz\,. \end{aligned} \tag{50}$$

The first mapping is the restriction of the system on the center manifold. The theorem reduces the investigation of dynamics near a nonhyperbolic fixed point to the study of the system on the center manifold.

Normally Hyperbolic Invariant Manifolds

As it is indicated above, a center manifold can be considered as a perturbed invariant manifold for the center subspace of the linearized system. The normal hyperbolicity conception arises as a natural condition for the persistence of invariant manifold under a system perturbation. Informally speaking, an f-invariant manifold M, where f-diffeomorphism, is normally hyperbolic if the action of Df along the normal space of M is hyperbolic and dominates over its action along the tangent one. (the rigorous definition is below). Many of the results concerning center manifold follows from the theory of normal hyperbolic invariant manifolds. In particular, the results related to center eigenvalues of Df with $|\lambda| \neq 1$ may be obtained using this theory.

The problem of existence and preservation for invariant manifolds has a long history. Initial results on invariant (integral) manifolds of differential equations were obtaned by Hadamard [26] and Perron [57], Bogoliubov, Mitropolskii [8] and Lykova [48], Pliss [60], Hale [28], Diliberto [16] and other authors (for references see [39,77]). In the late 1960s and throughout 1970s the theory of perturbations of invariant manifolds began to assume a very general and well-developed form. Sacker [66] and Neimark [50] proved (independently and by different methods) that a normally hyperbolic compact invariant manifold is preserved under C^1 perturbations. Final results on preservation of invariant manifolds were obtained by Fenichel [19,20] and Hirsch, Pugh, Shub [34]. The linearization theorem for a normally hyperbolic manifold was proved in [62].

Let $f\colon R^n \to R^n$ be a C^r-diffeomorphism, $1 \le r < \infty$, and a compact manifold M is f-invariant.

Definition 4 An invariant manifold M is called r-normally hyperbolic if there exists a continuous invariant decomposition

$$TR^n|_M = TM \oplus E^{\mathrm{s}} \oplus E^{\mathrm{u}} \tag{51}$$

of the tangent bundle TR^n into a direct sum of subbundles TM, E^{s}, E^{u} and constants a, $\lambda > 0$ such that for $0 \le k \le r$ and all $p \in M$,

$$\begin{aligned} |D^s f^n(p)|\ |(D^0 f^n(p))^{-1}|^k &\le a\exp(-\lambda n) \quad \text{for } n \ge 0\,, \\ |D^u f^n(p)|\ |(D^0 f^n(p))^{-1}|^k &\le a\exp(\lambda n) \quad \text{for } n \le 0\,. \end{aligned} \tag{52}$$

Here $D^0 f$, $D^{\mathrm{s}} f$ and $D^{\mathrm{u}} f$ are restrictions of Df on TM, E^{s} and E^{u}, respectively.

The invariance of the bundle E^* means that for every $p \in M_0$, the image of the fiber $E^*(p)$ at p under $Df(p)$ is the fiber $E^*(q)$ at $q = f(p)$. The bundles E^{s} and E^{u} are called stable and unstable, respectively. In other words, M is normally hyperbolic if the differential Df contracts (expands) along the normal (to M) direction and this contraction (expansion) is stronger in r times than a conceivable contraction (expansion) along M. Summarizing the results of [19,20,34,50,62,66] we obtain the following theorem.

Theorem 6 *Let a C^r diffeomorphism f be r-normally hyperbolic on a compact invariant manifold M with the decomposition $TR^n|_M = TM \oplus E^{\mathrm{s}} \oplus E^{\mathrm{u}}$. Then*

- *there exist invariant manifolds W^{s} and W^{u} near M, which are tangent at M to $TM \oplus E^{\mathrm{s}}$ and $TM \oplus E^{\mathrm{u}}$;*
- *the manifolds M, W^{s} and W^{u} are C^r-smooth;*
- *if g is another C^r-diffeomorphism C^r-close to f, then there exists the unique manifold M_g which is invariant and r-normally hyperbolic for g;*
- *near M f is topologically equivalent to $Df|_{E^{\mathrm{s}}\oplus E^{\mathrm{u}}}$, which in local coordinates has the form*

$$\begin{aligned} &(x, y, z) \to (f(x), Df(x)y, Df(x)z)\,, \\ &\qquad x \in M\,, \quad y \in E^{\mathrm{s}}(x)\,, \quad z \in E^{\mathrm{u}}(x)\,. \end{aligned} \tag{53}$$

Similarly result takes place for flows. Mañé [44] showed that a locally unique, preserved, compact invariant manifold is necessarily normally hyperbolic. Local uniqueness means that near M, an invariant set I of the perturbation g is in M_g. Conditions for the preservation of locally nonunique compact invariant manifolds and linearization were found by G. Osipenko [52,53].

Applications

Stability

As it was mentioned above, it was Lyapunov who pioneered in applying the concept of center manifold to establish the stability of equilibrium. V. Pliss [59] proved the general reduction principle in stability theory. According to this principle the equilibrium is stable if and only if it is stable on the center manifold. We have considered the motivating example where the center manifold concept was used. The system

$$\dot{x} = xy\,, \quad \dot{y} = -y + ax^2\,, \tag{54}$$

has the center manifold $y = h(x)$. Applying Theorem 3, we obtain

$$h(x) = ax^2 + \cdots\,.$$

The reduced system is of the form

$$\dot{x} = ax^3 + \ldots\,.$$

Thus, if $a < 0$, the origin is stable. The book [25] contains other examples of investigation of stability.

Bifurcations

Consider a parametrized system of differential equations

$$\dot{x} = A(\mu)x + f(x, \mu)\,, \tag{55}$$

where $\mu \in R^k$, f is C^1-small when μ is small. To study the bifurcation problem near $\mu = 0$ it is useful to deal with the extended system of the form

$$\begin{aligned} \dot{x} &= A(\mu)x + f(x, \mu)\,, \\ \dot{\mu} &= 0\,. \end{aligned} \tag{56}$$

Suppose that (55) has a n-dimensional center manifold for $\mu = 0$. Then the extended system (56) has a $n + k$-dimensional center manifold. The reduction principle guarantees that all bifurcations lie on the center manifold. Moreover, the center manifold has the form $y = h(x, \mu_0)$ for every μ_0 which is a solution of the equation $\dot{\mu} = 0$ and the mapping h may be presented as a power series in μ. Further interesting information regarding to recent advancements in the approximation and computation of center manifolds is in [37]. The book [31] deals with Hopf bifurcation and contains a lot of examples and applications. Invariant manifolds and foliations for nonautonomous systems are considered in [3,13]. Partial linearization for noninvertible mappings is studied in [4].

Center Manifold in Infinite-Dimensional Space

Center manifold theory is a standard tool to study the dynamics of discrete and continuous dynamical systems in infinite dimensional phase space. We start with the discrete dynamical system generated by a mapping of a Banach space. The existence of the center manifold of the mappings in Banach space was proved by Hirsch, Pugh and Shub [34]. Let $T\colon E \to E$ be a linear endomorphism of a Banach space E.

Definition 5 A linear endomorphism T is said to be ρ-hyperbolic, $\rho > 0$, if no eigenvalue of T has modulus ρ, i. e., its spectrum Spect(T) has no points on the circle of radius ρ in the complex plane C. A linear 1-hyperbolic isomorphism T is called hyperbolic.

For a ρ-hyperbolic linear endomorphism there exists a T-invariant splitting of $E = E_1 \oplus E_2$ such that the spectrum of the restriction $T_1 = T|_{E_1}$ lies outside of the disk of the radius ρ, where as the spectrum of $T_2 = T|_{E_2}$ lies inside it. So T_1 is automorphism and T_1^{-1} exists. It is known (for details see [34]) that one can define norms in E_1 and E_2 such that associated norms of T_1^{-1} and T_2 may be estimated in the following manner

$$|T_1^{-1}| < \tfrac{1}{\rho}\,, \quad |T_2| < \rho\,. \tag{57}$$

Conversely, if T admits an invariant splitting $T = T_1 \oplus T_2$ with $|T_1^{-1}| \equiv a$, $|T_2| \equiv b$, $ab < 1$ then Spect(T_1) lies outside the disk $\{\lambda \in C\colon |\lambda| < 1/a\}$, and Spect($T_2$) lies in the disk $\{\lambda \in C\colon |\lambda| \le b\}$. Thus, T is ρ-hyperbolic with $b < \rho < 1/a$.

Theorem 7 *Let T be a ρ-hyperbolic linear endomorphism, $\rho \le 1$. Assume that $f\colon E \to E$ is C^r, $r \ge 1$, $f = T + g$, $f(0) = 0$ and there is $\delta > 0$ such that if g is a Lipschitz mapping and*

$$\mathrm{Lip}(g) = \mathrm{Lip}(f - T) \le \delta\,, \tag{58}$$

then there exists a manifold W_f, which is a graph of a C^1 map $\varphi\colon E_1 \to E_2$, i. e.

$$W_f = \{x + y \mid y = \varphi(x),\ x \in E_1,\ y \in E_2\}\,,$$

with the following properties:

- *W_f is f-invariant;*
- *if $\|T_1^{-1}\|^j \|T_2\| < 1$, $j = 1, \dots, r$ then W_f is C^r and depends continuously on f in the C^r topology;*
- *$W_T = E_1$;*
- *for $x \in W_f$*

$$|f^{-1}(x)| \le (a + 2\varepsilon)\,|x|\,, \tag{59}$$

where $a < 1/\rho$, and ε is small provided δ is small;
- *if $Df(0) = T$ then W_f is tangent to E_1 at 0.*

Suppose that the spectrum of T is contained in $A_1 \bigcup A_2$ where

$$A_1 = \{z \in C,\ |z| \ge 1\}\,, \quad A_2 = \{z \in C,\ |z| \le a < 1\}\,.$$

Corollary 1 *If $f\colon E \to E$ is C^r, $1 \le r < \infty$, $f(0) = 0$ and $\mathrm{Lip}(f - T) \le \epsilon$ is small, then there exists a center-unstable manifold $W^{cu} = W_f$ which is the graph of a C^r function $E_1 \to E_2$. The center-unstable manifold is attractor, i. e. for any $x \in E$ the distance between $f^n(x)$ and W^{cu} tends to zero as $n \to \infty$. The manifold $W_f = W^c$ is center manifold when $A_1 = \{z \in C,\ |z| = 1\}$.*

Apply this theorem to a mapping of the general form

$$u \to Au + f(u)\,, \tag{60}$$

where E is a Banach space, $u \in E$, $A\colon E \to E$ is a linear operator, f is second-order at the origin. The question arises of whether there exists a smooth mapping g such that g coincides with f in a sufficiently small neighborhood of the origin and g is C^1-close to zero? The answer is positive if E admits C^∞-norm, i. e. the mapping $u \to \|u\|$ is C^∞-smooth for $u \neq 0$. It is performed for Hilbert space. The desired mapping g may be constructed with the use of a cut-off function. To apply Theorem 7 to (60) we have to suppose *Hypothesis on C^∞-norm*: the Banach space E admits C^∞-norm.

Thus, Theorem 7 together with Hypothesis on C^∞-norm guarantee an existence of center manifold for the system (60) in a Banach space. A. Reinfelds [63,64] prove a reduction theorem for homeomorphism in a metric space from which an analog of Reduction Theorem 5 for Banach space follows.

Flows in Banach Space

Fundamentals of center manifold theory for flows and differential equations in Banach spaces can be found in [10,21,43,73]. In Euclidean space a flow is generated by a solution of a differential equation and the theory of ordinary differential equations guarantees the clear connection between flows and differential equations. In infinite dimensional (Banach) space this connection is more delicate and at first, we consider infinite dimensional flows and then (partial) differential equations.

Definition 6 A flow (semiflow) on a domain D is a continuous family of mappings $F_t\colon D \to D$ where $t \in R\,(t \geq 0)$ such that $F_0 = I$ and $F_{t+s} = F_t F_s$ for $t, s \in R\,(t, s \geq 0)$.

Theorem 8 (Center Manifold for Infinite Dimensional Flows [43]) *Let the Hypothesis on C^{∞}-norm be fulfilled and $F_t\colon E \to E$ be a semiflow defined near the origin for $0 \leq t \leq \tau$, $F_t(0) = 0$. Suppose that the mapping $F_t(x)$ is C^0 in t and C^{k+1} in x and the spectrum of the linear semigroup $DF_t(0)$ is of the form $\mathrm{e}^{t(\sigma_1 \cup \sigma_2)}$, where $\mathrm{e}^{t(\sigma_1)}$ is on the unit circle (i. e. σ_1 is on the imaginary axis) and $\mathrm{e}^{t(\sigma_2)}$ is inside the unit circle with a positive distance from one as $t > 0$ (i. e. σ_2 is in the left half-plane). Let $E = E_1 \oplus E_2$ be the $DF_t(0)$-invariant decomposition corresponding to the decomposition of the spectrum $\mathrm{e}^{t(\sigma_1 \cup \sigma_2)}$ and $dimE_1 = d < \infty$.*

Then there exists a neighborhood U of the origin and C^k-submanifold $W^c \subset U$ of the dimension d such that

- *W^c is invariant for F_t in U, $0 \in W^c$ and W^c is tangent to E_1 at 0;*
- *W^c is attractor in U, i. e. if $F_t^n(x) \in U$, $n = 0, 1, 2, \ldots$ then $F_t^n(x) \to W^c$ as $n \to \infty$.*

In infinite dimensional dynamics it is also popular notion of "inertial manifold" which is an invariant finite dimensional attracting manifold corresponding to W^c of the Theorem 8.

Partial Differential Equations

At the present the center manifold method takes root in theory of partial differential equations. Applying center manifold to partial differential equations leads to a number of new problems. Consider an evolution equation

$$\dot{u} = Au + f(u)\,, \tag{61}$$

where $u \in E$, E is a Banach space, A is a linear operator, f is second-order at the origin. Usually A is a differential operator defined on a domain $D \subset E$, $D \neq E$. To apply Theorem 8 we have to construct a semiflow F_t defined near the origin of E. As a rule, an infinite dimensional phase space E is a functional space where the topology may be chosen by the investigator. A proper choice of functional space and its topology may essentially facilitate the study. As an example we consider a nonlinear heat equation

$$u'_t = \Delta u + f(u)\,, \tag{62}$$

where u is defined on a bounded domain $\Omega \subset R^n$ with Dirichlet condition on the boundary $u|_{\partial\Omega} = 0$, $\Delta u = (\partial^2/\partial x_1^2 + \cdots + \partial^2/\partial x_n^2)u$ is the Laplace operator defined on the set

$$C_0^2 = \{u \in C^2(\overline{\Omega}),\ u = 0 \text{ on } \partial\Omega\}\,.$$

According to [49] we consider a Hilbert space $E = L^2(\Omega)$ with the inner product $< u, v >= \int_\Omega uvdx$. The operator Δ may be extended to a self-conjugate operator $A\colon D_A \to L^2(\Omega)$ with the domain D_A that is the closure of C_0^2 in $L^2(\Omega)$. Consider the linear heat equation $u'_t = \Delta u$ and its extension

$$u'_t = Au, \quad u \in D_A\,. \tag{63}$$

What do we mean by a flow generated by (63)?

Definition 7 A linear operator A is the infinitesimal generator of a continuous semigroup $U(t)$, $t \geq 0$ if:
$U(t)$ is a linear mapping for each t;
$U(t)$ is a semigroup and $\|U(t)u - u\| \to 0$ as $t \to +0$;

$$Au = \lim_{t \to +0} \frac{U(t)u - u}{t} \tag{64}$$

whenever the limit exists.

For Laplace operator we have $< \Delta u, u >\leq 0$ for $u \in C_0^2$, hence the operator A is dissipative. It guarantees [6] the existence of the semigroup $U(t)$ with the infinitesimal generator A. The mapping $U(t)$ is the semigroup $DF_t(0)$ in Theorem 8.

The next problem is the relation between the linearized system $u' = Au$ and full nonlinear Equation (61). To consider the mapping f in (62) as C^1-small perturbation, the Hypothesis on C^{∞}-norm has to be fulfilled. To prove the existence of the solution of the nonlinear equation with $u(0) = u_0$ one uses the Duhamel formula

$$u(t) = U_t u_0 + \int_0^t U_{t-s} f(u(s))\mathrm{d}s$$

and the iterative Picard method. By this way we construct the semiflow required to apply Theorem 8. The relation between the spectrum of a semigroup $U(t)$ and the spectrum of its infinitisemal generator gives rise to an essential problem. All known existence theorems are formulated in terms of the semigroup as in Theorem 8. The existence of the spectrum decompositions of a semigroup $U(t)$ and the corresponding estimations on the appropriate projections are supposed. This framework is inconvenient for many applications, especially in partial differential equations. In finite dimensions, a linear system $\dot{x} = Ax$ has a solution of the form $U(t)x = \mathrm{e}^{At}x$ and λ is an eigenvalue of A if and only if $\mathrm{e}^{\lambda t}$ is an eigenvalue of $U(t)$. We have the spectral equality

$$\mathrm{Spect}(U(t)) = \mathrm{e}^{\mathrm{Spect}(A)t} .$$

In infinite dimensions, relating the spectrum of the infinitesimal generator A to that of the semigroup $U(t)$ is a spectral mapping problem which is often nontrivial. The spectral inclusion

$$\mathrm{Spect}(U(t)) \subset \mathrm{e}^{\mathrm{Spect}(A)t}$$

always holds and the inverse inclusion is a problem that is solved by the spectral mapping theorems [12,18,22,65].

Often an application of center manifold theory needs to prove an appropriate version of the reduction theorem [7,11,12,14,15,18]. Pages 1–5 of the book [40] give an extensive list of the applications of center manifold theory to infinite dimensional problems. Here we consider a few of typical applications. Reaction-diffusion equations are typical models in chemical reaction (Belousov–Zhabotinsky reaction), biological systems, population dynamics and nuclear reaction physics. They have the form

$$u'_t = (K(\lambda) + D\Delta)u + f(u, \lambda) , \tag{65}$$

where K is a matrix depending on a parameter, D is a symmetric, positive semi-definite, often diagonal matrix, Δ is the Laplace operator, λ is a control parameter. The papers [2,27,31,67,78] applied center manifold theory to the study of the reaction-diffusion equation. Invariant manifolds for nonlinear Schrodinger equations are studied in [22,40]. In the elliptic quasilinear equations the spectrum of the linear operator is unbounded in unstable direction and in this case the solution does not generate even a semiflow. Nevertheless, center manifold technique is successfully applied in this case as well [45]. Henry [32] proved the persistence of normally hyperbolic closed linear subspace for semilinear parabolic equations. It follows the existence of the center manifold which is a perturbed manifold for the center subspace. I. Chueshov [14,15] considered a reduction principle for coupled nonlinear parabolic-hyperbolic partial differential equations that has applications in thermoelastisity. Mielke [47] has developed the center manifold theory for elliptic partial differential equations and has applied it to problems of elasticity and hydrodynamics. The results for non-autonomous system in Banach space can be found in [46]. The reduction principle for stochastic partial differential equations is considered in [9,17,75].

Future Directions

Now we should realize that principal problems in the center manifolds theory of finite dimensional dynamics have been solved and we may expect new results in applications. However the analogous theory for infinite dimensional dynamics is far from its completion. Here we have few principal problems such as the reduction principle (an analogue of Theorem 2 or 5) and the construction of the center manifold. The application of the center manifold theory to partial differential equations is one of promising and developing direction. In particular, it is very important to investigate the behavior of center manifolds when Galerkin method is applied due to a transition from finite dimension to infinite one. As it was mentioned above each application of center manifold methods to nonlinear infinite dimensional dynamics is nontrivial and gives rise to new directions of researches.

We live in a hierarchically structured, complex Universe and the articles in this section demonstrate the breadth of vision required by astrophysicists addressing a vast spectrum of problems from dynamical systems to biological and galactic evolution to cosmology. Fundamentally, astronomical problems present a huge variety of scales of time, length, mass, and energy. For example, to understand the transport of energy in hot, opaque bodies without which we cannot understand the structure of stars requires kinetic theory of gases and atomic and molecular processes (the equation of state for stellar matter, and opacities), hydrodynamics, (especially turbulence for convective energy transport and circulation), magnetohydrodynamics and plasma physics (since stars generate magnetic fields by dynamo processes), nuclear and particle physics (for thermonuclear processing and energy loss), and even general relativity (for the late stages of evolution). But stars are formed and die within galaxies, self-gravitating ensembles of many billions of individual stars and cold clouds of millions of solar masses that are actually analogies of ecosystems. Thus the tools developed to address biological systems can be carried over into cosmic problems.

At the close of the 1920s, Arthur Eddington quipped that "someday, perhaps, we shall understand something as simple as a star". How wrong he was. Stars are self-gravitating nuclear engines and it is the mass of a gaseous body that determines whether it will or won't ignite its central thermonuclear energy source. Below a few percent of a solar mass, the stellar core never reaches the required temperature even if the densities are high enough to initiate nuclear reactions. Such a low mass object is called a brown dwarf if, during its initial contraction from an interstellar dark cloud, it can briefly burn deuterium. If even that source remains inaccessible, it is called a planet, regardless of whether it is bound in an orbit to another, more massive companion. Although various claims had been made throughout the 20th century for the presence of planetary systems, especially for the nearby very low mass object called Barnard's Star, the first direct detection of a planetary mass body orbiting another star came only in 1995 with the discovery of a massive Jupiter-like companion to the solar type star 51 Peg. Since then over 300 planets have been discovered orbiting stars other than the Sun, now including multiple systems and even several in other galaxies discovered by gravitational lensing. This sample is, however, currently still biased toward masses much greater than the Earth and systems that are still rather different from our solar system. But with the passage of years and the accumulation of velocity and photometric measurements, systems progressively more similar to ours have begun to emerge.

The first discoveries already, however, presented a paradox: It has generally been thought that the structure of our system is the product of thermal evaporation and restructuring the orbiting bodies by the early Sun, the evaporation of nearby gaseous masses and leaving behind only their rocky cores.

The detection of planetary mass bodies began, however, with the discovery of precisely such planets within a few hundred stellar radii of the central star. This has stimulated a renaissance in dynamical astronomy of few bodies and the re-discovery of effects previously thought to be of only minor importance in the present solar system. This too is reflected in the articles in this section. And because it is clear now that there must also be systems like our own, the study of extraterrestrial environments and the search for extrasolar Earths and the origin of life has emerged from the back rooms to take a central stage as a new sub-discipline: astrobiology (see ► Exobiology (theoretical), Complexity in, by Brandenburg and ► Exobiology and Complexity by Chaisson). It is particularly appropriate that this encyclopedia recognizes the immense promise of this field.

The interplanetary medium, the solar wind, is the topic of several articles. This is the supersonic mass outflow from the only star for which we have virtually all possible information. The wind, synonymous with the interplanetary medium, is the expanding coronal layer of the Sun. Heated by nonthemal mechanisms seated deep within he interior dynamo and convective envelope, magnetohydrodynamic waves and topological relaxation of the outer magnetic field (see ► Topological Magnetohydrodynamics and Astrophysics by Berger).

This is why several of the articles here deal with dynamo processes. This plasma is an ideal laboratory in which the Sun performs the experiments and we capture the results with in situ satellite measurements (see ► Self-

-Organization in Magnetohydrodynamic Turbulence by Veltri et al., and ► Space Plasmas, Dynamical Complexity in, by Chang).

Wave phenomena that are inaccessible under terrestrial laboratory conditions can be studied in detail with spacecraft, MHD turbulence can be observed on a vast range of length scales (from meters to astronomical units) and timescales (from milliseconds to days). We are in a new age of spacecraft measurement with SOHO and STEREO providing continuously monitored dynamical three dimensional imaging of the Sun.

And on the solar surface, in deep in its interior, we see the cyclic generation and decay of a dynamo whose superficial manifestations are the corona, magnetic loop structures of sizes comparable to the stellar radius, and dissipative processes that release high energy particles and locally heat the outer solar atmosphere. All of these topics show the complex interplay of many physical processes and are discussed in many of the articles in this section.

Cosmic rays were discovered at the start of the 20th century by Hess and others making balloon flights to high altitudes carrying devices for measuring atmospheric electricity. They discovered that the ionization increases with height, which led to the hypothesis of some form of extraterrestrial energetic particles impinging on the atmosphere. Further study showed these to be charged, high energy particles, protons, alpha particles, and electrons, whose source was a mystery. For some time, these were the only particles with which fundamental physics could be studied. Somehow, the universe is capable of producing relativistic ions and electrons that traverse the space between the galaxies, reaching energies well in excess of TeV. The Sun and solar type stars, during flares, are capable of accelerating electrons to GeV energies and beyond in milliseconds or shorter on scales of kilometers, but the process is still not understood. And on larger scales, the detection of TeV mission from supernova remnants, the supersonically ejected debris of stellar explosions, shows that these shocks can also accelerate particles on length scales of the size of the solar system throughout the life of the galaxy. Hyper-relativistic phenomena connected with stellar collapse and explosion, such as Gamma Ray Bursts, also demonstrate that complex acceleration processes happen on many different length and time scales in cosmic objects (see ► Acceleration Mechanisms by Melrose).

Historically, it was in problems arising within dynamical astronomy that chaos was first recognized – in the orbital dynamics of the solar system during the 19th century – and the richness of this field has extended far beyond the confines of the realm of the planets. It was the source of the analogies used by Boltzmann and Gibbs in the early stages of the development of statistical mechanics (see ► Astrophysics, Chaos and Complexity in, by Regev).

Beginning with the two body problem, for point masses the physical solution is almost trivial. The motion is conservative, the total energy is constant and, except for effect of general relativity for the most extreme systems, the problem can be solved in closed orbits knowing only the total energy and angular momentum. If one or both objects are extended, or if they are internally complicated, the problem ceases to be tractable in closed form. The orbits evolve in time, either periodically or secularly depending on whether or not there are internal dissipative processes in the constituent bodies. This feature, which complicates the dynamics of binary star systems and even planetary moons requires a sophisticated physical treatment of microphysical processes from gas laws to fluid mechanics.

Planetary ring systems are even more complex, showing a wealth of dynamical structuring that, from particle trajectories imaged in natural settings, produce images like those resulting from numerical models of nonlinear systems. At the next level, the apparently simple problem of the lunar orbit becomes almost impossible once tidal interactions and the effect of the Sun are included. This was the principal discovery of Poincare, Lyapunov, and the dynamicists of the late 19th century, that the perturbing influences on the motion of so small a body a the Moon, whose mass is negligible with respect to the two principals, has a complex temporal spectrum of resonances that produce, even without dissipation, extreme sensitivity of the predictions to the accuracy of the initial conditions for any dynamical calculation (see ► Orbital Dynamics, Chaos in, by Hadjidemetriou).

The extension of this complexity to N-body calculations (see ► Stellar Dynamics, *N*-body Methods for, by Makino) and the evolution of far more populous systems – clusters and galaxies (see ► Astrophysics: Dynamical Systems by Contopoulos) – are addressed in articles in this section.

Moving to the largest scale of all, the Universe as a whole, we reach the limits of current astronomical observations. In the last decade, gravitational wave observatories have opened a new type of astronomical observation, one connected with neither particles nor light and at the very limits of detection. During the formation of black holes and neutron stars, at the moment of collapse of tars either by intrinsic or extrinsic triggering, gravitational waves certainly carry away a significant portion of the binding energy of the initial system. Such emission is required by the theory of collapse and the detection of the secular evolution of binary pulsar orbits assures the physical correctness of the fundamentally relativistic phenomenon. However, the Universe is a very big place and in all galaxies, whatever their evolutionary history and distance, there must be sources for such waves.

These produce an incoherent signal, unlike the strong, identifiable signature of a single collapse event, that should form a stochastic background from the integration of all such sources. It is also clear that at some stage in the earliest stages of the cosmic expansion there were fluctuations in the matter and fields that were strongly coupled with the spacetime structure. These were not dissipatively damped as would happen in a normal fluid.

Instead, their spectrum was systematically altered by the cosmic expansion to the point of visibility in the present universe. How this might be found and what it tells us about the first moments of the Big Bang and the subsequent evolution of cosmic sources during the Hubble time is also treated in this section (see ▶ Cosmic Gravitational Background, Stochastic by Ungarelli and ▶ Cosmic Strings by Achúcarro and Martins).

Finally, because of this huge range of timescales and multiplicity of processes involved in even some of the apparently simplest phenomena, astronomical observations present particularly challenging problems of data analysis (see ▶ Astronomical Time Series, Complexity in, by Scargle).

From dynamical systems to stochastic fluctuations of spacetime, the problem of finding periods and spectra in complex, not spatially resolved and partially sampled data takes us to the limit of current statistical methodology.

In fact, this is a fundamental feature of all astrophysical research, to stretch all of our human capacities, intellectual and technological, in an ever-widening panorama.

Chaos and Ergodic Theory

Article Outline

Glossary

For simplicity, definitions are given for a continuous or smooth self-map or diffeomorphism T of a compact manifold M.

Entropy, measure-theoretic (or: metric entropy) For an ergodic invariant probability measure μ, it is the smallest exponential growth rates of the number of orbit segments of given length, with respect to that length, after restriction to a set of positive measure. We denote it by $h(T, \mu)$. See ▶ Entropy in Ergodic Theory and Subsect. "Local Complexity" below.

Entropy, topological It is the exponential growth rates of the number of orbit segments of given length, with respect to that length. We denote it by $h_{\text{top}}(f)$. See ▶ Entropy in Ergodic Theory and Subsect. "Local Complexity" below.

Ergodicity A measure is ergodic with respect to a map T if given any measurable subset S which is invariant, i. e., such that $T^{-1}S = S$, either S or its complement has zero measure.

Hyperbolicity A measure is hyperbolic in the sense of Pesin if at almost every point no Lyapunov exponent is zero. See ▶ Smooth Ergodic Theory.

Kolmogorov typicality A property is *typical in the sense of Kolmogorov* for a topological space $\mathcal{F}$ of parametrized families $f = (f_t)_{t \in U}$, U being an open subset of $\mathbb{R}^d$ for some $d \geq 1$, if it holds for f_t for Lebesgue almost every t and topologically generic $f \in \mathcal{F}$.

Lyapunov exponents
The Lyapunov exponents (▶ Smooth Ergodic Theory) are the limits, when they exist, $\lim_{n\to\infty} \frac{1}{n} \log \|(T^n)'(x).v\|$ where $x \in M$ and v is a non zero tangent vector to M at x. The Lyapunov exponents of an ergodic measure is the set of Lyapunov exponents obtained at almost every point with respect to that measure for all non-zero tangent vectors.

Markov shift (topological, countable state) It is the set of all infinite or bi-infinite paths on some countable directed graph endowed with the left-shift, which just translates these sequences.

Maximum entropy measure It is a measure μ which maximizes the measured entropy and, by the variational principle, realized the topological entropy.

Physical measure It is a measure μ whose basin, $\{x \in M \colon \forall \phi \colon M \to \mathbb{R}$ continuous $\lim_{n\to\infty} \frac{1}{n} \sum_{k=0}^{n-1}$

$\phi(f^k x) = \int \phi \, d\mu\}$ has nonzero volume.

Prevalence A property is *prevalent* in some complete metric, separable vector space X if it holds outside of a set N such that, for some Borel probability measure μ on X: $\mu(A+v) = 0$ for all $v \in X$. See [76,141,239].

Sensitivity on initial conditions T has *sensitivity to initial conditions* on $X' \subset X$ if there exists a constant $\rho > 0$ such that for every $x \in X'$, there exists $y \in X$, arbitrarily close to x, and $n \geq 0$ such that $d(T^n y, T^n x) > \rho$.

Sinai–Ruelle–Bowen measures It is an invariant probability measure which is absolutely continuous along the unstable foliation (defined using the unstable manifolds of almost every $x \in M$, which are the sets $W^u(x)$, of points y such that $\lim_{n\to\infty} \frac{1}{n} \log d(T^{-n} y, T^{-n} x) < 0$).

Statistical stability T is statistically stable if the physical measures of nearby deterministic systems are arbitrarily close to the convex hull of the physical measures of T.

Stochastic stability T is stochastically stable if the invariant measures of the Markov chains obtained from T by adding a suitable, smooth noise with size $\epsilon \to 0$ are arbitrarily close to the convex hull of the physical measures of T.

Structural stability T is structurally stable if any S close enough to T is topologically the same as T: there exists a homeomorphism $h\colon M \to M$ such that $h \circ T = S \circ h$ (orbits are sent to orbits).

Subshift of finite type It is a closed subset Σ_F of $\Sigma = \mathcal{A}^{\mathbb{Z}}$ or $\Sigma = \mathcal{A}^{\mathbb{N}}$ where $\mathcal{A}$ is a finite set satisfying: $\Sigma_F = \{x \in \Sigma\colon \forall k < \ell\colon x_k x_{k+1} \dots x_\ell \notin F\}$ for some finite set F.

Topological genericity Let X be a Baire space, e. g., a complete metric space. A property is *(topologically) generic* in a space X (or holds for the (topologically) generic element of X) if it holds on a nonmeager set (or set of second Baire category), i. e., on a dense G_δ subset.

Definition of the Subject

Chaotic dynamical systems are those which present unpredictable and/or complex behaviors. The existence and importance of such systems has been known at least since Hadamard [126] and Poincaré [208], however it became well-known only in the sixties. We refer to [36,128,226,236] and [80,107,120,125,192,213] for the relevance of such dynamics in other fields, mathematical or not (see also ▶ Ergodic Theory: Interactions with Combinatorics and Number Theory, ▶ Ergodic Theory: Fractal Geometry). The numerical simulations of chaotic dynamics can be difficult to interpret and to plan, even misleading, and the tools and ideas of mathematical dynamical system theory are indispensable. Arguably the most powerful set of such tools is ergodic theory which provides a statistical description of the dynamics by attaching relevant probability measures. In opposition to single orbits, the statistical properties of chaotic systems often have good stability properties. In many cases, this allows an understanding of the complexity of the dynamical system and even precise and quantitative statistical predictions of its behavior. In fact, chaotic behavior of single orbits often yields global stability properties.

Introduction

The word *chaos*, from the ancient Greek $\chi\alpha o\sigma$, "shapeless void" [131] and "raw confused mass" [199], has been used [*$\chi\alpha o\sigma$ also inspired Van Helmont to create the word "gas" in the seventeenth century and this other thread leads to the molecular chaos of Boltzmann in the nineteenth century and therefore to ergodic theory itself*.] since a celebrated paper of Li and Yorke [169] to describe evolutions which however deterministic and defined by rather simple rules, exhibit unpredictable or complex behavior.

Attempts at Definition

We note that, like many ideas [237], this is not captured by a single mathematical definition, despite several attempts (see, e. g., [39,112,158,225] for some discussions as well as the monographs on chaotic dynamics [15,16,58,60,78,104,121,127,215,250,261]). Let us give some of the most well-known definitions, which have been given mostly from the topological point of view, i. e., in the setting of a self-map $T\colon X \to X$ on a compact metric space whose distance is denoted by d:

T has *sensitivity to initial conditions* on $X' \subset X$ if there exists a constant $\rho > 0$ such that for every $x \in X'$, there exists $y \in X$, arbitrarily close to x with a finite separating time:

$$\exists n \geq 0 \quad \text{such that} \quad d(T^n y, T^n x) > \rho\,.$$

In other words, any uncertainty on the exact value of the initial condition x makes $T^n(x)$ completely unknown for n large enough. If X is a manifold, then *sensitivity to initial conditions in the sense of Guckenheimer* [120] means that the previous phenomenon occurs for a set X' with nonzero volume.

T is *chaotic in the sense of Devaney* [94] if it admits a dense orbit and if the periodic points are dense in X. It implies sensitivity to initial conditions on X.

T is *chaotic in the sense of Li and Yorke* [169] if there exists an uncountable subset $X' \subset X$ of points, such that, for all $x \neq y \in X'$,

$$\liminf_{n\to\infty} d(T^n x, T^n y) = 0 \quad \text{and}$$
$$\limsup_{n\to\infty} d(T^n x, T^n y) > 0\,.$$

T has *generic chaos* in the sense of Lasota [206] if the set

$$\{(x,y) \in X \times X\colon \liminf_{n\to\infty} d(T^n x, T^n y) = 0 < \limsup_{n\to\infty} d(T^n x, T^n y)\}$$

is topologically generic (*see glossary.*) in $X \times X$.

Topological chaos is also sometimes characterized by *nonzero topological entropy* (▶ Entropy in Ergodic Theory): there exist exponentially many orbit segments of a given length. This implies chaos in the sense of Li and Yorke by [39].

As we shall see ergodic theory describes a number of chaotic properties, many of them implying some or all of the above topological ones. The main such property for a smooth dynamical system, say a $C^{1+\alpha}$-diffeomorphism of a compact manifold, is the existence of an invariant probability measure which is:

1. Ergodic (cannot be split) and aperiodic (not carried by a periodic orbit);
2. Hyperbolic (nearby orbits converge or diverge at a definite exponential rate);
3. Sinai–Ruelle–Bowen (as smooth as it is possible).

(For precise definitions we refer to ▶ Smooth Ergodic Theory or to the discussions below.) In particular such a situation implies nonzero entropy and sensitivity to initial condition of a set of nonzero Lebesgue measure (i. e., positive volume).

Before starting our survey in earnest, we shall describe an elementary and classical example, the full tent map, on which the basic phenomena can be analyzed in a very elementary way. Then, in Sect. "Picking an Invariant Probability Measure", we shall give some motivations for introducing probability theory in the description of chaotic but deterministic systems, in particular the unpredictability of their individual orbits. We define two of the most relevant classes of invariant measures: the physical measures and those maximizing entropy. It is unknown in which generality these measures exist and can be analyzed but we describe in Sect. "Tractable Chaotic Dynamics" the major classes of dynamics for which this has been done. In Sect. "Statistical Properties" we describe some of the finer statistical properties that have been obtained for such good chaotic systems: sums of observables along orbits are statistically undistinguishable from sums of independent and identically distributed random variables. Sect. "Orbit Complexity" is devoted to the other side of chaos: the complexity of these dynamics and how, again, this complexity can be analyzed, and sometimes classified, using ergodic theory. Sect "Stability" describes perhaps the most striking aspect of chaotic dynamics: the unstability of individual orbit is linked to various forms of stability of the global dynamics.

Finally we conclude by mentioning some of the most important topics that we could not address and we list some possible future directions.

Caveat. The subject-matter of this article is somewhat fuzzy and we have taken advantage of this to steer our path towards some of our favorite theorems and to avoid the parts we know less (some of which are listed below). We make no pretense at exhaustivity neither in the topics nor in the selected results and we hope that our colleagues will excuse our shortcomings.

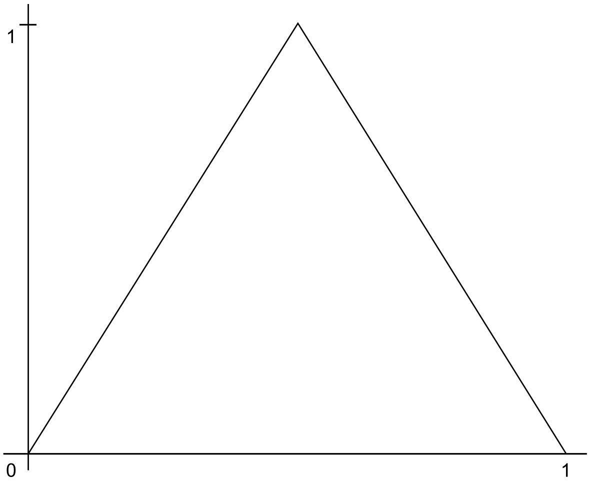
Remark 1 In this article we only consider *compact, smooth and finite-dimensional* dynamical systems *in discrete time*, i. e., defined by self-maps. In particular, we have omitted the natural and important variants applying to flows, e. g., evolutions defined by ordinary differential equations but we refer to the textbooks (see, e. g.,[15,128,148]) for these.

Elementary Chaos: A Simple Example

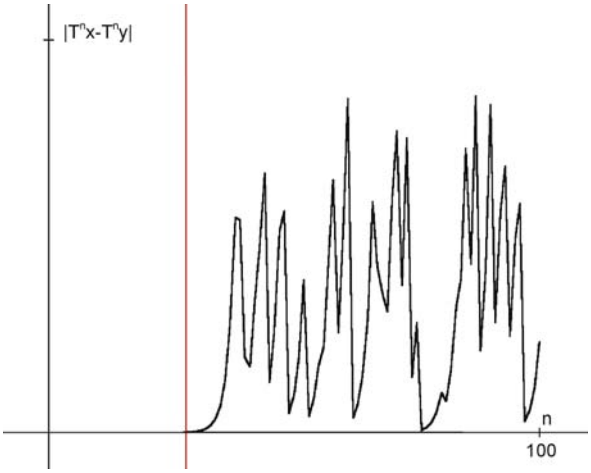
We start with a toy model: the full tent map T of Fig. 1. Observe that for any point $x \in [0,1]$, $T^{-n}(x) = \{(\sigma(k,n)x + k)\cdot 2^{-n}\colon k = 0,1,\dots,2^n - 1\}$, where $\sigma(k,n) = \pm 1$. Hence $\bigcup_{n\geq 0} T^{-n}(x)$ is dense in $[0,1]$. It easily follows that T exhibits *sensitive dependence to initial conditions*. Even worse in this example, the qualitative asymptotic behavior can be completely changed by this arbitrarily small perturbation: x may have a dense orbit whereas y is eventually mapped to a fixed point! This is Devaney chaos [94].

This kind of unstability was first discovered by J. Hadamard [126] in his study of the geodesic flow (i. e., the frictionless movement of a point mass constrained to remain on a surface). At that time, such an unpredictability was considered a purely mathematical pathology, necessarily devoid of any physical meaning [*Duhem qualified Hadamard's result as "an example of a mathematical deduction which can never be used by physics" (see pp. 206–211 in* [103]*)!*].

Returning to out tent map, we can be more quantitative. At any point $x \in [0,1]$ whose orbit never visits 1/2, the *Lyapunov exponent* $\lim_{n\to\infty} \frac{1}{n} \log |(T^n)'(x)|$



Chaos and Ergodic Theory, Figure 1
The graph of the full tent map $f(x) = 1 - |1 - 2x|$ over $[0, 1]$



Chaos and Ergodic Theory, Figure 2
$|T^n(x) - T^n(y)|$ for $T(x) = 1 - |1 - 2x|$, $|x - y| = 10^{-12}$ and $0 \le n \le 100$. The vertical red line is at $n = 28$ and shows when $|T^n x - T^n y| \ge 0.5 \cdot 10^{-4}$ for the first time

is $\log 2$. (*See the glossary*.) Such a positive Lyapunov exponent corresponds to infinitesimally close orbits getting separated exponentially fast. This can be observed in Fig. 2. Note how this exponential speed creates a rather sharp transition.

It follows in particular that experimental or numerical errors can grow very quickly to size 1, [*For simple precision arithmetic the uncertainty is* 10^{-16} *which grows to size 1 in 38 iterations of* T.] i. e., the approximate orbit may contain after a while *no information about the true orbit*. This casts a doubt on the reliability of simulations. Indeed, a simulation of T on most computers will suggest that all orbits quickly converge to 0, which is completely false [*Such a collapse to 0 does really occurs but only for a countable subset of initial conditions in* $[0, 1]$ *whereas the points with dense orbit make a subset of* $[0, 1]$ *with full Lebesgue measure (see below). This artefact comes from the way numbers are represented – and approximated – on the computer: multiplication by even integers tends to "simplify" binary representations. Thus the computations involved in drawing Fig.* 2 *cannot be performed too naively*.]. Though somewhat atypical in its dramatic character, this failure illustrates the *unpredictability* and *unstability* of individual orbits in chaotic systems.

Does this mean that all quantitative predictions about orbits of T are to be forfeited? Not at all, *if we are ready to change our point of view* and look beyond a single orbit. This can be seen easily in this case. Let us start with such a global analysis from the topological point of view. Associate to $x \in [0, 1]$, a sequence $i(x) = i = i_0 i_1 i_2 \dots$ of 0s and 1s according to $i_k = 0$ if $T^k x \le 1/2$, $i_k = 1$ otherwise. One can check that [*Up to a countable set of exceptions*.] $\{i(x) : x \in [0, 1]\}$ is the set $\Sigma_2 := \{0, 1\}^{\mathbb{N}}$ of *all* infinite sequences of 0s and 1s and that at most one $x \in [0, 1]$ can realize a given sequence as $i(x)$.

Notice how the transformation f becomes trivial in this representation:

$$i(f(x)) = i_1 i_2 i_3 \dots \quad \text{if } i(x) = i_0 i_1 i_2 i_3 \dots$$

Thus f is represented by the simple and universal "left-shift" on sequences, which is denoted by σ. This representation of a rather general dynamical system by the left-shift on a space of sequences is called *symbolic dynamics* (▶ Symbolic Dynamics), [171].

This can be a very powerful tool. Observe for instance how here it makes obvious that we have complete *combinatorial freedom* over the orbits of T: one can easily build orbits with various asymptotic behaviors: if a sequence of Σ_2 contains all the finite sequences of 0s and 1s, then the corresponding point has a dense orbit; if the sequence is periodic, then the corresponding point is itself periodic, to give two examples of the *richness* of the dynamics.

More quantitatively, the number of distinct subsequences of length n appearing in sequences $i(x)$, $x \in [0, 1]$, is 2^n. It follows that the *topological entropy* (▶ Entropy in Ergodic Theory) of T is $h_{\text{top}}(T) = \log 2$. [*For the coincidence of the entropy and the Lyapunov exponent see below*.] The positivity of the topological entropy can be considered as the signature of the complexity of the dynamics and considered as the definition, or at least the stamp, of a topologically chaotic dynamics.

Let us move on to a probabilistic point of view. Pick $x \in [0, 1]$ randomly according to, say, the uniform law in $[0, 1]$. It is then routine to check that $i(x)$ follows the (1/2, 1/2)-Bernoulli law: the probability that, for any given k, $i_k(x) = 0$ is 1/2 and the i_ks are independent. Thus $i(x)$, seen as a sequence of random 0 and 1 when x is subject to the uniform law on $[0, 1]$, is *statistically undistinguishable from coin tossing!* This important remark leads to quantitative predictions. For instance, the *strong law of large numbers* implies that, for Lebesgue-almost every $x \in [0, 1]$ (i. e., for all $x \in [0, 1]$ except in a set of Lebesgue measure zero), the fraction of the time spent in any dyadic interval $I = [k \cdot 2^{-N}, \ell \cdot 2^{-N}] \subset [0, 1]$, $k, \ell, N \in \mathbb{N}$, by the orbit of x,

$$\lim_{n\to\infty} \frac{1}{n} \#\{0 \le k < n \colon T^k x \in I\} \tag{1}$$

exists and is equal to the length, 2^{-N}, of that interval. [*Eq.* (1) *in fact holds for any interval I. This implies that the orbit of almost every* $x \in [0, 1]$ *visits all subintervals of* $[0, 1]$, *i. e., the orbit is dense: in complete contradiction with the above mentioned numerical simulation!*] More generally, we shall see that, if $\phi \colon [0, 1] \to \mathbb{R}$ is any continuous function, then, for Lebesgue almost every-x,

$$\lim_{n\to\infty} \frac{1}{n} \sum_{k=0}^{n-1} \phi(T^k x) \quad \text{exists and is equal to} \quad \int \phi(x)\, \mathrm{d}x\,. \tag{2}$$

Using strong *mixing properties* (▶ Ergodicity and Mixing Properties) of the Lebesgue measure under T, one can prove further properties, e. g., sensitivity on initial conditions in the sense of Guckenheimer [*The Lebesgue measure is* weak-mixing: *Lebesgue-almost all couples of points* $(x, y) \in [0, 1]^2$ *get separated. Note that it is not true of every couple off the diagonal: Counter-examples can be found among couples* (x, y) *with* $T^n x = T^n y$ *arbitrarily close to 1.*] and study the fluctuations of the averages $\frac{1}{n} \sum_{k=0}^{n-1} \phi(Tx)$ by the way of limit theorems.

The above analysis relied on the very special structure of T but, as we shall explain, the ergodic theory of differentiable dynamical systems shows that all of the above (and much more) holds in some form for rather general classes of chaotic systems. The different chaotic properties are independent in general (e. g., one may have topological chaos whereas the asymptotic behavior of almost all orbits is periodic) and the proofs can become much more difficult. We shall nonetheless be rewarded for our efforts by the discovery of unexpected links between chaos and stability, complexity and simplicity as we shall see.

Picking an Invariant Probability Measure

One could think that dynamical systems, such as those defined by self-maps of manifolds, being *completely deterministic*, have nothing to do with probability theory. There are in fact several motivations for introducing various invariant probability measures.

Statistical Descriptions

An abstract goal might be to enrich the structure: a smooth self-map is a particular case of a Borel self-map, hence one can canonically attach to this map its set of all invariant Borel probability measures [*From now on all measures will be Borel probability measures except if it is explicitly stated otherwise.*], or just the set of *ergodic* [*A measure is* ergodic *if all measurable invariant subsets have measure 0 or 1. Note that arbitrary invariant measures are averages of ergodic ones, so many questions about invariant measures can be reduced to ergodic ones.*] ones. By the Krylov–Bogoliubov theorem (see, e. g., [148]), this set is non-empty for any continuous self-map of a compact space.

By the following fundamental theorem ▶ Ergodic Theorems, each such measure is the statistical description of some orbit:

Birkhoff Pointwise Ergodic Theorem *Let* $(X, \mathcal{F}, \mu)$ *be a space with a* σ*-field and a probability measure. Let* $f \colon X \to X$ *be a measure-preserving map, i. e.,* $f^{-1}(\mathcal{F}) \subset \mathcal{F}$ *and* $\mu \circ f^{-1} = \mu$. *Assume ergodicity of* μ *(See the glossary.) and (absolute) integrability of* $\phi \colon X \to \mathbb{R}$ *with respect to* μ. *Then for* μ*-almost every* $x \in X$,

$$\lim_{n\to\infty} \frac{1}{n} \sum_{k=0}^{n-1} \phi(f^k x) \quad \textit{exists and is} \quad \int \phi \, \mathrm{d}\mu\,.$$

This theorem can be interpreted as saying that "time averages" coincide almost surely with "ensemble averages" (or "phase space average"), i. e., that Boltzmann's Ergodic Hypothesis of statistical mechanics [110] holds for dynamical systems that cannot be split in a measurable and non trivial way. [*This indecomposability is however often difficult to establish. For instance, for the hard ball model of a gas it is known only under some generic assumption (see* [238] *and the references therein).*] We refer to [161] for background.

Remark 2 One should observe that the existence of the above limit is not at all obvious. In fact it often fails from other points of view. One can show that for the full tent map $T(x) = 1 - |1 - 2x|$ analyzed above and many functions ϕ, the set of points for which it fails is large both *from the topological point of view* (it contains a dense G_δ set) and *from the dimension point of view* (it has Hausdorff dimension 1 [28]). This is an important point: the introduction of invariant measures allows one to avoid some of the wilder pathologies.

To illustrate this let us consider the full tent map $T(x) = 1 - |1 - 2x|$ again and the two ergodic invariant measures: δ_0 (the Dirac measure concentrated at the fixed point 0) and the Lebesgue measure $\mathrm{d}x$. In the first case, we obtain a complex proof of the obvious fact that the time average at $x = 0$ (some set of full measure!) and the ensemble average with respect to δ_0 are both equal to $f(0)$. In the second case, we obtain a very general proof of the above Eq. (2).

Another type of example is provided by the contracting map $S\colon [0,1] \to [0,1]$, $S(x) = x/2$. S has a unique invariant probability measure, δ_0. For Birkhoff theorem the situation is the same as that of T and δ_0: it asserts only that the orbit of 0 is described by δ_0.

One can understand Birkhoff theorem as a (first and rather weak) *stability result*: the time averages are independent of the initial condition, *almost surely with respect to* μ.

Physical Measures

In the above silly example S, much more is true than the conclusion of Birkhoff Theorem: *all* points of $[0,1]$ are described by δ_0. This leads to the definition of the *basin* of a probability measure μ for a self-map f of a space M:

$$\mathcal{B}(\mu) := \Bigg\{ x \in M\colon \forall \phi\colon \\ M \to \mathbb{R} \text{ continuous } \lim_{n\to\infty} \frac{1}{n} \sum_{k=0}^{n-1} \phi(f^k x) = \int \phi \, \mathrm{d}\mu \Bigg\} .$$

If M is a manifold, then there is a notion of volume and one can make the following definition. A *physical measure* is a probability measure whose basin has nonzero volume in M. Say that a dynamical system $f\colon M \to M$ on a manifold has a *finite statistical description* if there exists finitely many invariant probability measures $\mu_1, \ldots, \mu_n$ the union of whose basins is the whole of M, up to a set of zero Lebesgue measure.

Physical measures are among the main subject of interest as they are expected to be exactly those that are "experimentally visible". Indeed, if $x_0 \in \mathcal{B}(\mu)$ and $\epsilon_0 > 0$ is small enough, then, by Lebesgue density theorem, a point x picked according to, say, the uniform law in the ball $B(x_0, \epsilon_0)$ of center x_0 and radius ϵ_0, will be in $\mathcal{B}(\mu)$ with probability almost 1 and therefore its ergodic averages will be described by μ. Hence "experiments" can be expected to follow the physical measures and this is what is numerically observed in most of the situations (see however the caveat in the discussion of the full tent map).

The existence of a finite statistical description (or even of a physical measure) is, as we shall see, not automatic nor routine to prove. Attracting periodic points as in the above silly example provide a first type of physical measures. Birkhoff ergodic theorem asserts that absolutely continuous ergodic invariant measures, usually obtained from some expansion property, give another class of physical measures. These contracting and expanding types can be combined in the class of *Sinai–Ruelle–Bowen measures* [166] which are the invariant measures absolutely continuous "along expanding directions" (see for the precise but technical definition ▶ Smooth Ergodic Theory). Any ergodic Sinai–Ruelle–Bowen measure which is ergodic and without zero Lyapunov exponent [*That is, the set of points* $x \in M$ *such that* $\lim_{n\to\infty} \frac{1}{n} \log \|(f^n)'(x).v\| = 0$ *for some* $v \in T_x M$ *has zero measure.*] is a physical measure. Conversely, "most" physical measures [*For counter-examples see* [136].] are of this type [243,247].

Measures of Maximum Entropy

For all parameters $t \in [3.96, 4]$, the quadratic maps $Q_t(x) = tx(1-x)$, $Q_t\colon [0,1] \to [0,1]$, have nonzero topological entropy [91] and exponentially many periodic points [134]:

$$\lim_{n\to\infty} \frac{\#\{x \in [0,1]\colon Q_t^n(x) = x\}}{e^{n h_{\mathrm{top}}(Q_t)}} = 1 .$$

On the other hand, by a deep theorem [117,178] there is an open and dense subset of $t \in [0,4]$, such that Q_t has a unique physical measure *concentrated on a periodic orbit*! Thus the physical measures can completely miss the topological complexity (and in particular the distribution of the periodic points). Hence one must look at other measures to get a statistical description of the complexity of such Q_t. Such a description is often provided by *measures of maximum entropy* μ_M whose measured entropy [*The usual phrases are "measure-theoretic entropy", "metric entropy".*] (▶ Entropy in Ergodic Theory) satisfies:

$$h(f, \mu_M) = \sup_{\mu \in M(f)} h(f, \mu) =^1 h_{\mathrm{top}}(f) .$$

$M(f)$ is the set of all invariant measures. [*One can restrict this to the ergodic invariant measures without changing the value of the supremum* (▶ Entropy in Ergodic Theory).] Equality 1 above is the *variational principle*: it holds for all continuous self-maps of compact metric spaces. One can say that the ergodic complexity (the complexity of f as seen by its *invariant measures*) captures the full topological complexity (defined by counting *all* orbits).

Remark 3 The variational principle implies the existence of "complicated invariant measures" as soon as the topological entropy is nonzero (see [47] for a setting in which this is of interest).

Maximum entropy measures do not always exist. However, if f is C^∞ smooth, then maximum entropy measures exist by a theorem of Newhouse [195] and they indeed describe the topological complexity in the following sense. Consider the probability measures:

$$\mu_{n,\epsilon} := \frac{1}{n}\sum_{k=0}^{n-1}\sum_{x\in E(n,\epsilon)}\delta_{f^k x}$$

where $E(n,\epsilon)$ is an arbitrary (ϵ, n)-separated subset [*See* ▶ Entropy in Ergodic Theory: $\forall x, y \in E(n,\epsilon)\ x \neq y \implies \exists 0 \leq k < n\ d(T^k x, T^k y) \geq \epsilon$.] of M with maximum cardinality. Then accumulation points for the weak star topology on the space of probability measures on M of $\mu_{n,\epsilon}$ when $n \to \infty$ and then $\epsilon \to 0$ are maximum entropy measures [185].

Let us quote two important additional properties, discovered by Margulis [179], that often hold for the maximum entropy measures:

- The *equidistribution of periodic points* with respect to some maximum entropy measure μ_M:

$$\mu_M = \lim_{n\to\infty}\frac{1}{\#\{x \in X : x = f^n x\}}\sum_{x=f^n x}\delta_x\,.$$

- The *holonomy invariance* which can be loosely interpreted by saying that the past and the future are independent conditionally on the present.

Other Points of View

Many other invariant measures are of interest in various contexts and we have made no attempt at completeness: for instance, invariant measures maximizing dimension [111,204], or pressure in the sense of the thermodynamical formalism [148,222], or some energy [9,81,146], or quasi-physical measures describing the dynamics around saddle-type invariant sets [104] or in systems with holes [75].

Tractable Chaotic Dynamics

The Palis Conjecture

There is, at this point, no general theory allowing the analysis of all dynamical systems or even of most of them despite many recent and exciting developments in the theory of generic C^1-diffeomorphisms [51,84]. In particular, the question of the generality in which physical measures exist remains open. One would like generic systems to have a *finite statistical description* (see Subsect. "Physical Measures"). This fails in some examples but these look exceptional and the following question is asked by Palis [200]:

> *Is it true that any dynamical system defined by a C^r-diffeomorphism on a compact manifold can be transformed by an arbitrarily small C^r-perturbation to another dynamical system having a finite statistical description?*

This is completely open though widely believed [*Observe, however, that such a statement is false for conservative diffeomorphisms with high order smoothness as KAM theory implies stable existence of invariant tori foliating a subset of positive volume.*]. Note that such a good description is not possible for all systems (see, e. g., [136,194]). Note that one would really like to ask about unperturbed "typical" [*The choice of the notion of typicality is a delicate issue. The Newhouse phenomenon shows that among C^2-diffeomorphisms of multidimensional compact manifolds, one cannot use topological genericity and get a positive answer. Popular notions are* prevalence *and* Kolmogorov genericity *– see the glossary.*] dynamical systems in a suitable sense, but of course this is even harder.

One is therefore led to make simplifying assumptions: typically of small dimension, uniform expansion/contraction or geometry.

Uniformly Expanding/Hyperbolic Systems

The most easily analyzed systems are those with uniform expansion and/or contraction, namely the uniformly expanding maps and uniformly hyperbolic diffeomorphisms, see ▶ Smooth Ergodic Theory. [*We require uniform hyperbolicity on the so-called chain recurrent set. This is equivalent to the usual Axiom-A and no-cycle condition.*] An important class of example is obtained as follows. Consider $A : \mathbb{R}^d \to \mathbb{R}^d$, a linear map preserving $\mathbb{Z}^d$ (i. e., A is a matrix with integer coefficients in the canonical basis) so that it defines a map $\bar{A} : \mathbb{T}^d \to \mathbb{T}^d$ on the torus. If there is a constant $\Lambda > 1$ such that for all $v \in \mathbb{R}^d$, $\|A.v\| \geq \Lambda\|v\|$ then $\bar{A}$ is a *uniformly expanding map*. If A has determinant ± 1 and no eigenvalue on the unit circle, then $\bar{A}$ is a *uniformly hyperbolic diffeomorphism* (▶ Smooth Ergodic Theory) (see also [60,148,215,233]). Moreover all C^1-perturbations of the previous examples are again uniformly expanding or uniformly hyperbolic. [*One can define uniform hyperbolicity for flows and an important class of examples is provided by the geodesic flow on compact* *manifolds with negative sectional curvature* [148].] These uniform systems are sometimes called "strongly chaotic".

Remark 4 Mañé Stability Theorem (see below) shows that uniform hyperbolicity is a very natural notion. One can also understand on a more technical level uniform hyperbolicity as what is needed to apply an implicit function theorem in some functional space (see, e. g., [233]).

The existence of a finite statistical description for such systems has been proved since the 1970s by Bowen, Ruelle and Sinai [54,218,235] (the expanding case is much simpler [162]).

Theorem 1 *Let $f\colon M \to M$ be a $C^{1+\alpha}$ map of a compact manifold. Assume f to be (i) a uniformly expanding map on M or (ii) a uniformly hyperbolic diffeomorphism.*

- *f admits a finite statistical description by ergodic and hyperbolic Sinai–Ruelle–Bowen measures (absolutely continuous in case (i)).*
- *f has finitely many ergodic maximum entropy measures, each of which makes f isomorphic to a finite state Markov chain. The periodic points are uniformly distributed according to some canonical average of these ergodic maximum entropy measures.*
- *f is topologically conjugate [Up to some negligible subset.] to a subshift of finite type (See the glossary.)*

The construction of absolutely continuous invariant measures for a uniformly expanding map f can be done in a rather direct way by considering the pushed forward measures $\frac{1}{n}\sum_{k=0}^{n-1} f_*^k$ Leb and taking weak star limits while preventing the appearance of singularities, by, e. g., bounding some Hölder norm of the density using expansion and distortion of f.

The classical approach to the uniformly hyperbolic dynamics [52,222,233] is through symbolic dynamics and coding. Under the above hypothesis one can build a finite partition of M which is tailored to the dynamics (a *Markov partition*) so that the corresponding symbolic dynamics has a very simple structure: it is a full shift $\{1,\ldots,d\}^{\mathbb{Z}}$, like in the example of the full tent map, or a subshifts of finite type. The above problems can then be solved using the thermodynamical formalism inspired from the statistical mechanics of one-dimensional ferromagnets [217]: ergodic properties are obtained through the spectral properties of a suitable transfer operator acting on some space of regular functions, e. g., the Hölder-continuous functions defined over the symbolic dynamics with respect to the distance $d(x,y) := \sum_{n\in\mathbb{Z}} 2^{-n} 1_{x_n \neq y_n}$ where $1_{s\neq t}$ is 1 if $s \neq t$, 0 otherwise.

A recent development [24,43,116] has been to find suitable Banach spaces to apply the transfer operator technique directly in the smooth setting, which not only avoids the complication of coding (or rather replace them with functional analytic preliminaries) but allows the use of the smoothness beyond Hölder-continuity which is important for finer ergodic properties.

Uniform expansion or hyperbolicity can easily be obstructed in a given system: a "bad" point (a critical point or a periodic point with multiplier with an eigenvalue on the unit circle) is enough. This leads to the study of other systems and has motivated many works devoted to relaxing the uniform hyperbolicity assumptions [51].

Pesin Theory

The most general such approach is *Pesin theory*. Let f be a $C^{1+\alpha}$-diffeomorphism [*It is an important open problem to determine to which extent Pesin theory could be generalized to the C^1 setting.*] f with an ergodic invariant measure μ. By Oseledets Theorem ► Smooth Ergodic Theory, for almost every x with respect to any invariant measure, the behavior of the differential $T_x f^n$ for n large is described by the Lyapunov exponents $\lambda_1,\ldots,\lambda_d$, at x. Pesin is able to build charts around almost every orbit in which this asymptotic linear behavior describes that of f at the first iteration. That is, there are diffeomorphisms $\Phi_x\colon U_x \subset M \to V_x \subset \mathbb{R}^d$ with a "reasonable dependence on x" such that the differential of $\Phi_{f^n x} \circ f^n \circ \Phi_x^{-1}$ at any point where it is defined is close to a diagonal matrix with entries $(e^{(\lambda_1 \pm \epsilon)n}, e^{(\lambda_2 \pm \epsilon)n}, \ldots, e^{(\lambda_d \pm \epsilon)n})$.

In this full generality, one already obtains significant results:

- The entropy is bounded by the expansion: $h(f,\mu) \leq \sum_{i=1}^d \lambda_i^+(\mu)$ [219]
- At almost every point x, there are strong stable resp. unstable manifolds $W^{ss}(x)$, resp. $W^{uu}(x)$, coinciding with the sets of points y such that $d(T^n x, T^n y) \to 0$ exponentially fast when $n \to \infty$, resp. $n \to -\infty$. The corresponding holonomies are *absolutely continuous* (see, e. g., [59]) like in the uniform case. This allows Ledrappier's definition of Sinai–Ruelle–Bowen measures [166] in that setting.
- Equality in the above formula holds if and only if μ is a Sinai–Ruelle–Bowen measure [167]. More generally the entropy can be computed as $\sum_{i=1}^d \gamma_i(\mu)\lambda_i^+(\mu)$ where the γ_i are some fractal dimensions related to the exponents.

Under the only assumption of hyperbolicity (i. e., no zero Lyapunov exponent almost everywhere), one gets further properties:

- Existence of an hyperbolic measure which is not periodic forces $h_{\mathrm{top}}(f) > 0$ [*However* $h(f, \mu)$ *can be zero.*] by [147].
- μ is *exact dimensional* [29,256]: the limit $\lim_{r\to 0} \log \mu(B(x, r))/ \log r$ exists μ-almost everywhere and is equal to the Hausdorff dimension of μ (the infimum of the Hausdorff dimension of the sets with full μ-measure). This is deduced from a more technical "asymptotic product structure" property of any such measure.

For hyperbolic Sinai–Ruelle–Bowen measures μ, one can then prove, e. g.,:

- *local ergodicity* [202]: μ has at most countably many ergodic components and μ-almost every point has a neighborhood whose Lebesgue-almost every point are contained in the basin of an ergodic component of μ.
- *Bernoulli* [198]: Each ergodic component of μ is conjugate in a measure-preserving way, up to a period, to a Bernoulli shift, that is, a full shift $\{1, \dots, N\}^{\mathbb{Z}}$ equipped with a product measure. This in particular implies mixing and sensitivity on initial conditions for a set of positive Lebesgue measure.

However, establishing even such a weak form of hyperbolicity is rather difficult. The fragility of this condition can be illustrated by the result [44,45] that the topologically generic area-preserving surface C^1-diffeomorphism is either uniformly hyperbolic or has Lebesgue almost everywhere vanishing Lyapunov exponents, hence is never non-uniformly hyperbolic! (but this is believed to be very specific to the very weak C^1 topology). Moreover, such weak hyperbolicity is not enough, with the current techniques, to build Sinai–Ruelle–Bowen measures or analyze maximum entropy measures only assuming non-zero Lyapunov exponents. Let us though quote two conjectures. The first one is from [251] [*We slightly strengthened Viana's statement for expository reasons.*]:

Conjecture 1 *Let f be a $C^{1+\epsilon}$-diffeomorphism of a compact manifold. If Lebesgue-almost every point x has well-defined Lyapunov exponents in every direction and none of these exponents is zero, then there exists an absolutely continuous invariant σ-finite positive measure.*

The analogue of this conjecture has been proved for C^3 interval maps with unique critical point and negative Schwarzian derivative by Keller [150], but only partial results are available for diffeomorphisms [168].

We turn to measures of maximum entropy. As we said, C^∞ smoothness is enough to ensure their existence but this is through a functional-analytic argument (allowed by Yomdin theory [254]) which says nothing about their structure. Indeed, the following problem is open:

Conjecture 2 *Let f be a $C^{1+\epsilon}$-diffeomorphism of a compact surface. If the topological entropy of f is nonzero then f has at most countably many ergodic invariant measures maximizing entropy.*

The analogue of this conjecture has been proved for $C^{1+\epsilon}$ interval maps [64,66,70]. In the above setting a classical result of Katok shows the existence of uniformly hyperbolic compact invariant subsets with topological entropy arbitrarily close to that of f implying the existence of many periodic points:

$$\limsup_{n\to\infty} \frac{1}{n} \log \#\{x \in M\colon f^n(x) = x\} \geq h_{\mathrm{top}}(f) \,.$$

The previous conjecture would follow from the following one:

Conjecture 3 *Let f be a $C^{1+\epsilon}$-diffeomorphism of a compact manifold. There exists an invariant subset $X \subset M$, carrying all ergodic measures with maximum entropy, such that the restriction $f|X$ is conjugate to a countable state topological Markov shift (See the glossary.).*

Systems with Discontinuities

We now consider stronger assumptions to be able to build the relevant measures.

The simplest step beyond uniformity is to allow discontinuities, considering piecewise expanding maps. The discontinuities break the rigidity of the uniformly expanding situation. For instance, their symbolic dynamics are usually no longer subshifts of finite type though they still retain some "simplicity" in good cases (see [68]).

To understand the problem in constructing the absolutely continuous invariant measures, it is instructive to consider the pushed forwards of a smooth measure. Expansion tends to keep the measure smooth whereas discontinuities may pile it up, creating non-absolute continuity in the limit. One thus has to check that expansion wins. In dimension 1, a simple fact resolves the argument: under a high enough iterate, one can make the expansion arbitrarily large everywhere, whereas a small interval can be chopped into at most two pieces.

Lasota and Yorke [165] found a suitable framework. They considered C^2 interval maps with $|f'(x)| \geq \text{const} > 1$ except at finitely many points. They used the Ruelle transfer operator directly on the interval. Namely they studied

$$(L\phi)(x) = \sum_{y\in T^{-1}x} \frac{\phi(y)}{|T'(y)|}$$

acting on functions $\phi\colon [0,1] \to \mathbb{R}$ with bounded variation and obtained the invariant density as the eigenfunction associated to the eigenvalue 1. One can then prove a *Lasota–Yorke inequality* (which might more accurately be called Doeblin–Fortet since it was introduced in the theory of Markov chains much earlier):

$$\|L\phi\|_{\mathrm{BV}} \leq \alpha\|\phi\|_{\mathrm{BV}} + \beta\|\phi\|_1 \tag{3}$$

where $\|\cdot\|_{\mathrm{BV}}$, $\|\cdot\|_1$ are a strong and a weak norm, respectively and $\alpha < 1$ and $\beta < \infty$. One can then apply general theorems [143] or [196] (see [21] for a detailed presentation of this approach and its variants). Here α can essentially be taken as 2 (reflecting the locally simple discontinuities) divided by the minimum expansion: so $\alpha < 1$, perhaps after replacing T with an iterate. In particular, the existence of a finite statistical description then follows (see [61] for various generalizations and strengthenings of this result on the interval).

The situation in higher dimension is more complex for the reason explained above. One can obtain inequalities such as (3) on suitable if less simple functional spaces (see, e. g., [231]) but proving $\alpha < 1$ is another matter: discontinuities can get arbitrarily complex under iteration. [67,241] show that indeed, in dimension 2 and higher, piecewise uniform expansion (with a finite number of pieces) is not enough to ensure a finite statistical description if the pieces of the map have only finite smoothness. In dimension 2, resp. 3 or more, piecewise real-analytic, resp. piecewise affine, is enough to exclude such examples [65,240], resp. [242]. [82] has shown that, for any $r > 1$, an open and dense subset of piecewise C^r and expanding maps have a finite statistical description.

Piecewise hyperbolic diffeomorphisms are more difficult to analyze though several results (conditioned on technical assumptions that can be checked in many cases) are available [22,74,230,257].

Interval Maps with Critical Points

A more natural but also more difficult situation is a map for which the uniformity of the expansion fails because of the existence of critical points. [*Note that, by a theorem of Mañé a circle map without critical points or indifferent periodic point is either conjugate to a rotation or uniformly expanding* [181].]

A class which has been completely analyzed at the level of the above conjecture is that of *real-analytic families of maps of the interval* $f_t\colon [0,1] \to [0,1]$, $t \in I$, with a unique critical point, the main example being the quadratic family $Q_t(x) = tx(1-x)$ for $0 \leq t \leq 4$.

It is not very difficult to find quadratic maps with the following two types of behavior:

(stable) the orbit of Lebesgue-almost every $x \in [0,1]$ tends to an attracting periodic orbit;

(chaotic) there is an absolutely continuous invariant probability measure μ whose basin contains Lebesgue-almost every $x \in [0,1]$.

To realize the first it is enough to arrange the critical point to be periodic. One can easily prove that this stable behavior occurs on an open set of parameters –thus it is stable with respect to the parameter or the dynamical system. The second occurs for Q_4 with $\mu = dx/\sqrt{\pi x(1-x)}$. It is much more difficult to show that this chaotic behavior occurs for a set of parameters of positive Lebesgue measure. This is a theorem of Jakobson [145] for the quadratic family (see for a recent variant [265]). Let us sketch two main ingredients of the various proofs of this theorem. The first is *inducing*: around Lebesgue-almost every point $x \in [0,1]$ one tries to find a time $\tau(x)$ and an interval $J(x)$ such that $f^{\tau(x)}\colon J(x) \to f^{\tau(x)}(J(x))$ is a map with good expansion and distortion properties. This powerful idea appears in many disguises in the non-uniform hyperbolic theory (see for instance [133,262]). The second ingredient is *parameter exclusion*: one removes the parameters at which a good inducing scheme cannot be built. More precisely one proceeds inductively, performing simultaneously the inducing and the exclusion, the good properties of the early stage of the inducing allowing one to control the measure of the parameters that need to be excluded to continue [30,145]. Indeed, the expansion established at a given stage allows to transfer estimates in the dynamical space to the parameter space.

Using methods from complex analysis and renormalization theory one can go much further and prove the following difficult theorems (actually the product of the work of many people, including Avila, Graczyk, Kozlovski, Lyubich, de Melo, Moreira, Shen, van Strien, Swiatek), which in particular solves Palis conjecture in this setting:

Theorem 2 **([117,160,178])** *Stable maps (that is, such that Lebesgue almost every orbit converges to one of finitely many periodic orbits) form an open and dense set among C^r interval maps, for any $r \geq 2$. [In fact this is even true for polynomials.].*

The picture has been completed in the *unimodal case* (that is, with a unique critical point):

Theorem 3 **([19,20,117,159,178])** *Let $f_t\colon [0,1] \to [0,1]$, $t \in [t_0, t_1]$, be a real-analytic family of unimodal maps. Assume that it is not degenerate [f_{t_0} and f_{t_1} are not conjugate]. Then:*

- *The set of t such that f_t is chaotic in the above sense has positive Lebesgue measure;*
- *The set of t such that f_t is stable is open and dense;*
- *The remaining set of parameters has zero Lebesgue measure. [This set of "strange parameters" of zero Lebesgue measure has however positive Hausdorff dimension according to work of Avila and Moreira. In particular each of the following situations is realized on a set of parameters t of positive Hausdorff dimension: non-existence of the Birkhoff limit at Lebesgue-almost every point, the physical measure is δ_p for p a repelling fixed point, the physical measure is non-ergodic.]*

We note that the theory underlying the above theorem yields much more results, including a very paradoxical rigidity of typical analytic families as above. See [19].

Non-uniform Expansion/Contraction

Beyond the dimension 1, only partial results are available. The most general of those assume uniform contraction or expansion along some direction, restricting the non-uniform behavior to an invariant sub-bundle often one-dimensional, or "one-dimensional-like".

A first, simpler situation is when there is a *dominated decomposition* with a uniformly expanding term: there is a continuous and invariant splitting of the tangent bundle, $T_\Lambda M = E^{\mathrm{uu}} \oplus E^{\mathrm{cs}}$, over some Λ an attracting set: for all unit vectors $v^u \in E^{\mathrm{uu}}$, $v^c \in E^{\mathrm{cs}}$,

$$\|(f^n)'(x).v^u\| \geq C\lambda^n \quad \text{and}$$
$$\|(f^n)'(x).v^c\| \leq C\mu^n \|(f^n)'(x).v^u\| .$$

Standard techniques (pushing the Riemannian volume of a piece of unstable leaf and taking limits) allow the construction of Gibbs u-states as introduced by [205].

Theorem 4 (Alves–Bonatti–Viana [8]) *[A slightly different result is obtained in [49].] Let $f\colon M \to M$ be a C^2 diffeomorphism with an invariant compact subset Λ. Assume that there is a dominated splitting $T_\Lambda M = E^u \oplus E^{cs}$ such that, for some $c > 0$,*

$$\limsup_{n\to\infty} \frac{1}{n} \log \prod_{k=0}^{n-1} \|f'(f^x)|E^{cs}\| \leq -c < 0$$

on a subset of Λ of positive Lebesgue measure. Then this subset is contained, up to a set of zero Lebesgue measure, in the union of the basins of finitely many ergodic and hyperbolic Sinai – Ruelle – Bowen measures.

The non-invertible, purely expansive version of the above theorem can be applied in particular to the following maps of the cylinder ($d \geq 16$, a is properly chosen close to 2 and α is small):

$$f(\theta, x) = (\mathrm{d}x \bmod 2\pi, a - x^2 + \epsilon \sin(\theta))$$

which are natural examples of maps with multidimensional expansion and critical lines considered by Viana [249]. A series of works have shown that the above maps fit in the above non-uniformly expanding setting with a proper control of the critical set and hence can be thoroughly analyzed through variants of the above theorem [4,249] and the references in [5]. For a, b properly chosen close to 2 and small ϵ, the following maps should be even more natural examples:

$$f(x, y) = (a - x^2 + \epsilon y, b - y^2 + \epsilon x) . \qquad (4)$$

However the inexistence of a dominated splitting has prevented the analysis of their physical measures. See [66,70] for their maximum entropy measures.

Cowieson and Young have used completely different techniques (thermodynamical formalism, Ledrappier–Young formula and Yomdin theory on entropy and smoothness) to prove the following result (see [13] for related work):

Theorem 5 (Cowieson–Young [83]) *Let $f\colon M \to M$ be a C^∞ diffeomorphism of a compact manifold. Assume that f admits an attractor $\Lambda \subset M$ on which the tangent bundle has an invariant continuous decomposition $T_\Lambda M = E^+ \oplus E^-$ such that all vectors of $E^+ \setminus \{0\}$, resp. $E^- \setminus \{0\}$, have positive, resp. negative, Lyapunov exponents. Then any zero-noise limit measure μ of f is a Sinai–Ruelle–Bowen measure and therefore, if it is ergodic and hyperbolic, a physical measure.*

One can hope, that typically, the latter ergodicity and hyperbolicity assumptions are satisfied (see, e. g., [27]).

By pushing classical techniques and introducing new ideas for generic maps with one expanding and one weakly contracting direction, Tsujii has been able to prove the following generic result (which can be viewed as a 2-dimensional extension of some of the one-dimensional results above: one adds a uniformly expanding direction):

Theorem 6 (Tsujii [243]) *Let M be a compact surface. Consider the space of C^{20} self-maps $f\colon M \to M$ which admits directions that are uniformly expanded [More precisely, there exists a continuous, forward invariant cone field which is uniformly expanded under the differential of f.]*

Then existence of a finite statistical description is both topologically generic and prevalent in this space of maps.

Hénon-Like Maps and Rank One Attractors

In 1976, Hénon [130] observed that the diffeomorphism of the plane

$$H_{a,b}(x,y) = (1 - ax^2 + y, bx)$$

seemed to present a "strange attractor" for $a = 1.4$ and $b = 0.3$, that is, the points of a numerically simulated orbit seemed to draw a set looking locally like the product of a segment with a Cantor set. This attractor seems to be supported by the unstable manifold $W^u(P)$ of the hyperbolic fixed point P with positive absciss. On the other hand, the Plykin classification [207] excluded the existence of a uniformly hyperbolic attractor for a dissipative surface diffeomorphism.

For almost twenty years the question of the existence of such an attractor (by opposition to an attracting periodic orbit with a very long period) remained open. Indeed, one knew since Newhouse that, for many such maps, there exist infinitely many such periodic orbits which are very difficult to distinguish numerically. But in 1991 Benedicks and Carleson succeeded in proposing an argument refining (with considerable difficulties) their earlier proof of Jakobson one-dimensional theorem and established the first part of the following theorem:

Theorem 7 (Benedicks–Carleson [31]) *For any $\epsilon > 0$, for $|b|$ small enough, there is a set A with* $\mathrm{Leb}(A) > 0$ *satisfying: for all $a \in A$, there exists $z \in W^u(P)$ such that*

- *The orbit of z is dense in $W^u(P)$;*
- $\liminf_{n\to\infty} \frac{1}{n} \log \|(f^n)'(z)\| > 0.$

Further properties were then established, especially by Benedicks, Viana, Wang, Young [32,34,35,264]. Let us quote the following theorem of Wang and Young which includes the previous results:

Theorem 8 ([264]) *Let $T_{\mathrm{ab}}\colon S^1 \times [-1,1] \to S^1 \times [-1,1]$ be such that*

- *$T_{a0}(S^1 \times [-1,1]) \subset S^1 \times \{0\}$;*
- *For $b > 0$, T_{ab} is a diffeomorphism on its image with*

  $$c^{-1} b \le |\det T_{\mathrm{ab}}(x,y)| \le c \cdot b$$

  for some $c > 1$ and all $(x,y) \in S^1 \times [-1,1]$ and all (a,b).

Let $f_a\colon S^1 \to S^1$ be the restriction of T_{a0}. Assume that $f = f_0$ satisfies:

- *Non-degenerate critical points: $f'(c) = 0 \implies f''(c) \neq 0$;*
- *Negative Schwarzian derivative: for all $x \in S^1$ non-critical, $f'''(x)/f'(x) - 3/2(f''(x)/f'(x))^2 < 0$;*
- *No indifferent or attracting periodic point, i. e., x such that $f^n(x) = x$ and $|(f)'(x)| \le 1$;*
- *Misiurewicz condition: $d(f^n c, d) > c > 0$ for all $n \ge 1$ and all critical points c, d.*

Assume the following transversality condition on f at $a = 0$: for every critical point c, $(\mathrm{d}/da)(f_a(c_a) - p_a) \neq 0$ if c_a is the critical point of f_a near c and p_a is the point having the same itinerary under f_a as $f(c)$ under c. Assume the following non-degeneracy of T: $f_0'(c) = 0 \implies \partial T_{00}(c,0)/\partial y \neq 0$.

- *T_{ab} restricted to a neighborhood of $S^1 \times \{0\}$ has a finite statistical description by a number of hyperbolic Sinai–Ruelle–Bowen measures bounded by the number of critical points of f;*
- *There is exponential decay of correlations and a Central Limit Theorem (see below) – except, in an obvious way, if there is a periodic interval with period > 1;*
- *There is a natural coding of the orbits that remains for ever close to $S^1 \times \{0\}$ by a closed invariant subset of a full shift.*

Very importantly, the above dynamical situation has been shown to occur near typical homoclinic tangencies: [190] proved that there is an open and dense subset of the set of all C^3 families of diffeomorphisms unfolding a first homoclinic tangency such that the above holds. However [201] shows that the set of parameters with a Henon-like attractor has zero Lebesgue density at the bifurcation itself, at least under an assumption on the so-called stable and unstable Hausdorff dimensions. [95] establishes positive density for another type of bifurcation. Furthermore [191] has related the Hausdorff dimensions to the abundance of uniformly hyperbolic dynamics near the tangency.

[248] is able to treat situations with more than one contracting direction. More recently [266] has proposed a rather general framework, with easily checkable assumptions in order to establish the existence of such dynamics in various applications. See also [122,252] for applications.

Statistical Properties

The ergodic theorem asserts that time averages of integrable functions converge to phase space averages for any ergodic system. The speed of convergence is quite arbitrary in that generality [161] (only upcrossing inequalities seem to be available [38,132]), however many results are available under very natural hypothesis as we are going to explain in this section. The underlying idea is that for sufficiently chaotic dynamics T and reasonably smooth observables ϕ, the time averages

$$A_n\phi(x) := \frac{1}{n}\sum_{k=0}^{n-1} \phi \circ T^k(x)$$

should behave as averages of independent and identically distributed random variables and therefore satisfy the classical limit theorems of probability theory.

The dynamical systems which are amenable to current technology are in a large part [*But other approaches are possible. Let us quote the work* [98] *on partially hyperbolic systems, for instance.*] those that can be reduced to the following type:

Definition 1 Let $T: X \to X$ be a nonsingular map on a probability, metric space $(X, \mathcal{B}, \mu, d)$ with bounded diameter, preserving the probability measure μ. This map is said to be **Gibbs–Markov** if there exists a countable (measurable) partition α of X such that:

1. For all $a \in \alpha$, T is injective on a and $T(a)$ is a union of elements of α.
2. There exists $\lambda > 1$ such that, for all $a \in \alpha$, for all points $x, y \in a$, $d(Tx, Ty) \geq \lambda d(x, y)$.
3. Let Jac be the *inverse* of the Jacobian of T. There exists $C > 0$ such that, for all $a \in \alpha$, for all points $x, y \in a$, $|1 - Jac(x)/Jac(y)| \leq Cd(Tx, Ty)$.
4. The map T has the "big image property": $\inf_{a\in\alpha} \mu(Ta) > 0$.

Some piecewise expanding and C^2 maps are obviously Gibbs–Markov but the real point is that many dynamics can be reduced to that class by the use of inducing and tower constructions as in [262], in particular. This includes possibly piecewise uniformly hyperbolic diffeomorphisms, Collet–Eckmann maps of the interval [21] (typical chaotic maps in the quadratic family), billiards with convex scatterers [262], the stadium billiard [71], Hénon-like mappings [266].

We note that in many cases one is led to first analyze mixing properties through *decay of correlations*, i. e., to prove inequalities of the type [21]:

$$\left|\int_X \phi \cdot \psi \circ T^n \, \mathrm{d}\mu - \int_X \phi \, \mathrm{d}\mu \int_X \psi \, \mathrm{d}\mu\right| \leq \|\phi\| \cdot \|\psi\|_w \cdot a_n \tag{5}$$

where $(a_n)_{n\geq 1}$ is some sequence converging to zero, e. g., $a_n = \mathrm{e}^{-\lambda n}, 1/n^\alpha, \ldots$ and $\|\cdot\|, \|\cdot\|_w$ a strong and a weak norm (e. g., the variation norm and the L^1 norm). These rates of decay are often linked with return times statistics [263]. Rather general schemes have been developed to deduce various limit theorems such as those presented below from sufficiently quick decay of correlations (see notably [175] based on a dynamical variant of [113]).

Probabilistic Limit Theorems

The foremost limit property is the following:

Definition 2 A class C of functions $\phi: X \to \mathbb{R}$ is said to satisfy the Central Limit Theorem if the following holds: for all $\phi \in C$, there is a number $\sigma = \sigma(\phi) > 0$ such that:

$$\lim_{n\to\infty} \mu\left(\left\{x \in X : \frac{A_n\phi(x) - \int \phi \, \mathrm{d}\mu}{\sigma n^{-1/2}} \leq t\right\}\right) = \int_{-\infty}^{t} \mathrm{e}^{-x^2/2\sigma^2} \frac{\mathrm{d}x}{\sqrt{2\pi}\sigma} \tag{6}$$

except for the degenerate case when $\phi(x) = \psi(Tx) - \phi(x) + \text{const}$.

The Central Limit Theorem can be seen in many cases as essentially a by-product of fast decay of correlations [175], i. e., if $\sum_{n\geq 0} a_n < \infty$ in the notations of Eq. (5). It has been established for Hölder-continuous observables for many systems together with their natural invariant measures including: uniformly hyperbolic attractors, piecewise expanding maps of the interval [174], Collet–Eckmann unimodal maps on the interval [152,260], piecewise hyperbolic maps [74], billiards with convex scatterers [238], Hénon-like maps [35].

Remark 5 The classical Central Limit Theorem holds for square-integrable random variables [193]. For maps exhibiting *intermittency* (e.g, interval maps like $f(x) = x + x^{1+\alpha} \bmod 1$ with an indifferent fixed point at 0) the invariant density has singularities and the integrability condition is non longer automatic for smooth functions. One can then observe convergence to stable laws, instead of the normal law [114].

A natural question is the speed of the convergence in (6). The *Berry–Esseen inequality*:

$$\left|\mu\left(\left\{\frac{A_n\phi(x) - \int \phi \, \mathrm{d}\mu}{\sigma n^{-1/2}} \leq t\right\}\right) - \int_{-\infty}^{t} \mathrm{e}^{-x^2/2\sigma^2} \frac{\mathrm{d}x}{\sqrt{2\pi}\sigma}\right| \leq \frac{C}{n^{\delta/2}}$$

for some $\delta > 0$. It holds with $\delta = 1$ in the classical, probabilistic setting.

The *Local Limit Theorem* looks at a finer scale, asserting that for any finite interval $[a, b]$, any $t \in \mathbb{R}$,

$$\lim_{n\to\infty} \sqrt{n}\mu\left(\left\{x \in X\colon nA_n\phi(x) \in [a,b] + \sqrt{n}t + n\int \phi \,\mathrm{d}\mu\right\}\right) = |b-a|\frac{\mathrm{e}^{-t^2/2\sigma^2}}{\sqrt{2\pi}\sigma}\,.$$

Both the Berry–Esseen inequality and the local limit theorem have been shown to hold for non-uniformly expanding maps [115] (also [62,216]).

Almost Sure Results

It is very natural to try and describe the statistical properties of the averages $A_n(x)$ for almost every x, instead of the weaker above statements in probability over x. An important such property is the *almost sure invariance principle*. It asks for the discrete random walk defined by the increments of $\phi \circ T^n(x)$ to converge, after a suitable renormalization, to a Brownian motion. This has been proved for systems with various degrees of hyperbolicity [92,98,135,183]. Another one is the almost sure Central Limit Theorem. In the independent case (e.g., if $X_1, X_2, \ldots$ are independent and identically distributed random variables in L^2 with zero average and unit variance), the almost sure Central Limit Theorem states that, almost surely:

$$\frac{1}{\log n}\sum_{k=1}^{n}\frac{1}{k}\delta_{\sum_{j=0}^{k-1} X_j/\sqrt{k}}$$

converges in law to the normal distribution. This implies, that, almost surely, for any $t \in \mathbb{R}$:

$$\lim_{n\to\infty}\frac{1}{\log n}\sum_{k=1}^{n}\frac{1}{k}\delta_{\left\{\sum_{j=0}^{k-1} X_j/\sqrt{k}\le t\right\}} = \int_{-\infty}^{t} \mathrm{e}^{-x^2/2\sigma^2}\frac{\mathrm{d}x}{\sqrt{2\pi}\sigma}$$

compare to (6).

A general approach is developed in [73], covering Gibbs–Markov maps and those that can be reduced to it. They show in particular that the dynamical properties needed for the classical Central Limit Theorem in fact suffice to prove the above almost invariance principle and even the almost sure version of the Central Limit Theorem (using general probabilistic results, see [37,255]).

Other Statistical Properties

Essentially all the statistical properties of sums of independent identically distributed random variables can be established for tractable systems. Thus one can also prove large deviations [156,172,259], iterated law of the logarithm, etc. We note that the monograph [78] contains a nice introduction to the current work in this area.

Orbit Complexity

The orbit complexity of a dynamical system $f\colon M \to M$ is measured by its topological and measured entropies. We refer to ► Entropy in Ergodic Theory for detailed definitions.

The Variational Principle

Bowen–Dinaburg and Katok formulae can be interpreted as meaning that the topological entropy counts the number of arbitrary orbits whereas the measured entropy counts the number of orbits relevant for the given measure. In most situations, and in particular for continuous self-map of compact metric spaces, the following *variational principle* holds:

$$h_{\text{top}}(f) = \sup_{\mu\in M(f)} h(f,\mu)$$

where $M(f)$ is the set of all invariant probability measures.

This is all the more striking in light of the fact that for many systems, the set of points which are typical from the point of view of ergodic theory [*for instance, those x such that $\lim_{n\to\infty}\frac{1}{n}\sum_{k=0}^{n-1}\phi(T^k x)$ exists for all continuous functions ϕ.*] is topologically negligible [*A subset of a countable union of closed sets with empty interior, that is, meager or first Baire category.*].

Strict Inequality For a fixed invariant measure, one can only assert that $h(f,\mu) \le h_{\text{top}}(f)$. One should be aware that this inequality may be strict even for a measure with full support. For instance, it is not difficult to check that the full tent map with $h_{\text{top}}(f) = \log 2$, admits ergodic invariant measures with full support and zero entropy.

There are also examples of dynamical systems preserving Lebesgue measure which have simultaneously positive topological entropy and zero entropy with respect to Lebesgue measure. That this occurs for C^1 surface diffeomorphisms preserving area is a simple consequence of a theorem of Bochi [44] according to which, generically in the C^1 topology, such a diffeomorphism is either uniformly hyperbolic or with Lyapunov exponents Lebesgue-almost everywhere zero. [*Indeed, it is easy to build such a diffeomorphism having both a uniformly hyperbolic compact invariant subset which will have robustly positive topological entropy and a non-degenerate elliptic fixed point which will prevent uniform hyperbolicity and therefore force all Lyapunov exponents to be zero. But Ruelle–Margulis* *inequality then implies that the entropy with respect to Lebesgue measure is zero.*] Smooth examples also exist [46].

Remark 6 Algorithmic complexity [170] suggests another way to look at orbit complexity. One obtains in fact in this way another formula for the entropy. However this point of view becomes interesting in some settings, like extended systems defined by partial differential equations in unbounded space. Recently, [47] has used this approach to build interesting invariant measures.

Orbit Complexity on the Set of Measures

We have considered the entropies of each invariant measure separately, sharing only the common roof of topological entropy. One may ask how these different complexity sit together. A first answer is given by the following theorem in the symbolic and continuous setting. Let .

Theorem 9 (Downarowicz–Serafin [102]) *Let K be a Choquet simplex and $H\colon K \to \mathbb{R}$ be a convex function.*

Say that H is realized by a self-map $f\colon X \to X$ and its set $M(f)$ of f-invariant probability measures equipped with the weak star topology if the following holds. There exists an affine homeomorphism $\Psi\colon M(f) \to K$ such that, if $h\colon M(f) \to [0,\infty]$ is the entropy function, $H = h \circ \Psi$.

Then

- *H is realized by some continuous self-map of a compact space if and only if it is an increasing limit of upper semi-continuous and affine functions.*
- *H is realized by some subshift on a finite alphabet, i. e., by the left shift on a closed invariant subset Σ of $\{1,2,\dots,N\}^{\mathbb{Z}}$ for some $N < \infty$, if and only if it is upper semi-continuous*

Thus, in both the symbolic and continuous settings it is possible to have a unique invariant measure with any prescribed entropy. This stands in contrast to surface $C^{1+\epsilon}$-diffeomorphisms for which the set of the entropies of ergodic invariant measures is always the interval $[0, h_{\text{top}}(f)]$ as a consequence of [147].

Local Complexity

Recall that the topological entropy can be computed as: $h_{\text{top}}(f) = \lim_{\epsilon\to 0} h_{\text{top}}(f,\epsilon)$ where:

$$h_{\text{top}}(f,\epsilon) := \lim_{n\to\infty} \frac{1}{n} \log s(\delta, n, X)$$

where $s(\delta, n, E)$ is the maximum cardinality of a subset S of E such that:

$$x \neq y \implies \exists 0 \le k < n \; d(f^k x, f^k y) \ge \epsilon$$

(see Bowen's formula of the topological entropy ▶ Entropy in Ergodic Theory). Likewise, the measure-theoretic entropy $h(T,\mu)$ of an ergodic invariant probability measure μ is $\lim_{\epsilon\to 0} h(f,\mu,\epsilon)$ where:

$$h(T,\epsilon) := \lim_{n\to\infty} \frac{1}{n} \log r(\delta, n, \mu)$$

where $r(\delta, n, \mu)$ is the minimum cardinality of $C \subset X$ such that

$$\mu\left(\left\{x \in X\colon \exists y \in C \quad \text{such that} \quad \forall 0 \le k < n \; d(f^k x, f^k y) < \epsilon\right\}\right) > 1/2\,.$$

One can ask *at which scales does entropy arise for a given dynamical system?*, i. e., how the above quantities $h(T,\epsilon)$, $h(T,\mu,\epsilon)$ converge when $\epsilon \to 0$.

An answer is provided by the *local entropy*. [*This quantity was introduced by Misiurewicz* [186] *under the name* conditional topological entropy *and is called* tail entropy *by Downarowicz* [100].] For a continuous map f of a compact metric space X, it is defined as:

$$\begin{aligned} h_{\text{loc}}(f) &:= \lim_{\epsilon\to 0} h_{\text{loc}}(f,\epsilon) \quad \text{with} \\ h_{\text{loc}}(f,\epsilon) &:= \sup_{x\in X} h_{\text{loc}}(f,\epsilon,x) \quad \text{and} \\ h_{\text{loc}}(f,\epsilon,x) &:= \lim_{\delta\to 0} \limsup_{n\to\infty} \frac{1}{n} \log s\left(\delta, n, \left\{y \in X\colon \forall k \ge 0 \; d(f^k y, f^k x) < \epsilon\right\}\right) \end{aligned}$$

Clearly from the above formulas:

$$\begin{aligned} &h_{\text{top}}(f) \le h_{\text{top}}(f,\delta) + h_{\text{loc}}(f,\delta) \quad \text{and} \\ &h(f,\mu) \le h(f,\mu,\delta) + h_{\text{loc}}(f,\delta)\,. \end{aligned}$$

Thus the local entropy bounds the defect in uniformity with respect to the measure of the pointwise limit $h(f,\mu) = \lim_{\delta\to 0} h(f,\mu,\delta)$. An exercise in topology shows that the local entropy therefore also bounds the defect in upper semicontinuity of $\mu \mapsto h(f,\mu)$. In fact, by a result of Downarowicz [100] (extended by David Burguet to the non-invertible case), there is a *local variational principle*:

$$\begin{aligned} h_{\text{loc}}(f) &= \lim_{\delta\to 0} \left(\sup_{\mu} h(f,\mu) - h(f,\mu,\delta) \right) \\ &= \sup_{\mu} \limsup_{\nu\to\mu} h(f,\nu) - h(f,\mu) \end{aligned}$$

for any continuous self-map f of a compact metric space.

The local entropy is easily bounded for smooth maps using Yomdin's theory:

Theorem 10 ([64]) *For any C^r map f of a compact manifold, $h_{\text{loc}}(f) \leq \frac{d}{r} \log \sup_x \|f'(x)\|$. In particular, $h_{\text{loc}}(f) = 0$ if $r = \infty$.*

Thus C^∞ smoothness implies the existence of a maximum entropy measure (this was proved first by Newhouse) and the existence of *symbolic extension*: a subshift over a finite alphabet $\sigma : \Sigma \to \Sigma$ and a continuous and onto map $\pi : \Sigma \to M$ such that $\pi \circ \sigma = f \circ \sigma$. More precisely,

Theorem 11 (Boyle, Fiebig, Fiebig [56]) *Given a homeomorphism f of a compact metric space X, there exists a principal symbolic extension $\sigma : \Sigma \to \Sigma$, i. e., a symbolic extension such that, for every σ-invariant probability measure ν, $h(\sigma, \nu) = h(f, \nu \circ \pi^{-1})$, if and only if $h_{\text{loc}}(f) = 0$.*

We refer to [55,101] for further results, including a realization theorem showing that the continuity properties of the measured entropy are responsible for the properties of symbolic extensions and also results in finite smoothness.

Global Simplicity

One can marvel at the power of mathematical analysis to analyze such complex evolutions. Of course another way to look at this is to remark that this analysis is possible *once this evolution has been fitted in a simple setting*: one had to move focus away from an individual, unpredictable orbit, of, say, the full tent map to the set of all the orbits of that map, which is essentially the set of all infinite sequences over two symbols: a very simple set indeed corresponding to full *combinatorial freedom* [*[253] describes a weakening of this which holds for all positive entropy symbolic dynamics.*]. The complete description of a given typical orbit requires an infinite amount of information, whereas the set of all orbits has a finite and very tractable definition. The complexity of the individual orbits is seen now as coming from purely random choices inside a simple structure.

The classical systems, namely uniformly expanding maps or hyperbolic diffeomorphisms of compact spaces, have a *simple* symbolic dynamics. It is not necessarily a full shift like for the tent map, but it is a subshift of finite type, i. e., a subshift obtained from a full shift by forbidding finitely many finite subwords. What happens outside of the uniform setting?

A fundamental example is provided by *piecewise monotone maps*, i. e., interval maps with finitely many critical points or discontinuities. The partition cut by these points defines a symbolic dynamics. This subshift is usually not of finite type. Indeed, the topological entropy taking arbitrary finite nonnegative values [*For instance, the topological entropy of the β-transformation, $x \mapsto \beta x \bmod 1$, is $\log \beta$ for $\beta \geq 1$.*], a representation that respects it has to use an uncountable class of models. In particular models defined by finite data, like the subshifts of finite type, cannot be generally adequate. However there are tractable "almost finite representations" in the following senses:

Most symbolic dynamics $\Sigma(T)$ of piecewise monotone maps T can be defined by finitely many infinite sequences, the *kneading invariants* of Milnor and Thurston: $\kappa_0^+, \kappa_1^-, \kappa_1^+, \ldots, \kappa_{d+1}^- \in \{0, \ldots, d\}^{\mathbb{N}}$ if d is the number of critical/discontinuity points. [*The kneading invariants are the suitably defined (left and right) itineraries of the critical/discontinuity points and endpoints.*] Namely,

$$\Sigma(T) = \Big\{\alpha \in \{0, \ldots, d\}^{\mathbb{N}} : \forall n \geq 0 \qquad \kappa_{\alpha_n}^+ \preceq \sigma^n \alpha \preceq \kappa_{\alpha_n+1}^- \Big\}$$

where $\preceq$ is a total order on $\{0, \ldots, d\}^{\mathbb{N}}$ making the coding $x \mapsto \alpha$ non-decreasing. Observe how the kneading invariants determine $\Sigma(T)$ in an effective way: knowing their first n symbols is enough to know the sequences of length n which begin sequences of $\Sigma(T)$. We refer to [91] for the wealth of information that can be extracted from these kneading invariants following Milnor and Thurston [184].

This form of global simplicity can be extended to other classes of non-uniformly expanding maps, including those like Eq. (4) using the notions of subshifts and puzzles of *quasi-finite type* [68,69]. This leads to the notion and analysis of *entropy-expanding maps*, a new open class of non-uniformly expanding maps admitting critical hypersurfaces, defined purely in terms of entropies including the otherwise untractable examples of Eq. (4).

A generalization of the representation of uniform systems by subshifts of finite type is provided by *strongly positive recurrent countable state Markov shifts*, a subclass of Markov shifts (*see glossary*.) which shares many properties with the subshifts of finite type [57,123,124,224,229].

These "simple" systems admit a *classification result* which in particular identifies their measures with entropy close to the maximum [57]. Such a classification generalizes [164]. The "ideology" here is that complexity of individual orbits in a simple setting must come from randomness, but purely random systems are classified by their entropy according to Ornstein [197].

Stability

By definition, chaotic dynamical systems have orbits which are unstable and numerically unpredictable. It is all the more surprising that, once one accepts to consider their dynamics globally, they exhibit very good stability properties.

Structural Stability

A simple form of stability is *structural stability*: a system $f\colon M \to M$ is structurally C^r-stable if any system g sufficiently C^r-close to f is topologically the same as f, formally: g is topologically conjugate, i. e., there is some homeomorphism [*If h were* C^1, *the conjugacy would imply, among other things, that for every p-periodic point:* $\det((f^p)'(x)) = \det((g^p)'(h(p)))$, *a much too strong requirement*.] $h\colon M \to M$ mapping the orbits of f to those of g, i. e., $g \circ h = h \circ f$.

Andronov and Pontryaguin argued in the 1930's that only such structurally stable systems are physically relevant. Their idea was that the model of a physical system is always known only to some degree of approximation, hence mathematical model whose structure depends on arbitrarily small changes should be irrelevant.

A first question is: *What are these structurally stable systems?* The answer is quite striking:

Theorem 12 (Mañé [182]) *Let* $f\colon M \to M$ *be a* C^1 *diffeomorphism of a compact manifold.*

f is structurally stable among C^1*-diffeomorphisms of M if and only if f is uniformly hyperbolic on its chain recurrent set. [A point x is chain recurrent if, for all* $\epsilon > 0$, *there exists a finite sequence* $x_0, x_1, \dots, x_n$ *such that* $x_0 = x_n = x$ *and* $d(f(x_k), x_{k+1}) < \epsilon$. *The chain recurrent set is the set of all chain recurrent points.]*

A basic idea in the proof of the theorem is that failure of uniform hyperbolicity gives the opportunity to make an arbitrarily small perturbation contradicting the structural stability. In higher smoothness the required perturbation lemmas (e. g., the closing lemma [14,148,180]) are not available.

We note that uniform hyperbolicity without invertibility does not imply C^1-stability [210].

A second question is: *are these stable systems dense?* (So that one could offer structurally stable models for all physical situations). A deep discovery around 1970 is that this is not the case:

Theorem 13 (Abraham–Smale, Simon [3,234]) *For any* $r \geq 1$ *and any compact manifold M of dimension* ≥ 3, *the set of uniformly hyperbolic diffeomorphisms is not dense in the space of* C^r *diffeomorphisms of M. [They use the phenomenon called "heterodimensional homoclinic intersections".]*

Theorem 14 (Newhouse [194]) *For any* $r \geq 2$, *for any compact manifold M of dimension* ≥ 2, *the set of uniformly hyperbolic diffeomorphisms is not dense in the space of* C^r *diffeomorphisms of M. More precisely, there exists a nonempty open subset in this space which contains a dense* G_δ *subset of diffeomorphisms with infinitely many periodic sinks. [So these diffeomorphisms have no finite statistical description.]*

Observe that it is possible that uniform hyperbolicity could be dense among *surface* C^1*-diffeomorphisms* (this is the case for C^1 circle maps by a theorem of Jakobson [145]).

In light of Mañé C^1-stability theorem this implies that *structurally stable systems are not dense*, thus one can robustly see behaviors that are topologically modified by arbitrarily small perturbations (at least in the C^1-topology)! So one needs to look beyond these and face that topological properties of relevant dynamical system are not determined from "finite data". It is natural to ask whether the dynamics is almost determined by "sufficient data".

Continuity Properties of the Topological Dynamics

Structural stability asks the topological dynamics to remain *unchanged* by a small perturbation. It is probably at least as interesting to ask it to *change continuously*. This raises the delicate question of which topology should be put on the rather wild set of topological conjugacy classes. It is perhaps more natural to associate to the system a topological invariant taking value in a more manageable set and ask whether the resulting map is continuous.

A first possibility is Zeeman's *Tolerance Stability Conjecture*. He associated to each diffeomorphism the set of all the closures of all of its orbits and he asked whether the resulting map is continuous on a dense G_δ subset of the class of C^r-diffeomorphisms for any $r \geq 0$. This conjecture remains open, we refer to [85] for a discussion and related progress.

A simpler possibility is to consider our favorite topological invariant, the topological entropy, and thus ask whether the dynamical complexity as measured by the entropy is a stable phenomenon. $f \mapsto h_{\text{top}}(f)$ is lower semicontinuous for f among C^0 maps of the interval [*On the set of interval maps with a bounded number of critical points, the entropy is continuous* [188]. *Also* $t \mapsto h_{\text{top}}(Q_t)$ *is non-decreasing by complex arguments* [91], *though it is a non-smooth function*.] [187] and for f among $C^{1+\epsilon}$-diffeomorphisms of a compact surface [147]. [*It is an important open question whether this actually holds for* C^1*-diffeomorphisms. It fails for homeomorphisms* [214].] In both cases, one shows the existence of structurally stable invariant uniformly expanding or hyperbolic subsets with topological entropy close to that of the whole dynamics.

On the other hand $f \mapsto h_{\text{top}}(f)$ is upper semi-continuous for C^∞ maps [195,254].

Statistical Stability

Statistical stability is the property that *deterministic perturbations* of the dynamical system cause only small changes in the physical measures, usually with respect to the weak star topology on the space of measures. When the physical measure μ_g is uniquely defined for all systems g near f, statistic stability is the continuity of the map $g \mapsto \mu_g$ thus defined.

Statistical stability is known in the uniform setting and also in the piecewise uniform case, provided the expansion is strong enough [25,42,151] (otherwise there are counterexamples, even in the one-dimensional case).

It also holds in some non-uniform settings without critical behavior, in particular for maps with dominated splitting satisfying robustly a separation condition between the positive and negative Lyapunov exponents [247] (see also [7]).

However statistical unstability occurs in dynamics with critical behaviors [18]:

Theorem 15 *Consider the quadratic family $Q_t(x) = tx(1-x)$, $t \in [0,4]$. Let $I \subset [0,4]$ be the full measure subset of $[0,4]$ of good parameters t such that in particular Q_t admits a physical measure (necessarily unique). For $t \in I$, let μ_t be this physical measure.*

Lebesgue almost every $t \in I$ such that μ_t is not carried by a periodic orbit [At such parameters, statistical stability is easily proved.], is a discontinuity point of the map $t \mapsto \mu_t$ [$M([0,1])$ is equipped with the vague topology.]. However, for Lebesgue almost every t, there is a subset $I_t \subset I$ for which t is a Lebesgue density point [t is a Lebesgue density point if for all $r > 0$, the Lebesgue measure $m(I_t \cap [t-r, t+r]) > 0$ and $\lim_{\epsilon \to 0} m(I_t \cap [t-\epsilon, t+\epsilon])/2\epsilon = 1$.] and such that $\mu\colon I_t \to M([0,1])$ is continuous at t.

Stochastic Stability

A physically motivated and a technically easier approach is to study stability of the physical measure under *stochastic perturbations*. For simplicity let us consider a diffeomorphism of a compact subset of $\mathbb{R}^d$ allowing for a direct definition of *additive noise*. Let $\psi(x)\mathrm{d}x$ be an absolutely continuous probability law with compact support. [*Sometimes additional properties are required of the density, e. g., $\psi(x) = \phi(x)1_B$ where 1_B is the characteristic function of the unit ball and $C^{-1} \le \phi(x) \le C$ for some $C < \infty$.*] For $\epsilon > 0$, consider the Markov chain f_ϵ with state space M and transition probabilities:

$$P_\epsilon(x, A) = \int_A \psi\left(\frac{y - f(x)}{\epsilon}\right) \frac{\mathrm{d}y}{\epsilon^d} .$$

The evolution of measures is given by: $(f_\epsilon \mu)(A) = \int_M P_\epsilon(x, A)\, \mathrm{d}\mu$. Under rather weak irreducibility assumptions on f, f_ϵ has a *unique invariant measure* μ_ϵ (contrarily to f) and μ_ϵ is absolutely continuous. When f has a unique physical measure μ, it is said to be *stochastically stable* if $\lim_{\epsilon \to 0} \mu_\epsilon = \mu$ in the appropriate topology (the weak star topology unless otherwise specified).

It turns out that stochastic stability is a rather common property of Sinai–Ruelle–Bowen measures. It holds not only for uniformly expanding maps or hyperbolic diffeomorphisms [153,258], but also for most interval maps [25], for partially hyperbolic systems of the type $E^u \oplus E^{cs}$ or Hénon-like diffeomorphisms [6,13,33,40]. We refer to the monographs [21,41] for more background and results.

Untreated Topics

For reasons of space and time, many important topics have been left out of this article. Let us list some of them.

Other phenomena related to chaotic dynamics have been studied: entrance times [77,79], spectral properties and dynamical zeta functions [21], escape rates [104], dimension [204], differentiability of physical measures with respect to parameters [99,223], entropies and volume or homological growth rates [118,139,254].

As far as the structure of the setting is concerned, one can go beyond maps or diffeomorphisms or flows and study: more general group actions [128]; holomorphic and meromorphic structures [72] and the references therein; symplectic or volume-preserving [90,137] and in particular the Pugh–Shub program around stable ergodicity of partially hyperbolic systems [211]; random iterations [17,154,155].

A number of important problems have motivated the study of special forms of chaotic dynamics: equidistribution in number theory [105,109,138] and geometry [236]; quantum chaos [10,125]; chaotic control [227]; analysis of algorithms [245].

We have also omitted the important problem of *applying the above results*. Perhaps because of the lack of a general theory, this can often be a challenge (see for instance [244] for the already complex problem of verifying *uniform hyperbolicity* for a singular flow). Liverani has shown how theoretical results can lead to precise and efficient estimates for the toy model of piecewise expanding interval maps [176]. Ergodic theory implies that, in some settings at least, *adding noise may make some estimates more precise* (see [157]). We refer to [106] and the reference therein.

Future Directions

We conclude this article by a (very partial) selection of open problems.

General Theory

In dimension 1, we have seen that the analogue of the Palis conjecture (see above) is established (Theorem 2). However the description of the typical dynamics in Kolmogorov sense is only known in the unimodal, non-degenerate case by Theorem 3. Indeed, results like [63] suggest that the multimodal picture could be more complex.

In higher dimensions, our understanding is much more limited. As far as a general theory is concerned, a deep problem is the paucity of results on the generic dynamics in C^r smoothness with $r > 1$. The remarkable current progress in generic dynamics (culminating in the proof of the weak Palis conjecture, see [84], the references therein and [51] for background) seems restricted to the C^1 topology because of the lack of fundamental tools (e. g., closing lemmas) in higher smoothness. But Pesin theory requires higher smoothness at least technically. This is not only a hard technical issue but generic properties of physical measures, when they have been analyzed are often completely different between the C^1 case and higher smoothness [45].

Physical Measures

In higher dimensions, Benedicks and Carleson analysis of the Hénon map has given rise to a rather general theory of Hénon-like maps and more generally of the dynamical phenomena associated to homoclinic tangencies. However, the proofs are extremely technical. Could they be simplified? Current attempts like [266] center on the introduction of a simpler notion of critical points, possibly a non-inductive one [212].

Can this Hénon theory be extended to the weakly dissipative situation? to the conservative situation (for which the *standard map* is a well-known example defying analysis)? In the strongly dissipative setting, what are the typical phenomena on the complement of the Benedicks–Carleson set of parameters?

From a global perspective one of the main questions is the following:

> *Can infinitely many sinks coexist for a large set of parameters in a typical family or is Newhouse phenomenon atypical in the Kolmogorov or prevalent sense?*

This seems rather unlikely (see however [11]).

Away from such "critical dynamics", there are many results about systems with dominated splitting satisfying additional conditions. Can these conditions be weakened so they would be satisfied by typical systems satisfying some natural conditions (like robust transitivity)? For instance:

> *Could one analyze the physical measures of volume-hyperbolic systems?*

A more specific question is whether Tsujii's striking analysis of surface maps with one uniformly expanding direction can be extended to higher dimensions? can one weaken the uniformity of the expansion? The same questions for the corresponding invertible situation is considered in [83].

Maximum Entropy Measures and Topological Complexity

As we explained, C^∞ smoothness, by a Newhouse theorem, ensures the existence of maximum entropy measures, making the situation a little simpler than with respect to physical measures. This existence results allow in particular an easy formulation of the problem of the typicality of hyperbolicity:

> *Are maximum entropy ergodic measures of systems with positive entropy hyperbolic for most systems?*

A more difficult problem is that of the finite multiplicity of the maximum entropy measures. For instance:

> *Do typical systems possess finitely many maximum entropy ergodic measures?*

More specifically, can one prove intrinsic ergodicity (ie, uniqueness of the measure of maximum entropy) for an isolated homoclinic class of some diffeomorphisms (perhaps C^1-generic)? Can a generic C^1-diffeomorphism carry an infinite number of homoclinic classes, each with topological entropy bounded away from zero?

A perhaps more tractable question, given the recent progress in this area: Is a C^1-generic partially hyperbolic diffeomorphisms, perhaps with central dimension 1 or 2, intrinsically ergodic?

We have seen how uniform systems have simple symbolic dynamics, i. e., subshifts of finite type, and how interval maps and more generally entropy-expanding maps keep some of this simplicity, defining subshifts or puzzles of quasi-finite type [68,69]. [264] have defined symbolic dynamics for topological Hénon-like map which seems close to that of that of a one-dimensional system.

> *Can one describe Wang and Young symbolic dynamics of Hénon-like attractors and fit it in a class in which uniqueness of the maximum entropy measure could be proved?*

More generally, can one define nice combinatorial descriptions, for surface diffeomorphisms? Can one formulate variants of the entropy-expansion condition [*For instance building on our "entropy-hyperbolicity".*] of [66,70], that would be satisfied by a large subset of the diffeomorphisms?

Another possible approach is illustrated by the pruning front conjecture of [87] (see also [88,144]). It is an attempt to build a combinatorial description by trying to generalize the way that, for interval maps, kneading invariants determine the symbolic dynamics by considering the bifurcations from a trivial dynamics to an arbitrary one.

We hope that our reader has shared in our fascination with this subject, the many surprising and even paradoxical discoveries that have been made and the exciting current progress, despite the very real difficulties both in the analysis of such non-uniform systems as the Henon map and in the attemps to establish a general (and practical) ergodic theory of chaotic dynamical systems.

Acknowledgments

I am grateful for the advice and/or comments of the following colleagues: P. Collet, J.-R. Chazottes, and especially S. Ruette. I am also indebted to the anonymous referee.

Article Outline

Glossary

Equicontinuity All points are equicontinuity points (in compact settings).

Equicontinuity point A point for which the orbits of nearby points remain close.

Expansivity From two distinct points, orbits eventually separate.

Injectivity The next state function is injective.

Linear CA A CA with additive local rule.

Regularity The set of periodic points is dense.

Sensitivity to initial conditions For any point x there exist arbitrary close points whose orbits eventually separate from the orbit of x.

Strong transitivity There always exist points which eventually move from any arbitrary neighborhood to any point.

Surjectivity The next state function is surjective.

Topological mixing There always exist points which definitely move from any arbitrary neighborhood to any other.

Transitivity There always exist points which eventually move from any arbitrary neighborhood to any other.

Definition of the Subject

A discrete time dynamical system (DTDS) is a pair $\langle X, F \rangle$ where X is a set equipped with a distance d and $F\colon X \mapsto X$ is a mapping which is continuous on X with respect to the metric d. The set X and the function F are called the state space and the next state map. At the very beginning of the seventies, the notion of chaotic behavior for DTDS has been introduced in experimental physics [46]. Successively, mathematicians started investigating this new notion finding more and more complex examples. Although a general universally accepted theory of chaos has not emerged, at least some properties are recognized as basic components of possible chaotic behavior. Among them one can list: sensitivity to initial conditions, transitivity, mixing, expansively etc. [5,6,21,22,28,29,38,41,42,58,59,60].

In the eighties, S. Wolfram started studying some of these properties in the context of cellular automata (CA) [64]. These pioneering studies opened the way to a huge amount of successive paper which aimed to complete, precise and further develop the theory of chaos in the CA context (▶ Dynamics of Cellular Automata in Non–compact Spaces, ▶ Topological Dynamics of Cellular Automata, ▶ Ergodic Theory of Cellular Automata, [7,8,9,10,11,13,14,15,16,17,35,43,51]). This long quest has also been stimulated by the advent of more and more powerful computers which helped researchers in their investigations. However, remark that most of the properties involved in chaos definitions turned out to be undecidable [23,34,39,40,45]. Anyway, there are non-trivial classes of CA for which these properties are decidable. For this reason in the present work we focus on linear CA.

Introduction

Cellular automata are simple formal models for complex systems. They are used in many scientific fields ranging from biology to chemistry or from physics to computer science.

A CA is made of an infinite set of finite automata distributed over a regular lattice $\mathcal{L}$. All finite automata are identical. Each automaton assumes a value, chosen from a finite set A, called the *alphabet*. A *configuration* is a snapshot of the all automata values, i. e., a function from $\mathcal{L}$ to A.

In the present chapter, we consider the D dimensional lattice $\mathcal{L} = \mathbb{Z}^D$.

A *local rule* updates the value of an automaton on the basis of its current value and the ones of a fixed set of neighboring automata which are individuated by the *neighborhood frame* $N = \{\vec{u}_1, \dots, \vec{u}_s\} \subset \mathbb{Z}^D$. Formally, the local rule is a function $f \colon A^s \to A$.

All the automata of the lattice are updated synchronously in discrete time steps. In other words, the local rule f induces a *global rule* $F \colon A^{\mathbb{Z}^D} \to A^{\mathbb{Z}^D}$, describing the evolution of the whole system from a generic time $t \in \mathbb{N}$ to $t + 1$.

When one equips the configuration space with a metric, a CA can be viewed as a DTDS $\langle A^{\mathbb{Z}^D}, F \rangle$. The state space $A^{\mathbb{Z}^D}$ of a CA is also called the configuration space $A^{\mathbb{Z}^D}$. From now on, we identify a CA with the dynamical system induced by itself or with its global rule.

As we have already told, the studies on the chaotic behavior of CA have played a central role in the last twenty years. Unfortunately, most of the properties involved are undecidable. In this chapter, we illustrate these notions by means of a particular class of CA in which they turn out to be decidable constituting a valid source for examples and understanding. Indeed, we focus on *linear* CA, i. e., CA whose local rule is a linear function on a finite group G. For clarity's sake, we assume that G is the set $Z_m = \{0, 1, \dots, m-1\}$ of integers modulo m and $+$ the cell-wise addition.

Despite their simplicity, linear CA exhibit many of the complex features of general CA ranging from trivial to the most complicated behaviors.

Definitions

Given a DTDS $\langle X, g \rangle$ the next state function induces deterministic dynamics by its iterated application starting from a given initial state. Formally, for a fixed state $x \in X$, the *dynamical evolution* or *orbit of initial state* x is the sequence $\{F^n(x)\}_{n \in \mathbb{N}}$. A state $p \in X$ is a periodic point if there exists an integer $n > 0$ such that $F^n(p) = p$.

Deterministic Chaos

We are particularly interested in the properties which can be considered as components of "chaotic" behavior. Among them, sensitivity to initial conditions is the most intriguing, at least at a level of popular divulgement. It captures the feature that small errors in experimental measurements lead to large scale divergence in the evolution.

Definition 1 (Sensitivity) A DTDS $\langle X, F \rangle$ is *sensitive to the initial conditions* (or simply *sensitive*) if there exists a constant $\varepsilon > 0$ such that for any state $x \in X$ and any $\delta > 0$ there is a state $y \in X$ such that $d(y, x) < \delta$ and $d(F^n(y), F^n(x)) > \varepsilon$ for some $n \in \mathbb{N}$.

Intuitively, a DTDS is sensitive if for any state x there exist points arbitrarily close to x which eventually separate from x under iteration of F. Sensitivity is a strong form of instability. In fact, if a system is sensitive to the initial conditions and we are not able to measure with infinite precision the initial state, we cannot predict its dynamical evolution. This means that experimental or casual errors can lead to wrong results.

The following is another form of unpredictability.

Definition 2 (Positive Expansivity) A DTDS $\langle X, F \rangle$ is *positively expansive* if there exists a constant $\varepsilon > 0$ such that for any pair of distinct states $x, y \in X$ we have $d(F^n(y), F^n(x)) \geq \varepsilon$ for some $n \in \mathbb{N}$.

Remark that in perfect spaces (i. e., spaces without isolated points), expansive DTDS are necessarily sensitive to initial conditions.

Sensitivity alone, notwithstanding its intuitive appeal, has the drawback that, once taken as the unique condition for characterizing chaos, it appears to be neither sufficient nor as intuitive as it seems at a first glance.

Indeed, for physicists, a chaotic system must be necessarily nonlinear (the term linear in its classical meaning refers to the linearity of the equation which governs the behavior of a system). However, it is easy to find linear systems (on the reals, for instance) which are sensitive to initial conditions. Hence, a chaotic system has to satisfy further properties other than sensitivity.

Definition 3 (Transitivity) A DTDS $\langle X, F \rangle$ is (topologically) *transitive* if for all non empty open subsets U and V of X there exists a natural number n such that $F^n(U) \cap V \neq \emptyset$.

Intuitively, a transitive DTDS has points which eventually move under iteration of F from one arbitrarily small neighborhood to any other. As a consequence, the dynamical system cannot be decomposed into two disjoint clopen sets which are invariant under the iterations of F. Indecomposability is an important feature since, roughly speaking, it guarantees that the system behaves in the same way in the whole state space. Finally, note that transitivity implies surjectivity in the case of compact spaces.

Some DTDS may exhibit stronger forms of transitivity.

Definition 4 (Mixing) A DTDS $\langle X, F \rangle$ is *topologically mixing* if for all non-empty open subsets U, V of X there exists a natural number m such that for every $n \geq m$ it holds that $F^n(U) \cap V \neq \emptyset$.

The previous notion is the topological version of the well-known mixing property of ergodic theory. It is particularly useful when studying product of systems. Indeed, the product of two transitive systems is not necessarily transitive; it is transitive if one of the two systems is mixing [27].

Moreover, remark that any non-trivial (i. e. with at least two points) mixing system is sensitive to initial conditions [44].

Definition 5 (Strong Transitivity) A DTDS $\langle X, F\rangle$ is *strongly transitive* if for any nonempty open set $U \subseteq X$ we have that $\bigcup_{n=0}^{+\infty} F^n(U) = X$.

A strongly transitive map F has points which eventually move under iteration of F from one arbitrarily small neighborhood to any other *point*. As a consequence, a strongly transitive map is necessarily surjective.

Finally, remark that many well-known classes of transitive DTDS (irrational rotations of the unit circle, the tent map, the shift map, etc.) exhibit the following form of transitivity.

Definition 6 (Total Transitivity) A DTDS $\langle X, F\rangle$ is total transitive if for all integers $n > 0$, the system $\langle X, F^n\rangle$ is transitive.

Proposition 1 ([27]) *Any mixing DTDS is totally transitive.*

At the beginning of the eighties, Auslander and Yorke introduced the following definition of chaos [5].

Definition 7 (AY-Chaos) A DTDS is AY-chaotic if it is transitive and it is sensitive to the initial conditions.

This definition involves two fundamental characteristics: the undecomposability of the system, due to transitivity and the unpredictability of the dynamical evolution, due to sensitivity.

We now introduce a notion which is often referred to as an element of *regularity* a chaotic dynamical system must exhibit.

Definition 8 (DPO) A DTDS $\langle X, F\rangle$ has the *denseness of periodic points* (or, it is *regular*) if the set of its periodic points is dense in X.

The following is a standard result for compact DTDS.

Proposition 2 *If a compact DTDS has DPO then it is surjective.*

In his famous book [22], Devaney modified the AY-chaos adding the denseness of periodic points.

Definition 9 (D-Chaos) A DTDS is said to be D-chaotic if it is sensitive, transitive and regular.

An interesting result states that sensitivity, despite its popular appeal, is redundant in the Devaney definition of chaos.

Proposition 3 ([6]) *Any transitive and regular DTDS with an infinite number of states is sensitive to initial conditions.*

Note that neither transitivity nor DPO are redundant in the Devaney definition of chaos [37]. Further notions of chaos can be obtained by replacing transitivity or sensitivity with stronger properties (like expansively, strong transitivity, etc.).

Stability

All the previous properties can be considered as components of a chaotic, and then unstable, behavior for a DTDS. We now illustrate some properties concerning conditions of stability for a system.

Definition 10 (Equicontinuous Point) A state $x \in X$ of a DTDS $\langle X, F\rangle$ is an *equicontinuous point* if for any $\varepsilon > 0$ there exists $\delta > 0$ such that for all $y \in X$, $d(y, x) < \delta$ implies that $\forall n \in \mathbb{N},\ d(F^n(y), F^n(x)) < \varepsilon$.

In other words, a point x is equicontinuous (or Lyapunov stable) if for any $\varepsilon > 0$, there exists a neighborhood of x whose states have orbits which stay close to the orbit of x with distance less than ε. This is a condition of local stability for the system.

Associated with this notion involving a single state, we have two notions of global stability based on the "size" of the set of the equicontinuous points.

Definition 11 (Equicontinuity) A DTDS $\langle X, F\rangle$ is said to be *equicontinuous* if for any $\varepsilon > 0$ there exists $\delta > 0$ such that for all $x, y \in X$, $d(y, x) < \delta$ implies that $\forall n \in \mathbb{N}$, $(F^n(y), F^n(x)) < \varepsilon$.

Given a DTDS, let E be its set of equicontinuity points. Remark that if a DTDS is equicontinuous then the set E of all its equicontinuity points is the whole X. The converse is also true in the compact settings. Furthermore, if a system is sensitive then $E = \emptyset$. In general, the converse is not true [43].

Definition 12 (Almost Equicontinuity) A DTDS is *almost equicontinuous* if the set of its equicontinuous points E is residual (i. e., it can be obtained by a infinite intersection of dense open subsets).

It is obvious that equicontinuous systems are almost equicontinuous. In the sequel, almost equicontinuous systems which are not equicontinuous will be called strictly almost equicontinuous. An important result affirms that transitive systems on compact spaces are almost equicontinuous if and only if they are not sensitive [3].

Topological Entropy

Topological entropy is another interesting property which can be taken into account in order to study the degree of chaoticity of a system. It was introduced in [2] as an invariant of topological conjugacy. The notion of topological entropy is based on the complexity of the coverings of the systems. Recall that an open covering of a topological space X is a family of open sets whose union is X. The join of two open coverings $\mathcal{U}$ and $\mathcal{V}$ is $\mathcal{U} \vee \mathcal{V} = \{U \cap V : U \in \mathcal{U}, V \in \mathcal{V}\}$. The inverse image of an open covering $\mathcal{U}$ by a map $F: X \mapsto X$ is $F^{-1}(\mathcal{U}) = \{F^{-1}(U) : U \in \mathcal{U}\}$. On the basis of these previous notions, the entropy of a system $\langle X, F\rangle$ over an open covering $\mathcal{U}$ is defined as

$$\begin{aligned} &H(X,F,\mathcal{U}) \\ &\quad = \lim_{n\to\infty} \frac{\log|\mathcal{U} \vee F^{-1}(\mathcal{U}) \cdots \vee F^{-(n-1)}(\mathcal{U})|}{n}\,, \end{aligned}$$

where $|U|$ is the cardinality of U.

Definition 13 (Topological Entropy) The topological entropy of a DTDS $\langle X, F\rangle$ is

$$\begin{aligned} &h(X,F) \\ &\quad = \sup\{H(X,F,\mathcal{U}) : \mathcal{U} \text{ is an open covering of } X\} \end{aligned} \tag{1}$$

Topological entropy represents the exponential growth of the number of orbit segments which can be distinguished with a certain good, but finite, accuracy. In other words, it measures the uncertainty of the system evolutions when a partial knowledge of the initial state is given.

There are close relationships between the entropy and the topological properties we have seen so far. For instance, we have the following.

Proposition 4 ([3,12,28]) *In compact DTDS, transitivity and positive entropy imply sensitivity.*

Cellular Automata

Consider the set of configurations C which consists of all functions from $\mathbb{Z}^D$ into A. The space C is usually equipped with the Thychonoff (or Cantor) metric d defined as

$$\forall a, b \in C, \quad d(a,b) = 2^{-n}, \qquad \text{with} \quad n = \min_{\vec{v}\in\mathbb{Z}^D} \left\{\|\vec{v}\|_\infty : a(\vec{v}) \neq b(\vec{v})\right\},$$

where $\|\vec{v}\|_\infty$ denotes the maximum of the absolute value of the components of $\vec{v}$. The topology induced by d coincides with the product topology induced by the discrete topology on A. With this topology, C is a compact, perfect and totally disconnected space.

Let $N = \{\vec{u}_1, \ldots, \vec{u}_s\}$ be an ordered set of vectors of $\mathbb{Z}^D$ and $f: A^s \mapsto A$ be a function.

Definition 14 (CA) The D-dimensional CA based on the local rule f and the neighborhood frame N is the pair $\langle C\rangle, F$ where $F: C \mapsto C$ is the global transition rule defined as follows:

$$\begin{aligned} &\forall c \in C, \quad \forall \vec{v} \in \mathbb{Z}^D, \\ &\qquad F(c)(\vec{v}) = f(c(\vec{v}+\vec{u}_1), \ldots, c(\vec{v}+\vec{u}_s))\,. \end{aligned} \tag{2}$$

Note that the mapping F is (uniformly) continuous with respect to the Thychonoff metric. Hence, the pair $\langle C\rangle, F$ is a proper discrete time dynamical system.

Let $Z_m = \{0, 1, \ldots, m-1\}$ be the group of the integers modulo m. Denote by C_m the configuration space C for the special case $A = Z_m$. When C_m is equipped with the natural extensions of the sum and the product operations, it turns out to be a linear space. Therefore, one can exploit the properties of linear spaces to simplify the proofs and the overall presentation.

A function $f: Z_m^s \mapsto Z_m$ is said to be linear if there exist $\lambda_1, \ldots, \lambda_s \in Z_m$ such that it can be expressed as:

$$\forall (x_1, \ldots, x_s) \in Z_m^s, \quad f(x_1, \ldots, x_s) = \left[\sum_{i=1}^{s} \lambda_i x_i\right]_m$$

where $[x]_m$ is the integer x taken modulo m.

Definition 15 (Linear CA) A D-dimensional linear CA is a CA $\langle C\rangle_m, F$ whose local rule f is linear.

Note that for the linear CA Equ. (2) becomes:

$$\forall c \in C, \ \forall \vec{v} \in \mathbb{Z}^D, \ F(c)(\vec{v}) = \left[\sum_{i=1}^{s} \lambda_i c(\vec{v}+\vec{u}_i)\right]_m .$$

The Case of Cellular Automata

In this section the results seen so far are specialized to the CA setting, focusing on dimension one. The following result allows a first classification of one-dimensional CA according to their degree of chaoticity.

Theorem 1 ([43]) *A one-dimensional CA is sensitive if and only if it is not almost equicontinuous.*

In other words, for CA the dichotomy between sensitivity and almost equicontinuity is true and not only under the transitivity condition. As a consequence, the family of all one-dimensional CA can be partitioned into four classes [43]:

(k1) equicontinuous CA;
(k2) strictly almost equicontinuous CA;
(k3) sensitive CA;
(k4) expansive CA.

This classification almost fits for higher dimensions. The problem is that there exist CA between the classes $K2$ and $K3$ (i. e., non sensitive CA without any equicontinuity point). Even relaxing $K2$ definition to "CA having some equicontinuity point", the gap persists (see, for instance [57]).

Unfortunately, much like most of the interesting properties of CA, the properties defining the above classification scheme are also affected by undecidability.

Theorem 2 ([23]) *For each $i = 1, 2, 3$, there is no algorithm to decide if a one-dimensional CA belongs to the class Ki.*

The following conjecture stresses the fact that nothing is known about the decidability for the membership in $K4$.

Conjecture 1 (Folklore) *Membership in class $K4$ is undecidable.*

Remark that the above conjecture is clearly false for dimensions greater than 1 since there do not exist expansive CA for dimension strictly greater than 1 [53].

Proposition 5 ([7,11]) *Expansive CA are strongly transitive and mixing.*

In CA settings, the notion of total transitivity reduces to the simple transitivity. Moreover, there is a strict relation between transitive and sensitive CA.

Theorem 3 ([49]) *If a CA is transitive then it is totally transitive.*

Theorem 4 ([28]) *Transitive CA are sensitive.*

As we have already seen, sensitivity is undecidable. Hence, in view of the combinatorial complexity of transitive CA, the following conjectures sound true.

Conjecture 2 *Transitivity is an undecidable property.*

Conjecture 3 [48] *Strongly transitive CA are (topologically) mixing.*

Chaos and Combinatorial Properties

In this section, when referring to a one-dimensional CA, we assume that $u_1 = \min N$ and $u_s = \max N$ (see also Sect. "Definitions"). Furthermore, we call *elementary* a one-dimensional CA with alphabet $A = \{0, 1\}$ and $N = \{-1, 0, 1\}$ (there exist 256 possible elementary CA which can be enumerated according to their local rule [64]).

In CA settings, most of the chaos components are related to some properties of combinatorial nature like injectivity, surjectivity and openness.

First of all, remark that injectivity and surjectivity are dimension sensitive properties in the sense of the following.

Theorem 5 ([4,39]) *Injectivity and surjectivity are decidable in dimension 1, while they are not decidable in dimension greater than 1.*

A one-dimensional CA is said to be a *right CA* (resp., *left CA*) if $u_1 > 0$ (resp., $u_s < 0$).

Theorem 6 ([1]) *Any surjective and right (or left) CA is topologically mixing.*

The previous result can be generalized in dimension greater than 1 in the following sense.

Theorem 7 *If for a given surjective D-dimensional CA there exists a $(D-1)$-dimensional hyperplane H (as a linear subspace of $\mathbb{Z}^D$) such that:*

1. *all the neighbor vectors stay on the same side of a H, and*
2. *no vectors lay on H,*

then the CA is topologically mixing.

Proof Choose two configurations c and d and a natural number r. Let U and V be the two distinct open balls of radius 2^{-r} and of center c and d, respectively (in a metric space (X, d) the open ball of radius $\delta > 0$ and center $x \in X$ is the set $B_\delta(x) = \{y \in X \mid d(y, x) < \delta\}$). For any integer $n > 1$, denote by N_n the neighbor frame of the CA F^n and with $d_n \in F^{-n}(d)$ any n-preimage of d. The values $c(\vec{x})$ for $\vec{x} \in O$ depend only on the values $d_n(\vec{x})$ for $\vec{x} \in O + N_n$, where $O = \{\vec{v} \mid \|\vec{v}\|_\infty \leq r\}$. By the hypothesis, there exists an integer $m > 0$ such that for any $n \geq m$ the sets O and $O + N_n$ are disjoint. Therefore, for any $n \geq m$ build a configuration $e_n \in C$ such that $e_n(\vec{x}) = d(\vec{x})$ for $\vec{x} \in O$, and $e_n(\vec{x}) = d_n(\vec{x})$ for $\vec{x} \in O + N_n$. Then, for any $n \geq m$, $e_n \in V$ and $F^n(e_n) \in U$. □

Injectivity prevents a CA from being strong transitive as stated in the following

Theorem 8 ([11]) *Any strongly transitive CA is not injective.*

Recall that a CA of global rule F is open if F is an open function. Equivalently, in the one-dimensional case, every configuration has the same numbers of predecessors [33].

Theorem 9 ([55]) *Openness is decidable in dimension one.*

Remark that mixing CA are not necessarily open (consider, for instance, the elementary rule 106, see [44]). The following conjecture is true when replacing strong transitivity by expansively [43].

Conjecture 4 *Strongly transitive CA are open.*

Recall that the shift map $\sigma : A^{\mathbb{Z}} \mapsto A^{\mathbb{Z}}$ is the one-dimensional linear CA defined by the neighborhood $N = \{+1\}$ and by the coefficient $\lambda_1 = 1$. A configuration of a one-dimensional CA is called jointly periodic if it is periodic both for the CA and the shift map (i. e., it is also spatially periodic). A CA is said to have the joint denseness of periodic orbits property (JDPO) if it admits a dense set of jointly periodic configurations. Obviously, JDPO is a stronger form of DPO.

Theorem 10 ([13]) *Open CA have JDPO.*

The common feeling is that (J)DPO is a property of a class wider than open CA. Indeed,

Conjecture 5 [8] *Every surjective CA has (J)DPO.*

If this conjecture were true then, as a consequence of Theorem 5 and Proposition 2, DPO would be decidable in dimension one (and undecidable in greater dimensions). Up to now, Conjecture 5 has been proved true for some restricted classes of one-dimensional surjective CA beside open CA.

Theorem 11 ([8]) *Almost equicontinuous surjective CA have JDPO.*

Consider for a while a CA whose alphabet is an algebraic group. A configuration is said to be *finite* if there exists an integer h such that for any i, $|i| > k$, $c(i) = 0$, where 0 is the null element of the group. Denote $s(c) = \sum_i c(i)$ the sum of the values of a finite configuration. A one-dimensional CA F is called *number conserving* if for any finite configuration c, $s(c) = s(F(c))$.

Theorem 12 ([26]) *Number-conserving surjective CA have DPO.*

If a CA F is number-conserving, then for any $h \in \mathbb{Z}$ the CA $\sigma^h \circ F$ is number-conserving. As a consequence we have that

Corollary 1 *Number-conserving surjective CA have JDPO.*

Proof Let F be a number-conserving CA. Choose $h \in \mathbb{Z}$ in such a way that the CA $\sigma^h \circ F$ is a (number-conserving) right CA. By a result in [1], both the CA $\sigma^h \circ F$ and F have JDPO. □

In a recent work it is proved that the problem of solving Conjecture 5 can be reduced to the study of mixing CA.

Theorem 13 ([1]) *If all mixing CA have DPO then every surjective CA has JDPO.*

As a consequence of Theorem 13, if all mixing CA have DPO then all transitive CA have DPO.

Permutivity is another easy-to-check combinatorial property strictly related to chaotic behavior.

Definition 16 (Permutive CA) A function $f : A^s \mapsto A$ is permutive in the variable a_i if for any $(a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_s) \in A^{s-1}$ the function $a \mapsto f(a_1, \ldots, a_{i-1}, a, a_{i+1}, \ldots, a_s)$ is a permutation.

In the one-dimensional case, a function f that is permutive in the leftmost variable a_1 (resp., rightmost a_s), it is called leftmost (resp. rightmost) permutive. CA with either leftmost or rightmost permutive local rule share most of the chaos components.

Theorem 14 ([18]) *Any one-dimensional CA based on a leftmost (or, rightmost) permutive local rule with $u_1 < 0$ (resp., $u_s > 0$) is topologically mixing.*

The previous result can be generalized to any dimension in the following sense.

Theorem 15 *Let f and N be the local rule and the neighborhood frame, respectively, of a given D-dimensional CA. If there exists i such that*

1. *f is permutive in the variable a_i, and*
2. *the neighbor vector $\vec{u}_i$ is such that $\|\vec{u}_i\|_2 = \max\{\|\vec{u}\|_2 \mid \vec{u} \in N\}$, and*
3. *all the coordinates of $\vec{u}_i$ have absolute value l, for some integer $l > 0$,*

then the given CA is topologically mixing.

Proof Without loss of generality, assume that $\vec{u}_i = (l, \ldots, l)$. Let U and V be two distinct open balls of equal radius 2^{-r}, where r is an arbitrary natural number. For any integer $n \geq 1$, denote with N_n the neighbor frame of the CA F_n, with f^n the corresponding local rule, and with $N_n(\vec{x})$ the set $\{\vec{x} + \vec{v} \mid \vec{v} \in N_n\}$ for a given $\vec{x} \in \mathbb{Z}^D$. Note that f^n is permutive in the variable corresponding to the neighbor vector $n\vec{u}_i \in N_n$. Choose two configurations $c \in U$ and $d \in V$. Let m be the smaller natural number such that $ml > 2r$. For any $n \geq m$, we are going to build a configuration $d_n \in U$ such that $F^n(d_n) \in V$. Set $d_n(\vec{z}) = c(\vec{z})$ for $\vec{z} \in O$ where $O = \{\vec{v} \mid \|\vec{v}\|_\infty \leq r\}$. In this way $d_n \in U$. In order to obtain $F^n(d_n) \in V$, it is required that $F^n(d_n)(\vec{x}) = d(\vec{x})$ for each $\vec{x} \in O$. We complete the configuration d_n by starting with $\vec{x} = \vec{y}$, where $\vec{y} = (-r, \dots, -r)$. Choose arbitrarily the values $d_n(\vec{z})$ for $\vec{z} \in (N_n(\vec{y}) \setminus O) \setminus \{\vec{y} + n\vec{u}_i\}$ (note that $O \subset N_n(\vec{y})$). By permutivity of f^n, there exists $a \in A$ such that if one set $d_n(\vec{y} + n\vec{u}_i) = a$, then $F^n(d_n)(\vec{y}) = d(\vec{y})$. Let now $\vec{x} = \vec{y} + \vec{e}_1$. Choose arbitrarily the values $d_n(\vec{z})$ for $\vec{z} \in (N_n(\vec{x}) \setminus N_n(\vec{y})) \setminus \{\vec{x} + n\vec{u}_i\}$. By the same argument as above, there exists $a \in A$ such that if one set $d_n(\vec{x} + n\vec{u}_i) = a$, then $F^n(d_n)(\vec{x}) = d(\vec{x})$. Proceeding in this way one can complete d_n in order to obtain $F^n(d_n) \in V$. □

Theorem 16 ([16]) *Any one-dimensional CA based on a leftmost (or, rightmost) permutive local rule with $u_1 < 0$ (resp., $u_s > 0$) has (J)DPO.*

Theorem 17 ([54]) *Any one-dimensional CA based on a leftmost and rightmost permutive local rule with $u_1 < 0$ and $u_s > 0$ is expansive.*

As a consequence of Proposition 5, we have the following result for which we give a direct proof in order to make clearer the result which follows immediately after.

Proposition 6 *Any one-dimensional CA based on a leftmost and rightmost permutive local rule with $u_1 < 0$ and $u_s > 0$ is strongly transitive.*

Proof Choose arbitrarily two configurations $c, o \in A^{\mathbb{Z}}$ and an integer $k > 0$. Let $n > 0$ be the first integer such that $nr > k$, where $r = \max\{-u_1, u_s\}$. We are going to construct a configuration $b \in A^{\mathbb{Z}}$ such that $d(b, c) < 2^{-k}$ and $F^n(b) = o$. Fix $b(x) = c(x)$ for each $x = nu_1, \dots, nu_s - 1$. In this way $d(b, c) < 2^{-k}$. For each $i \in \mathbb{N}$ we are going to find suitable values $b(nu_s + i)$ in order to obtain $F^n(b)(i) = o(i)$. Let us start with $i = 0$. By the hypothesis, the local rule f^n of the CA F^n is permutive in the rightmost variable nu_s. Thus, there exists a value $a_0 \in A$ such that, if one sets $b(nu_s) = a_0$, we obtain $F^n(b)(0) = o(0)$. By the same reasons as above, there exists a value $a_1 \in A$ such that, if one set $b(nu_s + 1) = a_1$, we obtain $F^n(b)(1) = o(1)$. Proceeding in this way one can complete the configuration b for any position $nu_s + i$. Finally, since f^n is permutive also in the leftmost variable nu_1 one can use the same technique to complete the configuration b for the positions $nu_1 - 1, nu_1 - 2, \dots$, in such a way that for any integer $i < 0$, $F^n(b)(i) = o(i)$. □

The previous result can be generalized as follows. Denote $\vec{e}_1, \vec{e}_2, \dots, \vec{e}_D$ the canonical basis of $\mathbb{R}^D$.

Theorem 18 *Let f and N be the local rule and the neighborhood frame, respectively, of a given D-dimensional CA. If there exists an integer $l > 0$ such that*

1. *f is permutive in all the 2^D variable corresponding to the neighbor vectors $(\pm l, \dots, \pm l)$, and*
2. *for each vector $\vec{u} \in N$, we have $\|u\|_\infty \leq l$,*

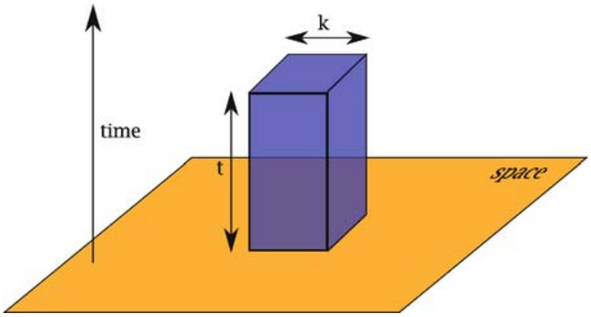
then the CA F is strongly transitive.

Proof For the sake of simplicity, we only trait the case $D = 2$. For higher dimensions, the idea of the proof is the same. Let $\vec{u}_2 = (l, l)$, $\vec{u}_3 = (-l, l)$, $\vec{u}_4 = (-l, -l)$, $\vec{u}_5 = (l, -l)$. Choose arbitrarily two configurations $c, o \in A^{\mathbb{Z}^2}$ and an integer $k > 0$. Let $n > 0$ be the first integer such that $nl > k$. We are going to construct a configuration $b \in A^{\mathbb{Z}^2}$ such that $d(b, c) < 2^{-k}$ and $F^n(b) = o$. Fix $b(x) = c(x)$ for each $\vec{x} \neq n\vec{u}_2$ with $\|\vec{x}\|_\infty \leq n$. In this way $d(b, c) < 2^{-k}$. For each $i \in \mathbb{Z}$ we are going to find suitable values for the configuration b in order to obtain $F^n(b)(i\vec{e}_1) = o(i\vec{e}_1)$. Let us start with $i = 0$. By the hypothesis, the local rule f^n of the CA F^n is permutive in the variable $n\vec{u}_2$. Thus, there exists a value $a_{(0,0)} \in A$ such that, if one set $b(n\vec{u}_1) = a_{(0,0)}$, we obtain $F^n(b)(\vec{0}) = o(\vec{0})$. Now, choose arbitrary values of b in the positions $(n + 1)\vec{e}_1 + j\vec{e}_2$ for $j = -n, \dots, n - 1$. By the same reasons as above, there exists a value $a_{(0,1)} \in A$ such that, if one sets $b(nu_2 + 1\vec{e}_1) = a_{(0,1)}$, we obtain $F^n(b)(\vec{e}_1) = o(\vec{e}_1)$. Proceeding in this way, at each step i ($i > 1$), one can complete the configuration b for all the positions $(n + i)\vec{e}_1 + j\vec{e}_2$ for $j = -n, \dots, n$, obtaining $F^n(b)(i\vec{e}_1) = o(i\vec{e}_1)$. In a similar way, by using the fact that the local rule f^n of the CA F^n is permutive in the variable $n\vec{u}_3$, for any $i < 0$ one can complete the configuration b for all the positions $(-n + i)\vec{e}_1 + j\vec{e}_2$ for $j = -n, \dots, n$, obtaining $F^n(b)(i\vec{e}_1) = o(i\vec{e}_1)$. Now, for each step $j = 1, 2, \dots$, choose arbitrarily the values of b in the positions $i\vec{e}_1 + (n + j)\vec{e}_2$ and $i\vec{e}_1 + (n + j)\vec{e}_2$ with $i = -n, \dots n - 1$. The permutivity of f^n in the variables $n\vec{u}_2$, $n\vec{u}_3$, $n\vec{u}_5$, and $n\vec{u}_4$ permits one to complete the configuration b in the positions $(n + i)\vec{e}_1 + (n + j)\vec{e}_2$ for all integers $i \geq 0$, $(-n + i)\vec{e}_1 + (-n + j)\vec{e}_2$ for all integer $i < 0$, $(-n + i)\vec{e}_1 + (-n - j)\vec{e}_2$ for all integers $i \geq 0$, and $(n + i)\vec{e}_1 + (-n - j)\vec{e}_2$ for all integers $i < 0$, so that for each step j we obtain $\forall i \in \mathbb{Z}, F^n(b)(i\vec{e}_1 + j\vec{e}_2) = o(i\vec{e}_1 + j\vec{e}_2)$. □

CA, Entropy and Decidability

In [34], it is shown that, in the case of CA, the definition of topological entropy can be restated in a simpler form than (1).

The space-time diagram $S(c)$ generated by a configuration c of a D-dimensional CA is the $(D + 1)$-dimensional infinite figure obtained by drawing in sequence the elements of the orbit of initial state c along the temporal axis.



Chaotic Behavior of Cellular Automata, Figure 1
$\mathcal{N}(k,t)$ is the number of distinct *blue blocks* that can be obtained starting from any initial configuration (*orange plane*)

Formally, $S(c)$ is a function from $\mathbb{N} \times \mathbb{Z}^D$ in A defined as $\forall t \in \mathbb{N}, \forall \vec{v} \in \mathbb{Z}^D$, $S(c)(t,\vec{v}) = F^t(c)(\vec{v})$. For a given CA, fix a time t and a finite square region of side of length k in the lattice. In this way, a finite $(D+1)$-dimensional figure (hyper-rectangle) is identified in all space-time diagrams. Let $\mathcal{N}(k,t)$ be the number of distinct finite hyper-rectangles obtained by all possible space-time diagrams for the CA (i. e., $\mathcal{N}(k,t)$ is the number of the all space-time diagrams which are distinct in this finite region). The topological entropy of any given CA can be expressed as

$$h(C,F) = \lim_{k\to\infty} \lim_{t\to\infty} \mathcal{N}(k,t)$$

Despite the expression of the CA entropy is simpler than for a generic DTDS, the following result holds.

Theorem 19 ([34]) *The topological entropy of CA is uncomputable.*

Nevertheless there exist some classes of CA where it is computable [20,45]. Unfortunately, in most of these cases it is difficult to establish if a CA is a member of these classes.

Results for Linear CA: Everything Is Detectable

In the sequel, we assume that a linear CA on C_m is based on a neighborhood frame $N = \vec{u}_1, \dots, \vec{u}_s$ whose corresponding coefficients of the local rule are $\lambda_1, \dots, \lambda_s$. Moreover, without loss of generality, we suppose $\vec{u}_1 = \vec{0}$. In most formulas the coefficient λ_1 does not appear.

Decidability Results for Chaotic Properties

The next results state that all chaotic properties introduced in Section III are decidable. Yet, one can use the formulas to build samples of cellular automata that has the required properties.

Theorem 20 ([17,19,47])

Sensitivity *a linear CA is sensitive to the initial conditions if there exists a prime number p such that $p|m$ and $p \nmid \gcd\{\lambda_2,\dots,\lambda_s\}$.*

Transitivity *a linear CA is topologically transitive if and only if $\gcd\{\lambda_2,\dots,\lambda_s\} = 1$.*

Mixing *a linear CA is topologically mixing if and only if it is topologically transitive.*

Strong transitivity *a linear CA is strongly transitive if for each prime p dividing m, there exist at least two coefficients λ_i, λ_j such that $p \nmid \lambda_i$ and $p \nmid \lambda_j$.*

Regularity (DPO) *a linear CA has the denseness of periodic points if it is surjective.*

Concerning positive expansively, since in dimensions greater than one, there are no such CA, the following theorem characterizes expansively for linear CA in dimension one. For this situation we consider a local rule f with expression $f(x_{-r},\dots,x_r) = \left[\sum_{i=-r}^{r} a_i x_i\right]_m$.

Theorem 21 ([47]) *A linear one dimensional CA is positively expansive if and only if $\gcd\{m, a_{-r},\dots,a_{-1}\} = 1$ and $\gcd\{m, a_1,\dots,a_r\} = 1$.*

Decidability Results for Other Properties

The next result was stated incompletely in [47] since the case of non sensitive CA without equicontinuity points is not treated, tough they exist [57].

Theorem 22 *Let F be a linear cellular automaton. Then the following properties are equivalent*

1. *F is equicontinuous*
2. *F has an equicontinuity point*
3. *F is not sensitive*
4. *for all prime p such that $p|m$, p divides $gcd(\lambda_2,\dots,\lambda_s)$.*

Proof 1) $\Longrightarrow$ 2) and 2) $\Longrightarrow$ 3) are obvious. 3) $\Longrightarrow$ 4) is done by negating the formula for sensitive CA in Theorem 20.

Let us prove that 4) $\Longrightarrow$ 1). Suppose that F is a linear CA. We decompose $F = G + H$ by separating the term in λ_1 from the others:

$$H(x)(\vec{v}) = \lambda_1 x(\vec{v}) \quad G(x)(\vec{v}) = \left[\sum_{i=2}^{s} \lambda_i c(\vec{v}+\vec{u}_i)\right]_m .$$

Let $m = p_1^{\alpha_1} \cdots p_l^{\alpha_l}$ be the decomposition in prime factors and $a = \text{lcm}\{\alpha_i\}$. The condition 4) gives that for all k, $\Pi_{i=1}^{l} p_i | \lambda_k$ and then m divides any product of a factors λ_i.

Let $\vec{v}$ be a vector such that for all i, $\vec{u}_i - \vec{v}$ has nonnegative coordinates. Classically, we represent local rules of linear CA by D-variable polynomials (this representation, together with the representation of configurations by formal power series allows to simplify the calculus of images through the iterates of the CA [36]). Let $X_1, \ldots, X_D$ be the variables. For $\vec{y} = (y_1, \ldots, y_D) \in \mathbb{Z}^D$, we note $X^{\vec{y}}$ the monomial $\Pi_{i=1}^{D} X_i^{y_i}$. We consider the polynomial P associated with G combined with a translation of vector $\vec{v}$, $P = \Pi_{i=2}^{s} \lambda_i X^{\vec{u}_i - \vec{v}}$. The coefficients of P^a are products of a factors λ_i hence $[P^a]_m = 0$. This means that the composition of G and the translation of vector $\vec{v}$ is nilpotent and then that G is nilpotent. As F is the sum of λ_1 times the identity and a nilpotent CA, we conclude that F is equicontinuous. □

The next theorem gives the formula for some combinatorial properties

Theorem 23 **([36]).**

Surjectivity *a linear CA is surjective if and only if* $\gcd\{\lambda_1, \ldots, \lambda_s\} = 1$.

Injectivity *a linear CA is injective if and only if for each prime p decomposing m there exists an unique coefficient λ_i such that p does not divide λ_i.*

Computation of Entropy for Linear Cellular Automata

Let us start by considering the one-dimensional case.

Theorem 24 *Let us consider a one dimensional linear CA. Let $m = p_1^{k_1} \cdots p_h^{k_h}$ be the prime factor decomposition of m. The topological entropy of the CA is*

$$h(C, F) = \sum_{i=1}^{h} k_i (R_i - L_i) \log(p_i)$$

where $L_i = \min P_i$ and $R_i = \max P_i$, with $P_i = \{0\} \cup \{j\colon \gcd(a_j, p_i) = 1\}$.

In [50], it is proved that for dimensions greater than one, there are only two possible values for the topological entropy: zero or infinity.

Theorem 25 *A D-dimensional linear CA $\langle C, F\rangle$ with $D \geq 2$ is either sensitive and $h(C, F) = \infty$ or equicontinuous and $h(C, F) = 0$.*

By a combination of Theorem 25 and 20, it is possible to establish if a D dimensional linear CA with $D \geq 2$ has either zero or infinite entropy.

Linear CA, Fractal Dimension and Chaos

In this section we review the relations between strong transitivity and fractal dimension in the special case of linear CA. The idea is that when a system is chaotic then it produces evolutions which are complex even from a (topological) dimension point of view.

Any linear CA F, can be associated with its *W-limit set*, a subset of the $(D+1)$-dimensional Euclid space defined as follows. Let t_n be a sequence of integers (we call them times) which tends to infinity. A subset $S_F(t_n)$ of $(D+1)$-dimensional Euclid space represents a space-time pattern until time $t_n - 1$:

$$S_F(t_n) = \left\{(t, i) \text{s.t.} F^t(e_1)_i \neq 0,\ t < t_n\right\} .$$

A *W-limit set* for F is defined by $\lim_{n\to\infty} S_F(t_n)/t_n$ if the limit exists, where $S_F(t_n)/t_n$ is the contracted set of $S_F(t_n)$ by the rate $\frac{1}{t_n}$ i. e. $S_F(t_n)/t_n$ contains the point $(t/t_n, i/t_n)$ if and only if $S_F(t_n)$ contains the point (t, i). The limit $\lim_{n\to\infty} S_F(t_n)/t_n$ exists when $\liminf_{n\to\infty} S_F(t_n)/t_n$ and $\limsup_{n\to\infty} S_F(t_n)/t_n$ coincide, where

$$\liminf_{n\to\infty} \frac{S_F(t_n)}{t_n} = \Bigg\{ x \in \mathbb{R}^{D+1} \ :\ \forall j, \exists x_j \in \frac{S_F(t_j)}{t_j}, x_j \to x \text{ when } j \to \infty \Bigg\}$$

and

$$\limsup_{n\to\infty} \frac{S_F(t_n)}{t_n} = \Bigg\{ x \in \mathbb{R}^{D+1} \ :\ \exists \left\{t_{n_j}\right\}, \forall j, \exists x_{n_j} \in \frac{S_F(t_{n_j})}{t_{n_j}}, x_{n_j} \to x \text{ when } j \to \infty \Bigg\} ,$$

for a subsequence $\left\{t_{n_j}\right\}$ of $\{t_n\}$.

For the particular case of linear CA, the W-limit set always exists [30,31,32,56]. In the last ten years, the W-limit set of additive CA has been extensively studied [61,62,63]. It has been proved that for most of additive CA, it has interesting dimensional properties which completely characterize the set of quiescent configurations [56]. Here we link dimension properties of a W-limit set with chaotic properties. Correlating dimensional properties of invariant sets to dynamical properties has become during the years a fruitful source of new understanding [52].

Let X be a metric space. The *Hausdorff dimension* D_H of $V \subseteq X$ is defined as:

$$D_H(V) = \sup\left\{ h \in \mathbb{R} |\ \lim_{\epsilon\to 0} \left(\inf \sum |U_i|^h\right) = \infty \right\}$$

where the infimum is taken over all countable coverings U_i of V such that the diameter $|U_i|$of each U_i is less than ϵ (for more on Hausdorff dimension as well as other definitions of fractal dimension see [24]).

Given a CA F we denote $D_H(F)$ the Hausdorff dimension of its W-limit set.

Proposition 7 ([25,47]) *Consider a linear CA F over Z_{p^k} where p is a prime number. If $1 < D_H(F) < 2$ then F is strongly transitive.*

The converse relation is still an open problem. It would be also an interesting research direction to find out similar notions and results for general CA.

Conjecture 6 *Consider a linear CA F over Z_{p^k}, where p is a prime number. If F is strongly transitive then $1 < D_H(F) < 2$.*

Future Directions

In this chapter we reviewed the chaotic behavior of cellular automata. It is clear from the results seen so far that there are close similarities between the chaotic behavior of dynamical systems on the real interval and CA. To complete the picture, it remains only to prove (or disprove) Conjecture 5. Due to its apparent difficulty, this problem promises to keep researchers occupied for some years yet.

The study of the decidability of chaotic properties like expansively, transitivity, mixing etc. is another research direction which should be further addressed in the near future. It seems that new ideas are necessary since the proof techniques used up to now have been revealed as unsuccessful. The solution to these problems will be a source of new understanding and will certainly produce new results in connected fields.

Finally, remark that most of the results on the chaotic behavior of CA are concerned with dimension one. A lot of work should be done to verify what happens in higher dimensions.

Article Outline

Glossary

Chaotic systems The time evolution of a deterministic mechanical system defines a trajectory in the phase space of all the generalized coordinates and generalized momenta. Consider two infinitesimally separated points that lie on two different trajectories in this phase space. If these two trajectories typically separate exponentially with time, the systems is called chaotic provided the set of all points with an exponentially separating partner is of positive measure.

Chaotic hypothesis The hypothesis that systems of large numbers of particles interacting with short ranged forces can be treated mathematically as if the system were chaotic with no pathologies in the mathematical description of the systems' trajectories in phase space.

Dynamical systems theory The mathematical theory of the time evolution in phase space, or closely related spaces, of a deterministic system, such as a mechanical system obeying Hamiltonian equations of motion.

Ergodic systems A mechanical system is called ergodic if a typical trajectory in a phase space of finite total measure spends a fraction of its time in a set which is equal to the ratio of the measure of the set to the total measure of the phase space.

Escape rate formula Consider a chaotic dynamical system with a phase space constructed in such a way that the phase space has some kind of an absorbing boundary. The set of points, $\mathcal{R}$, in the phase space such that trajectories through them never escape through the absorbing boundary either in the forward or the backward motion is called a repeller. One can define a set of Lyapunov exponents, $\lambda_i(\mathcal{R})$ and a Kolmogorov–Sinai entropy, $h_{\text{KS}}(\mathcal{R})$ for motion on the repeller. Dynamical systems theory shows that the rate of escape, γ, of points, not on the repeller, through the boundary is given by

$$\gamma = \sum_i \lambda^+(\mathcal{R}) - h_{\text{KS}}(\mathcal{R}) \,, \tag{1}$$

where the sum is over all of the positive Lyapunov exponents on the repeller.

Gaussian thermostats A dynamical friction acting on the particles in a mechanical system which keeps the total energy, or the total kinetic energy of the system at a fixed value. It was invented by Gauss as the simplest solution to the problem of finding the equations of motion for a mechanical system with a constraint of fixed energy.

Gelfand triplet An operator with right and left hand eigenfunctions, possibly defined in different function spaces, and an inner product of one function from the *right* space and one from the *left* space. Generally one of these spaces contains singular functions such as Schwartz distributions and the other contains sufficiently smooth functions so that the inner product is well defined. The term *rigged Hilbert space* is also used to denote a Gelfand triplet.

Hyperbolic dynamical system A chaotic system where the tangent space to almost all trajectories in its phase space can be separated into well-defined stable and unstable manifolds, that intersect each other transversally.

Kolmogorov–Sinai entropy per unit time A measure of the rate at which information about the initial point of a chaotic trajectory is produced in time. The exponential separation of trajectories in phase space, characteristic of chaotic motion, implies that trajectories starting at very close-by, essentially indistinguishable, initial points will eventually be distinguishable. Hence as time evolves we can specify more precisely the initial point of the trajectory. Pesin has proved that for closed, hyperbolic systems, the Kolmogorov–Sinai entropy is equal to the sum of the positive Lyapunov exponents. The Kolmogorov–Sinai entropy is often called the metric entropy.

Lyapunov exponents Lyapunov exponents, λ_i, are the rates at which infinitesimally close trajectories separate or approach with time on the unstable and stable manifolds of a chaotic dynamical system. For closed phase spaces, that is, no absorbing boundaries present, Pesin theorem states that for hyperbolic dynamical system the Kolmogorov–Sinai entropy, h_{KS} is given by the sum of all the positive Lyapunov exponents.

$$h_{\mathrm{KS}} = \sum_i \lambda_i^+ \,. \tag{2}$$

Mixing systems Mixing systems are dynamical systems with stronger dynamical properties than ergodic systems in the sense that every mixing system is ergodic but the converse is not true. A system is mixing if the following statement about the time development of a set A_t is satisfied

$$\lim_{T\to\infty} \frac{\mu(A_T \cap B)}{\mu(B)} = \frac{\mu(A)}{\mu(\mathcal{E})} \,, \tag{3}$$

where B is any set of finite measure, and $\mu(\mathcal{E})$ is the measure of the full phase space. This statement is the mathematical expression of the fact that for a mixing system, every set of finite measure becomes uniformly distributed throughout the full phase space, with respect to the measure μ.

Normal variables Microscopic variables whose values are approximately constant on large regions of the constant energy surface in phase space.

Pseudo-chaotic systems A pseudo-chaotic system is a dynamical system where the separation of nearby trajectories is algebraic in time, rather than exponential. Pseudo-chaotic systems are weakly mixing as defined by the relation

$$\lim_{T\to\infty} \frac{1}{T} \int_0^T \mathrm{d}\tau \left[\mu(A_\tau \cap B) - \frac{\mu(A)\mu(B)}{\mu(\mathcal{E})} \right] = 0 \,. \tag{4}$$

Sinai–Ruelle–Bowen (SRB) measure SRB measures for a chaotic system are invariant measures that are smooth on unstable manifolds and possibly singular on stable manifolds.

Stable manifold A stable manifold about a point P in phase space is the set of points that will approach P at time t approaches positive infinity, that is in the infinite future of the motion.

Transport coefficients Transport coefficients characterize the proportionality between the currents of particles, momentum, or energy in a fluid, and the gradients of density, fluid velocity or temperature in the fluid. The coefficients of diffusion, shear and bulk viscosity, and thermal conductivity are transport coefficients, and appear as coefficients of the second order gradients in the Navier–Stokes and similar equations.

Unstable manifold An unstable manifold about a point P in phase space is the set of points that will approach P as time approaches negative infinity, that is, as one follows the motion backwards in time to the infinitely remote past.

Definition of the Subject

For most of its history, non-equilibrium statistical mechanics has produced mathematical descriptions of irreversible processes by invoking one or another stochastic assumptions in order to obtain useful equations. Central to our understanding of transport in fluids, for example, are random walk processes, which typically are described by stochastic equations. These in turn lead to the Einstein relation for diffusion, and its generalizations to other transport processes. This relation, as formulated by Einstein, states that the mean square displacement of a diffusing particle grows linearly in time with a proportionality constant given by the coefficient of diffusion. If we assume that such a description applies to mechanical systems of many particles, we must explain the origins of irreversibility in deterministic – and time reversible – mechanical systems, and we must locate the source of stochasticity that is invoked to derive transport equations. For systems of particles that are chaotic, it is possible to make some progress on resolving these issues, and to gain some insights into the analogous properties of systems that are not chaotic or that have both chaotic and non-chaotic behaviors. This article summarizes the current status of the application of dynamical systems theory to non-equilibrium statistical mechanics, focuses on the behavior of chaotic systems, and presents some of the important open issues needing resolution.

Introduction

Statistical mechanics is devoted to the study of the collective properties of large numbers of particles, typically atoms, molecules, electrons, etc., but can also be stars, or even galaxies. The mechanical properties of the individual particles and their mutual interactions are presumed to be known, and the emphasis is on the statistical properties of collections of large numbers of them [1,2,3]. The study of statistical mechanics has always involved both an examination of its foundations and the devising of methods to compute thermodynamic, transport, and related quantities for systems of large numbers of particles. In recent years there has been a great deal of attention focused on the foundations of statistical mechanics prompted by developments in: (i) dynamical systems theory, particularly chaotic dynamics, (ii) the mathematics of Anosov and hard-ball systems, and in (iii) the computational physics of systems of particles undergoing processes of various kinds [4,5,6,7,8,9,10,11,12,13,14]. Moreover, modern developments in quantum physics, particularly those of some relevance for the foundations of quantum mechanics, for cosmology, and for quantum computation have some bearing on the foundations of quantum statistical mechanics [15].

Non-equilibrium statistical mechanics is faced with the task of describing the wide range of non-thermodynamic, generally time dependent behaviors of large systems, such as the transport of particles, momentum, and/or energy from one region in space to another over some time interval. Despite a large number of, as yet, unsolved problems, non-equilibrium statistical mechanics has been able to explain and provide quantitative predictions for a wide range of transport phenomena. Here we will discuss some of these applications and describe the role played by the microscopic dynamics of the constituent particles, particularly when the microscopic dynamics is classical and chaotic [14]. Most of this article will be devoted to a study of the role of chaotic dynamics in non-equilibrium transport for classical, chaotic systems. We will also consider, to some extent, classical, non-chaotic systems as well as quantum systems, where the usual notions of chaotic dynamics do not apply but one can nevertheless understand some main features of the behavior of a quantum system by examining its classical counterpart, if there is one.

This article is devoted to the role played by chaotic dynamics in our understanding non-equilibrium statistical mechanics. It will focus on two main topics: (1) Basic issues in statistical mechanics, namely the approach of systems of particles to thermodynamic equilibrium. Here we give an updated view of the role of ergodic and mixing properties, proposed by Boltzmann and Gibbs, respectively, as the basis for understanding the approach to equilibrium [1,2,3,4]. (2) Applications of dynamical systems theory to non-equilibrium statistical mechanics and the theory of transport processes. Here we show that for chaotic systems, at least, on can find some very deep relationships between macroscopic transport and microscopic dynamics [5,6,7,8,9,10,11,12,13]. We also discuss, briefly, the closely related topic of fluctuation theorems for non-equilibrium stationary states which apply even in far-from equilibrium situations [16,17,18,19,20,21].

By way of introduction we begin with some observations about transport processes in fluids in order to set the stage for describing the role of chaotic dynamics in transport theory. As we will discuss in more detail below, normal transport processes in fluids are characterized by a linear growth in time of the mean square fluctuations of an appropriate time dependent microscopic variable of the system. Typical of such a fluctuation formula is the Einstein relation which states that the mean square displacement of a particle undergoing Brownian motion in a fluid grows linearly in time with a coefficient that is, apart from a numerical factor, the diffusion coefficient of the Brownian particle [22]. That is

$$\left\langle (\mathbf{r}(t) - \mathbf{r}(0))^2 \right\rangle = 2dDt \,. \tag{5}$$

Here $\mathbf{r}(t)$ is the spatial location of the Brownian particle at some time t, and d is the number of spatial dimensions of the system. D is the diffusion coefficient appearing in the linear relation, known as Fick's Law, that relates the probability current, $\mathbf{J}(\mathbf{r}, t)$ for the Brownian particle to its probability density, $P(\mathbf{r}, t)$,

$$\mathbf{J}(\mathbf{r}, t) = -D\nabla P(\mathbf{r}, t) \,. \tag{6}$$

The angular brackets denote an average over an ensemble of trajectories of time duration t, at least. At the heart of the Einstein formula is the fact that the Brownian particle undergoes a random walk on sufficiently long time scales. The distinguishing feature of a random walk is the linear growth in time of the mean square displacement. Thus, normal transport in general is a form of a random walk process. This was formalized by Helfand in 1960 [23], who generalized the Einstein formula to other transport processes such as viscous flow, and heat conduction. By normal transport we mean transport that can be described macroscopically by linear relations between the currents of globally conserved quantities such as mass, energy, and/or momentum, and the gradients of the densities of these quantities. The coefficients of proportionality are transport coefficients, such as the coefficients of shear and bulk viscosity, thermal conductivity, diffusion, and so on. These coefficients, for normal transport, do not depend on time, but may depend on the local densities of mass and the local temperature of the fluid.

Helfand was able to show that each transport process may be regarded as a random walk process characterized by a linear growth as a function of time of the mean square fluctuation of a microscopic quantity, $M_\sigma(\Gamma, t)$, called a Helfand moment. The Helfand moments depend on all of the phase space variables of the system, now denoted collectively by Γ, and time t. For normal transport, the generalized Einstein relation becomes

$$\left\langle (M_\sigma(\Gamma, t) - M_\sigma(\Gamma, t = 0))^2 \right\rangle = \sigma C_\sigma t \,. \tag{7}$$

Here σ is a transport coefficient appearing in the Navier–Stokes or diffusion equations, C_σ is a constant, and the average is over an equilibrium ensemble. For diffusion of a Brownian particle, for example, the Helfand moment is simply the spatial location of the particle. This result implies that normal transport processes are essentially random walk processes with a generalized "displacement", namely the Helfand moment.

If we think of a system of particles, undergoing some kind of hydrodynamic flow as a deterministic dynamical system, with, typically but not exclusively, Hamiltonian dynamics, a deep question immediately presents itself: *Where does the randomness come from that is required for transport processes to be generalized random-walk processes?* While there are a variety of answers to this question, the main point of this article is to argue that for *chaotic systems* the randomness is an intrinsic property of the dynamics of the system [14], and then to illustrate some of the results that have been obtained recently which connect microscopic dynamics to macroscopic transport for such systems. We emphasize that many chaotic systems display the kind of randomness needed for good transport properties even though such systems are deterministic, and time reversible. However chaos is neither necessary nor sufficient for normal transport. There are examples of non-chaotic systems that exhibit normal diffusion The wind-tree model to be discussed below is an example [24,25]. There are also chaotic systems that exhibit abnormal transport. The two dimensional periodic Lorentz gas with circular scatterers is chaotic and exhibits both normal and abnormal diffusion, depending upon the lattice structure and the separation distance between neighboring scatterers [26,27].

Nevertheless, chaotic systems have sufficiently many nice properties that for them it is possible to obtain a number of rather, general connections between microscopic dynamics and macroscopic transport, and to understand the approach of systems to thermodynamic equilibrium from a dynamical standpoint. Such connections, should they exist, are not yet available for those non-chaotic systems which exhibit normal transport. The dynamical properties of most non-chaotic systems are not yet sufficiently well understood for the construction of a more or less general theory for generic connections between microscopic dynamics and macroscopic transport. Most realistic dynamical systems have a *mixed* phase space, where chaotic and non-chaotic regions, to be defined below, are intermingled [28,29]. It is generally supposed that for systems of large numbers of particles in macroscopic volumes, the non-chaotic regions occupy a very small part of phase space and can be ignored for all practical purposes. However this remains to be proved, and the effects of the non-chaotic regions require much more elucidation.

The plan of this article is as follows: We begin with a discussion of the foundations of statistical mechanics in Sect. "The Roles of Ergodicity and Mixing for the Approach to Equilibrium". There we discuss dynamical properties that are often considered to be important for statistical mechanics, such as ergodicity and mixing. There we argue that these properties, by themselves, are not sufficient to explain the approach to equilibrium of systems of large numbers of particles and that further notions are required. This will lead us in Sect. "Integrable, Pseudo-chaotic, and Chaotic Systems" to a discussion of some of the dynamical systems encountered in classical statistical mechanics, particularly integrable, pseudo-chaotic, and chaotic systems. In Sect. "Anosov and Anosov-like Systems; the Chaotic Hypothesis", we consider chaotic systems in more detail and show for a simple model of a chaotic system that the stochastic behavior needed for diffusion can be seen as a natural consequence of chaotic dynamics. Despite its simplicity and low dimensionality, this model will also allow us to provide a dynamical picture of the approach of a system to equilibrium. These models are simple examples of classes of dynamical systems called Anosov and Anosov-like systems. They have very useful mathematical properties for the description of non-equilibrium phenomena in simple systems, and it is convenient to assume, whenever possible, that the systems of interest to physicists have these good properties. These properties are then used for the applications of chaotic dynamics to non-equilibrium statistical mechanics in Sect. "Applications of Dynamical Systems Theory to Non-equilibrium". There we discuss a number of results that connect microscopic dynamical properties such as Lyapunov exponents and Kolmogorov–Sinai entropies [4,5,6,7,8,9,10,11,12,13,14] to macroscopic transport coefficients for chaotic systems. In Sect. "Discussion" we review the previous discussion and give brief comments about quantum systems, where the concepts of classical chaotic dynamics do not apply, but certain features of these systems can be understood in terms of the chaotic dynamics of their classical counterparts. Finally, we mention some future directions and open questions in Sect. "Future Directions".

The Roles of Ergodicity and Mixing for the Approach to Thermodynamic Equilibrium

Ergodic Systems

Boltzmann invented the notion of ergodicity in an attempt to reconcile the apparently irreversible behavior of large systems of particles, especially their approach to thermodynamic equilibrium, with the microscopic reversibility of

Newton's equations of motion [1,2,3]. Briefly put, Boltzmann argued as follows: Consider an isolated system of particles, and follow the system's trajectory on the appropriate constant energy surface in phase space. Suppose that the underlying microscopic dynamics of the system is such that the phase space trajectory of the system, over a long time interval, spends an amount of time in every region of phase space, A, that is proportional to the measure of that region, $\mu(A)$. Here the measure is the standard equilibrium phase space measure on a constant energy surface given by

$$\mu(A) = \int_A \frac{\mathrm{d}S}{|\nabla H|}\,, \tag{8}$$

where dS is the area of an infinitesimal region of the constant energy surface, and $|\nabla H|$ is the magnitude of the gradient of the Hamiltonian function for the system at the point of integration. Boltzmann's supposition above is called the *ergodic hypothesis*, and in mathematical terms it can be stated as [4]

$$\lim_{T\to\infty} \frac{\tau(A)}{T} = \frac{\mu(A)}{\mu(\mathcal{E})}\,. \tag{9}$$

Here $\tau(A)$ is the amount of time the system spends in region A during a time interval T, and $\mu(\mathcal{E})$ is the measure of the entire constant energy surface, which we assume to be finite. If one accepts the hypothesis, then one can easily show, by approximating integrals by sums, for example, that the *time average* of any well behaved dynamical quantity approaches its equilibrium, micro-canonical ensemble average as the time interval over which the average is taken approaches infinity. Boltzmann's hypothesis holds equally well for the time reversed motion of the system, and is consistent with the reversibility of the microscopic dynamics.

The kinds of elementary physical systems one studies in physics courses, such as coupled systems of harmonic oscillators, are generally not ergodic, although some simple systems, such as a single, one dimensional harmonic oscillator, can be shown to be ergodic. Another simple example is the discrete time motion of a point particle on the circumference of a circle, where the particle moves a fixed irrational fraction of the length of the circumference at successive time steps. In the long time limit, the circumference is uniformly covered by points visited by the particle [30]. A great deal of mathematical research over the past few decades, and longer, has been devoted to a study of more complicated ergodic systems. The first dramatic example of a system with ergodic properties, and one that has influenced most of the more recent efforts in this direction is the geodesic motion of a point on a surface of constant negative curvature. This was proved by E. Hopf [31], and the techniques employed remain useful today. Sinai and coworkers [32], as well as many other workers, particularly Simányi [33], have given careful mathematical proofs of ergodic behavior of various systems composed of hard disks or hard spheres, generally referred to as hard-ball systems. Turaev and Rom-Kedar, Donnay and others [28,29] have shown that by softening the hard sphere potential one may change an ergodic system into a non-ergodic one. Thus, the problem of proving that a system of interest to physicists is actually ergodic, or ergodic for practical purposes, is still far from a general solution.

Mixing Systems

Gibbs took a different approach to the problem of irreversibility. He used the analogy of an ink drop being stirred in a container of glycerin to introduce the stronger notion of a *mixing system* in his efforts to understand the approach of a non-equilibrium ensemble distribution function to an equilibrium distribution [4,8]. In considering a non-equilibrium phase space distribution one has to follow the trajectories of a set of points in phase space, not just a typical trajectory, as in the study of ergodic behavior. Gibbs suggested that the an initial set of points concentrated in a small region of phase space might spread out over the entire available phase space in the course of time, and become finely mixed throughout the phase space in much the same way as the ink drop will become mixed in the glycerin, in such a way that a coarse grained observation of the ink would lead to the conclusion that it is uniformly mixed, but a fine grained observation would reveal the individual threads of ink. Returning to phase space, Gibbs argued that although the measure of phase space occupied by the set of points should remain constant in time, in accordance with Liouville's theorem, the set eventually gets distributed over the constant energy surface such that a coarse grained observation of the phase space would lead to the conclusion that the set uniformly covers the energy surface, while a fine grained observation would reveal that the coverage consists of one long, thin set of total measure much less than that of the whole energy surface. Of course, mechanical reversibility ensures that one can recover the initial distribution of points by time reversing the motion but eventually mixing takes place for the time reversed motion, as well.

The mathematical definition of a mixing system [30] is given by looking at the time development of the initial set of phase points. We denote by A, the initial set of phase points on which the initial ensemble is concentrated, and the set to which this initial set evolves after a time T, by A_T. Then, to examine the mixing of the set in phase space, we consider some arbitrary set of positive measure B and consider the intersection $B \cap A_T$. If the dynamics of the system is mixing, then eventually the fraction of the set B occupied by A_T should approach the fraction of A in the entire phase space, no matter what sets of positive measure A and B we consider. That is, a system is mixing if for any sets A and B of positive measure

$$\lim_{T\to\infty} \frac{\mu(A_T \cap B)}{\mu(B)} = \frac{\mu(A)}{\mu(\mathcal{E})} \,. \tag{10}$$

Here we used the conservation of phase space measure, namely that $\mu(A) = \mu(A_T)$. One can easily prove that a mixing system is also ergodic, but the reverse need not be true [30].

For a system of particles with the mixing property one can prove that a non-equilibrium phase space distribution will approach an equilibrium phase space distribution in a *weak*, long time limit [8]. That is, average quantities taken with respect to the non-equilibrium distribution approach equilibrium averages. The proof can easily be constructed by approximating integrals by sums in the usual way.

Mathematicians have considered proofs of the mixing property for various systems of interest to physicists. The most important of such systems are hard ball systems mentioned above, where the proofs of ergodicity and mixing are consequences of proving a stronger dynamical property, the Bernoulli property of the system, which implies that the system is mixing and therefore ergodic as well. We leave a proper definition of a Bernoulli system to the literature [34] and we will not consider it any further here. Needless to say, the class of systems which can be proved to be mixing is not yet large enough to encompass the typical systems studied in statistical mechanics or in kinetic theory, although considerable progress has been made in this direction over the past several years.

What is the Relevance of These Notions for Statistical Mechanics?

It would appear that with the proof that a system of a large number of particles in a reasonable container is mixing, the foundation for the applications of statistical mechanics to such a system would be secure. That this is not a complete explanation may be seen for the following reasons, among others:

1. We have assumed that our systems have fixed energies and that all the forces acting between the particles or on the system, due to the walls of the container, say, are conservative and known. Strictly speaking, this is not true of any laboratory system.
2. We have not examined how long it might take for the time average to be reasonably close to the ensemble average for an ergodic system or how long it would take a reasonable initial set to get uniformly mixed over the appropriate phase space, for a mixing system. One can argue that the appropriate times are very long, typically very much longer than the duration of an experiment. A partial but useful answer to this objection to the use of ergodicity and/or mixing properties is to consider Reduced distribution functions, particularly the single particle and two-particle distribution functions. These reduced distribution functions approach equilibrium, or more generally, local equilibrium forms, on much more realistic time scales.
   The notion of local equilibrium arises in the context of the decay of a non-equilibrium state in a many particle system to total equilibrium, through hydrodynamic processes. In the usual picture, due to Chapman, Enskog, and Bogoliubov [35,36], the initial state becomes, on the time scale of the duration of a collision, one that can be described by reduced distribution functions. Then on the time scale of the time between collisions, set by the microscopic properties of the system such as the density and the size of the particles, the system becomes close to a state of local equilibrium with a local temperature, density and mean velocity. Finally, on a time scale set by the physical size of the container, the system relaxes to total equilibrium. The approach to local equilibrium is set by the dynamical interactions between the particles.
   In addition, many non-equilibrium as well as equilibrium properties of a many-particle system can be formulated in terms of these reduced functions. This being the case, the questions are: What is the reason that reduced distribution functions approach local equilibrium forms, and what are the time scales involved in the approach to local equilibrium, and eventually to total equilibrium? For chaotic systems, at least, there is reason to believe that one can provide satisfactory answers to these questions.
   Another approach to resolving the issue of time scales in applying these notions to laboratory systems, and one closely related to the use of reduced distribution functions is to focus attention on a set of microscopic variables called *normal variables* [1]. These variables are defined by the requirement that they not vary much over the constant energy surface. These variables then have the property that their value is almost the same

no matter where the phase point happens to be on the constant energy surface. In this picture an initial nonequilibrium state would be one where the values of the normal variables are far from their equilibrium or average values, but the time evolution of the system leads to regions where these variables have values closer to their equilibrium averages. In this picture the relevant time scale is the average time needed for the system to evolve to regions of phase space where the normal variables are close to their average values. Presumably this time will be much shorter than the time needed for the trajectory to cover the phase space. However, we need a detailed description of these variables and a description of their behavior as a system approaches local, then total equilibrium via kinetic and hydrodynamic processes, respectively. In the absence of such an understanding of normal variables, in general, the reduced distribution functions provide a clearer way to address the questions of time scales for the approach of distribution functions to their equilibrium values.

One can imagine, that both the reduced distribution resolution and the normal variable resolution of the time scale issue become easier to justify as the number of degrees of freedom, or the number of particles become large. In either case, although the phase space measure will also grow, and the time needed to cover it will increase, the relative fluctuations in the reduced distribution functions and normal variables will become smaller. It should be emphasized that the notions of ergodicity and mixing have an important role to play in statistical mechanics, despite the issues raised here concerning the time needed for covering the full phase space. Using ergodicity one can motivate the use of the micro-canonical ensemble and ultimately all of the Gibbs ensembles that provide methods for computing equilibrium properties of systems. Similarly, the mixing property can be used to show that time correlation functions decay in time, an important property needed for many applications of non-equilibrium statistical mechanics, particularly for the Green–Kubo formalism [2,3].

3. We have used classical mechanics as our description of dynamics, but nature is fundamentally quantum mechanical.

In the following sections we will address point (2) in some detail, and point (3), briefly. It is important to note, however, that the answers we shall provide, while encouraging, are very incomplete and much more work needs to be done to make these answers believable and secure. Here we consider point (1). As mentioned in the previous section, in order to produce a random walk of the Helfand moments needed for normal transport, some sort of stochastic or stochastic-like mechanism is required. Possible sources of stochastic behavior could be random external influences or some built-in structural randomness, however subtle and difficult to identify. Evidence for the effectiveness of built-in randomness is provided by a useful model of a statistical system, such as the Ehrenfest wind-tree model [24] where diamond shaped scatterers (trees) are placed at random in a plane, with their diagonals aligned parallel to the x- and y-axes. Then point particles (wind) move among the trees with velocities only in the $\pm x$ and $\pm y$ directions. The random placement of the trees provides a clear stochastic mechanism leading to normal diffusion and an approach to equilibrium and thereby simulate a mixing system. Such systems are not chaotic and some source of randomness beyond the dynamics is necessary for normal transport in such non-chaotic models. Moreover there are periodic versions of the wind-tree model that also exhibit normal diffusion [12,25], with more subtle sources of randomness, possibly connected with the splitting of two nearby trajectories at the corners of the scatterers. Below we turn our attention to the case of chaotic systems and argue that for such systems, the dynamics can be enough to allow normal transport and the approach of an ensemble of such systems to equilibrium, even when the system is spatially periodic.

Integrable, Pseudo-chaotic, and Chaotic Systems

The kind of systems one studies in courses on classical mechanics are typically *integrable system*. These are systems with N canonical coordinates, N canonical momenta, and N independent constants of the motion [2]. The canonical coordinates of such systems can be transformed to a set of action-angle variables, and when expressed in these variables, the systems become quasi-periodic in time, and the motion is confined to regions in phase space called invariant tori. Systems of coupled harmonic oscillators are good examples of integrable systems. There is another class of mechanical systems, of which the Ehrenfest wind-tree model described above is an example, called *pseudo-chaotic* systems [37]. These systems have the property that two infinitesimally close trajectories will separate algebraically with time, for sufficiently long times. For example, two distinct trajectories moving in initially parallel directions in a wind-tree system will eventually separate algebraically with time, no matter how close they are to each other initially, due to the random placement of scatterers and the fact that one of the two trajectories will eventually hit a scatterer that is "just missed" by the other one. Pseudo-chaotic systems have a *weak mixing* property [30,37], namely that

$$\lim_{T\to\infty} \frac{1}{T}\int_0^T \mathrm{d}\tau \left[\mu(A_\tau \cap B) - \frac{\mu(A_\tau)\mu(B)}{\mu(\mathcal{E})}\right] = 0\,. \quad (11)$$

Chaotic systems are usually defined by the condition that two infinitesimally close trajectories will, in the appropriate long time limit, separate exponentially [4]. We will give a more careful discussion of chaotic systems in the next section.

Anosov and Anosov-like Systems; the Chaotic Hypothesis

Earlier in this discussion we argued that the notions of ergodicity and mixing are not, in themselves, fully sufficient for understanding the approach to thermodynamic equilibrium for systems of many particles due to problems of time scales. In addition we argued that in many cases reduced distribution functions may very well be better indicators of the approach to equilibrium than the full phase space distribution function. We also suggested that for chaotic systems at least, these observations can be verified to the extent that we can make some more detailed statements concerning the approach to equilibrium and transport properties. Here we will provide some justification for these comments.

It is helpful to consider simple model systems that display the kind of irreversible behavior that we would like to be able to describe for more realistic, many particle systems. Two model systems that have this feature are the baker's map [31,38] and the Arnold Cat Map, which itself is an example of more general models called hyperbolic toral automorphisms [14]. We will explain this terminology as we proceed.

The baker's map is a map of a two dimensional "unit square", $0 \le x, y \le 1$ onto itself, given by (see Fig. 1)

$$\begin{aligned} \begin{pmatrix} x' \\ y' \end{pmatrix} &= \begin{pmatrix} 2x \\ y/2 \end{pmatrix} \quad \text{for } 0 \le x \le 1/2\,; \\ \text{and} \quad &= \begin{pmatrix} 2x-1 \\ (y+1)/2 \end{pmatrix} \quad \text{for } 1/2 < x < 1\,. \end{aligned} \quad (12)$$

This map consists of a stretching of the square in the x-direction by a factor of 2, and squeezing in the y-direction by a factor of 1/2. The elongated image of the unit square is then cut in half and the right side is put on top of the left side so that a unit square is reconstructed, after each application of the map. Of course this is an area preserving map, and it has a discontinuity at $x = 1/2$.

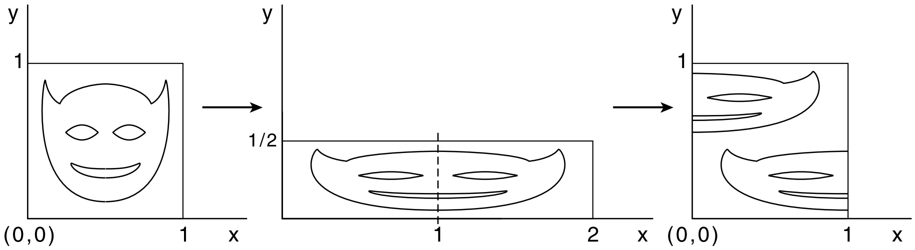
Suppose the x, y-plane is our (two-dimensional) phase space and the motion of a phase point is confined to the unit square. We now apply some of the usual techniques of statistical mechanics to baker-map distribution functions defined on the unit square. The phase space distribution function changes at each time step according to

$$\begin{aligned} \rho_n(x, y,) &= \rho_{n-1}(x/2, 2y) \quad \text{for } 0 \le y \le 1/2\,; \\ \text{and} \quad &= \rho_{n-1}((x+1)/2, 2y-1) \quad \text{for } 1/2 < y < 1\,. \end{aligned} \quad (13)$$

For statistical mechanics, we often are interested in the reduced distribution functions of fewer variables. Here there are only two variables, so we consider the reduced distribution function, $W_n(x)$ obtained by integrating $\rho_n(x, y)$ over the y coordinate. Using Eq. (13), we obtain the equation [38]

$$W_n(x) = \frac{1}{2}\left[W_{n-1}\left(\frac{x}{2}\right) + W_{n-1}\left(\frac{x+1}{2}\right)\right]. \quad (14)$$

If one assumes that the initial value, $W_0(x)$, of the reduced distribution function is a reasonably smooth function of x, for example, if it can be represented by a convergent Fourier series, then $W_n(x)$ approaches a constant value as $n \to \infty$! The reason for this is that Eq. (14) says that the



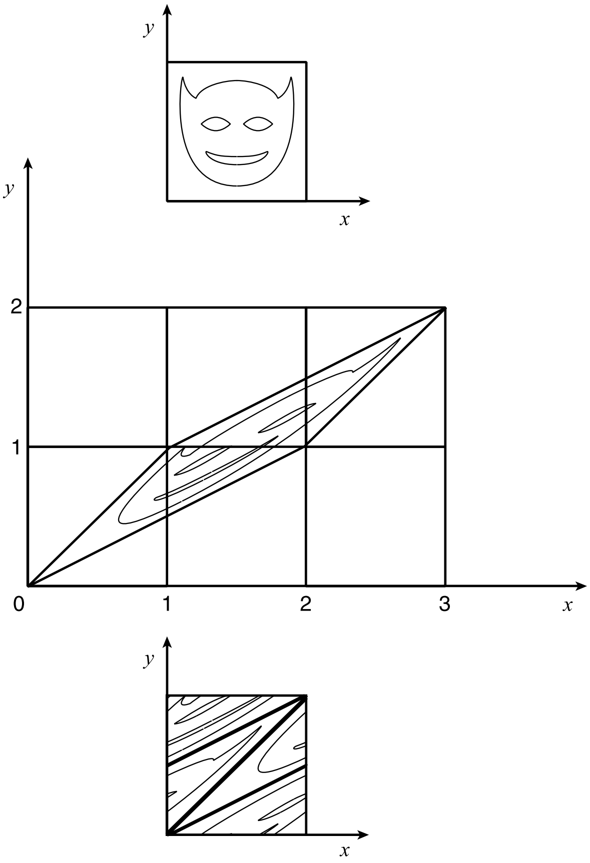
Chaotic Dynamics in Nonequilibrium Statistical Mechanics, Figure 1
The baker's map: The unit square is mapped onto itself by stretching by a factor *2* in the *x*-direction and by a compression by a factor of 1/2 in the *y*-direction. This is followed by cutting and re-arranging the resulting rectangle

reduced distribution at time n at a point x is the average value of the distribution at two points, $x/2$ and $(x+1)/2$ at the previous time, $n-1$. This averaging, if carried on long enough, produces a function which is constant in x. One can readily estimate the time it takes to reach this uniform state in the following way. Suppose that $l < 1$ is some length scale on which $W_0(x)$ varies with x. Then since the baker's map stretches sets of length l into sets of length $2l$ we can estimate the time to reach equilibrium as the time it takes a set of length l to be stretched to a set of length 1, which is $(-\ln l)/(\ln 2)$. This can be much shorter than the time it takes for the ergodic or mixing properties of the baker's map to make themselves manifest, which takes an additional time of order $\ln N/\ln 2$ to produce N horizontal strips of unit length, stacked in the y-direction. If we were to consider the reduced distribution function in the y variable, we would not get a nice equation with a distribution function that approaches equilibrium. Why that is so will be clear in a moment.

We have not introduced any stochastic features into our derivation of Eq. (14), but only integrated the Liouville equation over one of the variables. Thus we have been able to start from the Liouville equation, and by introducing nothing but an initial condition and integrating over the appropriate number of unmeasured variables, obtain an irreversible equation for a reduced distribution function which approaches equilibrium. Incidentally, the quantity $S = -\int_0^1 \mathrm{d}x\, W_n(x) \ln W_n(x)$ exhibits a monotonic increase with time n [8].

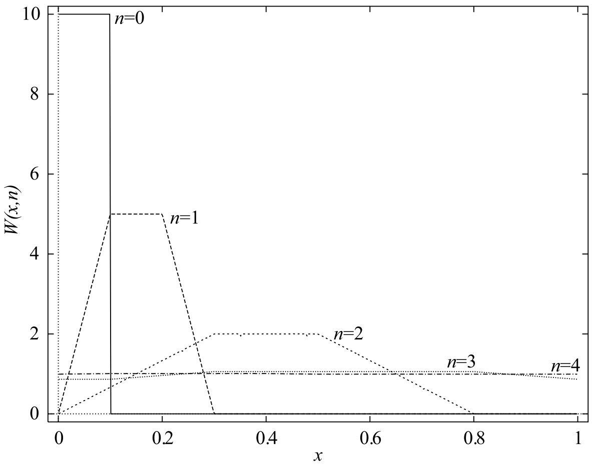
Our analysis of the approach to equilibrium of the function $W_n(x)$ made strong use of the stretching nature of the map in the x-direction. To get some further insight into the importance of the stretching of the phase space regions, we consider another model, the Arnold Cat Map [14] (see Fig. 2). Here the unit square, with opposite sides identified, represents a torus. This transformation maps the torus (that is, there is no cutting and moving of any section as there is in the baker's map) onto itself and may be described by a 2×2 matrix with unit determinant and integer elements. Such maps are called *toral automorphisms* [14], of which the Cat Map is a specific example. This map has an additional, *hyperbolic*, property, namely, that one of its eigenvalues be greater than unity. It follows from the fact that the determinant is unity, that the other eigenvalue is less than unity, and the product of the two is 1. The standard version of the map is given by the symmetric matrix

$$\begin{pmatrix} x' \\ y' \end{pmatrix} = \mathbf{T} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix}, \quad \text{modulo } 1. \tag{15}$$



Chaotic Dynamics in Nonequilibrium Statistical Mechanics, Figure 2
The Arnold Cat Map of the unit torus onto itself

The eigenvalues of $\mathbf{T}$ are $(3 \pm \sqrt{5})/2$. The eigendirections are perpendicular to each other, and make non-zero angles with the x- and y-axes. There is a stretching direction which corresponds to the direction of the larger eigenvalue, and a contracting direction which corresponds to the smaller eigenvalue. While the equation for the projection of the "phase space" distribution function onto the x- or y-directions is not as simple as that for $W_n(x)$ given above, it is not difficult to write a computer program which shows the values of these projections after a few time steps, starting with some initial distribution on the unit torus. Figures 3 and 4 show the behavior of the projected distribution functions, $W_n(x)$ and $G_n(y)$, onto the x- and y-directions, respectively, for an initial set of points that is uniform over the region $0 \leq x, y \leq 0.1$ and zero everywhere else. Both these distribution functions become uniform after three or four time steps. In Figs. 4 and 5, we show the evolution of the phase space distribution function at some of the same times. Here we clearly see the difference on



Chaotic Dynamics in Nonequilibrium Statistical Mechanics, Figure 3
The projection of the Cat Map distribution onto the x-axis, $W_n(x)$, at various times, n. By $n = 3, 4$ the distribution is essentially uniform

the rate of evolution of projected vs. full phase space distribution functions, and why, for simple models at least, the notions of ergodicity and mixing demand more than is physically required for an approach to equilibrium for the reduced distribution functions.

The important feature that both the baker's map and the cat map have in common is that they are both area preserving maps with a stretching direction, or *unstable* direction, and a contracting direction, called a *stable* direction [14]. These directions are associated with *stretching* and *contracting* factors that depend exponentially upon time. The logarithms of these factors per unit time are the *Lyapunov exponents* [4,6,14,39]. For the baker's map the two Lyapunov exponents are $\lambda_{\pm} = \pm \ln 2$, and for the cat map above, the two Lyapunov exponents are $\lambda_{\pm} = \ln[(3 \pm \sqrt{5})/2]$. In general, for higher dimensional systems, the stable and unstable directions span the so-called stable and unstable manifolds, respectively. For the baker's map the y-axis and the x-axis are stable and unstable manifolds, respectively, for the baker's map, as are the axes in the eigen-directions of the cat map. The importance of the unstable manifolds resides in the fact that on them non-uniform functions become smoothed with time, if they are not too singular, on a time scale that is determined by the positive Lyapunov exponents. In order to get a reduced distribution function that approaches an equilibrium distribution for long enough times, one clearly must project the Liouville distribution onto manifolds that are not orthogonal to all of the unstable directions. This is one reason to examine the Cat Map, namely, to show that projections onto either direction, x or y equally lead to a uniform distribution after a few time steps. This would be the case for the baker's map, if we were to project on any direction that makes a non-zero angle with the y-direction. Generally, the unstable directions in phase space are so complex that practically any projected distribution will not be orthogonal to them. Under time reversal the unstable and stable manifolds are interchanged, and the picture remains essentially the same. It is worth mentioning that if we were to project the distribution function onto a stable manifold we would not obtain an equilibrium distribution function, but rather a very complicated function since any irregularities in the initial distribution function become more irregular with time, along stable directions [6,8,40,41]. This is why a projection onto the y-axis would not lead to an equilibrium distribution for the baker's map, without some sort of coarse graining to "smooth out" an otherwise singular function.

Dynamical systems that have properties similar to the cat map or the baker's map are called *Anosov* or *Anosov-like* systems, respectively [6,14,18]. *Anosov* systems are continuous dynamical systems such that at every point in phase space there are stable and unstable directions, with positive and negative Lyapunov exponents, respectively. There may also be some *neutral* directions with zero Lyapunov exponents, but there must be at least one positive Lyapunov exponent. The presence of positive Lyapunov exponents is characteristic of a *hyperbolic* system. Furthermore there must be at least one trajectory in phase space that is dense, a requirement which is called *transitivity*. Systems of particles with some manageable singularities such as hard spheres are not strictly Anosov systems but are close enough to be considered *Anosov-like*. The Arnold Cat Map is an example of an Anosov system, while the baker's map is Anosov-like. Of course in a multidimensional Anosov system, there are a number of stable and unstable directions, and all stable manifolds intersect all unstable manifolds transversally. Systems with at least one positive Lyapunov exponents are commonly referred to as being *chaotic*. We have chose simple systems to illustrate the main ideas, but the reader should be aware that it is possible to define Lyapunov exponents for motion on invariant sets in phase space, even for sets of measure zero, such as periodic orbits, or as we discuss below, fractal repellers.

Returning to statistical mechanics, we see that the simple examples of the baker's map and the Cat Map give us some reason to believe that, for chaotic systems at least, reduced distribution functions will approach equilibrium values, or more precisely, local equilibrium values, on reasonable time scales. This conclusion depends, of course, on the assumption that the underlying microscopic dynamics is of the Anosov or Anosov-like variety. It is therefore useful to assume that systems of large numbers of particles with short ranged interactions, of general interest for statistical mechanics, are ergodic, Anosov-like systems as far as their dynamical properties are concerned. This assumption has been made a central feature of the dynamical systems approach to non-equilibrium statistical mechanics by Gallavotti and Cohen [18], who have called it *the chaotic hypothesis*. This hypothesis allows one to apply the results of chaotic dynamics, such as those discussed in the next section, to realistic systems. In actuality we know little a priori about the dynamics of such systems, such as their Lyapunov exponents, or the structure and properties of unstable and stable manifolds in phase space. Furthermore, due to the work of Turaev, Rom-Kedar, Donnay [28,29], and others, we know that if the intermolecular potential is smooth, there may exist regions in phase space where the dynamics is not chaotic. For these systems, the chaotic hypothesis implies the additional statement that the total volume of the non-chaotic regions in phase space is small enough so that for determining the important averages, they can be ignored.

Fractal Dimensions

An important concept used in applications of dynamical systems theory to statistical mechanics, among many other applications, is the notion of *fractal dimensions*. As we will mention in the next section, for chaotic systems many of the connections between macroscopic transport coefficients and microscopic dynamical quantities such as Lyapunov exponents can be related to the dimensions of fractal structures that form in the phase spaces of nonequilibrium systems. Generally, but not exclusively, fractals are defined by the statement that their dimension is not an integer. However, this definition is complicated by the fact that there are many ways to define the dimension of a set, and some fractals may have a dimension that is an integer by some definition and non-integer by others. Fractals that have a variety of different dimensions are referred to as *multifractals*. There are also other definitions of fractals based upon self-similarity at all scales, or upon differentiability and continuity properties. We refer to the literature for more details [42].

In order to present one definition of the fractal dimension of a set, imagine that the set is embedded an a d-dimensional space. Cover the set with cubes of length ϵ on a side, each labeled by an index i and suppose that one needs at least $N(\epsilon)$ of these cubes for a full coverage. Suppose further that we have a way to assign a measure μ_i to each cube. We can suppose that the total measure is normalized to some constant, say unity,

$$\sum_{1}^{N(\epsilon)} \mu_i = 1 \,. \tag{16}$$

The measure μ_i may be a normalized Lebesgue measure of the cube, or it may be the fraction of time that a typical trajectory on the fractal spends in cube i, for example. In terms of this measure we can define a dimension D_q that depends on a continuous variable q, as

$$D_q = \frac{-1}{1-q} \lim_{\epsilon \to 0} \frac{I(q,\epsilon)}{\ln \epsilon} \,, \tag{17}$$

where $I(q,\epsilon)$ is given by

$$I(q,\epsilon) = \sum_{i=1}^{N(\epsilon)} \mu_i^q \,. \tag{18}$$

In this construction the quantity, D_0 is called the *box-counting dimension*, D_1 is called the *information dimension*, and D_2 is called the *correlation dimension*. The dimension D_q is a monotonic non-decreasing function of q. Other dimensions frequently employed to characterize fractals include the *Hausdorff dimension*, and we refer to the literature for a careful definition and discussion of this and other dimensions. As an example of a fractal, consider the *middle third Cantor Set*. This set is constructed by taking a unit interval, discarding the middle third of it, then take each of the two remaining pieces, discarding the middle third of each of them, and so on. It is easy to show that the dimensions, D_q, of the remaining set, are all equal to $\ln 2/ln 3$.

Applications of Dynamical Systems Theory to Non-equilibrium Statistical Mechanics

The connections between normal transport, random walk processes, and the generalized Einstein formulae have allowed results from dynamical systems theory to be applied to non-equilibrium statistical mechanics in a direct way, at least for chaotic systems. However, one must study transport processes in a way that takes advantage of the fundamental properties of chaotic dynamics. Among the useful properties of chaotic systems are the formation of fractal structures in phase space. If the phase space is of sufficiently low dimensions then the fractal structures can be studied both by analytical methods and by computer simulated molecular dynamics. In addition to providing some insights into the approach to equilibrium for large systems, the dynamical systems approach gives us deep results of a more practical sort. Among these results are: (i) relations between transport coefficients and dynamical quantities, such as Lyapunov exponents and Kolmogorov–Sinai entropies, to be defined below [5,6,7,8,9,12,42,43,44,45,46]; (ii) a theory of entropy production in non-equilibrium steady states and in the approach of a system to equilibrium [5,6,7,8,9,10,16,17,18,20,40,49,50,51,52,53,54]; and (iii) a number of fluctuation theorems – Evans–Searles–Gallavotti–Cohen theorems – which describe fluctuations in entropy production in non-equilibrium steady states [16,17,18,19,20,21,52,55]. Here we will summarize these results, and we refer the reader to the literature for a more complete discussion of these and related topics.

Microscopic Dynamical Quantities and Macroscopic Transport Coefficients

Among the many reasons dynamical systems theory attracted the attention of workers in non-equilibrium statistical mechanics were the connections between macroscopic transport coefficients of a system of particles and quantities that characterize the system's chaotic behavior discovered by Gaspard and Nicolis [6,8,43,44,45,46,47], for Hamiltonian systems, and by Evans, Morriss, Hoover, Posch, and coworkers, for dissipative systems with Gaussian thermostats [5,7,9,12,48,49]. We discuss each case separately.

The Escape-Rate Formulae for Transport Coefficients Previously we noted that the Helfand moments related to transport undergo a random walk motion in phase space. Gaspard and Nicolis pointed out that if one considers a random walk in a space with *absorbing* boundaries one can combine results from random walk theory and from dynamical systems theory to obtain very interesting previously unknown connections between transport coefficients and quantities that characterize the microscopic chaotic dynamics.

The random walk theory that one needs for this connection is based on a Fokker–Planck equation for the probability distribution of the Helfand moments, $P(M_\sigma, t)$, where M_σ is a Helfand moment. We assume that the transport process is normal, that is, that the mean square fluctuations of the Helfand moment grows linearly with time. In such a situation the Fokker–Planck equation takes the simple form of a diffusion equation:

$$\frac{\partial P(M_\sigma, t)}{\partial t} = \alpha \frac{\partial^2 P(M_\sigma, t)}{\partial M_\sigma^2} \tag{19}$$

Here α is a constant proportional to the transport coefficient σ. Suppose now that we solve this diffusion equation in M-space with boundary conditions that when M_σ reaches the values $\pm\chi/2$, $P(M_\sigma, t) = 0$. That is, the Helfand moments undergo a Brownian motion in a space with absorbing boundaries such that the probability distribution vanishes whenever $|M_\sigma|$ reaches a specific value for the first time. Under these conditions, the probability distribution will decay exponentially, with a decay rate γ

given by

$$\gamma = \alpha \left(\frac{\pi}{\chi} \right)^2 . \tag{20}$$

A remarkable result from dynamical systems theory is that for chaotic systems, another expression holds for the same escape rate in terms of Lyapunov exponents and a quantity called the Kolmogorov–Sinai entropy per unit time [6,14,56,57]. This microscopic escape-rate formula for the escape-rate, γ_{mic} is

$$\gamma_{\text{mic}} = \sum_i \lambda_i^+(\mathcal{R}) - h_{\text{KS}}(\mathcal{R}) . \tag{21}$$

All of the terms on the right hand side of Eq. (21) require some explanation. To get some insight into this formula, we now consider the microscopic dynamics of the system of particles and imagine that there is a set of initial conditions for all the particles for which the Helfand moment is in the region $-\chi/2 < M_\sigma < \chi/2$, and such that as the initial system evolves in time, either forward or backward, the Helfand moment will never reach the boundary. The set of all such initial conditions is called a *repeller* and denoted by $\mathcal{R}$. It is typically a fractal set of points in phase space, usually of measure zero in the set of all initial phase points, and a highly unstable set since an arbitrarily small displacement of the initial phase of the system from a point in $\mathcal{R}$ will lead to escape, unless the new initial point is also on the repeller. Now imagine that we consider an infinitesimally small set of points in $\mathcal{R}$, and observe how these points separate in phase space in the course of time. If the dynamics on $\mathcal{R}$ is Anosov-like, there will be a set of positive Lyapunov exponents which we have denoted by $\lambda_i^+(\mathcal{R})$ in Eq. (21). The positive Lyapunov exponents on the repeller describe the rate with which trajectories on the repeller move apart. apart. The other term in the escape-rate formula, $h_{\text{KS}}(\mathcal{R})$, is the Kolmogorov–Sinai entropy per unit time of the trajectories on $\mathcal{R}$, and can be understood in the following way. In general, dynamic entropies characterize the rate at which information about the exact trajectory of a system is gained or lost in the course of time. For example, if we know that the initial phase of a system is within some small region of phase space, then the *stretching* of the small region with time due to the dynamical instability allows us to locate the initial location of the trajectory ever more precisely as we follow the motion of the small initial set. If the system is closed, that is, there is no possibility of escape, then the amount of information about the initial location of the trajectory grows exponentially as the sum of the positive exponents. This result is known as Pesin's theorem. On the other hand, if the system is open and there is a possibility of escape, then the escaping trajectories lead to a loss of information [58]. Hence a better way to write Eq. (21) is

$$h_{\text{KS}}(\mathcal{R}) = \sum_i \lambda_i^+(\mathcal{R}) - \gamma_{\text{mic}} . \tag{22}$$

In any case we now have two expressions for the same escape-rate for a hyperbolic system, and by equating them, we obtain an expression for the transport coefficient in terms of microscopic dynamical quantities, as

$$\alpha = \lim_{\chi \to \infty} \frac{\chi^2}{\pi^2} \left[\sum_i \lambda_i^+(\mathcal{R}) - h_{\text{KS}}(\mathcal{R}) \right] . \tag{23}$$

We have taken the large system limit to remove any possible dependence of the right hand side of Eq. (23) on the shape of the boundaries or on the size of the system. This result is due to Gaspard and Nicolis [43].

For two dimensional systems, one can reformulate the escape rate formula in terms of the information dimension, d_1, of the repeller along the unstable direction [6,59], which is given by $d_1 = h_{\text{KS}}/\lambda^+$, so that $\gamma = \lambda^+(1 - d_1)$.

The escape-rate formula has been used in molecular dynamics studies to obtain values for transport coefficients in a number of cases such as diffusion coefficients in periodic Lorentz gases, viscosities of simple systems and chemical reaction rates [27,47,60,61,62]. The results for the transport coefficients obtained by using the escape-rate methods agree with those obtained by other methods, often based on the Green–Kubo time correlation method, or, as discussed below, on Gaussian thermostat methods. There are as yet very few theoretical methods to compute the Kolmogorov–Sinai entropy for the repeller [6,27,47], while both the transport coefficients, and, as it turns out, the sum of the positive Lyapunov exponents on the repeller are sometimes amenable to treatment by the usual methods of statistical mechanics and kinetic theory [63,64,65].

Transport Coefficients and Phase-Space Contraction in Gaussian Thermostatted Systems An alternative method for relating macroscopic transport coefficients to Lyapunov exponents was developed by Evans, Hoover, Posch and co-workers in their work on developing computer algorithms to simulate non-equilibrium flows in many-particle systems [5,7,9,48,49,66,67,68,69,70,71,72,73,74,75]. A problem arose in these simulations because the systems tended to heat up considerably due to the presence of viscous friction or, for charged particle systems, ohmic heating. To counteract this heating, these authors introduced a fictitious thermostat which maintains a constant value for either the total energy or the total kinetic energy of the system. The thermostat was introduced by a modification of the equations of motion by the addition of a frictional force in such a way that the Hamiltonian nature of the system, in the usual coordinate, momentum, and time variables, is lost. This kind of frictional force was first introduced by Gauss in his study of mechanical systems with various constraints.

For systems with Gaussian thermostats, Liouville's theorem, which states that the phase space density at a point moving under the equations of motion does not change with time, is no longer satisfied. It is replaced by a conservation equation that relates the time derivative of the distribution function to the parameters characterizing the frictional forces. As a consequence phase space volumes for thermostatted systems do not remain constant in time, but rather, on the average the phase space volume of a set decreases with time, the system approaches a *non-equilibrium* stationary state, and the system's distribution function approaches a distribution with fractal properties. The average rate of decrease of the phase space volume is given by a negative value of the sum of all of the Lyapunov exponents of the system. The non-equilibrium stationary state distribution is characterized by a special type of measure, called a Sinai–Ruelle–Bowen (SRB) measure, which describes the probability of finding a system in different regions of phase space. The SRB measure is characterized by the fact that it is smooth in the unstable directions in phase space but typically is fractal in the stable directions [14]. Simple examples of this type of measure can be found in the literature [41]. The resulting fractal is called an *attractor*.

It is important to note that the decrease of the phase space volume and the concomitant formation of an attractor with a non-trivial SRB measure, does not mean that the fractal has zero dimension. Indeed due to the decrease in phase space volume the *Lebesgue measure* of the phase space region where the trajectories are located approaches zero. However the dimension of the resulting fractal is not zero. The box counting dimension, D_0, of the fractal may even coincide with the dimension of phase space, and the information dimension, D_1, can often be expressed in terms of the Lyapunov exponents. For example for two-dimensional, thermostatted systems, with one positive Lyapunov exponent, λ^+ and one negative exponent, $-|\lambda^-|$, with $\lambda^+ - |\lambda^-| < 0$, the information dimension of the attractor is given by the *Kaplan–Yorke–Young formula* [4,42,69,71] for two dimensional ergodic systems, as $D_1 = 1 + \lambda^+/|\lambda|$.

The decrease of the phase space volume can also be related to the entropy production in the system+thermostat. This entropy production can also be related to the transport coefficients via the usual macroscopic laws of irreversible thermodynamics. Thus one has a way to relate transport coefficients to the sum of the Lyapunov exponents for these thermostatted systems.

To make this discussion more concrete, we consider the example of a hard-ball Lorentz gas [53,69,70,74,75]. We assume that the moving particles have a bounded free path between collisions with the fixed scatterers, and that the scatterers do not form traps without escape for the moving particles. We suppose the moving particles have mass. m, and carry a charge, q, (but still do not interact with each other) and are placed in a constant, external electric field, $\boldsymbol{E}$. Ordinarily, the field will accelerate the moving particles in such a way that their energy increases over time. To avoid this we add a frictional force to the equations of motion of the moving particle, and adjust the frictional force so as to keep the kinetic energy of the moving particle constant in time. The equations of motion for the position, $\boldsymbol{r}$ and velocity, $\boldsymbol{v}$, of the moving particle between collisions with scatterers are

$$\dot{\boldsymbol{r}} = \boldsymbol{v} \tag{24}$$

$$\dot{\boldsymbol{v}} = \frac{q\boldsymbol{E}}{m} - \alpha\boldsymbol{v}\,, \tag{25}$$

where α is a dynamical variable defined by the constant energy condition, $\dot{\boldsymbol{v}} \cdot \boldsymbol{v} = 0$. Thus we find that

$$\alpha = \frac{q\boldsymbol{v} \cdot \boldsymbol{E}}{m\boldsymbol{v}^2}\,. \tag{26}$$

The equations of motion given above for the moving particle must be supplemented by the equations describing the collisions of the moving particles with the scatterers. To simplify matters, we will suppose that the particles make instantaneous, elastic, and specular collisions with the scatterers.

If we define the Gibbs entropy for this system in terms of the phase space distribution function, $\rho(\boldsymbol{r}, \boldsymbol{v}, t)$, by

$$S_G(t) = -k_{\mathrm{B}} \int \mathrm{d}\boldsymbol{r} \int \mathrm{d}\boldsymbol{v}\rho(\boldsymbol{r}, \boldsymbol{v}, t)[\ln \rho(\boldsymbol{r}, \boldsymbol{v}, t) - 1]\,, \tag{27}$$

where k_{B} is Boltzmann's constant, one finds that

$$\frac{\mathrm{d}S_G}{\mathrm{d}t} = -k_{\mathrm{B}} \int \mathrm{d}\boldsymbol{r} \int \mathrm{d}\boldsymbol{v}\alpha\rho = -k_{\mathrm{B}}\langle\alpha\rangle\,. \tag{28}$$

The average value is taken with respect to the phase space distribution function for the moving particles, ρ. This entropy actually decreases with time, since on the average α is positive. This decrease in entropy must be matched, at least, by an increase in entropy of the reservoir that is responsible for the additional frictional force. Thus

$$\frac{\mathrm{d}S_{\text{reservoir}}}{\mathrm{d}t} \geq k_{\mathrm{B}}\langle\alpha\rangle \geq 0\,. \tag{29}$$

We now take the entropy production in the reservoir to be given by the usual macroscopic laws, in particular,

$$\frac{\mathrm{d}S_{\text{reservoir}}}{\mathrm{d}t} = \frac{\boldsymbol{J}\cdot\boldsymbol{E}}{T} = \frac{\sigma\boldsymbol{E}^2}{T}\,, \tag{30}$$

where $\boldsymbol{J} = \sigma\boldsymbol{E}$ is the electrical current produced by the moving particles and σ is the coefficient of electrical conductivity. Then, by combining Eqs. (29) and (30), and assuming that we take the entropy production in the reservoir to be exactly $k_{\mathrm{B}}\langle\alpha\rangle$, we obtain and expression for σ as

$$\sigma = \frac{k_{\mathrm{B}}T\langle\alpha\rangle}{\boldsymbol{E}^2}\,. \tag{31}$$

The final step in this process is to relate the average friction coefficient, $\langle\alpha\rangle$, to the Lyapunov exponents for the trajectories of the moving particles. We note, first of all, that the volume, $\mathcal{V}$ of a small region in phase space will change exponentially in time with an exponent equal to the sum of all the Lyapunov exponents, as

$$\mathcal{V}(t) = \mathcal{V}(0)\exp\sum_i \lambda_i\,, \tag{32}$$

since the Lyapunov exponents describe the rates of stretching or of contracting of small distances in phase space. A simple argument shows that

$$\left\langle\frac{\mathrm{d}\ln\mathcal{V}}{\mathrm{d}t}\right\rangle = -\langle\alpha\rangle = \left\langle\sum_i \lambda_i\right\rangle\,. \tag{33}$$

In the non-equilibrium stationary state, all averages remain constant with time, so that we can now use Eq. (31) to obtain the desired connection between a transport coefficient, in this case the conductivity σ, and the average Lyapunov exponents,

$$\sigma = -\frac{k_{\mathrm{B}}T}{\boldsymbol{E}^2}\left\langle\sum_i \lambda_i\right\rangle\,. \tag{34}$$

This result has been used to determine the conductivity and the diffusion coefficient of the moving particles in the Lorentz gas by means of efficient computer algorithms for determining the Lyapunov exponents [70,74,75]. Similar methods have been used to determine the shear viscosity [48] and other transport properties of systems with short range, repulsive potentials.

One important result of the analysis of these thermostatted systems is the *conjugate pairing rule*. This is a generalization of the result for chaotic Hamiltonian systems that non-zero Lyapunov exponents come in pairs, with the same magnitude but with opposite signs so that members of each conjugate pair sum to zero [42]. This is called the *symplectic conjugate pairing rule*. For many chaotic systems with Gaussian thermostats it is possible to prove another conjugate pairing rule where the Lyapunov exponents form conjugate pairs which sum to a non-zero value, independent of which pair of exponents is chosen [48,76,77]. The conjugate pairing rule is very helpful for analyzing relations such as that given by Eq. (34), since the right hand side is completely determined by the sum of any one conjugate pair of exponents. The easiest pair to use is the pair formed by the positive and negative exponents with the largest magnitude.

Ruelle–Pollicott Resonances and Irreversible Processes

For a Hamiltonian N-particle system, the phase space distribution function, $\rho(\Gamma, t)$ evolves in time according to the relation given by the Liouville equation, in terms of a time evolution operator, $S(-t)$, as

$$\rho(\Gamma, t) = S(-t)\rho(\Gamma, 0) = \exp - t\mathcal{L}\rho(\Gamma, 0) = \rho(\Gamma(-t), 0), \tag{35}$$

where we indicate that the phase space variables Γ evolve as

$$\Gamma(t) = S(t)\Gamma = \exp t\mathcal{L}\Gamma\,. \tag{36}$$

Here $\mathcal{L}$ is the Liouville operator, when acting on differentiable functions, is given, for an isolated system of N particles, by

$$\mathcal{L} = \sum_{i=1}^{N} \boldsymbol{p}_i\cdot\frac{\partial}{\partial\boldsymbol{r}_i} + \sum_i^N \boldsymbol{F}_i\cdot\frac{\partial}{\partial\boldsymbol{p}_i}\,, \tag{37}$$

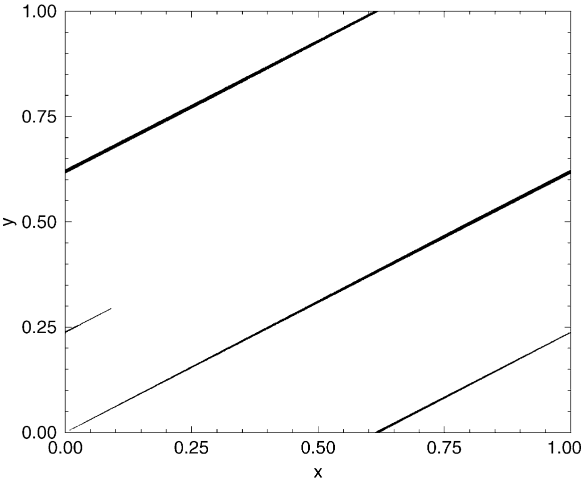
where $\boldsymbol{F}_i$ is the total force on particle i due to the other particles, and external sources such as walls of a container.

If one insists that the functions on which the time displacement operator acts be ordinary functions with well behaved derivatives, the exponential operators, S appearing in Eqs. (35), (36) are unitary with spectrum on the unit circle. In view of this observation it is difficult to see how a satisfactory theory of irreversible behavior, including decays in time, might be obtained from such an operator. The answer is to be found by enlarging the space of functions to include singular functions such as Schwartz distributions [6]. The discussion in the previous subsection has indicated that distributions may evolve to fractals, which are typically non-differentiable functions, so it is very natural to include singular functions in the space of functions on which the time evolution operator may act. In this enlarged function space, the time evolution operator may have properties that do not obtain in a more restricted space of functions. Under these circumstances one studies the right and left eigenfunctions of the Liouville operator, $\mathcal{L}$ in a structure called a *Gelfand triplet* or *rigged Hilbert space* [78]. There are two sets of such triplets corresponding to forward and time reversed motion.

A Gelfand triplet is an operator, together with the two spaces spanned by its right and left eigenfunctions, and an inner product involving one function from each of the two spaces. If the right eigenfunctions are singular functions, the left eigenfunctions must be sufficiently well behaved so that the inner product of a function in the "singular" space with a function in the "smooth" space is well defined. The eigenvalues for the time displacement operator appear as two different sets of poles of the resolvent operator, $(z - \mathcal{L})^{-1}$, in the complex plane, one for forward and one for time-reversed motion. The poles are called *Ruelle–Pollicott* resonances [79,80,81,82], and they give the relaxation rates for various processes that can take place in the system. The time reversal symmetry of the motion provides the relation between the two sets of resonances in the complex plane. For simple models it is possible to construct the functions, singular and smooth, in a Gelfand triplet and to locate the resonances in the complex plane [83,84,85]. In addition to poles of the resolvent one may, in general, expect to find branch cuts, etc. in the complex plane [6]. The existence of these resonances provides an argument that the rates of relaxation to equilibrium found by using traditional methods of statistical mechanics, including kinetic theory, are not artifacts of the approximations made in arriving at these results, but are reflections of the existence of Ruelle–Pollicott resonances for the system.

Fractal Forms in Diffusion and a Dimension Formula

For chaotic systems, the relation between the mean square displacement of a diffusing particle and the diffusion coefficient conceals a fractal function. This can be understood on the basis of the following observation: Since the actual displacement of the diffusing particle depends on the initial phases of the particles in the system, even the slightest change in these phases will make a large change in the displacement of the Brownian particle. One way to try to capture some features of this variation of the displacement is to consider simple models of diffusion that are deterministic, chaotic, and diffusive [86,87]. The process of diffusion in these models is often referred to as deterministic diffusion, since no stochastic elements are introduced in the dynamics of the models. Here we illustrate this idea using the two dimensional periodic Lorentz gas with finite free paths of the moving particle between collisions, so that diffusion is well defined in this system [86,87,88].



Chaotic Dynamics in Nonequilibrium Statistical Mechanics, Figure 6

The evolution of the phase space distribution of Figure 5 after three iterations of the Arnold Cat Map

It is very convenient to use the van Hove intermediate scattering function as a way of describing the diffusive process. This function, denoted by $F_{\boldsymbol{k}}(t)$, is defined as

$$F_{\boldsymbol{k}}(t) = \left\langle \mathrm{e}^{[i\boldsymbol{k}\cdot(\boldsymbol{r}(t)-\boldsymbol{r}(0))]} \right\rangle , \tag{38}$$

where the average is taken over an equilibrium ensemble. The van Hove function is related to the probability of finding the diffusing particle at point $\boldsymbol{r}$ at time t, $P(\boldsymbol{r}, t)$ by

$$P(\boldsymbol{r}, t) = \int \frac{\mathrm{d}\boldsymbol{k}}{(2\pi)^{\mathrm{d}}} P_{\boldsymbol{k}} F_{\boldsymbol{k}}(t) , \tag{39}$$

where d is the number of spatial dimensions of the system and $P_{\boldsymbol{k}}$ is the Fourier transform of the initial probability distribution for the diffusing particle. One can use a cumulant expansion in the exponent to show that $F_{\boldsymbol{k}}(t)$ is given by

$$F_{\boldsymbol{k}}(t) = \mathrm{e}^{s(k)t} , \tag{40}$$

where $s(k)$ is the wave-number dependent decay rate for diffusive motion. Thus, for wave numbers, k much smaller than the inverse of a lattice spacing, in this case, unity, this function takes the form

$$s(k) = -Dk^2 + \tilde{D}k^4 + O(k^6) \,, \tag{41}$$

where D is the diffusion coefficient, $\tilde{D}$ is called the super-Burnett diffusion coefficient, etc. In order to see the physics that is obscured by taking the equilibrium average, consider the microscopic quantity that is averaged, namely, $\exp[i\boldsymbol{k} \cdot (\boldsymbol{r}(t) - \boldsymbol{r}(0))]$. If the motion of the particle is chaotic, the displacement over a time t is a very rapidly varying function of the initial point $\boldsymbol{r}(0)$. As a result, the exponential containing this displacement will be a rapidly oscillating function of the initial point. To capture these oscillations and to explore the fractal structure of the exponential function, we consider a partially averaged quantity, which we will call a normalized, incomplete van Hove function, $F_{\boldsymbol{k}}(\theta, t)$, defined by

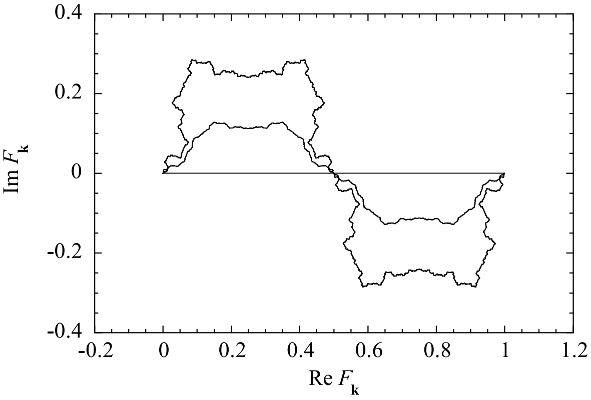
$$F_{\boldsymbol{k}}(\theta, t) = \frac{\int_0^{\theta} \mathrm{d}\theta' \mathrm{e}^{[i\boldsymbol{k}\cdot(\boldsymbol{r}(\theta',t)-\boldsymbol{r}(\theta',0))]}}{\int_0^{2\pi} \mathrm{d}\theta' \mathrm{e}^{[i\boldsymbol{k}\cdot(\boldsymbol{r}(\theta',t)-\boldsymbol{r}(\theta',0))]}} \,. \tag{42}$$

Here we take initial points to be uniformly distributed just outside the surface of one of the scatterers in the periodic Lorentz gas, with initial velocity directed radially outward. The point on the surface is indicated by the angle θ taken with respect to some fixed direction. If one waits for a sufficient number of collisions to take place so that the motion is diffusive, and then plots $\mathrm{Im}\, F_{\boldsymbol{k}}(\theta, t)$ vs $\mathrm{Re}\, F_{\boldsymbol{k}}(\theta, t)$ one finds a fractal curve for small values of the wave number, $|\boldsymbol{k}|$. Computer results obtained by Claus et al. [89] for the hard disk Lorentz gas are plotted in Fig. 7 for various values of the wave number.

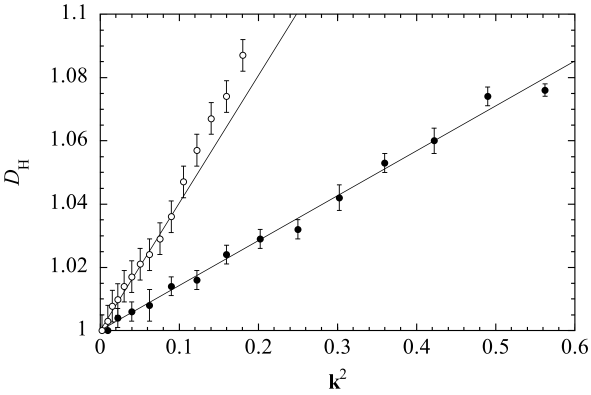
It is possible to prove that there exists a striking connection between the fractal Hausdorff dimension, $\mathcal{D}_H$, of the curve $(\mathrm{Re}\, F_{\boldsymbol{k}}(x), \mathrm{Im}\, F_{\boldsymbol{k}}(x))$, for the incomplete van Hove function [87,88], for small k, the diffusion coefficient, D, and the positive Lyapunov exponent, λ, characterizing the chaotic process underlying the diffusive motion of the particle. This connection is illustrated in Fig. 8 and given by the equation

$$\mathcal{D}_H(k) = 1 + \frac{D}{\lambda}k^2 + O(k^4) \,. \tag{43}$$

Also illustrated in Fig. 8 is the analogous curve obtained from the incomplete van Hove function when the hard disk potential is replaced by a repulsive Coulomb potential. For sufficiently high energy of the moving particle, the motion of the moving particle is chaotic and the van Hove function also shows fractal properties. Thus the fractal curves are not artifacts of the hard disk potential. Equation (43) illustrates the fact that for chaotic models such as the one discussed here, the incomplete van Hove function encodes in its structure both a macroscopic property of the system, the diffusion coefficient, and a microscopic property, the Lyapunov exponent. Such interesting connections are central to a deeper understanding of the microscopic foundations of transport processes.



Chaotic Dynamics in Nonequilibrium Statistical Mechanics, Figure 7
The incomplete van Hove function for a periodic Lorentz gas where a point particle of unit mass and velocity undergoes elastic collisions with hard disks of unit radius forming a triangular lattice with interdisk distance $d = 2.3$: Curves of the cumulative functions for wavenumber $k_x = 0.0$, 0.5, and 0.9 with $k_y = 0$. Note that the fractality increases with the wavenumber



Chaotic Dynamics in Nonequilibrium Statistical Mechanics, Figure 8
Hausdorff dimension D_H of the incomplete van Hove function versus $k^2 = k_x^2$ ($k_y = 0$) for both periodic Lorentz gases with hard-disk scatterers (filled circles) and for the case where the hard disks are replaced by repulsive Coulomb scatterers on a square lattice, and the energy of the particle is sufficiently high for the motion to be chaotic (open circles). Both solid lines have slopes equal to $\mathcal{D}/\lambda$ for the respective diffusion coefficient $\mathcal{D}$ and Lyapunov exponent λ of the Lorentz gases

Entropy Production in Non-equilibrium, Hamiltonian Systems

One of the subjects of most active research in recent years has been the theory of entropy production in non-equilibrium systems. Dynamical systems theory has provided some new insights into this old problem. Briefly formulated, the problem is to explain the positive, irreversible production of entropy using the fundamental ideas in statistical mechanics, particularly the Liouville equation. The obstacle in this direction that must be overcome somehow is the fact that the Gibbs entropy

$$S_G(t) = -k_{\mathrm{B}} \int \mathrm{d}\Gamma \rho(\Gamma, t)[\ln \rho(\Gamma, t) - 1] \,, \tag{44}$$

remains constant in time if $\rho(\Gamma, t)$ satisfies the Liouville equation for Hamiltonian systems

$$\frac{\mathrm{d}\rho(\Gamma, t)}{\mathrm{d}t} = 0 \,. \tag{45}$$

Here Γ represents all of the coordinate and momentum variables of the system. The usual way around this difficulty is to introduce a coarse grained entropy, obtained by either defining an entropy in terms of reduced distribution functions, as is done in Boltzmann's famous H-theorem, or by coarse graining the phase space itself, and defining an entropy in terms of the average phase space distribution in each of the coarse graining regions [9]. In either case, it is possible to show that the rate of production of the redefined entropy is positive, and for the Boltzmann case at least, is in agreement with the predictions of irreversible thermodynamics when the gas is close to a local equilibrium state.

Ideas from dynamical systems theory have not changed the fundamental need for coarse graining. Instead they have provided strong reasons for doing it, reasons that were lacking in the previous approaches, where the motivation for coarse graining seemed only to be that it was necessary to coarse grain in some way to get a positive entropy production. The central new idea in this area is that the phase space description of a non-equilibrium process requires, in the thermodynamic limit at least, the use of distribution functions that are defined on fractal sets. A simple example is provided by a system in which diffusion can take place in a region between two particle reservoirs, each reservoir being maintained at a different density of particles [6,40]. Then if the dynamics that leads to transport of the particles between the reservoirs is Anosov-like, one can argue, and in simple enough cases show explicitly, that the regions in phase space that correspond to regions of different density in the system get so tangled up and enmeshed that the distribution function is a wildly varying fractal function. As such, it is no longer differentiable and the steps that lead to the proof of the constancy of the Gibbs entropy can no longer be justified. The only way to treat this kind of fractal behavior of the distribution function is to smooth the function in one or another way, typically by defining cumulative distribution functions over small regions of phase space, leading to the construction of SRB measures. In simple cases, one can show that fractal forms appear in the phase space distribution function for systems in non-equilibrium stationary states produced by particle reservoirs, or in the relaxation of a system with particle diffusion to equilibrium, and that the rate of entropy production agrees with the predictions of irreversible thermodynamics [6,40,50,90,91]. However, much needs to be done to extend this work to other hydrodynamic processes and to understand why the results of macroscopic theory are obtained in this way. Recently, Gaspard has presented an expression for the rate of entropy production in chaotic as well as in stochastic systems as the difference in two dynamical entropies per unit time, one a form of the Kolmogorov–Sinai entropy per unit time, and the other, an entropy per unit time for the time reversed motion but as measured by the measure of the forward process. It is possible to prove that this rate of entropy production is positive, and for the cases studied so far, agrees with the results of irreversible thermodynamics [51,52].

Kinetic Theory Methods for Analytical Calculations of Lyapunov Spectra

As we demonstrated in the examples given above for the applications of chaos theory to non-equilibrium processes, an important role is played by Lyapunov exponents and Kolmogorov–Sinai entropies per unit time. Apart from computer simulations, it is not always clear how one might obtain expressions and values for these quantities. In some simple cases such as the baker's map and toral automorphisms, the calculation of the Lyapunov exponents is a simple matter. However these cases are very special and rarely are realistic models for physical systems. Thus the problem remains of finding general methods for an analytic determination of Lyapunov exponents and Kolmogorov–Sinai entropies. One such method is kinetic theory. Using the Boltzmann and related equations [8,35], van Beijeren and co workers have been able to obtain expressions for Lyapunov exponents, and in some cases, Kolmogorov–Sinai entropies, for dilute gases with short range potentials, such as hard ball systems, and for dilute Lorentz gases [8,63,64,65,92,93]. Results obtained this way are in good agreement with the results of computer simulations. We refer to the literature for details.

Entropy Production in Systems with Gaussian Thermostats and the Cohen–Gallavotti Fluctuation Theorem

As a final example of the applications of dynamical systems theory to non-equilibrium statistical mechanics we briefly discuss one example of a number of closely related fluctuation theorems, first obtained by Evans, Searles, and by Gallavotti, and Cohen, and generalized by Spohn and Lebowitz, among others [16,17,18,19,20,21]. These fluctuation theorems are very closely related to a class of work-free energy fluctuation results due to Jarzynski [94], and Crooks [20], as well as to the expression for entropy production given by Gaspard [51,52], as mentioned above. By now the literature is quite extensive and the reader is directed there for more details. Here we discuss, briefly, the Gallavotti–Cohen version of a fluctuation theorem appropriate for systems with Gaussian thermostats [18]. In the discussion of systems with energy conserving thermostats, we have introduced another idea for entropy production, namely entropy production in a reservoir associated with phase space contraction of a thermostatted system. Here the central idea is that the thermostatted dynamics produces an attractor for the system's trajectories in phase space. The friction coefficient, which we have denoted by α, is a dynamical function taking on positive or negative values depending on the trajectory of the system in phase space. To produce an overall phase space contraction, the friction coefficient should be positive on average, but from time to time it may be negative. Loosely speaking, we might say that the entropy production in the system is positive when the value of α is positive at the time, and negative when α is negative. For example, in the Lorentz gas that we have been discussing, when the particle moves in the direction of the field, α is positive, and when it moves opposite to the direction of the field, α is negative, provided the charge q is positive. One might imagine some time interval τ, say, and ask for the probability that the time-averaged entropy production per unit time, ϵ_τ, as measured by the phase space contraction, has a value a over this time interval. This probability can be expressed in terms of the SRB measure on the attractor of the steady state system. The fluctuation theorem for this system is a result for the ratio of the probability that the time-average entropy production per unit time over an interval τ will be the value a, to the probability that this value will be $-a$. For a reversible, Anosov-like system with a Gaussian thermostat, the theorem is

$$\frac{\mathrm{Prob}(\epsilon_\tau = a)}{\mathrm{Prob}(\epsilon_\tau = -a)} = \mathrm{e}^{a\tau} \tag{46}$$

Note that for long times this ratio approaches zero or infinity depending upon the sign of a.

This result was first discovered by means of computer simulations by Evans, Cohen, and Morriss [16], and this observation was explained on the basis of Anosov-like dynamics by Gallavotti and Cohen [18]. A closely related fluctuation formula was derived by Evans and Searles [17]. By now this class of fluctuation theorems has been generalized considerably to include analogous results for stochastic and other kinds of systems. We refer to the literature mentioned above for further details.

Discussion

Here we described some aspects of the theory of irreversible processes, as seen from the point of view of dynamical systems theory. We described the notions of ergodic and mixing properties of a dynamical system and argued that they alone are insufficient for a full explanation of the approach to equilibrium as seen on laboratory time scales. However, we tried to argue that if the microscopic system has positive Lyapunov exponents connected to unstable manifolds in the phase space, then one can argue that an approach to equilibrium of reduced distribution functions can occur on much shorter times scales than those needed to establish the mixing of phase space regions throughout the entire phase space. Moreover the existence of a chaotic microscopic dynamics allows us to derive some very striking connections between macroscopic transport coefficients and quantities such as Lyapunov exponents, fractal dimensions, Kolmogorov–Sinai entropies, that characterize the underlying chaotic, microscopic dynamics of the system. Much, but not all, of our discussion was based on some very simple examples of classical chaotic systems with few degrees of freedom, the baker's map and the Arnold Cat Map. These are simple Anosov-like and Anosov systems where one can analyze many points in some detail. However, this analysis is still very far from an analysis of systems of real interest to statistical mechanics, where the number of degrees of freedom is generally much, much larger, even for systems of particles studied on computers, and where the dynamics is not always chaotic. Therefore, it is very much an open question to show that this picture persists when the systems studied are of macroscopic size, and the dynamics is treated in a more realistic way.

Finally we should say something about the role that quantum mechanics plays in our understanding of the approach of a system to equilibrium. "Quantum chaos" is a subject that has developed an enormous literature [15,95,96,97], primarily associated with the quantum behavior of systems with few degrees of freedom which are chaotic in the classical limit of $\hbar \to 0$. This work is clearly of great importance for understanding the behavior of *mesoscopic* quantum devices such as quantum dots and related materials. However, there is no analog of dynamical chaos in quantum mechanics and no direct translation of the results described here to quantum systems. This is a result of the fact that the limit as $\hbar$ approaches zero *does not commute* with the limit of t approaching infinity. Therefore one cannot typically study the asymptotically long time behavior of a quantum system whose classical counterpart is chaotic, and then by taking the limit of $\hbar$ approaching zero, obtain the correct, chaotic behavior of the classical system. Instead one may look for some sign in the quantum motion that the classical system is chaotic. Typically a quantum system will exhibit some signs of the chaotic behavior of the classical system in the semi-classical region of small, but not zero $\hbar$, for some period of time known as the *Ehrenfest time*. The Ehrenfest time is essentially the time that it takes an initially small wave packet to expand to some characteristic length in the system. While the packet is small, the semi-classical behavior is essentially that of a classical system. The rate of the expansion of the wave packet is determined by the classical Lyapunov exponents. When the wave packet reaches a certain size, then the motion of the system is governed by interference and diffraction effects that have no classical counterpart. For example, while a classical particle moving among a random array of fixed scatterers exhibits normal diffusion, its quantum counterpart can be localized, or move diffusively, depending upon the spatial dimension of the system and the particle's energy.

The comments above suggest that chaotic dynamics has a large role to play in quantum systems when one looks at the semi-classical regime, namely the regime where $\hbar$, in proper dimensionless units, can be considered very small [95,96]. One important result, known as *Schnirelman's Theorem* [98]states that in the semi-classical limit, most of the wave functions for a quantum system, whose classical counterpart is chaotic and ergodic, become "equidistributed" on the constant energy surface. This means that the probability of finding of finding the system in some region becomes equal to the ratio of the measure of that region to the total measure of the region available to the system. Nevertheless, there are some wavefunctions for classically chaotic systems that exhibit *scars* in the semi-classical limit, where the wave function is concentrated on periodic orbits of the classical motion. The scarred wave functions then form a special class which do not satisfy Schnirelman's Theorem. In this connection we also mention *Berry's conjecture* [99] which states that the high energy wavefunctions for a classically chaotic, ergodic system can be represented as a Gaussian random function, such as a superposition of plane waves with random phases. For further details we refer to the literature listed above.

The understanding of the approach to equilibrium in macroscopic systems typically requires a treatment of quantum systems with a very large number of degrees of freedom. Such systems are not likely to be in one or in a superposition of a few energy eigenstates. Instead, such systems are likely to be in a state that is a superposition of a huge number of such quantum states, and destructive interference of the phase relations among the states is an important ingredient of the behavior of such systems [100]. In fact there is a large literature that deals with the phenomenon of the loss of coherence, or *decoherence*, of superpositions of large numbers of quantum states for a macroscopic system, and helps us understand a bit more clearly why classical mechanics is a good approximation for describing systems that we know to be intrinsically quantum mechanical.

Future Directions

We conclude with a list of open questions that will provide some indication of what directions might be fruitful further work in the future. This list is far from exhaustive, but focuses upon the particular issues addressed here.

1. Most of the results described here that connect microscopic dynamics and macroscopic transport, such as the escape rate formulae, Eq. (23), the dimension formula Eq. (43), and the Lyapunov exponents-transport coefficient relations for Gaussian thermostatted systems Eq. (34), have been proven for purely chaotic, Anosov or Anosov-like systems, only. The phase spaces of most realistic systems are not likely to be purely chaotic. Instead one expects realistic systems to have mixed phase spaces with both chaotic regions and non-chaotic regions. So far a satisfactory treatment of transport in mixed systems is in a very rudimentary shape, except for some models which have been studied extensively. It would be useful to have estimates of the size and importance of non-chaotic regions in many-particle systems and to determine what corrections, if any, are needed to generalize the results mentioned above to mixed systems.
2. Most of the results given here have been illustrated, and in some cases only derived, for low dimensional systems. How much of this discussion is relevant for

systems with many particles where the dimension of phase space is very large? For example, the formula connecting diffusion and Lyapunov exponents, given by Eq. (43), has only been derived for diffusion in two dimensional chaotic systems Lorentz gases. What is the generalization of this formula to higher dimensions and to general transport processes?

3. The fact that our detailed understanding of the role of chaos in non-equilibrium processes is for systems of low dimensionality suggests that applications of chaos to nanoscale systems might be very fruitful [52].
4. Pseudo-chaotic systems present a great challenge both to physicists and to mathematicians [101,102]. Are there general statements one can make about the motion of a particle in a collection of scatterers, such as hard squares or other scatterers where the motion is not chaotic at all, and the rate of separation of trajectories is at best algebraic? How do these properties depend on the geometrical structure and arrangements of the scatterers? Are there generalizations of the escape-rate formula, and the others mentioned here, to pseudo-chaotic systems?
5. There are at least a few logical gaps in the applications of dynamical systems theory to non-equilibrium statistical mechanics. One one hand we have argued that as far as the approach to equilibrium is concerned it makes sense to look at projected distributions since these distribution functions reach equilibrium forms long before the full phase space distribution function does. This statement itself needs a careful proof for realistic systems. Moreover, the derivations of the formulae that connect transport properties with microscopic dynamical quantities rely upon the use of the full phase space. This suggests that there is a fundamental issue of relevant time scales that needs to be resolved, in order to determine the time scales on which these results become valid.

Acknowledgments

I would like to thank Henk van Beijeren for reading a draft of this article and for his very helpful remarks. I would also like to thank Rainer Klages for his new book (Reference [12]), which was very helpful when preparing this article.

Article Outline

Glossary

Bit Elementary unit of classical information represented by a binary digit.

Qubit (or quantum bit) Elementary unit of quantum information. The qubit refers also to the physical system whose state encodes the qubit of information.

Quantum gate Logical operation performed on one or a few qubits, that change their state according to a unitary transformation. Quantum gates are reversible by definition.

Quantum entanglement Property possessed by two or more quantum systems, when the state of the global system that includes all of them cannot be described by the simple composition of their states. Two entangled systems show quantum correlations between their states that have no classical analogue.

Bell's inequality Relation between two sets of measurements performed on two quantum systems spatially separated. Bell's inequality can only be violated if the two systems are entangled.

Quantum wire Metallic or semiconductor wire with nanometric thickness. While the longitudinal current carrying states form a continuum in the energy spectrum, the transverse component of the carriers wave functions originates a discrete spectrum.

Two-dimensional electron gas (2DEG) Gas of electrons that are quantum-confined in one dimension and free to move in the remaining two. In the confinement direction the single-particle states have a quantized energy spectrum. 2DEGs are usually obtained through the modulation of the material conduction band in a semiconductor heterostructure.

Surface acoustic wave (SAW) Elastic acoustic wave that propagates on the surface of a material. In piezoelectric materials SAWs couples with electrons through the SAW-induced piezoelectric field.

Definition of the Subject

The physical implementation of the *qubit*, the dicotomic unit of quantum information, has been, and still is, the starting point of any proposal for a quantum information processing device. Its proper definition is a necessary, although not sufficient, condition for a practical system to be able to exploit the quite large number of quantum algorithms that have been proven to outperform the corresponding classical ones. The first period of quantum information processing research saw many proposals for qubits based on a large spectrum of systems and approaches, but later, the focus was put on solid-state devices, mainly due to their promises for scalability and better integrability with present-day semiconductor electronics. Furthermore, a deep understanding of the quantum-based physics of semiconductor devices is available, due to the long-standing research on the field, mainly driven by the huge commercial success of semiconductor microprocessors. In fact, the application of quantum mechanics to solid-state systems has resulted in a large number of semiconductor devices with novel functionalities, and the quantum mechanical aspects of the device properties start to dominate their behavior, as device dimensions get smaller. While this may become a problem for traditional electronic devices, it is a prerequisite for the implementation of quantum technology in general and quantum information processing in particular. These possibilities have inspired a number of proposals for creating qubits, quantum gates and quantum registers from semiconductor devices and using them for implementing quantum algorithms. Theoretical studies of the device properties have been undertaken, but the challenging technological hurdles have slowed down experimental progress.

Introduction

In what follows, we will describe a class of solid-state qubits, known as *charge flying qubits*, whose characteristic is the evolution with time of their spatial localization. We will first briefly introduce the concept of quantum information processing and, more specifically, of quantum computing. Then we will focus on the definition of the qubit and of quantum entanglement, stemming from the non-separability of the multi-particle state. The logic transformations that must be applied to the qubit in order to implement quantum algorithms, namely the *quantum gates*, will be described and the requirements for a practical realization of quantum computing devices, listed by DiVincenzo in his famous checklist [41], will be reviewed. Then we will enter into the details of a specific proposal for the realization of quantum bits and quantum gates, based on the charge state of electrons in semiconductor quantum wires.

In the last sections, we will return to the concept of qubit entanglement and will present specific calculations for the entanglement creation in a quantum-wire system and, more general, in a carrier-carrier scattering. In fact quantum entanglement can be considered both a resource and a detriment for quantum computing. It is a resource since any quantum algorithm is based on the entanglement of two or more qubit states, it is a detriment when a qubit is entangled with a degree of freedom that is outside the computational space, i. e. the environment, giving rise to the phenomenon of decoherence. It is the aim of the theoretical modeling to identify the proper system parameters for the controlled production of the first kind of entanglement, while avoiding, or at leas reducing, the second one.

The idea of a solid-state qubit, whose state is encoded by the localization of one electron traveling in two coupled semiconductor quantum wires, is here anticipated. The basic qubit structure consists of two parallel quantum wires, close to each other and separated by a potential barrier. The state of the qubit is represented by the location of a single electron traveling in one (state $|0\rangle$) or the other (state $|1\rangle$) of the two wires with a controlled velocity. If a coupling window is introduced between the wires through the lowering of the potential barrier that separates them, the electronic wave function crossing the coupling region oscillates between the wires. When the electron reaches the end of the coupling window, the oscillation process terminates, and the wave function is eventually divided into two parts running along the left and right wires. The necessary superposition of quantum states is thus obtained. The introduction of a low potential barrier in one of the two wires, able to delay the propagation of the wave function with negligible reflection, delays the propagation of the part of the wave function in that particular wire and generates a phase shift between the two components of the qubit. Combinations of these two transformations allow for the implementation of a general single-qubit operation.

A two-qubit gate requires two pairs of wires. They are designed in such a way that only the electron running in the 1 component of the first qubit and the electron running in the 0 component of the second qubit feel their Coulomb interaction, thus generating the necessary entanglement. As a consequence, the electrons are slowed down, and the system undergoes a phase shift that originates from the spatial delay of the two interacting electrons. This last transformation and the two single-qubit transformations described above form a universal set of gates for quantum computing. Numerical simulation of the quantum dynamics of the proposed devices have been performed, in order to obtain the parameters for the experimental realization and to estimate the performance and decoherence times of these systems.

Prototypes of single-qubit devices have been realized experimentally, based on coupled electron wave guides obtained from two-dimensional electron gases (2DEGs) through split-gate or AFM nanolithography techniques. Their basic functioning is currently under investigation. The experiments and the different realization strategies will be mentioned.

Although the electrical properties of quantum wires are nowadays well established both theoretically and from the point of view of experimental realization, the feasibility of complex devices, with a network of coupled quantum wires, remains a challenge. Some considerations about the practical realizability of quantum computers based on solid-state flying qubits will be presented, and an example of a simple quantum-gate network will be given. A number of mechanisms of carrier injection into the QWRs, such as surface acoustic waves (SAW), electron pumps, resonant tunneling devices have been proposed in literature. We will describe, in particular, surface acoustic waves, that have demonstrated the ability to inject and drive single electrons in quantum wires. Numerical simulations of a simple model of such systems will be presented. In fact, surface acoustic waves are also expected to reduce decoherence effects due to the quantized energy spectrum induced on the embedded carriers. Concerning the detection of the final state of the charge qubit, it can be achieved by single-electron transistors placed at the end of each quantum wire. Different kinds of solid-state flying qubits have been proposed, as for example, the qubit encoding realized through the spin state of single electrons propagating in quantum wires [5]. We will not enter into the details of these proposals.

Quantum Information Processing and Quantum Computation

Over the few decades following the discovery of quantum mechanics, the tight link between information theory and physics has been recognized and, in 1961, Rolf Landauer pointed out that any irreversible process leading to erasure of information is necessarily a dissipative process. Landauer's statement [28] about the entropy cost of information, opened the search for understanding of how physics constrains the ability to use and manipulate information. Once recognized that "information is physical" [33], the next step is to consider that the universe is fundamentally quantum mechanical: the classical theories about information need to be revised according to quantum physics.

By taking into account the quantum nature of the information-storing devices it was clear that also the corresponding theory about information processing needed to include the distinctive feature of quantum physics: quantum entanglement. The first widespread proposal of a quantum information processing system was advanced by Richard Feynman, as a means of simulating a quantum system. In fact, an exact classical simulation of a quantum system needs to follow, separately, its possible quantum states, leading to a growth of the resources needed. On the other hand, a quantum simulation would follow a superposition state of the quantum system, with a corresponding superposition of the simulation tool.

However, quantum information processing burst onto the scene of active research in 1994, when Peter Shor proposed a quantum algorithm for the factorization of integer numbers that requires a computational time which is polynomial in $\log(N)$, with N the number to be factorized. Since no classical algorithm is known that can perform such a task more efficiently, the importance of the Shor algorithm was immediately realized. In fact, since many widely used public-key cryptographic methods are based on the practical impossibility of factorizing large integers, an "efficient" factorization algorithm could jeopardize their secrecy.

A number of branches of quantum information theory are nowadays fertile research topics, whose borders are, however, not sharp. We mention the fields of quantum algorithms, quantum cryptography, quantum communication, quantum teleportation and, finally, quantum computation. The starting point of all of the above tasks, is the *qubit*, i. e. the elementary particle of quantum information. A brief description of its basic properties, the formalism adopted to describe it, and the differences with classical bits, are given in the following. Then the specific case of a qubit based on coherent electron transport in coupled wires will be analyzed.

The Qubit

Classical computer systems store and process information in binary encoding. Any integer N is represented by an ordered sequence of n bits $a_n, a_{n-1}, \dots, a_1, a_0$ according to

$$N = \sum_{i=0}^{n-1} a_i 2^i \tag{1}$$

with $0 \leq N \leq (2^n - 1)$ and $a_i \in \{0, 1\}$. In conventional computers, single bits are usually stored as the charge or magnetic state of an electronic device, and transistors are used to realize logic gates, i. e. the transformation of a multiple bit state according to an established rule. Any bit can be in one and only one of two possible states: either 0 or 1. In the quantum case, a bit of information is also represented by one of two possible states, namely $|0\rangle$ and $|1\rangle$, of a given system, but now, since the latter is described by the laws of quantum mechanics, the bit can be in any superposition of the two states. In fact, the states are associated with two specific eigenstates ($|\psi_0\rangle$ and $|\psi_1\rangle$ respectively) of a suitable observable and now the system can be in any state

$$|\psi\rangle = c_0|\psi_0\rangle + c_1|\psi_1\rangle \tag{2}$$

with c_0 and c_1 complex numbers and $|c_0|^2 + |c_1|^2 = 1$. This means that the quantum analog of a bit, the qubit [14], can be simultaneously in both states 0 and 1. If we measure the qubit we will find it with probability $|c_0|^2$ with the value 0 and with probability $|c_1|^2$ with the value 1. It is important to underline that Eq. (2) describes a coherent superposition rather than a generic mixture between 0 and 1. The essential point here is that there is always a base in which the value of the qubit system is well defined, while an incoherent mixture is a mixture whatever base we choose to describe it. As anticipated, the two states of a qubit are usually indicated with $|0\rangle$ and $|1\rangle$, following the Dirac ket notation used in quantum mechanics. Also, it must be noted that the space spanned by a single qubit is isomorphic to the spin space of a spin 1/2 particle. This will allow us to use the formalism for spin states and spin rotations when dealing with single qubits.

Let us suppose now to process some information encoded in an array of n bits. Classically, an input state must be chosen from the 2^n possibilities given by the array, then the information is elaborated, finally an output is produced. To have the output corresponding to a different input, another elaboration must be performed. Things are different if the information is encoded in an array of qubits and if the information is elaborated by means of some kind of "quantum machine" able to preserve the quantum coherence of states. In this case it is possible to create an input state that is a linear superposition of q classical inputs (2^n possibilities *each*), then the output of the elaboration will be the same linear superposition of the q corresponding classical outputs.

In this case, quantum computation exhibits a kind of "natural" massive parallelism, but this peculiarity of quantum mechanics can not be easily exploited. In fact, in order to know the output of the elaboration, a *measure*, in the quantum mechanical sense, must be performed, this producing a collapse of the quantum state into a single component of the linear combination. In our simple example this means that only one random result, among the results of the q classical computations, can be revealed. To get benefit from quantum processing of information, specific algorithms must be implemented, as mentioned in the previous section, that exploit the main peculiarity of quantum physics i. e. quantum entanglement.

Quantum Entanglement

The deep difference between classical information and quantum information becomes evident when a state of two or more qubits is taken. In this case the whole many-qubit system can be in a superposition of states in which none of the qubits has a definite value but there is a fixed correlation between their values. In other terms, an entangled state is any state that cannot be written as a direct product of single-qubit states.

For example, in the two-qubit entangled state

$$\frac{1}{\sqrt{2}} \left(|0\rangle_1|1\rangle_2 + |1\rangle_1|0\rangle_2\right) , \tag{3}$$

where $|0\rangle_n$ ($|1\rangle_n$) indicate the zero (one) state of the qubit n, the probability to obtain the value 0 as the outcome of a measure on either the first or the second qubit is 50%. However, once a measure has been performed, the outcome of a measure on the remaining qubit is known with 100% confidence. The correlation between two systems in a joint quantum state is "stronger" than any classical correlation and leads to effects that are unknown in classical physics. This offers the possibility to encode information in a completely new way, in which the information is stored by the multi-qubit system as a whole and no information is carried by single qubits. In order to compact our notation, we will follow the usual convention of indicating the state of the qubits, lexicographically ordered, with a single ket vector and dropping their index. For example, $|01\rangle$ will be used to indicate the two-qubit state $|0\rangle_1|1\rangle_2$.

Entanglement is closely related to the issue of non-locality of quantum measurement. In fact it was evident since the early days of quantum physics that if two particles are in an entangled state, quantum theory predicts that a measurement process performed on a particle is able to change instantaneously the state of the other, even if they are spatially separated. It was indeed Schrödinger that introduced the word *entanglement* to indicate the superposition in a multi-particle system. Because of this "action at distance", quantum theory was strongly criticized by many physicists. Among them, Albert Einstein, Boris Podolsky and Nathan Rosen, in a famous paper [16] dated 1935, refused the non-locality implied by quantum mechanics and in the epistemological discussion that followed, addressed the new theory as incomplete. The discussion about incompleteness of quantum mechanics was considered merely philosophical until 1964. In that year John Bell showed [6] that, for entangled systems, measurements of correlated quantities should yield different results in the quantum mechanical case with respect to those expected if one assumes that the properties of the measured system are present prior to, and independent of, the observation (reality hypothesis).

In the last section, a proposal for an experimental setup able to violate Bell inequality, based on coherent electron transport in coupled quantum wires will be sketched and the generation of maximally entangled Bell's states by means of solid-state flying qubits will be analyzed. Some results of numerical simulations of such a system will be presented.

Bell's states, using the qubit formalism, are two-qubit states that do not carry any information on the state itself on the single qubits. In fact, the usual way is to encode a bit onto each system separately which gives the following four possibilities: $|00\rangle$, $|01\rangle$, $|10\rangle$, $|11\rangle$. By exploiting the features of entanglement it is possible to encode the information using four non-separable states of two qubits, the so-called Bell states:

$$\begin{aligned} |\Psi^+\rangle &= \frac{(|01\rangle + |10\rangle)}{\sqrt{2}}\,, \qquad |\Psi^-\rangle = \frac{(|01\rangle - |10\rangle)}{\sqrt{2}}\,, \\ |\Phi^+\rangle &= \frac{(|00\rangle + |11\rangle)}{\sqrt{2}}\,, \qquad |\Phi^-\rangle = \frac{(|00\rangle - |11\rangle)}{\sqrt{2}}\,. \end{aligned} \tag{4}$$

Note that in each of the four states, any single qubit has 50% of probability to give 0 or 1 when measured. As a consequence a single-qubit reading does not provide even partial information on the state. Only a measure on the joint state of two qubits allows to read the stored information.

We finally note that the search for an experimental violation of Bell's inequality started straight after its discovery but it was only in the 1980s that the violation was obtained experimentally [3] using polarization entangled photons from a spontaneous parametric down conversion. On the other hand, the violation of Bell's inequality in semiconductor-based devices has not been, so far, revealed.

Quantum Gates and the Universal Set

In this section, we introduce some of the simplest quantum logic gates that are at the basis of more complex transformations presented in the following and introduce the concept of a universal set of quantum gates.

For a (classical) digital computer the simplest logic gate is the single-bit NOT gate. It simply changes the state of the input bit from 0 to 1 and vice versa. In the quantum case a NOT gate will perform the transformation

$$|\psi_{\text{in}}\rangle = c_0|0\rangle + c_1|1\rangle \xrightarrow{\mathsf{NOT}} |\psi_{\text{out}}\rangle = c_0|1\rangle + c_1|0\rangle\,, \tag{5}$$

in which the complex coefficients of states $|0\rangle$ and $|1\rangle$ are exchanged.

Another useful single-qubit quantum gate that has no correspondence in classical information processing, is the Hadamard gate H, that transforms the two qubit states $|0\rangle$ and $|1\rangle$ according to:

$$|0\rangle \xrightarrow{\mathsf{H}} \frac{|0\rangle + |1\rangle}{\sqrt{2}} \quad \text{and} \quad |1\rangle \xrightarrow{\mathsf{H}} \frac{|0\rangle - |1\rangle}{\sqrt{2}}\,. \tag{6}$$

Although the idea of a quantum logic-gate operation is strictly related to that of classical logic operation, a crucial difference must be underlined. For many classical gates, like AND, OR, XOR, the number of input and output bits is different. In fact the basic logic gates used to implement digital computers are "many-to-one" operations and are not logically reversible. Once the input state is given, it is straightforward to compute the output state, but it is not possible to identify the input from the output. Thus, the logical transformations performed by these classical gates imply a loss of information. We will not enter here into the topic of reversible and non-reversible computation (see,

Charge-Based Solid-State Flying Qubits, Table 1
Truth table defining the controlled-NOT and Toffoli reversible gates

CNOT	
in	out
00	00
01	01
10	01
11	10

Toffoli			
in	out	in	out
000	000	100	000
001	001	101	101
010	010	110	111
011	010	111	110

for example, [7,33]), but simply report a fundamental result of quantum information theory: a quantum logic gate is a unitary transformation of the input state, therefore any quantum gate must be reversible. This means that it is not possible to start from the well-known classical logic gates and find quantum analogues (as for the NOT gate), but reversible transformations must be used instead, in order to identify a universal set of transformations.

A reversible classical gate of special interest, that will be described in the framework of solid-state flying qubit devices in the following section, is the controlled-NOT (CNOT). It is a two-bit to two-bit gate that has, as the first bit of output, a copy of the first bit of input, and as the second bit of output the XOR between the two input bits. The truth table for the controlled-NOT gate is given in Table 1.

It is easy to identify the quantum version of the CNOT gate. The operation performed on a generic two-qubit state $|\psi_{\text{in}}\rangle$ is:

$$\begin{aligned} & c_a|00\rangle + c_b|01\rangle + c_c|10\rangle + c_d|11\rangle \\ & \quad \xrightarrow{\text{CNOT}} c_a|00\rangle + c_b|01\rangle + c_c|11\rangle + c_d|10\rangle \,. \end{aligned} \tag{7}$$

Let us introduce here a last reversible classical gate, the Toffoli gate (sometimes called control-control-NOT). It is a three-bit to three-bit gate whose operation is: the first two bits are unchanged, the third bit undergoes a NOT operation if, and only if, first and second bits are both 1. The truth table for the Toffoli gate is given in Table 1. Even in this case it is trivial to find the quantum version of the Toffoli gate. We will omit the explicit expression for the sake of brevity.

In strict analogy with the usual quantum mechanics formalism, an n-qubit state can be written both in ket formalism and as a column vector, once a basis is chosen.

Here and in the following the matrix representation of operators is expressed on the lexicographically ordered basis, i.e., $|0\ldots00\rangle, |0\ldots01\rangle, |0\ldots10\rangle, \ldots, |1\ldots11\rangle$. For example for a 2-qubit system, the basis will be $\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}$.

With this notation, vector representation of the 2-qubit state representing the entangled state $a|00\rangle + b|01\rangle + c|11\rangle$ results to be

$$\begin{pmatrix} a \\ b \\ 0 \\ c \end{pmatrix} . \tag{8}$$

This formalism allows a fast calculation of the effect of a quantum gate on a qubit state, once the transformation matrix is given. The matrix representation for three quantum gates introduced previously, (NOT, controlled-NOT, Hadamard) is:

$$\text{NOT} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} ,$$

$$\text{CNOT} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix} ,$$

$$\text{H} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} .$$

Let us now introduce a compact notation to represent the action performed by a transformation acting on a subset composed of n qubits of an m-qubit system (with $n < m$). The identity operation on the remaining $(m - n)$ qubits will be understood. Let us consider a generic basis ket of the m-qubit system $|b_1, b_2, \ldots, b_m\rangle$ and a generic basis ket of the n-qubit subsystem $|a_1, a_2, \ldots, a_n\rangle$ (with $a_i, b_i \in \{0, 1\}$). If $\mathbf{A}$ is a linear operator acting on $|a_1, a_2, \ldots, a_n\rangle$, we define the operator $\mathbf{A}^{(x_1, x_2, \ldots, x_n)}$ (with $x_i \leq m$ and $x_i \neq x_j$ iff $i \neq j, \forall i, j \leq n$) acting on the m-qubit state $|b_1, b_2, \ldots, b_m\rangle$ as the operator that transforms the n qubits state $|b_{x_1}, b_{x_2}, \ldots, b_{x_n}\rangle$, according the transformation $\mathbf{A}$ and leave the other qubits unchanged.

For example, the four-dimensional matrices $\mathbf{M}^{(1)}$ and $\mathbf{M}^{(2)}$ that represent the action of a generic single-qubit transformation

$$\mathbf{M} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

on a two-qubit system, and that will be used in the following sections, are:

$$\begin{aligned} \mathbf{M}^{(1)} &= \begin{pmatrix} a & 0 & b & 0 \\ 0 & a & 0 & b \\ c & 0 & d & 0 \\ 0 & c & 0 & d \end{pmatrix} , \\ \mathbf{M}^{(2)} &= \begin{pmatrix} a & b & 0 & 0 \\ c & d & 0 & 0 \\ 0 & 0 & a & b \\ 0 & 0 & c & d \end{pmatrix} . \end{aligned} \tag{9}$$

In fact, for a 2-qubit system the transformation $\mathbf{M}^{(1)}$ corresponds to the transformation $\mathbf{M}$ applied on the first qubit, while $\mathbf{M}^{(2)}$ corresponds to the transformation $\mathbf{M}$ applied on the second qubit.

To conclude this section, we introduce the concept of a universal set of gates, i. e. the set of simple transformations that can be combined in order to create any possible complex transformation of bits, (or qubits in the present case). We will show, in the following sections that, by using three types of coupled quantum wire devices, it is possible, at least in principle to implement such a universal set.

The concept is analogous to classical computation, where any given transformation can be obtained, for example, using AND and NOT gates. However, as mentioned above, the AND gate is not a reversible gate. This means that the transformations realized using the set {NOT, AND} are, in general, not reversible and we need a different choice for the quantum case.

In 1995 David DiVincenzo [40] showed that, for quantum computation, a universal set formed solely by one-qubit and two-qubit gates exists. A further simplification of the set of universal quantum gates was introduced by Barenco et al. [4]. They proved that a non-universal, classical two-bit gate can be found that, in conjunction with a generic quantum one-qubit gate, form a universal set for quantum computing. On the basis of this last result, we describe, in the following, the universal set implemented by the charge flying qubit.

Let us start by analyzing the one-qubit gate. The space of a two-component vector representing a single flying qubit is isomorphic to the spin space of a spin 1/2 particle. This means that a general transformation of one qubit is represented by a rotation matrix of the SU(2) group, i. e.

$$\mathbf{U}(\alpha,\beta,\theta) = \begin{pmatrix} \mathrm{e}^{i(\alpha/2+\beta/2)}\cos\left(\frac{\theta}{2}\right) & \mathrm{e}^{i(\alpha/2-\beta/2)}\sin\left(\frac{\theta}{2}\right) \\ -\mathrm{e}^{i(-\alpha/2+\beta/2)}\sin\left(\frac{\theta}{2}\right) & \mathrm{e}^{i(-\alpha/2-\beta/2)}\cos\left(\frac{\theta}{2}\right) \end{pmatrix}, \tag{10}$$

where α, β, θ are three real numbers representing three rotation angles around two orthogonal axes: α and β are rotations around Z, between them, a rotation around Y of γ is performed [39]. Any transformation $\mathbf{U}$ can be obtained using two of the three basic rotations:

$$\mathbf{R_x}(\theta) = \begin{pmatrix} \cos\left(\frac{\theta}{2}\right) & i\sin\left(\frac{\theta}{2}\right) \\ i\sin\left(\frac{\theta}{2}\right) & \cos\left(\frac{\theta}{2}\right) \end{pmatrix}, \tag{11}$$

around the X axis,

$$\mathbf{R_y}(\theta) = \begin{pmatrix} \cos\left(\frac{\theta}{2}\right) & \sin\left(\frac{\theta}{2}\right) \\ -\sin\left(\frac{\theta}{2}\right) & \cos\left(\frac{\theta}{2}\right) \end{pmatrix}, \tag{12}$$

around the Y axis, and

$$\mathbf{R_z}(\theta) = \begin{pmatrix} \mathrm{e}^{i\frac{\theta}{2}} & 0 \\ 0 & \mathrm{e}^{-i\frac{\theta}{2}} \end{pmatrix}, \tag{13}$$

around Z axis.

In particular, the generic transformation $\mathbf{U}$ in the form (10) can be obtained using only $\mathbf{R_y}$ and $\mathbf{R_z}$:

$$\mathbf{U}(\alpha,\beta,\theta) = \mathbf{R_z}(\alpha)\ \mathbf{R_y}(\theta)\ \mathbf{R_z}(\beta)\,. \tag{14}$$

Furthermore, one of the above three rotations can be obtained using the other two. In fact

$$\mathbf{R_x}(\theta) = \mathbf{R_z}(\pi/2)\ \mathbf{R_y}(\theta)\ \mathbf{R_z}(-\pi/2) \tag{15}$$

$$\mathbf{R_y}(\theta) = \mathbf{R_z}(-\pi/2)\ \mathbf{R_x}(\theta)\ \mathbf{R_z}(\pi/2) \tag{16}$$

$$\mathbf{R_z}(\theta) = \mathbf{R_x}(-\pi/2)\ \mathbf{R_y}(\theta)\ \mathbf{R_x}(\pi/2)\,. \tag{17}$$

This means that in order to obtain a generic single-qubit transformation (the first gate in our universal set) it is sufficient to have two of the rotations (11), (12), (13).

We now consider the two-qubit gate of the set. A typical choice for the latter is the CNOT introduced above. Another possibility is to use a two-qubit conditional phase shifter. This gate adds a phase factor to a given component of the qubit state. The usual form for the conditional phase shifter present in literature adds a phase $\mathrm{e}^{i\gamma}$ to the state $|11\rangle$:

$$|\psi_{\text{in}}\rangle = c_a|00\rangle + c_b|01\rangle + c_c|10\rangle + c_d|11\rangle \longrightarrow$$
$$\longrightarrow |\psi_{\text{out}}\rangle = c_a|00\rangle + c_b|01\rangle + c_c|10\rangle + \mathrm{e}^{i\gamma}c_d|11\rangle\,.$$

For any value of the angle γ, not equal to an integer multiple of π, we have a transformation that, together with the one-qubit gates $\mathbf{U}$ of Eq. (10), form a universal set.

In the following section, the conditional phase shifter used is slightly different from the one described above. In fact it adds a phase to the $|10\rangle$ component of the state. Its matrix representation is:

$$\mathbf{T}(\gamma) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \mathrm{e}^{i\gamma} & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{18}$$

and forms, together with the one-qubit gates $\mathbf{U}$, a universal set.

The DiVincenzo Criteria

The concrete realization of quantum-computing capable hardware must face a number of general tasks and requirements that have been listed by David DiVincenzo [41] in the form of a checklist. Five criteria were listed, that must be met by physical systems that are to form the basis of a useful quantum computer.

For the sake of completeness, we report in the following the checklist, as given in [2]:

1. A scalable physical system of well-characterized qubits.
2. The ability to initialize the state of the qubits to a simple fiducial state.
3. Long relative decoherence times, much longer than the gate-operation time.
4. A universal set of quantum gates.
5. A qubit-specific measurement capability.

The above criteria are largely qualitative, but more quantitative bounds have been proposed [27,34]. A universally accepted criterion is the number of gate operations that can be executed before decoherence processes have degraded the quantum information significantly. This number is often estimated as the ratio of the decoherence time by the single gate operation time. However, additional mechanisms leading to the loss of quantum information must also be considered, such as the accuracy of the logic operation performed by the quantum gate. In fact, a problem that is often present in the design of quantum information devices is that optimization of one of the relevant parameters conflicts with the requirements for another operation. As an example, good readout sensitivity and fast gate operations require strong coupling to the classical apparatus that drives the device. However, strong interactions with the environment increases the speed of decoherence. Optimizing performance of the full system, i. e. from initialization through computation and readout, therefore forces one to make choices and to accept some additional decoherence if this results in improved readout sensitivity.

In addition to the above points, two additional points have been added in order to consider the issues related to the transfer of quantum information between different devices implementing the quantum operations:

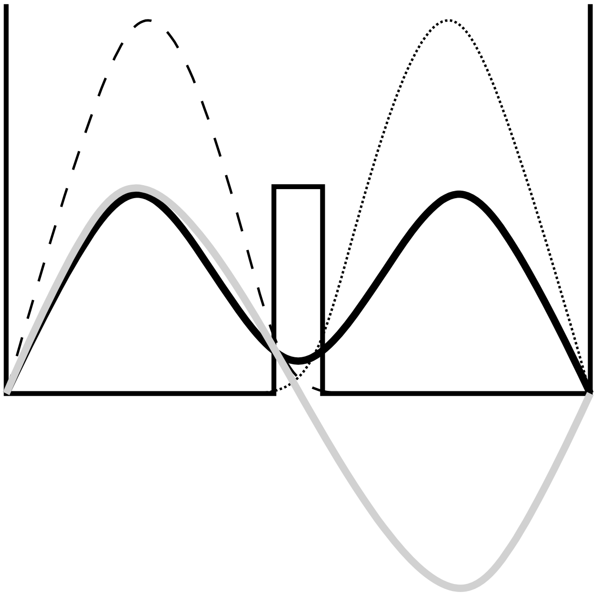
6. The ability to interconvert stationary and flying qubits.
7. The ability to faithfully transmit flying qubits between specified locations.

The latter criteria, related to quantum computer networkability, are automatically met by proposals whose qubit definition is based on flying qubits. In fact, in order to perform a quantum computation the qubits must undergo a sequence of logical operations, represented by unitary transformations on the multi-qubit state. Two classes of proposals can be identified, according to the kind of qubit encoding [8]. The first one is characterized by qubits that are defined by the quantum state of given physical systems, fixed into space, with quantum gates implemented by changing in time the coupling between the qubits. Quantum computation based on charge and spin degrees of freedom of semiconductor quantum dots are an example of these implementations, where a logic operation is performed by a proper time-dependent tuning of interdot coupling. The second class is represented by the flying qubits, where, contrary to the previous case, quantum gates are fixed, while the position of the qubits changes in time. At each stage, the outputs of a quantum transformation, i. e. the state of a qubit register, must be moved to the inputs of the following quantum gate. This process, overlooked in the early times of quantum information processing research, results to be critical in viable practical realizations and strictly connected to the problem of quantum communication [41].

Flying Qubits Based on Coherent Electron Transport in Coupled Quantum Wires

In this section, a physical system able to perform the basic operations needed for quantum computation is proposed and investigated theoretically. As anticipated in the Introduction, the elementary qubit is defined as the state of an electron running along a couple of quantum wires. We will not enter into the details of the modeling of a realistic device, for which we refer to recent literature [1,29,32,38,42]. We will use hard-wall confining potentials and simple models in order to focus on the functioning principles of the quantum gates. However, we will use GaAs-AlGaAs heterostructure parameters in the simulations presented in the following. We will show that a proper design of the system, together with the action of Coulomb interaction between electrons, allows the implementation of basic one-qubit and two-qubit quantum logic gates.

Let us consider the quantum well formed by a modulation-doped heterostructure. If we assume low free carrier density, less than $10^{10}/\mathrm{cm}^2$, in the so-formed two-dimensional electron gas (2DEG), the confining potential profile along the direction orthogonal to the layers can be considered as a narrow triangular well (see, for example, [19]). Along this direction the wave function is quantized and has, for the lower, bound states, a discrete energy spectrum. The motion of the carriers in the plane parallel to the interfaces is free, so that, for any transverse energy, there exist a continuum of two-dimensional states called



Charge-Based Solid-State Flying Qubits, Figure 1
Schematic transverse potential profile of two weakly coupled quantum wires (double well). The *dark* and *light solid lines* show the two lower eigenfunctions: $|\psi_e\rangle$ and $|\psi_o\rangle$, with even and odd parity, respectively. The *dashed* and *dotted lines* represent their sum ($|0\rangle$ state, localized in the left well) and difference ($|1\rangle$ state, localized in the right well), respectively

subbands. Such a 2DEG system is the basis from which quantum wire structures can be realized by lithographic process or electrostatic confinement. In the following, the confined direction, i. e. the material growth direction, is ignored since it is supposed that a single electron, injected in the system, will remain in the lowest subband.

The basic device consists of two parallel quantum wires [10]. It is supposed to operate at very low temperature in order to have a negligible number of electrons in the conduction band and to minimize the decoherence due to the interactions of the electrons with lattice vibrations. The transverse potential profile of the two-wire system is shown in Fig. 1 together with its ground eigenfunction $|\psi_e\rangle$, that has even parity, and the first excited state $|\psi_o\rangle$, that has odd parity.

Figure 1 shows also that the sum and difference of the two lower eigenfunctions are almost fully localized in the left and right well, respectively. The widths of the two wires are equal and constant along the whole device. This avoids any effect due to unalignment of subbands in the two quantum wires [24].

Let us consider a single electron injected into one of the two wires and assume that the injection process is able to keep the electron in the transverse ground state, and that, in the longitudinal direction along the wire, it is well described by a minimum uncertainty wave packet.

$$\psi(x,y) = \sqrt{\frac{2}{L}}\cos\left[\frac{\pi}{L}(x-x_0)\right] \frac{1}{\sqrt{\sigma\sqrt{2\pi}}}\mathrm{e}^{-\left(\frac{y-y_0}{2\sigma}\right)^2}\mathrm{e}^{ik_0 y}\,, \tag{19}$$

where, L is the width of the quantum wire, whose center is x_0, σ is the standard deviations of the Gaussian function and gives an estimate of the wave function extension in space along the wire direction, y_0 is the coordinate of the center of the wave function, k_0 is the wave number, representing the kinetic energy of the electron along the y direction. This is the initial condition for the following time-dependent numerical simulations.

The state of the qubit is defined as $|0\rangle$ if the electron is in the left wire, $|1\rangle$ if it is in the right wire. This means, in terms of transverse wave functions:

$$\begin{aligned}\langle x|0\rangle &= \frac{1}{\sqrt{2}}(\langle x|\psi_e\rangle + \langle x|\psi_o\rangle) = \sqrt{\frac{2}{L}}\cos\left(\frac{\pi}{L}(x-x_0)\right)\\ \langle x|1\rangle &= \frac{1}{\sqrt{2}}(\langle x|\psi_e\rangle - \langle x|\psi_o\rangle) = \sqrt{\frac{2}{L}}\cos\left(\frac{\pi}{L}(x-x_1)\right)\end{aligned} \tag{20}$$

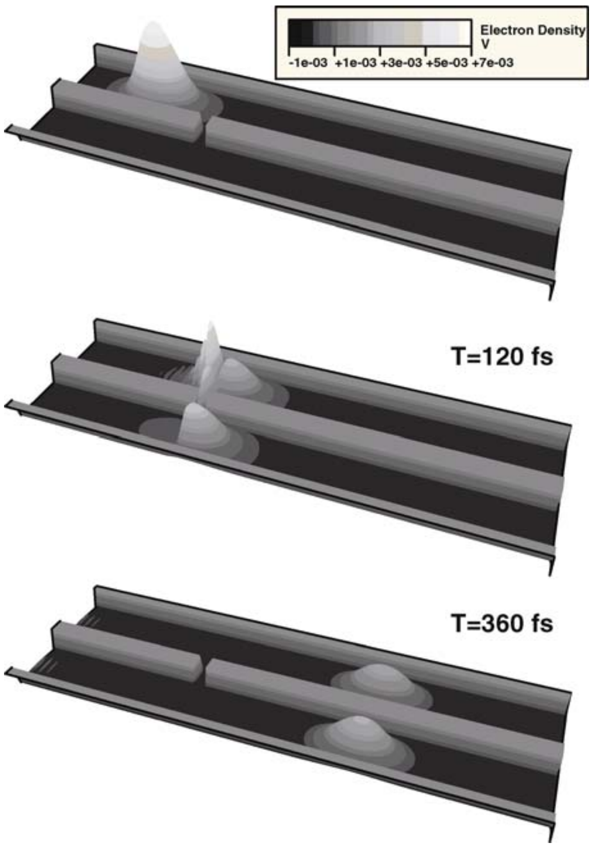
where $x_0(x_1)$ is the central point of the left (right) well formed by the potential in the direction orthogonal to the wires.

The time evolution of the states defined by Eq. (20), as regards the x component, is simply given by a multiplying factor $\mathrm{e}^{-i\omega t}$ with ω frequency of the two degenerate eigenstates.

One-Qubit Gates

If a coupling window is introduced between the wires, a significant lowering of the symmetric transverse state energy ω_e is produced. It can be easily shown that, with good approximation the energy of the anti-symmetric state is unchanged ($\omega_o = \omega$). It is well known (and it has been verified experimentally, see for example [18]) that the electronic wave function crossing this coupling region, oscillates between the wires with a period $\tau = 2\pi/(\omega - \omega_e)$. When the electron reaches the end of the coupling window, the oscillation process terminates and the wave function is eventually separated in two parts running along the left and the right wires, as shown in Fig. 2.

If T is the time that the electron spends in the coupling region, the transverse states in Eq. (20) evolve according



Charge-Based Solid-State Flying Qubits, Figure 2
Numerical solution of the time-dependent Schrödinger equation for one electron injected in a system of two coupled quantum wires [10]. The model potential profile and the square modulus of the wave function are shown at three different time steps. The width of the wires is $L = 6$ nm and the coupling window is 10 nm long. Note that different scales have been used for the two axes. The initial condition (in the upper image) is the wave function in Eq. (19) with $\sigma = 20$ nm and k_0 corresponding to an energy of 50 meV. The effective mass for GaAs has been used

to:

$$\begin{aligned}|0\rangle &\rightarrow \frac{e^{-i\omega T}}{\sqrt{2}}\left(e^{i(\omega-\omega_e)T}|\psi_e\rangle + |\psi_o\rangle\right)\\ &= e^{-i\omega T}\, e^{i\frac{\theta}{2}}\left(\cos\frac{\theta}{2}|0\rangle + i\sin\frac{\theta}{2}|1\rangle\right)\\ |1\rangle &\rightarrow \frac{e^{-i\omega T}}{\sqrt{2}}\left(e^{i(\omega-\omega_e)T}|\psi_e\rangle - |\psi_o\rangle\right)\\ &= e^{-i\omega T}\, e^{i\frac{\theta}{2}}\left(i\sin\frac{\theta}{2}|0\rangle + \cos\frac{\theta}{2}|1\rangle\right),\end{aligned} \tag{21}$$

where $\theta = (\omega - \omega_e)T$. The length of the coupling window, the height of the barrier in it and the velocity of the electron, can be properly chosen to perform a given transfer of the electronic wave function between the wires. It is easy to see that, using the matrix formalism introduced in the previous section, the transformation **S** performed is represented by the rotation matrix $\mathbf{R_x}$ multiplied by a phase factor:

$$\mathbf{S}(\theta) = e^{i\frac{\theta}{2}}\begin{pmatrix}\cos\left(\frac{\theta}{2}\right) & i\sin\left(\frac{\theta}{2}\right)\\ i\sin\left(\frac{\theta}{2}\right) & \cos\left(\frac{\theta}{2}\right)\end{pmatrix} = e^{i\frac{\theta}{2}}\mathbf{R_x}(\theta)\,. \tag{22}$$

The global phase factor $e^{-i\omega T}$, due to the time evolution of the state, is ignored for simplicity: it is present in each of the transformations proposed and also in the free propagation of the electron, therefore it can be considered a global multiplying factor for the many-qubit system that gives no contribution.

Similarly, the exponential $e^{i\frac{\theta}{2}}$ of Eq. (22) results to be a global phase factor and can be neglected. Thus, in the following, the operation performed by the geometry described in this section (coupling window), will be indicated by either $\mathbf{S}(\theta)$ or $\mathbf{R_x}(\theta)$.

A second kind of transformation on a single qubit can be obtained with the introduction of a potential barrier able to delay the propagation of the wave function in one of the two wires (but low enough to avoid reflections [9]). This induces a phase shift between the two components of the qubit.

Let us suppose to have a qubit in a state $a|0\rangle + b|1\rangle$ (with a and b complex numbers and $|a^2 + b^2| = 1$). This means that the initial wave function $\psi_i(x, y)$: (a) in the longitudinal direction along the wires still has the form of a minimum uncertainty wave packet, (b) in the transverse x direction it is split in two parts, one in each wire, i. e., according to Eq. (20):

$$\begin{aligned}\psi_i(x, y) &= \left[a\cos\left(\frac{\pi}{L}(x - x_0)\right) + b\cos\left(\frac{\pi}{L}(x - x_1)\right)\right]\\ &\quad\times\sqrt{\frac{2}{L}}\frac{1}{\sqrt{\sigma\sqrt{2\pi}}}e^{-\left(\frac{y-y_0}{2\sigma}\right)^2}e^{ik_0 y}\\ &= [a\langle x|0\rangle + b\langle x|1\rangle]\frac{1}{\sqrt{\sigma\sqrt{2\pi}}}e^{-\left(\frac{y-y_0}{2\sigma}\right)^2}e^{ik_0 y}\,,\end{aligned}$$

or, as a column vector,

$$\psi_i(x, y) = \frac{1}{\sqrt{\sigma\sqrt{2\pi}}}\begin{pmatrix}a\, e^{-(\frac{y-y_0}{2\sigma})^2}e^{ik_0 y}\\ b\, e^{-(\frac{y-y_0}{2\sigma})^2}e^{ik_0 y}\end{pmatrix}. \tag{23}$$

It is known, from elementary quantum mechanics [30], that the effect of a potential barrier on a propagating wave function (like the one described in Eq. (19)) can be reduced, with good approximation, to a spatial delay ΔS, provided either that (i) the mean kinetic energy of the wave packet is much higher than the barrier, or that (ii) $k_0 L$ is a multiple of π and the broadening in momentum space is small (σ is large).

If the delaying potential barrier is inserted on the 0 wire, only the $|0\rangle$ component of the wave function will undergo the spatial delay ΔS. The state of Eq. (23) will be transformed in

$$\psi_f(x,y) = \frac{1}{\sqrt{\sigma\sqrt{2\pi}}} \begin{pmatrix} a\,\mathrm{e}^{-\left(\frac{y+\Delta S-y_0}{2\sigma}\right)^2} \mathrm{e}^{ik_0(y+\Delta S)} \\ b\,\mathrm{e}^{-\left(\frac{y-y_0}{2\sigma}\right)^2} \mathrm{e}^{ik_0 y} \end{pmatrix} . \tag{24}$$

The delay ΔS is small compared to the parameter σ of the enveloping Gaussian function, thus the difference induced by the substitution $y \rightarrow y + \Delta y$ in the real exponential, is small compared to the variation of the imaginary exponential representing the enveloped plane wave. As a consequence it is possible to make the approximation

$$\mathrm{e}^{-\left(\frac{y+\Delta S-y_0}{2\sigma}\right)^2} \mathrm{e}^{ik_0(y+\Delta S)} \approx \mathrm{e}^{-\left(\frac{y-y_0}{2\sigma}\right)^2} \mathrm{e}^{ik_0(y+\Delta S)} \tag{25}$$

and to rewrite the state of Eq. (24) as

$$\psi_f(x,y) \approx \frac{1}{\sqrt{\sigma\sqrt{2\pi}}} \mathrm{e}^{-\left(\frac{y-y_0}{2\sigma}\right)^2} \mathrm{e}^{ik_0 y} \begin{pmatrix} a\,\mathrm{e}^{ik_0\Delta S} \\ b \end{pmatrix} . \tag{26}$$

We introduce, now, an angle ϕ defined as

$$\phi = k_0 \Delta S\,. \tag{27}$$

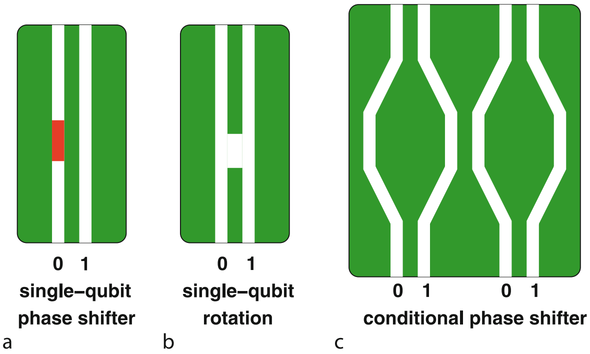
It is easy to verify that the transformation $\psi_i \longrightarrow \psi_f$ on the qubit state is given by

$$\mathbf{R_0}(\phi) = \begin{pmatrix} \mathrm{e}^{i\phi} & 0 \\ 0 & 1 \end{pmatrix} , \quad \text{or} \quad \mathbf{R_1}(\phi) = \begin{pmatrix} 1 & 0 \\ 0 & \mathrm{e}^{i\phi} \end{pmatrix} , \tag{28}$$

if the delay is realized on the wire representing the 0 or 1 component, respectively. The value of ϕ depends on the delay ΔS that depends, in turn, on the height and length of the potential barrier.

The transformations $\mathbf{R_0}$ and $\mathbf{R_1}$ can be combined to obtain a transformation $\mathbf{R_z}$, i. e. the rotation around the $\hat{z}$ axis defined in Eq. (13), that is rewritten here for convenience:

$$\mathbf{R_0}(\alpha/2)\mathbf{R_1}(-\alpha/2) = \mathbf{R_z}(\alpha) = \begin{pmatrix} \mathrm{e}^{i\frac{\alpha}{2}} & 0 \\ 0 & \mathrm{e}^{-i\frac{\alpha}{2}} \end{pmatrix} . \tag{29}$$



Charge-Based Solid-State Flying Qubits, Figure 3
Schematic representation of the three devices that constitute the universal set of quantum gates: a a delaying potential barrier (*red*) along the 0 wire realizes the R_0 transformation; b a coupling window between the wires realizes the R_x transformation; c a two-qubit Coulomb coupler is able to entangle the two qubit states and to realize a T transformation (see Eq. (18))

As described in the previous section, $\mathbf{R_z}$ together with $\mathbf{R_x}$, gives any rotation of the group SU(2). Thus, the two basic transformations proposed are able to realize the general rotation $\mathbf{U}$ of Eq. (10) that is the single-qubit gate of the universal set for the proposed qubit system.

A schematic representation of the two devices implementing the $\mathbf{R_0}$ and $\mathbf{R_x}$ transformations are reported in Fig. 3 (a) and (b), respectively.

It is straightforward to note that the transformations $\mathbf{R_x}$ and $\mathbf{R_z}$ for the electronic wave function are analogues to the transformations induced, in a two-path interferometer, by a photon beam splitter and a photon phase shifter. Furthermore, a simple calculation, that we omit for brevity, shows that the Hadamard gate of Eq. (6) can be obtained by using the above transformations.

Two-Qubit Gate

In order to implement the conditional phase shifter gate T, whose operation is described in Eq. (18), two qubits must be considered. Figure 3c represents the geometry of the two-qubit device. In the following we will call "first" the qubit represented by the left couple of wires, "second" the one represented by the right couple. In the two-qubit binary encoding of the state of the system, the second qubit is the less significant bit.

The device is designed as follows [10]. The four wires of the two qubits run parallel to each other and, in a small region, the wire 1 of the first qubit and the wire 0 of the second qubit get close to each other, enough to give rise to a significant Coulomb coupling between two electrons running along them. In fact, when the two electrons approach each other, part of their kinetic energy is transformed into a repulsive coupling potential and the velocity along the wires is reduced. Then, when the distance between them increases again to the original value, the potential energy is transformed back into kinetic energy and the initial velocity is restored. As a result of this process, the two electrons running along the right wire (state $|1\rangle$) of the first qubit and the left wire (state $|0\rangle$) of the second qubit, will suffer a delay in their propagation compared to the case in which either the first or the second qubit are not in one of the two central wires. This delay depends on the length of the coupling region and on the distance between the two central wires, and corresponds to a phase factor in front of the $|10\rangle$ component of the two-qubit system.

The transformation T induced by the described geometry (shown in Fig. 3c) can be also understood by analyzing the effect on the two electrons separately. If the first electron is in state $|1\rangle$ (the electron is in the wire near the second qubit), the slowing down caused on the second qubit is similar to the slowing down caused by a delaying potential barrier and the transformation on the second qubit is of the kind $\mathbf{R_0}$; similarly, if the second qubit is $|0\rangle$ the transformation on the first qubit is $\mathbf{R_1}$. As can be easily seen by direct inspection, if the whole two-qubits system is considered, the behavior described above gives rise to the two-qubits transformation T.

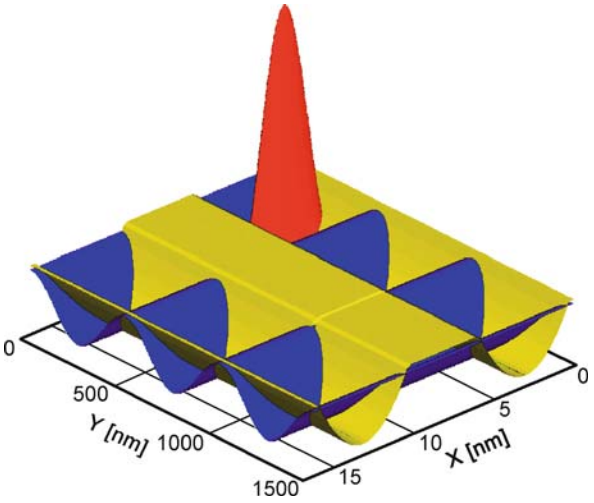
This proposal for the physical realization of a two-qubit gate is alternative to the one advanced in [25], where a CNOT gate was proposed (instead of the T gate proposed here) exploiting the difference in the oscillation period, induced by the Coulomb interaction between two electrons. It must be noted that, together with single qubit rotations, the conditional phase shifter is the basic transformation for the quantum discrete Fourier transform, needed to implement Shor's algorithm [17]. Starting from the CNOT gate, a quantum network is needed to implement a $\mathbf{T}$ transformation:

$$\mathbf{T}(\gamma) = \mathbf{R_1}^{(1)}\left(\frac{\gamma}{2}\right)\mathbf{R_1}^{(2)}\left(-\frac{\gamma}{2}\right)\text{CNOT}\;\;\mathbf{R_1}^{(2)}\left(\frac{\gamma}{2}\right)\text{CNOT}\,. \tag{30}$$

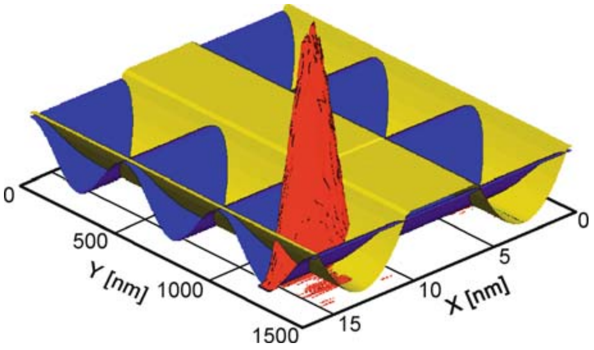
This network is simple, but the present proposal can avoid this step and directly realize the conditional phase shifter.

Electrons Driven by Surface Acoustic Waves

As an alternative to the ballistic propagation of electrons along the quantum wires, the use of surface acoustic waves (SAW) has been proposed. The SAW technology presents the drawback of some local heating near the SAW transducer. However, Barnes et al. [5] have successfully applied the SAW technique for the electron injection and transport along quantum wires. Within this approach a number of electrons are captured from a 2DEG and placed into the minima of a sinusoidal acoustic wave that propagates along the device. The 2DEG region is connected to the quantum-wire region in which a single electron must be injected. When the SAW minimum reaches the 1D channel, the trapped electrons undergo a further confinement due to the lateral potential that constitutes the wire, so that a moving quantum dot is formed. With a suitable choice of the SAW parameters it is possible to create a dot that carries a single electron. The electron moving inside the 1D channel is embedded in the minimum of the dot and, like in the free-propagation case, it experiences the cascade of



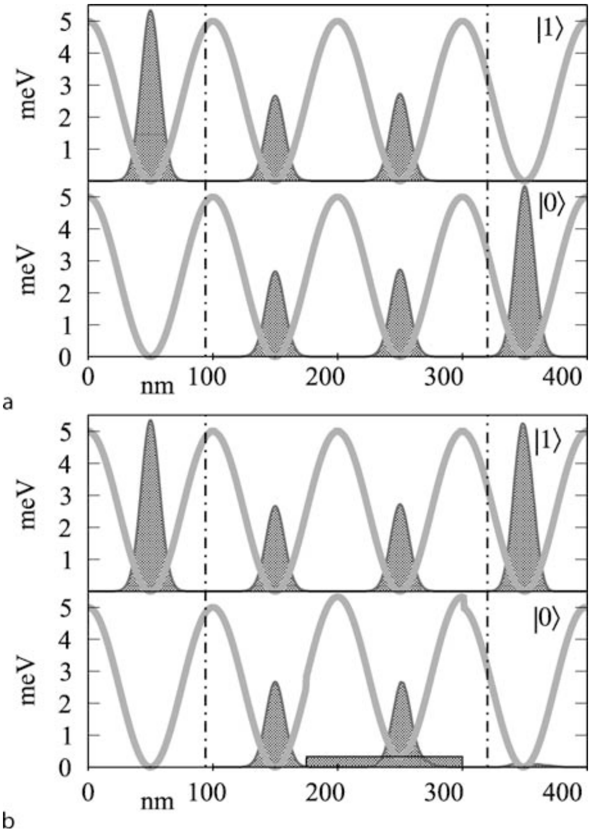
Charge-Based Solid-State Flying Qubits, Figure 4
Electron wave function (*red*) driven along a double wire device by the time-dependent sinusoidal potential of the SAW (*blue*) that are propagating from left to right



Charge-Based Solid-State Flying Qubits, Figure 5
Electron wave function (*red*) of Fig. 4 after the R_x transformation induced by the inter-wire coupling window at $y = 1000$ nm

quantum gates. In this way, the wave-packet could be more immune to decoherence effects, as it is confined along the three dimensions.

Figures 4 and 5 show the results, at initial and final time, respectively, of a time-dependent numerical simulation of a $\mathbf{R_x}$ gate device with SAW. Because of the long wave length of the SAWs (about 500 nm here), the spatial spreading of the electron wave function is large. Furthermore, the coupling window, located at $y = 1000$ nm, is small and hardly visible. However, the system parameters have been tuned in order to obtain a NOT operation and the electron wave function embedded in the SAW minimum is transferred from the wire 1 to the wire 0, thus confirming the proper functioning of the device.



Charge-Based Solid-State Flying Qubits, Figure 6

One-dimensional time-dependent simulation of an electron wave function trapped inside a minimum of a surface acoustic wave (*sinusoidal solid line*), propagating from the left to the right. The square modulus of the wave function is shown at four different time steps (*shaded regions*). The coupled-wire device has two single-qubit rotations $R_x(\pi/2)$ (represented by *dashed-dotted lines*). In the *lower graph* a phase shifter $R_z(\pi)$ (small potential around 200–300 nm) is inserted in the wire 0 between the rotations, leading to a different final state of the qubit

While the action of the coupling window ($\mathbf{R_x}$ transformation) is not altered in the SAW approach, the functioning of the gates $\mathbf{R_z}$ and $\mathbf{T}$ need to be revised [12]. In fact, the confinement along the wire, due to the SAW, prevents the spatial delay of the wave packet, since the velocity of the electron is fixed by the SAW velocity. However, also in this case the $\mathbf{R_z}$ transformation can be realized by means of a potential barrier along the wire. Now the phase shift originates from the change of the energy levels of the moving dot, caused by the additional potential of the barrier. The $\mathbf{R_z}$ and $\mathbf{T}$ transformations in the frame of the SAW approach have been validated by numerical simulations and an example is shown in Fig. 6, where two 1D simulations for a SAW-driven electron are reported [8]. The wave function, shown at four different time steps, is initialized in the ground state of the sinusoidal SAW potential, inside the $|1\rangle$-state wire. Two quantum gate networks are simulated, namely $\mathbf{R_x}(\pi/2)\mathbf{R_x}(\pi/2)$ (with two coupling windows) and $\mathbf{R_x}(\pi/2)\mathbf{R_z}(\pi)\mathbf{R_x}(\pi/2)$ (with a coupling window, a potential barrier and a second coupling window) in the two uppermost and the two lowermost plots, respectively. In the second case the presence of a small potential barrier between the two splitting windows is able to change the final state of the qubit, as in the case of free propagation of the carrier. The use of SAW-induced electron interferometry in QWRs is being actively investigated both theoretically [13,23,37] and experimentally [15].

Entangled States and Estimation of Quantum Entanglement

The simulation presented in the previous section, is the result of a time-dependent Schrödinger solver that evolves the electrons in a single particle approximation. This is necessary due to the high computational effort that is needed for a ballistic evolution, with Coulomb interaction, in two dimensions. In the above approach, each electron wave-function $\psi(x, y)$ is represented, at a given time step, by a two-dimensional array. This means that no entanglement between electrons can be simulated. Nevertheless, the simulations performed validated the devices using a base of factorizable qubit states: the effect on entangled states can be easily deduced once the behavior on the given basis is known, thanks to the superposition principle. For example, the result of a transformation $\mathbf{R_x}^{(2)}(\pi/2)\mathbf{T}(\pi)\mathbf{R_x}^{(2)}(\pi/2)$ on a state $(|00\rangle + |10\rangle)$ is an entangled state:

$$\mathbf{R_x}^{(2)}(\pi/2)\mathbf{T}(\pi)\mathbf{R_x}^{(2)}(\pi/2)(|00\rangle + |10\rangle) = -(|01\rangle + i|10\rangle)\,. \quad (31)$$

The condition of separability imposed on the wave function will be dropped in this section. In fact, the possibility to simulate an entangled two-electron state allows the study of the physical system proposed in [26] for the test of Bell inequality using quantum-wire semiconductor devices.

Since the straightforward numerical simulation, in two dimensions, of the time evolution of $\psi(x_1, y_1, x_2, y_2, t)$ results to be too expensive from a computational point of view, a simpler semi-1D model can be used to study the proposed quantum wire system [11]. Let us consider, for the moment, a single qubit, i. e. an electron running along a couple of QWRs, with its wave function $\psi(x_1, y_1)$ eventually split between the wires. If the transverse component (orthogonal to the wires) of the electron wave function remains in the ground state of the transverse potential, i. e. the inter-subband scattering is negligible, then, along the device, the transverse dynamics can be neglected. This is obviously false in the regions of the $\mathbf{R_x}$ coupling windows, which will be considered in the following.

Two possible states of the qubit can be used to label the two possible forms for the transverse wave function, a cosine centered either in the wire 0 or 1:

$$\begin{aligned} x_1 = 0 &\longrightarrow \langle x|0\rangle = \sqrt{\frac{2}{L}}\cos\left(\frac{\pi}{L}(x - X_0)\right) \\ x_1 = 1 &\longrightarrow \langle x|1\rangle = \sqrt{\frac{2}{L}}\cos\left(\frac{\pi}{L}(x - X_1)\right) , \end{aligned} \tag{32}$$

where X_0 and X_1 are the central points of wires 0 and 1, respectively, and L is their width.

Concerning the $\mathbf{R_x}(\theta)$ transformation, within this semi-1D model, it is not possible to simulate directly the wave function splitting induced by the coupling window. In fact the wave function evolution that originates the transformation comes from the transverse dynamics whose detailed description is now lost. It is, however, possible to directly use the analytical expression of $\mathbf{R_x}$ in order to account for the coupling window, once it has been validated through numerical simulations [11]. The above considerations allow one to include the effect of an $\mathbf{R_x}(\theta)$ transformation, directly by the application of the proper transformation matrix. A similar approach has been used to include the two beam-splitters in the simulations of Fig. 6.

Let us consider now the third gate, namely the two-qubit conditional phase shifter sketched in Fig. 3c. As for the single-qubit case, it is possible to associate to each wire of the first or second qubit, a given value (either 0 or 1) of the x coordinate, considered now as a parameter. This is done for both the first and second qubit. With this approach, the model is strongly simplified: from a time-dependent Schrödinger equation for the five-variable wave function $\psi(x_1, y_1, x_2, y_2, t)$, to four equations:

$$\begin{aligned} i\hbar\frac{\partial}{\partial t}\psi_{x_1,x_2}(y_1, y_2, t) = &-\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial y_1^2} + \frac{\partial^2}{\partial y_2^2}\right) \\ &\cdot \psi_{x_1,x_2}(y_1, y_2, t) \\ &+ V_{x_1,x_2}(y_1, y_2)\psi_{x_1,x_2}(y_1, y_2, t) \end{aligned} \tag{33}$$

with $x_1, x_2 \in \{0, 1\}$. During the time evolution, the four different components of the wave function

$$\psi_{x_1,x_2}(y_1, y_2, t) \quad \text{with} \quad x_1, x_2 \in \{0, 1\} , \tag{34}$$

are coupled by the $\mathbf{R_x}^{(1)}$ and $\mathbf{R_x}^{(2)}$ transformations, given by (see Eq. (9) for the notation):

$$\mathbf{R_x}^{(1)}(\theta) = \begin{pmatrix} \cos\left(\frac{\theta}{2}\right) & 0 & i\sin\left(\frac{\theta}{2}\right) & 0 \\ 0 & \cos\left(\frac{\theta}{2}\right) & 0 & i\sin\left(\frac{\theta}{2}\right) \\ i\sin\left(\frac{\theta}{2}\right) & 0 & \cos\left(\frac{\theta}{2}\right) & 0 \\ 0 & i\sin\left(\frac{\theta}{2}\right) & 0 & \cos\left(\frac{\theta}{2}\right) \end{pmatrix} , \tag{35}$$

$$\mathbf{R_x}^{(2)}(\theta) = \begin{pmatrix} \cos\left(\frac{\theta}{2}\right) & i\sin\left(\frac{\theta}{2}\right) & 0 & 0 \\ i\sin\left(\frac{\theta}{2}\right) & \cos\left(\frac{\theta}{2}\right) & 0 & 0 \\ 0 & 0 & \cos\left(\frac{\theta}{2}\right) & i\sin\left(\frac{\theta}{2}\right) \\ 0 & 0 & i\sin\left(\frac{\theta}{2}\right) & \cos\left(\frac{\theta}{2}\right) \end{pmatrix} . \tag{36}$$

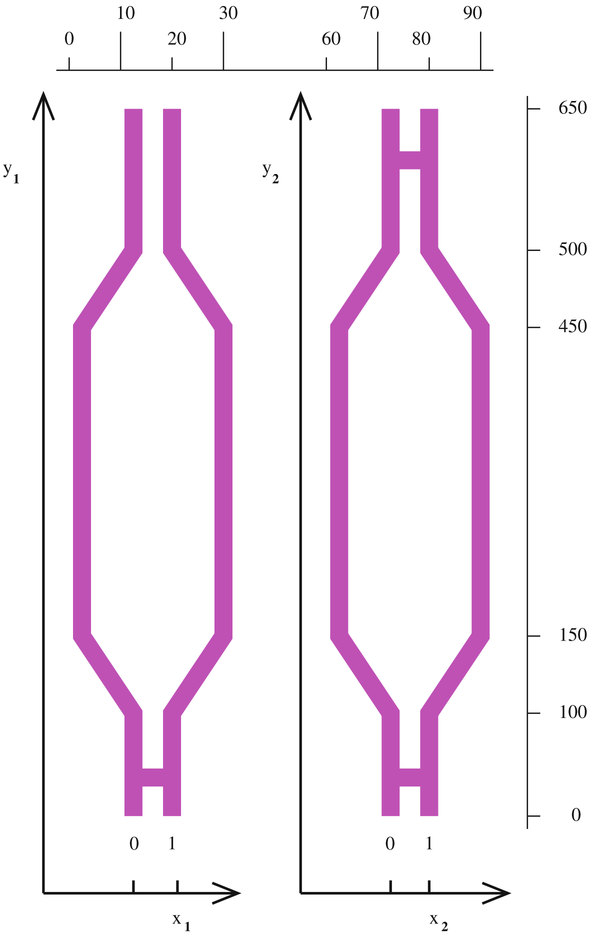
The geometry of the system is contained in the two-particle potential $V_{x_1,x_2}(y_1, y_2)$. It consists of three terms: the two structure potentials along the wires 0 and 1 of each qubit, and the Coulomb interaction between the electrons:

$$V_{x_1,x_2}(y_1, y_2) = U_{x_1}(y_1) + V_{x_2}(y_2) + \frac{e^2}{\epsilon D_{x_1,x_2}(y_1, y_2)} . \tag{37}$$

where $D_{x_1,x_2}(y_1, y_2)$ represents the distance between point y_1 in x_1 wire of the first qubit and point y_2 in x_2 wire of the second qubit and is given explicitly by

$$D_{x_1,x_2}(y_1, y_2) = \sqrt{[p_{x_1}(y_1) - q_{x_2}(y_2)]^2 + [y_1 - y_2]^2} \tag{38}$$

where $p_{x_1}(y_1)$ is the x coordinate of a point that has y coordinate y_1 on the wire representing the x_1 state of the first qubit.



Charge-Based Solid-State Flying Qubits, Figure 7
QWRs network that realizes the transformation $R_x^{(2)}(\pi/2)T(\pi)$ $R_x^{(2)}(\pi/2)R_x^{(1)}(\pi/2)$. The geometry shown is able to produce the four maximally entangled two-qubit Bell states [11]

Since the phase shift $\mathbf{R_0}$ of the first qubit is obtained with a delaying potential barrier inserted along a wire, its functioning is not altered with respect to the full-2D model. The potential barrier is accounted for in potential $U_0(y_1)$. Similarly, for the second qubit the potential is inserted in $V_0(y_1)$. We stress that, within the proposed universal set of gates, the conditional phase shifter is the only two-qubit gate and, as a consequence, the only one able to produce an entangled state.

In conclusion, let us present the result of a numerical simulation of a simple gate network able to produce a maximally entangled Bell's state. The transformation is

$$\mathbf{R_x}^{(1)}(\pi/2)\mathbf{R_x}^{(2)}(\pi/2)\mathbf{T}(\pi)\mathbf{R_x}^{(2)}(\pi/2)\,, \tag{39}$$

and the network obtained is schematized in Fig. 7. Two electrons are injected in the device. One electron is injected in the wire 1 of the first qubit and one in the wire 0 of the second qubit. The initial state is $|10\rangle$. It is easy to verify that the network described will perform the transformation:

$$\mathbf{R_x}^{(2)}(\pi/2)\mathbf{T}(\pi)\mathbf{R_x}^{(2)}(\pi/2)\mathbf{R_x}^{(1)}(\pi/2)|10\rangle \\ = \frac{1-i}{2}(|01\rangle + |10\rangle)\,. \tag{40}$$

The numerical simulations performed, and shown in Fig. 8, confirm the good functioning of the device and the production of the entangled Bell's state

$$|\Psi^+\rangle = \frac{(|01\rangle + |10\rangle)}{\sqrt{2}}\,. \tag{41}$$

Future Directions

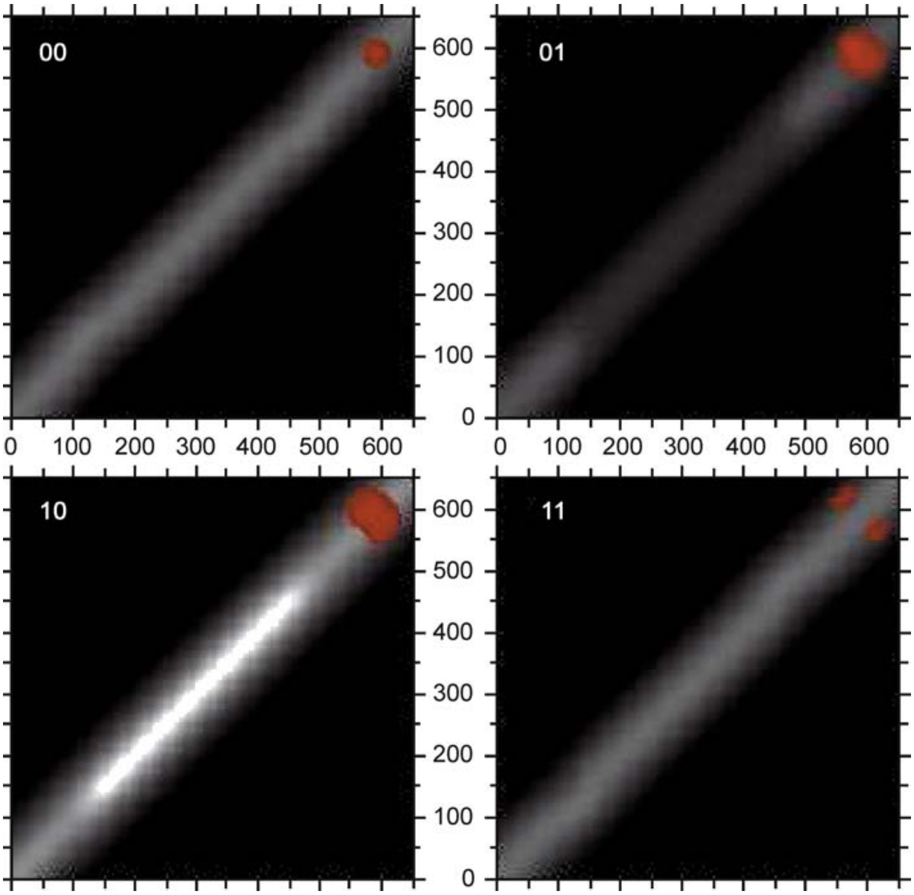
The devices presented in this work have, in principle, the full potentiality to create entangled states of electrons and to perform the logic operations of the universal quantum set of gates. For the modeling of realistic structures, we refer to the literature [1,29,32,38,42].

Concerning experimental realizations of prototypes of the single-qubit gates, we note that Pingue et al. [31] obtained the evidence of switching capabilities of the coupled-wire device, but the presence of occupied localized states in a quantum wire near the coupling window, also predicted in [29], and the Coulomb blockade regime of the experiment, made the device not suitable as a quantum gate.

Both vertical [20,22] and planar [35,36] double-channel structures are currently under investigation. In particular, Ramamoorty et al. [36] obtained switching characteristics whose temperature dependence show a clear signature of coherent behavior of a coupling-window device. It is also worth noting that Fischer et al. demonstrated that the control of the coupling between two modes of two 1D channels is feasible. The two modes were obtained exploiting the two minima of the conduction-band edge in the growth direction of a GaAs 2DEG [21] of two vertically coupled 2DEGs [22]: in both cases clear signatures of coherent coupling have been observed.

Acknowledgment

I would like to express my sincere thanks to the groups of Carlo Jacoboni and Massimo Rudan, that performed, together with the author, a large part of the work here reported. Furthermore, I thank, for most fruitful discussions, Marco Fanciulli and Peter Vogl.



Charge-Based Solid-State Flying Qubits, Figure 8
Square modulus of the two-particle wave function (*red*) at the final time step of the simulation represented in Eq. (40). The four graphs represent the cases: $x_1 = 0, x_2 = 0; x_1 = 0, x_2 = 1; x_1 = 1, x_2 = 0; x_1 = 1, x_2 = 1$, as indicated in the *upper left corners* (see Eq. (33)). The *vertical and horizontal axes* of each graph represent the position y_1 of the first electron and y_2 of the second electron, respectively. The *white region along the diagonals* represent the electron–electron potential given by Eq. (37) [11]

Chronological Calculus in Systems and Control Theory

MATTHIAS KAWSKI
Department of Mathematics, Arizona State University, Tempe, USA

Article Outline

Glossary

Controllability A control system is controllable if for every pair of points (*states*) p and q there exists an admissible control such that the corresponding solution curve that starts at p ends at q. Local controllability about a point means that all states in some open neighborhood can be reached.

Pontryagin Maximum Principle of optimal control Optimality of a control-trajectory pair geometrically is a property *dual* to local controllability in the sense that an optimal trajectory (endpoint) lies on the boundary of the reachable sets (after possibly augmenting the state of the system by the running cost). The maximum principle is a necessary condition for optimality. Geometrically it is based on analyzing the effect of families of control variations on the endpoint map. The chronological calculus much facilitates this analysis.

$\mathcal{E}(M) = C^\infty(M)$ The algebra of smooth functions on a finite dimensional manifold M, endowed with the topology of uniform convergence of derivatives of all orders on compact sets.

$\Gamma^\infty(M)$ The space of smooth vector fields on the manifold M.

Chronological calculus An approach to systems theory based on a functional analytic operator calculus, that replaces nonlinear objects such as smooth manifolds by infinite dimensional linear ones, by commutative algebras of smooth functions.

Chronological algebra A linear space with a bilinear product ★ that satisfies the identity $a \star (b \star c) - b \star (a \star c) = (a \star b) \star c - (b \star a) \star c$. This structure arises naturally via the product $(f \star g)_t = \int_0^t [f_s, g_s']\mathrm{d}s$ of time-varying vector fields f and g in the chronological calculus. Here [,] denotes the Lie bracket.

Zinbiel algebra A linear space with a bilinear product that satisfies the identity $a * (b * c) = (a * b) * c + (b * a) * c$. This structure arises naturally in the special case of affine control systems for the product $(U * V)(t) = \int_0^t U(s)V'(s)\mathrm{d}s$ of absolutely continuous scalar valued functions U and V.

The name Zinbiel is Leibniz read backwards, reflecting the duality with Leibniz algebras, a form of noncommutative Lie algebras. There has been some confusion in the literature with Zinbiel algebras incorrectly been called chronological algebras.

$\mathcal{IIF}(\mathcal{U}^Z)$ For a suitable space $\mathcal{U}$ of *time-varying scalars*, e. g. the space of locally absolutely continuous real-valued functions defined on a fixed time interval, and an indexing set Z, $\mathcal{IIF}(\mathcal{U}^Z)$ denotes the space of iterated integral functionals from the space of Z-tuples with values in $\mathcal{U}$ to the space $\mathcal{U}$.

Definition of the Subject

The chronological calculus is a functional analytic operator calculus tool for nonlinear systems theory. The central idea is to replace nonlinear objects by linear ones, in particular, smooth manifolds by commutative algebras of smooth functions. Aside from its elegance, its main virtue is to provide tools for problems that otherwise would effectively be untractable, and to provide new avenues to investigate the underlying geometry. Originally conceived to investigate problems in optimization and control, specifically for extending Pontryagin's Maximum Principle, the chronological calculus continues to establish itself as the preferred language of geometric control theory, and it is spawning new sets of problems, including its own set of algebraic structures that are now studied in their own right.

Introduction, History, and Background

This section starts with a brief historical survey of some landmarks that locate the chronological calculus at the interface of systems and control theory with functional analysis. It is understood that such brief survey cannot possibly do justice to the many contributors. Selected references given are meant to merely serve as starting points for the interested reader.

Many problems in modern systems and control theory are inherently nonlinear and e. g., due to conserved quantities or symmetries, naturally *live* on manifolds rather than on Euclidean spaces. A simple example is the problem of stabilizing the attitude of a satellite via feedback controls. In this case the natural state space is the tangent bundle $TSO(3)$ of a rotation group. The controlled dynamics are described by generally nonautonomous nonlinear differential equations. A key characteristic of their flows is their general lack of commutativity. Solutions of nonlinear differential equations generally do not admit closed form expressions in terms of the traditional sets of elementary functions and symbols. The chronological calculus circumvents such difficulties by reformulating systems and control problems in a different setting which is infinite dimensional, but linear. Building on well established tools and theories from functional analysis, it develops a new formalism and a precise language designed to facilitate studies of nonlinear systems and control theory.

The basic plan of replacing nonlinear objects by linear ones, in particular smooth manifolds by commutative algebras of smooth functions, has a long history. While its roots go back even further, arguably this approach gained much of its momentum with the path-breaking innovations by John von Neumann's work on the *"Mathematical Foundations of Quantum Mechanics"* [104] and Marshall Stone's seminal work on *"Linear Transformations in Hilbert Space"* [89], quickly followed by Israel Gelfand's dissertation on *"Abstract Functions and Linear Operators"* [34] (published in 1938). The fundamental concept of maximal ideal justifies this approach of identifying manifolds with commutative normed rings (algebras), and vice versa. Gelfand's work is described as uniting previously uncoordinated facts and revealing the close connections between classical analysis and abstract functional analysis [102]. In the seventy years since, the study of Banach algebras, C^*-algebras and their brethren has continued to develop into a flourishing research area.

In the different arena of systems and control theory, major innovations at formalizing the subject were made in the 1950s. The Pontryagin Maximum Principle [8] of optimal control theory went far beyond the classical calculus of variations. At roughly the same time Kalman and his peers introduced the Kalman filter [51] for extracting signals from noisy observations, and pioneered state-space approaches in linear systems theory, developing the fundamental concepts of controllability and observability. Linear systems theory has bloomed and grown into a vast array of subdisciplines with ubiquitous applications. Via well-established transform techniques, linear systems lend themselves to be studied in the *frequency domain*. In such settings, systems are represented by linear operators on spaces of functions of a complex variable. Starting in the 1970s new efforts concentrated on rigorously extending linear systems and control theory to nonlinear settings. Two complementary major threads emerged that rely on differential geometric methods, and on operators represented by formal power series, respectively. The first is exemplified in the pioneering work of Brockett [10,11], Haynes and Hermes [43], Hermann [44], Hermann and Krener [45], Jurdjevic and Sussmann [50], Lobry [65], and many others, which focuses on state-space representations of nonlinear systems. These are defined by collections of vector fields on manifolds, and are analyzed using, in particular, Lie algebraic techniques. On the other side, the input-output approach is extended to nonlinear settings primarily through a formal power series approach as initiated by Fliess [31]. The interplay between these approaches has been the subject of many successful studies, in which a prominent role is played by Volterra series and the problem of *realizing* such input-output descriptions as a state-space system, see e. g. Brockett [11], Crouch [22], Gray and Wang [37], Jakubczyk [49], Krener and Lesiak [61], and Sontag and Wang [87].

In the late 1970s Agrachëv and Gamkrelidze introduced into nonlinear control theory the aforementioned abstract functional analytic approach, that is rooted in the work of Gelfand. Following traditions from the physics community, they adopted the name chronological calculus. Again, this abstract approach may be seen as much unifying what formerly were disparate and isolated pieces of knowledge and tools in nonlinear systems theory. While originally conceived as a tool for extending Pontryagin's Maximum Principle in optimal control theory [1], the chronological calculus continues to yield a stream of new results in optimal control and geometry, see e. g. Serres [85], Sigalotti [86], Zelenko [105] for very recent results utilizing the chronological calculus for studying the geometry.

The chronological calculus has led to a very different way of thinking about control systems, epitomized in e. g. the monograph on geometric control theory [5] based on the chronological calculus, or in such forceful advocacies for this approach for e. g. nonholonomic path finding by Sussmann [95]. Closely related are studies of nonlinear controllability, e. g. Agrachëv and Gamkrelidze [3,4], Tretyak [96,97,98], and Vakhrameev [99], including applications to controllability of the Navier–Stokes equation by Agrachëv and Sarychev [6]. The chronological calculus also lends itself most naturally to obtaining new results in averaging theory as in Sarychev [83], while Cortes and Martinez [20] used it in motion control of mechanical systems with symmetry and Bullo [13,68] for vibrational control of mechanical systems. Noteworthy applications include locomotion of robots by Burdick and Vela [100], and even robotic fish [71]. Instrumental is its interplay with series expansion as in Bullo [12,21] that utilize affine connections of mechanical systems. There are further applications to stability and stabilization Caiado and Sarychev [15,82], while Monaco et.al. [70] extended this approach to discrete-time dynamics and Komleva and Plotnikov used it in differential game theory [60].

Complementing such *applications* are new subjects of study such as the abstract algebraic structures that underlie the chronological calculus. The chronological algebra itself has been the subject of study as early as Agrachëv and Gamkrelidze [2]. The closely related structure of Zinbiel structures has recently found more attention, see work by Dzhumadil'daev [25,26], Kawski and Sussmann [57] and Kawski [54,55]. Zinbiel algebras arise in the special case when the dynamics ("*time-varying vector fields*") splits into a sum of products of time-varying coefficients and autonomous vector fields. There is an unfortunate confusion of terms in the literature as originally Zinbiel algebras had also been called chronological algebras. Recent usage disentangles these closely related, but distinct, structures and reflects the primacy of the latter term coined by Loday [66,67] who studies Leibniz algebras (which appear in cyclic homology). *Zinbiel* is simply *Leibniz* spelled backwards, a choice which reflect that Leibniz and Zinbiel are dual operands in the sense of Koszul duality as investigated by Ginzburg and Kapranov [36].

Fundamental Notions of the Chronological Calculus

From a Manifold to a Commutative Algebra

This and the next sections very closely follow the introductory exposition of Chapter 2 of Agrachëv and Sachkov [5], which is also recommended for the full technical and analytical details regarding the topology and convergence.

The objective is to develop the basic tools and formalism that facilitate the analysis of generally nonlinear systems that are defined on smooth manifolds. Rather than primarily considering points on a smooth manifold M, the key idea is to instead focus on the commutative algebra of $\mathcal{E}(M) = C^\infty(M, \mathbb{R})$ of real-valued smooth functions on M. Note that $\mathcal{E}(M)$ not only has the structure of a vector space over the field $\mathbb{R}$, but it also inherits the structure of a commutative ring under pointwise addition and multiplication from the codomain $\mathbb{R}$.

Every point $p \in M$ gives rise to a functional $\hat{p}\colon \mathcal{E}(M) \mapsto \mathbb{R}$ defined by $\hat{p}(\varphi) = \varphi(p)$. This functional is linear and multiplicative, and is a homomorphism of the algebras $\mathcal{E}(M)$ and $\mathbb{R}$: For every $p \in M$, for $\varphi, \psi \in \mathcal{E}(M)$ and $t \in \mathbb{R}$ the following hold

$$\hat{p}(\varphi + \psi) = \hat{p}\varphi + \hat{p}\varphi, \quad \hat{p}(\varphi \cdot \psi) = (\hat{p}\varphi) \cdot (\hat{p}\psi)\,, \quad \text{and} \quad \hat{p}(t\varphi) = t \cdot (\hat{p}\varphi)\,.$$

Much of the power of this approach derives from the fact that this correspondence is invertible: For a nontrivial multiplicative linear functional $\theta\colon \mathcal{E}(M) \mapsto \mathbb{R}$ consider its kernel $\ker\theta = \{\varphi \in \mathcal{E}(M)\colon \theta\varphi = 0\}$. A critical observation is that this is a maximal ideal, and that it must be of the form $\{\varphi \in \mathcal{E}(M)\colon \varphi(p) = 0\}$ for some, uniquely defined, $p \in M$. For the details of a proof see appendix A.1. of [5].

Proposition 1 *For every nontrivial multiplicative linear functional $\theta\colon \mathcal{E}(M) \mapsto \mathbb{R}$ there exists $p \in M$ such that $\theta = \hat{p}$.*

Note on the side, that there may be maximal ideals in the space of all multiplicative linear functionals on $\mathcal{E}(M)$ that do not correspond to any point on M – e. g. the ideal of all linear functionals that vanish on every function with compact support. But this does not contradict the stated proposition.

Not only can one *recover* the manifold M as a set from the commutative ring $\mathcal{E}(M)$, but using the weak topology on the space of linear functionals on $\mathcal{E}(M)$ one also recovers the topology on M

$$p_n \longrightarrow p \ \text{ if and only if } \ \forall f \in \mathcal{E}(M),\ \widehat{p_n} f \longrightarrow \hat{p} f\,. \quad (1)$$

The smooth structure on M is recovered from $\mathcal{E}(M)$ in a trivial way: A function g on the space of multiplicative linear functionals $\hat{p}\colon p \in M$ is smooth if and only if there exists $f \in \mathcal{E}(M)$ such that for every $\hat{p}$, $g(\hat{p}) = \hat{p}f$.

In modern differential geometry it is routine to identify tangent vectors to a smooth manifold with either equivalence classes of smooth curves, or with first order partial differential operators. In this context, tangent vectors at a point $q \in M$ are derivations of $\mathcal{E}(M)$, that is, linear functionals $\hat{f}_q$ on $\mathcal{E}(M)$ that satisfy the Leibniz rule. Using $\hat{q}$, this means for every $\varphi, \psi \in \mathcal{E}(M)$,

$$\hat{X}_q(\varphi\psi) = (\hat{X}_q\varphi)(\hat{q}\psi) + (\hat{q}\varphi)(\hat{X}_q\psi)\,. \quad (2)$$

Smooth vector fields on M correspond to linear functionals $\hat{f}\colon \mathcal{E}(M) \mapsto \mathcal{E}(M)$ that satisfy for all $\varphi, \psi \in \mathcal{E}(M)$

$$\hat{f}(\varphi\psi) = (\hat{f}\varphi) \cdot \psi + \varphi \cdot (\hat{f}\psi)\,. \quad (3)$$

Again, the correspondence between tangent vectors and vector fields and the linear functionals as above is invertible. Write $\Gamma^\infty(M)$ for the space of smooth vector fields on M.

Finally, there is a one-to-one correspondence between smooth diffeomorphisms $\Phi\colon M \mapsto M$ and automorphisms of $\mathcal{E}(M)$. The map $\hat{\Phi}\colon \mathcal{E}(M) \mapsto \mathcal{E}(M)$ defined for $p \in M$ and $\varphi \in \mathcal{E}(M)$ by $\hat{\Phi}(\varphi)(p) = \varphi(\Phi(p))$ clearly has the desired properties. For the reverse direction, suppose $\Psi\colon \mathcal{E}(M) \mapsto \mathcal{E}(M)$ is an automorphism. Then for every $p \in M$ the map $\hat{p} \circ \Psi\colon \mathcal{E}(M) \mapsto \mathbb{R}$ is a nontrivial linear multiplicative functional, and hence equals $\hat{q}$ for some $q \in M$. It is easy to see that the map $\Phi\colon M \mapsto M$ is indeed a diffeomorphism, and $\Psi = \hat{\Phi}$.

In the sequel we shall omit the *hats*, and simply write, say, p for the linear functional $\hat{p}$. The role of each object is usually clear from the order. For example, for a point p, a smooth function φ, smooth vector fields f, g, h, with flow e^{th} and its tangent map $\left(e^{th}\right)_*$, what in traditional format might be expressed as $(\left(e^{th}\right)_* g)\varphi(e^{\tau f}(p))$ is simply written as $pe^{\tau f} g e^{th}\varphi$, not requiring any parentheses.

Frechet Space and Convergence

The usual topology on the space $\mathcal{E}(M)$ is the one of uniform convergence of all derivatives on compact sets, i. e., a sequence of functions $\{\varphi_k\}_{k=1}^\infty \subseteq \mathcal{E}(M)$ converges to $\phi \in \mathcal{E}(M)$ if for every finite sequence $f_1, f_2, \ldots, f_s$ of smooth vector fields on M and every compact set $K \subseteq M$ the sequence $\{f_s \ldots f_2 f_1 \varphi_k\}_{k=1}^\infty$ converges uniformly on K to $f_s \ldots f_2 f_1 \varphi$.

This topology is also obtained by a countable family of semi-norms $\|\cdot\|_{s,K}$ defined by

$$\|\varphi\|_{s,K} = \sup\{\, |p f_s \ldots f_2 f_1 \varphi| : \\ p \in K,\ f_i \in \Gamma^\infty(M),\ s \in \mathbb{Z}^+ \,\} \quad (4)$$

where K ranges over a countable collection of compact subsets whose union is all of M. In an analogous way define semi-norms of smooth vector fields $f \in \Gamma^\infty(M)$

$$\|f\|_{s,K} = \sup\{\ \|f\varphi\|_{s,K} : \ \|f\varphi\|_{s+1,K} = 1\ \}\,. \tag{5}$$

Finally, for every smooth diffeomorphism Φ of M, $s \in \mathbb{Z}^+$ and $K \subseteq M$ compact there exist $C_{s,K,\Phi} \in \mathbb{R}$ such that for all $\varphi \in \mathcal{E}(M)$

$$\|\Phi\varphi\|_{s,K} \ \leq\ C_{s,K,\Phi}\|\varphi\|_{s,\varphi(K)}\,. \tag{6}$$

Regularity properties of one-parameter families of vector fields and diffeomorphisms (*"time-varying vector fields and diffeomorphisms"*) are understood in the weak sense. In particular, for a family of smooth vector fields $f_t \in \Gamma^\infty(M)$, its integral and derivative (if they exist) are defined as the operators that satisfy for every $\varphi \in \mathcal{E}(M)$

$$\left(\frac{\mathrm{d}}{\mathrm{d}t}f_t\right)\varphi = \frac{\mathrm{d}}{\mathrm{d}t}\left(f_t\varphi\right) \quad \text{and} \quad \left(\int_a^b f_t \mathrm{d}t\right)\varphi = \int_a^b \left(f_t\varphi\right)\mathrm{d}t\,. \tag{7}$$

The convergence of series expansions of vector fields and of diffeomorphisms encountered in the sequel are to be interpreted in the analogous weak sense.

The Chronological Exponential

This section continues to closely follow [5] which contains full details and complete proofs. On a manifold M consider generally time-varying differential equations of the form $\frac{\mathrm{d}}{\mathrm{d}t}q_t = f_t(q_t)$. To assure existence and uniqueness of solutions to initial value problems, make the typical regularity assumptions, namely that in every coordinate chart $U \subseteq M$, $x \colon U \mapsto \mathbb{R}^n$ the vector field $(x_* f_t)$ is (i) measurable and locally bounded with respect to t for every fixed x and (ii) smooth with locally bounded partial derivatives with respect to x for every fixed t. For the purposes of this article and for clarity of exposition, also assume that vector fields are complete. This means that solutions to initial value problems are defined for all times $t \in \mathbb{R}$. This is guaranteed if, for example, all vector fields considered vanish identically outside a common compact subset of M.

As in the previous sections, for each fixed t interpret $q_t \colon \mathcal{E}(M) \mapsto \mathbb{R}$ as a linear functional on $\mathcal{E}(M)$, and note that this family satisfies the time-varying, but linear differential equation, suggestively written as

$$\dot{q}_t = q_t \circ f_t\,. \tag{8}$$

on the space of linear functionals on $\mathcal{E}(M)$. It may be shown that under the above assumptions it has a unique solution, called the *right chronological exponential* of the vector field f_t as the corresponding flow. Formally, it satisfies for almost all $t \in \mathbb{R}$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\overrightarrow{\exp}\int_0^t f_\tau\,\mathrm{d}\tau\right) = \left(\overrightarrow{\exp}\int_0^t f_\tau\,\mathrm{d}\tau\right) \circ f_t\,. \tag{9}$$

Analogously the *left chronological exponential* satisfies

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\overleftarrow{\exp}\int_0^t f_\tau\,\mathrm{d}\tau\right) = f_t \circ \left(\overleftarrow{\exp}\int_0^t f_\tau\,\mathrm{d}\tau\right)\,. \tag{10}$$

Formally, one obtains a series expansion for the chronological exponentials by rewriting the differential equation as an integral equation and solving it by iteration

$$q_t = q_0 + \int_0^t q(\tau)\circ f_\tau\,\mathrm{d}\tau \tag{11}$$

$$= q_0 + \int_0^t \left(q_0 + \int_0^\tau q(\sigma)\circ f_\sigma\, d\sigma\right)\circ f_\tau\,\mathrm{d}\tau \tag{12}$$

to eventually, formally, obtain the expansion

$$\overrightarrow{\exp}\int_0^t f_\tau\,\mathrm{d}\tau \sim \mathrm{Id} + \sum_{k=1}^{\infty}\int_0^t\int_0^{t_k}\cdots\int_0^{t_2} \cdot f_{\tau_k}\circ\cdots\circ f_{\tau_2}\circ f_{\tau_1}\,\mathrm{d}\tau_k\ldots\mathrm{d}\tau_2\,\mathrm{d}\tau_1 \tag{13}$$

and analogously for the left chronological exponential

$$\overleftarrow{\exp}\int_0^t f_\tau\,\mathrm{d}\tau \sim \mathrm{Id} + \sum_{k=1}^{\infty}\int_0^t\int_0^{t_k}\cdots\int_0^{t_2} \cdot f_{\tau_1}\circ f_{\tau_2}\circ\cdots\circ f_{\tau_k}\,\mathrm{d}\tau_k\ldots\mathrm{d}\tau_2\,\mathrm{d}\tau_1\,. \tag{14}$$

While this series never converges, not even in a weak sense, it nonetheless has an interpretation as an asymptotic expansion. In particular, for any fixed function $\phi \in \mathcal{E}(M)$ and any semi-norm as in the previous section, on any compact set one obtains an error estimate for the remainder after truncating the series at any order N which establishes that the truncation error is of order $O(t^N)$ as $t \to 0$. When one considers the restrictions to any f_t-invariant normed linear subspace $L \subseteq \mathcal{E}(M)$, i. e. for all t, $f_t(L) \subseteq L$, on which f_t is bounded, then the asymptotic series converges to the chronological exponential and it satisfies for every $\varphi \in L$

$$\left\|\left(\overrightarrow{\exp}\int_0^t f_\tau\,\mathrm{d}\tau\right)\varphi\right\| \ \leq\ \mathrm{e}^{\int_0^t\|f_\tau\|\,\mathrm{d}\tau}\ \|\varphi\|\,. \tag{15}$$

In the case of analytic vector fields f_τ and analytic functions φ one obtains convergence of the series for sufficiently small t.

While in general there is no reason why the vector fields f_t should commute at different times, the chronological exponentials nonetheless still share some of the usual properties of exponential and flows, for example the composition of chronological exponentials satisfies for all $t_i \in \mathbb{R}$

$$\left(\overrightarrow{\exp}\int_{t_1}^{t_2} f_\tau \, \mathrm{d}\tau\right) \circ \left(\overrightarrow{\exp}\int_{t_2}^{t_3} f_\tau \, \mathrm{d}\tau\right) = \left(\overrightarrow{\exp}\int_{t_1}^{t_3} f_\tau \, \mathrm{d}\tau\right) . \tag{16}$$

Moreover, the left and right chronological exponentials are inverses of each other in the sense that for all $t_0, t_1 \in \mathbb{R}$

$$\begin{aligned}\left(\overrightarrow{\exp}\int_{t_0}^{t_1} f_\tau \, \mathrm{d}\tau\right)^{-1} &= \overrightarrow{\exp}\int_{t_1}^{t_0} f_\tau \, \mathrm{d}\tau \\ &= \overleftarrow{\exp}\int_{t_0}^{t_1} (-f_\tau) \, \mathrm{d}\tau \, .\end{aligned} \tag{17}$$

Variation of Parameters and the Chronological Logarithm

In control one rarely considers only a single vector field, and, instead, for example, is interested in the interaction of a perturbation or control vector field with a reference or drift vector field. In particular, in the nonlinear setting, this is where the chronological calculus very much facilitates the analysis. For simplicity consider a differential equation defined by two, generally time varying, vector fields (with the usual regularity assumptions)

$$\dot{q} = f_t(q) + g_t(q) \, . \tag{18}$$

The objective is to obtain a formula for the flow of the field $(f_t + g_t)$ as a *perturbation* of the flow of f_t. Writing

$$\Phi_t = \overrightarrow{\exp}\int_0^t f_\tau \, \mathrm{d}\tau \quad \text{and} \quad \Theta_t = \overrightarrow{\exp}\int_0^t (f_\tau + g_\tau) \, \mathrm{d}\tau , \tag{19}$$

this means one is looking for a family of operators Ψ_t such that for all t

$$\Theta_t = \Psi_t \circ \Phi_t \, . \tag{20}$$

Differentiating and using the invertibility of the flows one obtains a differential equation in the standard form

$$\begin{aligned}\dot{\Psi}(t) \;=\; \Psi_t \circ \Phi_t \circ g_t \circ \Phi_t^{-1} \;&=\; \Psi_t \circ (\mathrm{Ad}\Phi_t) \; g_t \\ &= \Psi_t \circ \left(\overrightarrow{\exp}\int_0^t \mathrm{ad} f_\tau \, \mathrm{d}\tau\right) \; g_t \, ,\end{aligned} \tag{21}$$

which has the unique solution

$$\Psi_t = \overrightarrow{\exp}\int_0^t \left(\overrightarrow{\exp}\int_0^\tau \mathrm{ad} f_\sigma \, \mathrm{d}\sigma\right) \; g_\tau \, \mathrm{d}\tau \, , \tag{22}$$

and consequently one has the *variations formula*

$$\begin{aligned}\overrightarrow{\exp}\int_0^t (f_\tau + g_\tau) \, \mathrm{d}\tau = \Bigg(\overrightarrow{\exp}\int_0^t \left(\overrightarrow{\exp}\int_0^\tau \mathrm{ad} f_\sigma \, \mathrm{d}\sigma\right) \\ \cdot \; g_\tau \, \mathrm{d}\tau\Bigg) \circ \left(\overrightarrow{\exp}\int_0^t f_\tau \, \mathrm{d}\tau\right) \, .\end{aligned} \tag{23}$$

This formula is of fundamental importance and used ubiquitously for analyzing controllability and optimality: One typically considers f_t as defining a reference dynamical system and then considers the effect of adding a control term g_t. A special application is in the theory of averaging where g_t is considered a perturbation of the field f_t, which in the most simple form may be assumed to be time-periodic. The monograph [81] by Sanders and Verhulst is the classical reference for the theory and applications of averaging using traditional language. The chronological calculus, in particular the above variations formula, have been used successfully by Sarychev [83] to investigate in particular higher order averaging, and by Bullo [13] for averaging in the context of mechanical systems and its interplay with mechanical connections. Instrumental to the work [83] is the notion of the chronological logarithm, which is motivated by rewriting the defining Eqs. (9) and (10) [2,80] as

$$\begin{aligned}f_t &= \left(\overrightarrow{\exp}\int_0^t f_\tau \, \mathrm{d}\tau\right)^{-1} \circ \frac{\mathrm{d}}{\mathrm{d}t}\left(\overrightarrow{\exp}\int_0^t f_\tau \, \mathrm{d}\tau\right) \\ &= \frac{\mathrm{d}}{\mathrm{d}t}\left(\overleftarrow{\exp}\int_0^t f_\tau \, \mathrm{d}\tau\right) \circ \left(\overleftarrow{\exp}\int_0^t f_\tau \, \mathrm{d}\tau\right)^{-1} \, .\end{aligned} \tag{24}$$

While in general the existence of the logarithm is a delicate question [62,83], under suitable hypotheses it is instrumental for the derivation of the nonlinear Floquet theorem in [83].

Theorem 1 (Sarychev [83]) *Suppose $f_t = f_{t+1}$ is a period-one smooth vector field generating the flow Φ_t and $\Lambda = \log \Phi_1$, then there exists a period-one family of diffeomorphisms $\Psi_t = \Psi_{t+1}$ such that for all t $\Phi_t = e^{t\Lambda} \circ \Psi_t$.*

The logarithm of the chronological exponential of a time-varying vector field εf_t may be expanded as a formal chronological series

$$\log \overrightarrow{\exp}\left(\int_0^1 \varepsilon f_\tau \, \mathrm{d}\tau\right) \;=\; \sum_{j=1}^{\infty} \varepsilon^j \Lambda^j \, . \tag{25}$$

The first three terms of which are given explicitly [83] as

$$\Lambda^1 = \int_0^1 f_\tau \ \mathrm{d}\tau \,, \quad \Lambda^2 = \frac{1}{2}\int_0^1 \left[\int_0^\tau f_\sigma \, \mathrm{d}\sigma \ , \ f_\tau \right] \ \mathrm{d}\tau,$$
$$\text{and} \quad \Lambda^3 = -\frac{1}{2}[\Lambda^1, \Lambda^2] + \frac{1}{3}\int_0^1 \mathrm{ad}^2 \left(\int_0^\tau f_\sigma \, \mathrm{d}\sigma \right) f_\tau \ \mathrm{d}\tau \,. \qquad (26)$$

Aside from such applications as averaging, the main use of the chronological calculus has been for studying the dual problems of optimality and controllability, in particular controllability of families of diffeomorphisms [4]. In particular, this approach circumvents the limitations encountered by more traditional approaches that use parametrized families of control variations that are based on a finite number of switching times. However, since [52] it is known that a general theory must allow also, e. g., for increasing numbers of switchings and other more general families of control variations. The chronological calculus is instrumental to developing such general theory [4].

Chronological Algebra

When using the chronological calculus for studying controllability, especially when differentiating with respect to a parameter, and also in the aforementioned averaging theory, the following *chronological product* appears almost everywhere: For two time-varying vector fields f_t and g_t that are absolutely continuous with respect to t, define their chronological product as

$$(f \star g)_t = \int_0^t [f_s, g_s']\mathrm{d}s \qquad (27)$$

where $[\cdot, \cdot]$ denotes the Lie bracket. It is easily verified that this product is generally neither associative nor satisfies the Jacobi identity, but instead it satisfies the chronological identity

$$x \star (y \star z) - y \star (x \star z) = (x \star y) \star z - (y \star x) \star z \,. \quad (28)$$

One may define an abstract chronological algebra (over a field $\mathbf{k}$) as a linear space that is equipped with a bilinear product that satisfies the chronological identity (28). More compactly, this property may be written in terms of the left translation λ that associates with any element $x \in \mathcal{A}$ of a not-necessarily associative algebra $\mathcal{A}$ the map $\lambda_x \colon y \mapsto xy$. Using this λ, the chronological identity (28) is simply

$$\lambda_{[x,y]} = [\lambda_x, \lambda_y] \,, \qquad (29)$$

i. e., the requirement that the map $x \mapsto \lambda_x$ is a homomorphism of the algebra $\mathcal{A}$ with the commutator product $(x, y) \mapsto xy - yx$ into the Lie algebra of linear maps from $\mathcal{A}$ into $\mathcal{A}$ under its commutator product.

Basic general properties of chronological algebras have been studied in [2], including a discussion of free chronological algebras (over a fixed generating set S). Of particular interest are bases of such free chronological algebras as they allow one to minimize the number of terms in series expansions by avoiding redundant terms. Using the graded structure, it is shown in [2] that an ordered basis of a free chronological algebra over a set S may be obtained recursively from products of the form $\lambda_{b_1}\lambda_{b_2} \cdots \lambda_{b_k} s$ where $s \in S$ is a generator and $b_1 \preccurlyeq b_2 \preccurlyeq \cdots \preccurlyeq b_k$ are previously constructed basis elements. According to [2], the first elements of such a basis over the single-element generating set $S = \{s\}$ may be chosen as (using juxtaposition for multiplication)

$$\begin{aligned} &b_1 = s \,, \quad b_2 = \lambda_{b_1} s = s^2 \,, \quad b_3 = \lambda_{b_2} s = s^2 s \,, \\ &b_4 = \lambda_{b_1}\lambda_{b_1} s = ss^2 \,, \quad b_5 = \lambda_{b_3} s = (s^2 s)s \,, \\ &b_6 = \lambda_{b_4} s = (ss^2)s \,, \quad b_7 = \lambda_{b_1}\lambda_{b_2} s = s(s^2 s) \,, \\ &\qquad b_8 = \lambda_{b_2}\lambda_{b_1} s = s(ss^2) \,, \ldots \qquad (30) \end{aligned}$$

Using only this algebraic and combinatorial structure, one may define exponentials (and logarithms) and analyze the group of formal flows [2]. Of particular interest systems and control is an explicit formula that allows one to express products (compositions) of two or more exponentials (flows) as a single exponential. This is tantamount to a formula for the logarithm of a product of exponentials of two noncommuting indeterminates X and Y. The classical version is known as the Campbell–Baker–Hausdorff formula [16], the first few terms being

$$\mathrm{e}^X \cdot \mathrm{e}^Y = \mathrm{e}^{X+Y+\frac{1}{2}[X,Y]+\frac{1}{12}[X-Y,[X,Y]]-\frac{1}{24}[X,[Y,[X,Y]]]-\ldots} \,. \qquad (31)$$

A well-known short-coming of the classical formula is that the higher-order iterated Lie brackets appearing in this formula are always linearly dependent and hence the coefficients are never well-defined. Hence one naturally looks for more compact, minimal formulas which avoid such redundancies. The chronological algebra provides one such alternative and has been developed and utilized in [2]. The interested reader is referred to the original reference for technical details.

Systems That Are Affine in the Control

Separating Time-Varying Control and Geometry

The chronological calculus was originally designed for work with nonstationary (time-varying) families of vector fields, and it arguably reaps the biggest benefits in that setting where there are few other powerful tools available. Nonetheless, the chronological calculus also much streamlines the analysis of autonomous vector fields. The best studied case is that of affine control systems in which the time-varying control can be separated from the geometry determined by autonomous vector fields. In classical notation such control systems are written in the form

$$\dot{x} = u_1(t) f_1(x) + \dots + u_m(t) f_m(x) \,. \tag{32}$$

where f_i are vector fields on a manifold M and u is a measurable function of time taking values typically in a compact subset $U \subseteq \mathbb{R}^m$. This description allows one to also accommodate physical systems that have an *uncontrolled drift term* by simply fixing $u_1 \equiv 1$. For the sake of clarity, and for best illustrating the kind of results available, assume that the fields f_i are smooth and complete. Later we specialize further to real analytic vector fields. This set-up does not necessarily require an interpretation of the u_i as controls: they may equally well be disturbances, or it may simply be a dynamical system which splits in this convenient way.

As a starting point consider families of piecewise constant control functions $u\colon [0, T] \mapsto U \subseteq \mathbb{R}^m$. On each interval $[t_j, t_{j+1}]$ on which the control is constant $u_{[t_j, t_{j+1}]} = u^{(j)}$, the right hand side of (32) is a fixed vector field $g_j = u_1^{(j)} f_1 + \dots u_m^{(j)} f_m$. The endpoint of the solution curve starting from $x(0) = p$ is computed as a directed product of ordinary exponentials (flows) of vector fields

$$p\mathrm{e}^{(t_1 - t_0) g_1} \circ \mathrm{e}^{(t_2 - t_1) g_2} \circ \dots \mathrm{e}^{(T - t_{s-1}) g_s} \,. \tag{33}$$

But even in this case of autonomous vector fields the chronological calculus brings substantial simplifications. Basically this means that rather than considering the expression (33) as a point on M, consider this product as a functional on the space $\mathcal{E}(M)$ of smooth functions on M. To reiterate the benefit of this approach [5,57] consider the simple example of a tangent vector to a smooth curve $\gamma\colon (-\varepsilon, \varepsilon) \mapsto M$ which one might want to define as

$$\dot{\gamma}(0) = \lim_{t \to 0} \frac{1}{t} (\gamma(t) - \gamma(0)) \,. \tag{34}$$

Due to the lack of a linear structure on a general manifold, with a classical interpretation this does not make any sense at all. Nonetheless, when interpreting $\gamma(t)$, $\gamma(0)$, $\gamma'(0)$, and $\frac{1}{t}(\gamma(t) - \gamma(0))$ as linear functionals on the space $\mathcal{E}(M)$ of smooth functions on M this is perfectly meaningful. The meaning of the limit can be rigorously justified as indicated in the preceding sections, compare also [1].

A typical example to illustrate how this formalism almost trivializes important calculations involving Lie brackets is the following, compare [57]. Suppose f and g are smooth vector fields on the manifold M, $p \in M$, and $t \in R$ is sufficiently small in magnitude. Using that $\frac{\mathrm{d}}{\mathrm{d}t} p\mathrm{e}^{tf} = p\mathrm{e}^{tf} f$ and so on, one immediately calculates

$$\begin{aligned} &(\mathrm{d}/\mathrm{d}t)(p\mathrm{e}^{tf}\mathrm{e}^{tg}\mathrm{e}^{-tf}\mathrm{e}^{-tg}) \\ &\quad = p\mathrm{e}^{tf} f \mathrm{e}^{tg}\mathrm{e}^{-tf}\mathrm{e}^{-tg} + p\mathrm{e}^{tf}\mathrm{e}^{tg} g \mathrm{e}^{-tf}\mathrm{e}^{-tg} \\ &\quad - p\mathrm{e}^{tf}\mathrm{e}^{tg}\mathrm{e}^{-tf} f \mathrm{e}^{-tg} - p\mathrm{e}^{tf}\mathrm{e}^{tg}\mathrm{e}^{-tf}\mathrm{e}^{-tg} g \,. \end{aligned} \tag{35}$$

In particular, at $t = 0$ this expression simplifies to $pf + pg - pf - pg = 0$. Analogously the second derivative is calculated as

$$\begin{aligned} &\frac{\mathrm{d}^2}{\mathrm{d}t^2}(p\mathrm{e}^{tf}\mathrm{e}^{tg}\mathrm{e}^{-tf}\mathrm{e}^{-tg}) = p\mathrm{e}^{tf} f^2 \mathrm{e}^{tg}\mathrm{e}^{-tf}\mathrm{e}^{-tg} + p\mathrm{e}^{tf} f \\ &\cdot \mathrm{e}^{tg} g \mathrm{e}^{-tf}\mathrm{e}^{-tg} - p\mathrm{e}^{tf} f \mathrm{e}^{tg}\mathrm{e}^{-tf} f \mathrm{e}^{-tg} - p\mathrm{e}^{tf} f \mathrm{e}^{tg}\mathrm{e}^{-tf} \\ &\cdot \mathrm{e}^{-tg} g + p\mathrm{e}^{tf} f \mathrm{e}^{tg} g \mathrm{e}^{-tf}\mathrm{e}^{-tg} + p\mathrm{e}^{tf}\mathrm{e}^{tg} g^2 \mathrm{e}^{-tf}\mathrm{e}^{-tg} \\ &- p\mathrm{e}^{tf}\mathrm{e}^{tg} g \mathrm{e}^{-tf} f \mathrm{e}^{-tg} - p\mathrm{e}^{tf}\mathrm{e}^{tg} g \mathrm{e}^{-tf}\mathrm{e}^{-tg} g - p\mathrm{e}^{tf} f \\ &\cdot \mathrm{e}^{tg}\mathrm{e}^{-tf} f \mathrm{e}^{-tg} - p\mathrm{e}^{tf}\mathrm{e}^{tg} g \mathrm{e}^{-tf} f \mathrm{e}^{-tg} + p\mathrm{e}^{tf}\mathrm{e}^{tg}\mathrm{e}^{-tf} \\ &\cdot f^2 \mathrm{e}^{-tg} + p\mathrm{e}^{tf}\mathrm{e}^{tg}\mathrm{e}^{-tf} f \mathrm{e}^{-tg} g - p\mathrm{e}^{tf} f \mathrm{e}^{tg}\mathrm{e}^{-tf}\mathrm{e}^{-tg} g \\ &- p\mathrm{e}^{tf}\mathrm{e}^{tg} g \mathrm{e}^{-tf}\mathrm{e}^{-tg} g + p\mathrm{e}^{tf}\mathrm{e}^{tg}\mathrm{e}^{-tf} f \mathrm{e}^{-tg} g + p\mathrm{e}^{tf} \\ &\cdot \mathrm{e}^{tg}\mathrm{e}^{-tf}\mathrm{e}^{-tg} g^2 \end{aligned} \tag{36}$$

which at $t = 0$ evaluates to

$$\begin{aligned} &pf^2 + pfg - pf^2 - pfg + pfg + pg^2 - pgf - pg^2 \\ &- pf^2 - pgf + pf^2 + pfg - pfg - pg^2 + pfg + pg^2 \\ &= 2pfg - 2pgf = 2p[f, g] \,. \end{aligned}$$

While this simple calculation may not make sense on a manifold with a classical interpretation in terms of points and vectors on a manifold, it does so in the context of the chronological calculus, and establishes the familiar formula for the Lie bracket as the limit of a composition of flows

$$p\mathrm{e}^{tf}\mathrm{e}^{tg}\mathrm{e}^{-tf}\mathrm{e}^{-tg} = p + t^2 p[f, g] + O(t^2) \;\text{ as }\; t \to 0 \,. \tag{37}$$

Similar examples may be found in [5] (e. g. p. 36), as well as analogous simplifications for the variations formula for autonomous vector fields ([5] p. 43).

Asymptotic Expansions for Affine Systems

Piecewise constant controls are a starting point. But a general theory requires being able to take appropriate limits and demands completeness. Typically, one considers measurable controls taking values in a compact subspace $U \subseteq \mathbb{R}^m$, and uses $L^1([0,t],U)$ as the space of admissible controls. Correspondingly the finite composition of exponentials as in (33) is replaced by continuous formulae. These shall still separate the effects of the time-varying controls from the underlying geometry determined by the autonomous vector fields. This objective is achieved by the Chen–Fliess series which may be interpreted in a number of different ways. Its origins go back to the 1950s when K. T. Chen [18], studying geometric invariants of curves in $\mathbb{R}^n$, associated to each smooth curve a formal noncommutative power series. In the early 1970s, Fliess [30,31] recognized the utility of this series for studying control systems. Using a set $X_1, X_2, \ldots, X_m$ of indeterminates, the Chen–Fliess series of a measurable control $u \in L^1([0,t],U)$ as above is the formal power series

$$S_{\mathrm{CF}}(T,u) = \sum_I \int_0^T u_{i_s}(t_s) \int_0^{t_{s-1}} \cdots \int_0^{t_3} u_{i_2}(t_2) \cdot \int_0^{t_2} u_{i_1}(t_1)\,\mathrm{d}t_1 \ldots \mathrm{d}t_s \cdot X_{i_1} \ldots X_{i_s} \quad (38)$$

where the sum ranges over all multi-indices $I = (i_1, \ldots, i_s)$, $s \geq 0$ with $i_j \in \{1,2\ldots m\}$. This series gives rise to an asymptotic series for solution curves of the system (32). For example, in the analytic setting, following [91], one has:

Theorem 2 *Suppose f_i are analytic vector fields on $\mathbb{R}^n$ $\phi\colon \mathbb{R}^n \mapsto \mathbb{R}$ is analytic and $U \subset \mathbb{R}^m$ is compact. Then for every compact set $K \subseteq \mathbb{R}^n$, there exists $T > 0$ such that the series*

$$S_{\mathrm{CF},f}(T,u,p)(\varphi) = \sum_I \int_0^T u_{i_s}(t_s) \int_0^{t_{s-1}} \cdots \int_0^{t_3} u_{i_2}(t_2) \cdot \int_0^{t_2} u_{i_1}(t_1)\,dt_1 \ldots dt_s \cdot p f_{i_1} \ldots f_{i_s} \varphi \quad (39)$$

converges uniformly to the solution of (32) for initial conditions $x(0) = p \in K$ and $u\colon [0,T] \mapsto U$ measurable.

Here the series $S_{\mathrm{CF},f}(T,u,p)$ is, for every fixed triple (f,u,p), interpreted as an element of the space of linear functionals on $\mathcal{E}(M)$. But one may abstract further. In particular, for each fixed multi-index I as above, the iterated integral coefficient is itself a functional that takes as input a control function $u \in \mathcal{U}^m$ and maps it to the corresponding iterated integral. It is convenient to work with the primitives $U_j\colon t \mapsto \int_0^t u_j(s)\,ds$ of the control functions u_j rather than the controls themselves. More specifically, if e. g. $\mathcal{U} = AC([0,T],[-1,1])$ then for every multi-index $I = (i_1, \ldots, i_s) \in \{1, \ldots, m\}^s$ as above one obtains the iterated integral functional $\Upsilon_I\colon \mathcal{U}^m \mapsto \mathcal{U}$ defined by

$$\Upsilon_I\colon U \mapsto \int_0^T U'_{i_s}(t_s) \int_0^{t_{s-1}} \cdots \int_0^{t_3} U'_{i_2}(t_2) \cdot \int_0^{t_2} U'_{i_1}(t_1)\,\mathrm{d}t_1 \mathrm{d}t_2 \ldots \mathrm{d}t_s\,. \quad (40)$$

Denoting by $\mathcal{IIF}(\mathcal{U}^Z)$ the linear space of iterated integral functionals spanned by the functionals of the above form, the map Υ maps multi-indices to $\mathcal{IIF}(\mathcal{U}^Z)$. The algebraic and combinatorial nature of these spaces and this map will be explored in the next section.

On the other side, there is the map $\mathcal{F}$ that maps a multi-index $(i_1, i_2, \ldots, i_s)$ to the partial differential operator $f_{i_1} \ldots f_{i_s}\colon \mathcal{E}(M) \mapsto \mathcal{E}(M)$, considered as a linear transformation of $\mathcal{E}(M)$. In the analytic case one may go further, since as a basic principle, the relations between the iterated Lie brackets of the vector fields f_j completely determine the geometry and dynamical behavior [90,91]. Instead of considering actions on $\mathcal{E}(M)$, it suffices to consider the action of these partial differential operators, and of the dynamical system (32) on a set of polynomial functions. In a certain technical sense, an associative algebra (of polynomial functions) is dual to the Lie algebra (generated by the analytic vector fields f_j). However, much further simplifications and deeper insights are gained by appropriately accounting for the intrinsic noncommutative structure of the flows of the system. Using a different product structure, the next section will *lift* the system (32) to a *universal* system that has no nontrivial relations between the iterated Lie brackets of the formal vector fields and which is modeled on an algebra of noncommutative polynomials (and noncommutative power series) rather than the space $\mathcal{E}(M)$ of all smooth functions on M. An important feature of this approach is that it does not rely on polynomial functions with respect to an a-priori chosen set of local coordinates, but rather uses polynomials which map to intrinsically geometric objects.

Zinbiel Algebra and Combinatorics

Just as the chronological calculus of time-varying vector fields is intimately connected to chronological algebras, the calculus of affine systems gives rise to its own algebraic and combinatorial structure. This, and the subsequent section, give a brief look into this algebra structure and demonstrate how, together with the chronological calculus, it leads to effective solution formulas for important control problems and beyond.

It is traditional and convenient to slightly change the notation and nomenclature. For further details see

[78] or [57]. Rather than using small integers $1, 2, \dots, m$ to index the components of the control and the vector fields in (32), use an arbitrary index set Z whose elements will be called *letters* and denoted usually by $a, b, c, \dots$ For the purposes of this note the *alphabet* Z will be assumed to be finite, but much of the theory can be developed for infinite alphabets as well. Multi-indices, i. e. finite sequences with values in Z are called *words*, and they have a natural associative product structure denoted by juxtaposition. For example, if $w = a_1a_2 \dots a_r$ and $z = b_1b_2 \dots b_s$ then $wz = a_1a_2 \dots a_rb_1b_2 \dots b_s$. The empty word is denoted e or 1. The set of all words of length n is Z^n, $Z^* = \cup_{n=0}^{\infty} Z^n$ and $Z^+ = \cup_{n=1}^{\infty} Z^n$ are the sets of all words and all nonempty words. Endow the associative algebra $A(Z)$, generated by the alphabet Z with coefficients in the field $\mathbf{k} = \mathbb{R}$, with an inner product $\langle \cdot, \cdot \rangle$ so that Z^* is an orthonormal basis. Write $\hat{A}(Z)$ for the completion of $A(Z)$ with respect to the uniform structure in which a fundamental system of basic neighborhoods of a polynomial $p \in A(Z)$ is the family of subsets $\{q \in A(Z) \colon \forall w \in W,\ \langle w, p - q\rangle = 0\}$ indexed by all finite subsets $W \subset Z^*$.

The smallest linear subspace of the associative algebra $A(Z)$ that contains the set Z and is closed under the commutator product $(w, z) \mapsto [w, z] = wz - zw$ is isomorphic to the free Lie algebra $L(Z)$ over the set Z. On the other side, one may equip $A^+(Z)$ with a Zinbiel algebra structure by defining the product $*\colon A^+(Z) \times A^+(Z \mapsto A^+(Z)$ for $a \in Z$ and $w, z \in Z^+$ by

$$w * a = wa \quad \text{and} \quad w * (za) = (w * z + z * w)a \quad (41)$$

and extending bilinearly to $A^+(Z) \times A^+(Z)$. One easily verifies that this product satisfies the Zinbiel identity for all $r, s, t \in A^+(Z)$

$$r * (s * t) = (r * s) * t + (s * r) * t\,. \quad (42)$$

The symmetrization of this product is the better known associative *shuffle product* $w \sqcup\!\sqcup z = w * z + z * w$ which may be defined on all of $A(Z) \times A(Z)$. Algebraically, the shuffle product is characterized as the transpose of the coproduct $\Delta\colon A(Z) \mapsto A(Z) \otimes A(Z)$ which is the *concatenation* product homomorphism that on letters $a \in Z$ is defined as

$$\Delta\colon a \mapsto a \otimes 1 + 1 \otimes a\,. \quad (43)$$

This relation between this coproduct and the shuffle is that for all $u, v, w \in A(Z)$

$$\langle \Delta(w), u \otimes v\rangle = \langle w, u \sqcup\!\sqcup v\rangle\,. \quad (44)$$

After this brief side-trip into algebraic and combinatorial objects we return to the control systems. The shuffle product $\sqcup\!\sqcup$ has been utilized for a long time in this and related contexts. But the Zinbiel product structure was only recently recognized as encoding important information. Its most immediate role is seen in the fact that the aforementioned map Υ from multi-indices to iterated integral functionals, now easily extends to a map (using the same name) $\Upsilon\colon A(Z) \mapsto \mathcal{IIF}(\mathcal{U}^Z)$ is a Zinbiel algebra homomorphism when the latter is equipped with a *pointwise* product induced by the product $*$ on $\mathcal{U} = AC([0, T], [-1, 1])$ defined by

$$(U * V)(t) = \int_0^t U(s)V'(s)\mathrm{d}s\,. \quad (45)$$

It is straightforward to verify that this product indeed equips $\mathcal{U}$ with a Zinbiel structure, and hence also $\mathcal{IIF}(\mathcal{U}^Z)$. On the side, note that the map Υ maps the shuffle product of words (noncommuting polynomials) to the associative pointwise product of scalar functions. The connection of the Zinbiel product with differential equations and the Chen–Fliess series is immediate. First *lift* the system (32) from the manifold M to the algebra $A(Z)$, roughly corresponding to the linear space of polynomial functions in an algebra of iterated integral functionals. Formally consider curves $S\colon [0, T] \mapsto A(Z)$ that satisfy

$$\dot{S} = S \sum_{a \in Z} a u_a(t)\,. \quad (46)$$

Using the Zinbiel product (45), and writing $U_a(t) = \int_0^t u_a(\tau)\,\mathrm{d}\tau$ for the primitives of the controls, the integrated form of the *universal control system* (46)

$$S(t) = 1 + \int_0^t S(\tau)F'(\tau)\,\mathrm{d}\tau \quad \text{with} \quad F = \sum_{a \in Z} U_a\,, \quad (47)$$

is most compactly written as

$$S = 1 + S * F\,. \quad (48)$$

Iteration yields the explicit series expansion

$$\begin{aligned} S &= 1 + (1 + S * F) * F \\ &= 1 + F + ((1 + S * F) * F) * F \\ &= 1 + F + (F * F) + (((1 + S * F) * F) * F) * F \\ &= 1 + F + (F * F) + ((F * F) * F) \\ &\qquad + ((((1 + S * F) * F) * F) * F) * F \\ &\ \vdots \\ &= 1 + F + (F * F) + ((F * F) * F) \\ &\qquad + (((F * F) * F) * F) \dots \end{aligned}$$

Using intuitive notation for Zinbiel powers this solution formula in the form of an infinite series is compactly written as

$$S = \sum_{n=0}^{\infty} F^{*n} = 1 + F + F^{*2} + F^{*3} + F^{*4} + F^{*5} + F^{*6} + \cdots \tag{49}$$

The reader is encouraged to expand all of the terms and match each step to the usual computations involved in obtaining Volterra series expansions. Indeed this formula (49) is nothing more than the Chen–Fliess series (38) in very compact notation. For complete technical details and further discussion we refer the interested reader to the original articles [56,57] and the many references therein.

Application: Product Expansions and Normal Forms

While the Chen–Fliess series as above has been extremely useful to obtain precise estimates that led to most known necessary conditions and sufficient conditions for local controllability and optimality, compare e. g. [53,88,94], this series expansion has substantial shortcomings. For example, it is clear from Ree's theorem [77] that the series is an exponential Lie series. But this is not at all obvious from the series as presented (38). Most detrimental for practical purposes is that finite truncations of the series *never* correspond to any approximating systems. Much more convenient, in particular for path planning algorithms [47,48,63,64,75,95], but also in applications for numerical integration [17,46] are expansions as directed infinite products of exponentials or as an exponential of a Lie series.

In terms of the map $\mathcal{F}$ that substitutes for each letter $a \in Z$ the corresponding vector field f_a, one finds that the Chen–Fliess series (39) is simply the image of a natural object under the map $\Upsilon \otimes \mathcal{F}$. Indeed, under the usual identification of the space $\mathrm{Hom}(V, W)$ of linear maps between vector spaces V and W with the product $V^* \otimes W$, and noting that Z^* is an orthonormal basis for $A(Z)$, the identity map from $A(Z)$ to $A(Z)$ is identified with the series

$$\mathrm{Id}_{A(Z)} \equiv \sum_{w \in Z^*} w \otimes w \quad \in \; A(Z) \otimes \hat{A}(Z)\,. \tag{50}$$

Thus, any rewriting of the combinatorial object on the right hand side will, via the map $\Upsilon \otimes \mathcal{F}$, give an alternative presentation of the Chen–Fliess series. In particular, from elementary consideration, using also the Hopf-algebraic structures of $A(Z)$, it is a-priori clear that there exist expansions in the forms

$$\begin{aligned} \sum_{w \in Z^*} w \otimes w &= \exp\left(\sum_{h \in \mathcal{H}} \zeta_h \otimes [h] \right) \\ &= \overleftarrow{\prod_{h \in \mathcal{H}}} \exp\left(\xi_h \otimes [h]\right) \end{aligned} \tag{51}$$

where $\mathcal{H}$ indexes an ordered basis $\{[h] \colon H \in \mathcal{H}\}$ of the free Lie algebra $L(Z)$ and for each $h \in \mathcal{H}, \xi_h$ and ζ_h are polynomials in $A(Z)$ that are mapped by Υ to corresponding iterated integral functionals. The usefulness of such expression depends on the availability of simple formulas for $\mathcal{H}, \xi_h$ and ζ_h.

Bases for free Lie algebras are well-known since Hall [42], and have been unified by Viennot [101]. Specifically, a Hall set over a set Z is any strictly ordered subset $\tilde{\mathcal{H}} \subseteq \mathcal{T}(\mathbb{Z})$ from the set $\mathcal{M}(Z)$ labeled binary trees (with leaves labeled by Z) that satisfies

(i) $Z \subseteq \tilde{\mathcal{H}}$
(ii) Suppose $a \in Z$. Then $(t, a) \in \tilde{\mathcal{H}}$ iff $t' \in \tilde{\mathcal{H}}$, $t' < a$ and $a < (t', a)$.
(iii) Suppose $u, v, w, (u, v) \in \tilde{\mathcal{H}}$. Then $(t', (t''', t'''')) \in \tilde{\mathcal{H}}$ iff $t''' \leq t' \leq (t''', t'''')$ and $t' < (t', (t''', t''''))$.

There are natural mappings $\theta\colon \mathcal{T}(Z) \mapsto L(Z) \subseteq A(Z)$ and $\vartheta\colon \mathcal{T}(Z) \mapsto A(Z)$ (the *foliage map*) that map labeled binary trees to Lie polynomials and to words, and which are defined for $a \in Z$, $(t', t'') \in \mathcal{T}(Z)$ by $\theta(a) = \vartheta(a) = a$ and recursively $\theta((t', t'')) = [\theta(t'), \theta(t'')]$ and $\vartheta((t', t'')) = \vartheta(t')\vartheta(t'')$. The image of a Hall set under the map θ is a basis for the free Lie algebra $L(Z)$. Moreover, the restriction of the map ϑ to a Hall-set is one-to-one which leads to a fundamental unique factorization property of words into products of Hall-words, and a unique way of recovering Hall trees from the Hall words that are their images under ϑ [101]. This latter property is very convenient as it allows one to use Hall words rather than Hall trees for indexing various objects.

The construction of Hall sets, as well as the proof that they give rise to bases of free Lie algebras, rely in an essential way on the process of *Lazard elimination* [9] which is intimately related to the solution of differential Eqs. (32) or (46) by a successive variation of parameters [93]. As a result, using Hall sets it is possible to obtain an extremely simple and elegant recursive formula for the coefficients ξ_h in (51), whereas formulas for the ζ_h are less immediate, although they may be computed by straightforward formulas in terms of natural maps of the Hopf algebra structure on $A(Z)$ [33]. Up to a normalization factor μ in terms of multi-factorials, the formula for the ξ_h is extremely simple in terms of the Zinbiel product on $A(Z)$. For letters $a \in Z$ and Hall words $h, k, hk \in \mathcal{H}$ one has

$$\xi_a = a \quad \text{and} \quad \xi_{hk} = \mu_{hk} \cdot \xi_h * \xi_k \,. \tag{52}$$

Using completely different notation, this formula appeared originally in the work of Schützenberger [84], and was later rediscovered in various settings by Grayson and Grossman [38], Melancon and Reutenauer [69] and Sussmann [93]. In the context of control, it appeared first in [93].

To illustrate the simplicity of the recursive formula, which is based on the factorization of Hall words, consider the following *normal form* for a free nilpotent system (of rank $r = 5$) using a typical Hall set over the alphabet $Z = \{0, 1\}$. This is the closest nonlinear analogue to the Kalman controller normal form of a linear system, which is determined by Kronecker indices that classify the lengths of chains of integrators. For practical computations nilpotent systems are commonly used as approximations of general nonlinear systems – and every nilpotent system (that is, a system of form (32) whose vector fields f_a generate a nilpotent Lie algebra) is the image of a free nilpotent system as below under some projection map. For convenience, the example again uses the notation x_h instead of ξ_h.

$$\begin{aligned}
\dot{x}_0 &= u_0\\
\dot{x}_1 &= u_1\\
\dot{x}_{01} &= x_0 \cdot \dot{x}_1 = x_0\, u_1\\
\dot{x}_{001} &= x_0 \cdot \dot{x}_{01} = x_0^2\, u_1\\
&\quad \text{using } \vartheta^{-1}(001) = (0(01))\\
\dot{x}_{101} &= x_1 \cdot \dot{x}_{01} = x_1 x_0\, u_1\\
&\quad \text{using } \vartheta^{-1}(101) = (1(01))\\
\dot{x}_{0001} &= x_0 \cdot \dot{x}_{001} = x_0^3\, u_1\\
&\quad \text{using } \vartheta^{-1}(0001) = (0(0(01)))\\
\dot{x}_{1001} &= x_1 \cdot \dot{x}_{001} = x_1 x_0^2\, u_1\\
&\quad \text{using } \vartheta^{-1}(1001) = (1(0(01)))\\
\dot{x}_{1101} &= x_1 \cdot \dot{x}_{101} = x_1^2 x_0\, u_1\\
&\quad \text{using } \vartheta^{-1}(1101) = (1(1(01)))\\
\dot{x}_{00001} &= x_0 \cdot \dot{x}_{001} = x_0^4\, u_1\\
&\quad \text{using } \vartheta^{-1}(00001) = (0(0(0(01))))\\
\dot{x}_{10001} &= x_1 \cdot \dot{x}_{0001} = x_1 x_0^3\, u_1\\
&\quad \text{using } \vartheta^{-1}(10001) = (1(0(0(01))))\\
\dot{x}_{11001} &= x_1 \cdot \dot{x}_{1001} = x_1^2 x_0^2\, u_1\\
&\quad \text{using } \vartheta^{-1}(11001) = (1(1(0(01))))\\
\dot{x}_{01001} &= x_{01} \cdot \dot{x}_{001} = x_{01} x_0^3\, u_1\\
&\quad \text{using } \vartheta^{-1}(01001) = ((01)(0(01)))\\
\dot{x}_{01101} &= x_{01} \cdot \dot{x}_{101} = x_{01} x_1^2 x_0\, u_1\\
&\quad \text{using } \vartheta^{-1}(01101) = ((01)(1(01)))\,.
\end{aligned}$$

This example may be interpreted as a system of form (32) with the x_h being a set of coordinate functions on the manifold M, or as the truncation of the lifted system (46) with the x_h being a basis for a finite dimensional subspace of the linear space $\mathcal{E}(M)$. For more details and the technical background see [56,57].

Future Directions

The chronological calculus is still a young methodology. Its intrinsically infinite dimensional character demands a certain sophistication from its users, and thus it may take some time until it reaches its full potential. From a different point of view this also means that there are many opportunities to explore its advantages in ever new areas of applications. A relatively straightforward approach simply checks classical topics of systems and control for whether they are amenable to this approach, and whether this will be superior to classical techniques. The example of [70] which connects the chronological calculus with discrete time systems is a model example for such efforts. There are many further opportunities, some more speculative than others.

Control The chronological calculus appears ideally suited for the investigation of fully nonlinear systems – but in this area there is still much less known than in the case of nonlinear control systems that are affine in the control, or the case of linear systems. Specific conditions for the existence of solutions, controllability, stabilizability, and normal forms are just a few subjects that, while studies have been initiated [1,2,4], deserve further attention.

Computation In recent years much effort has been devoted to understanding the foundations of numerical integration algorithms in nonlinear settings, and to eventually design more efficient algorithms and eventually prove their superiority. The underlying mathematical structures, such as the compositions of noncommuting flows are very similar to those studies in control, as observed in e. g. [23], one of the earlier publications in this area. Some more recent work in this direction is [17,46,72,73,74]. This is also very closely related to the studies of the underlying combinatorial and algebraic structures – arguably [27,28,29,76] are some of the ones most closely related to the subject of this article. There appears to be much potential for a two-way exchange of ideas and results.

Geometry Arguably one of the main thrusts will continue to be the use of the chronological calculus for studying the differential geometric underpinnings of systems and control theory. But it is conceivable that such studies may eventually abstract further – just like after the 1930s – to studies of generalizations of algebras that stem from systems on classical manifolds, much in the spirit of modern noncommutative geometry with [19] being the best-known proponent.

Algebra and combinatorics In general very little is known about possible ideal and subalgebra structures of chronological and Zinbiel algebras. This work was initiated in [2], but relatively little progress has been made since. (Non)existence of finite dimensional (nilpotent) Zinbiel algebras has been established, but only over a complex field [25,26]. Bases of free chronological algebras are discussed in [2], but many other aspects of this algebraic structure remain unexplored. This also intersects with the aforementioned efforts in foundations of computation – on one side there are Hopf-algebraic approaches to free Lie algebras [78] and nonlinear control [33,40,41], while the most recent breakthroughs involve dendriform algebras and related subjects [27,28,29]. This is an open field for uncovering the connections between combinatorial and algebraic objects on one side and geometric and systems objects on the other side. The chronological calculus may well serve as a vehicle to elucidate the correspondences.

University College London, London, UK

Article Outline

Glossary

Agent-based models Systems composed of individuals who act purposely in making locational/spatial decisions.

Bifurcation A process whereby divergent paths are generated in a trajectory of change in an urban system.

City size distribution A set of cities ordered by size, usually population, often in rank order.

Emergent patterns Land uses or economic activities which follow some spatial order.

Entropy maximizing The process of generating a spatial model by maximizing a measure of system complexity subject to constraints.

Equilibrium A state of the urban system which is balanced and unchanging.

Exponential growth The process whereby an activity changes through positive feedback on itself.

Fast dynamics A process of frequent movement between locations, often daily.

Feedback The process whereby a system variable influences another variable, either positively or negatively.

Fractal structure A pattern or arrangement of system elements that are self-similar at different spatial scales.

Land use transport model A model linking urban activities to transport interactions.

Life cycle effects Changes in spatial location which are motivated by aging of urban activities and populations.

Local neighborhood The space immediately around a zone or cell.

Logistic growth Exponential growth capacitated so that some density limit is not exceeded.

Lognormal distribution A distribution which has fat and long tails which is normal when examined on a logarithmic scale.

Microsimulation The process of generating synthetic populations from data which is collated from several sources.

Model validation The process of calibrating and testing a model against data so that its goodness of fit is optimized.

Multipliers Relationships which embody *n*th order effects of one variable on another.

Network scaling The in-degrees and out-degrees of a graph whose nodal link volumes follow a power law.

Population density profile A distribution of populations which typically follows an exponential profile when arrayed against distance from some nodal point.

Power laws Scaling laws that order a set of objects according to their size raised to some power.

Rank size rule A power law that rank orders a set of objects.

Reaction-diffusion The process of generating changes as a consequence of a reaction to an existing state and interactions between states.

Scale-free networks Networks whose nodal volumes follow a power law.

Segregation model A model which generates extreme global segregation from weak assumptions about local segregation.

Simulation The process of generating locational distributions according to a series of sub-model equations or rules.

Slow dynamics Changes in the urban system that take place over years or decades.

Social physics The application of classical physical principles involving distance, force and mass to social situations, particularly to cities and their transport.

Spatial interaction The movement of activities between different locations ranging from traffic distributions to migration patterns.

Trip distribution The pattern of movement relating to trips made by the population, usually from home to work but also to other activities such as shopping.

Urban hierarchy A set of entities physically or spatially scaled in terms of their size and areal extent.

Urban morphology Patterns of urban structure based on the way activities are ordered with respect to their locations.

Urban system A city represented as a set of interacting subsystems or their elements.

Definition of the Subject

Cities have been treated as systems for fifty years but only in the last two decades has the focus changed from aggregate equilibrium systems to more evolving systems whose structure emerges from the bottom up. We first outline the rudiments of the traditional approach focusing on equilibrium and then discuss how the paradigm has changed to one which treats cities as emergent phenomena generated through a combination of hierarchical levels of decision, driven in decentralized fashion. This is consistent with the complexity sciences which dominate the simulation of urban form and function. We begin however with a review of equilibrium models, particularly those based on spatial interaction, and we then explore how simple dynamic frameworks can be fashioned to generate more realistic models. In exploring dynamics, nonlinear systems which admit chaos and bifurcation have relevance but recently more pragmatic schemes of structuring urban models based on cellular automata and agent-based modeling principles have come to the fore. Most urban models deal with the city in terms of the location of its economic and demographic activities but there is also a move to link such models to urban morphologies which are clearly fractal in structure. Throughout this chapter, we show how key concepts in complexity such as scaling, self-similarity and far-from-equilibrium structures dominate our current treatment of cities, how we might simulate their functioning and how we might predict their futures. We conclude with the key problems that dominate the field and suggest how these might be tackled in future research.

Cities were first conceived as complex systems in the 1960s when architects and urban planners began to change their perceptions that cities be treated as ‘works of art’ to something much more akin to a functioning economic system that required social engineering. Since the time of Newton, social scientists had speculated that social systems could be described using concepts from classical physics and the notion that interrelationships between the component parts of such systems might be articulated using concepts of mass, force and energy established a rudimentary framework that came to be known as social physics. Together with various macro-economic theories of how economies function based on Keynesian ideas of input, output and economic multipliers, cities were assumed to be equilibrium systems in which their interactions such as traffic, trade flows, and demographic migration could be modeled in analogy to gravitation. These flows were seen as complementary to the location of employment and population which reflected costs of travel and land rent, in turn the product of micro-economic theories of how agents resolved their demand for and the supply of space through the land market. Operational models for policy analysis were initially built on this basis and used for testing the impact of different plans for making cities more efficient, locationally and in terms of their movement/traffic patterns.

This early work did not emphasize the dynamics of urban change or the morphology of cities. Thus theories and models were limited in their ability to predict patterns of urban growth as reflected in sprawl and the regeneration of urban areas. The first wave of models which treated the city system in aggregate, static and top down fashion, fell into disrepute due to these limitations. To address them, the focus moved in the 1980s to more theoretical considerations in which static social physics types of model were embedded in nonlinear dynamic frameworks built around ideas in chaos, and bifurcation theory. A parallel development in simulating urban morphology was built around treating cities as fractals which evolved from the bottom up and operational models in which such morphologies were governed using cellular automata were developed. Developments in moving from aggregate to disaggregate or bottom-up individual-based models were spawned from these developments with agent-based modeling providing a new focus to the field. There is now a momentum for treating urban aggregates through new ideas about growth and form through scaling while new forms of representing cities through networks linking these to fractal morphologies are being developed through network science at different scales. These will ultimately lead to operational urban and transport models built from the bottom up which simulate spatial processes operating on networks and other morphologies. These have the potential to address key problems of urban growth and evolution, congestion, and inequality.

Introduction

Cities were first treated formally as systems when General System Theory and Cybernetics came to be applied to the softer social sciences in the 1950s. Ludwig von Bertalanffy [67] in biology and Norbert Wiener [73] in engineering gave enormous impetus to this emerging interdisciplinary field that thrust upon us the idea that phenomena of interest in many disciplines could be articulated in generic terms as 'systems'. Moreover the prospect that the systems approach could yield generic policy, control and management procedures applicable to many different areas, appeared enticing. The idea of a general systems theory was gradually fashioned from reflections on the way distinct entities which were clearly collections of lower order elements, organized into a coherent whole, displaying pattern and order which in the jargon of the mid-twentieth century was encapsulated in the phrase that "the whole is greater than the sum of the parts". The movement began in biology in the 1920s, gradually eclipsing parts of engineering in the 1950s and spreading to the management and social sciences, particularly sociology and political science in the 1960s. It was part of a wave of change in the social sciences which began in the late 19th century as these fields began to emulate the physical sciences, espousing positivist methods which had appeared so successful in building applicable and robust theory.

The focus then was on ways in which the elements comprising the system interacted with one another through structures that embodied feedbacks keeping the system sustainable within bounded limits. The notion that such systems have controllers to 'steer' them to meet certain goals or targets is central to this early paradigm and the science of "…control and communication in the animal and the machine" was the definition taken up by Norbert Wiener [73] in his exposition of the science of cybernetics. General system theory provided the generic logic for both the structure and behavior of such systems through various forms of feedback and hierarchical organization while cybernetics represented the 'science of steersmanship' which would enable such systems to move towards explicit goals or targets. Cities fit this characterization admirably and in the 1950s and 1960s, the traditional approach that articulated cities as structures that required physical and aesthetic organization, quickly gave way to deeper notions that cities needed to be understood as general systems. Their control and planning thus required much more subtle interventions than anything that had occurred hitherto in the name of urban planning.

Developments in several disciplines supported these early developments. Spatial analysis, as it is now called, began to develop within quantitative geography, linked to the emerging field of regional science which represented a synthesis of urban and regional economics in which location theory was central. In this sense, the economic structure of cities and regions was consistent with classical macro and micro economics and the various techniques and models that were developed within these domains had immediate applicability. Applications of physical analogies to social and city systems, particularly ideas about gravitation and potential, had been explored since the mid 19th century under the banner of 'social physics' and as transportation planning formally began in the 1950s, these ideas were quickly adopted as a basis for transport modeling. Softer approaches in sociology and political science also provided support for the idea of cities as organizational systems while the notion of cybernetics as the basis for management, policy and control of cities was adopted as an important analogy in their planning [26,53].

The key ideas defined cities as sets of elements or components tied together through sets of interactions. The archetypal structure was fashioned around land use activities with economic and functional linkages between them represented initially in terms of physical movement, traffic. The key idea of feedback, which is the dynamic that holds a general system together, was largely represented in terms of the volume and pattern of these interactions, at a single point in time. Longer term evolution of urban structure was not central to these early conceptions for the focus was largely on how cities functioned as equilibrium structures. The prime imperative was improving how interactions between component land uses might be made more efficient while also meeting goals involving social and spatial equity. Transportation and housing were of central importance in adopting the argument that cities should be treated as examples of general systems and steered according to the principles of cybernetics.

Typical examples of such systemic principles in action involve transportation in large cities and these early ideas about systems theory hold as much sway in helping make sense of current patterns as they did when they were first mooted fifty or more years ago. Different types of land use with different economic foci interact spatially with respect to how employees are linked to their housing locations, how goods are shipped between different locations to service the production and consumption that define these activities, how consumers purchase these economic activities which are channeled through retail and commercial centers, how information flows tie all these economies together, and so on: the list of linkages is endless. These activities are capacitated by upper limits on density and capacity. In Greater London for example, the traffic has reached saturation limits in the central city and with few new roads being constructed over the last 40 years, the focus has shifted to improving public transport and to road pricing.

The essence of using a systems model of spatial interaction to test the impact of such changes on city structure is twofold: first such a model can show how people might shift mode of transport from road to rail and bus, even to walking and cycling, if differential pricing is applied to the road system. The congestion charge in central London imposed in 2003 led to a 30 percent reduction in the use of vehicles and this charge is set to increase massively for certain categories of polluting vehicles in the near future. Second the slightly longer term effects of reducing traffic are to increase densities of living, thus decreasing the length and cost of local work journeys, also enabling land use to respond by changing their locations to lower cost areas. All these effects ripple through the system with the city system models presented here designed to track and predict such *n*th order effects which are rarely obvious. Our focus in this chapter is to sketch the state-of-the-art in these complex systems models showing how new developments in the methods of the complexity sciences are building on a basis that was established half century ago.

Since early applications of general systems theory, the paradigm has changed fundamentally from a world where systems were viewed as being centrally organized, from the top down, and notions about hierarchy were predominant, to one where we now consider systems to be structured from the bottom up. The idea that one or the other – the centralized or the decentralized view – are mutually exclusive of each other is not entirely tenable of course but the balance has certainly changed. Theories have moved from structures and behaviors being organized according to some central control to theories about how systems retain their own integrity from the bottom up, endorsing what Adam Smith over 300 years ago, called "the hidden hand". This shift has brought onto the agenda the notion of equilibrium and dynamics which is now much more central to systems theory than it ever was hitherto. Systems such as cities are no longer considered to be equilibrium structures, notwithstanding that many systems models built around equilibrium are still eminently useful. The notion that city systems are more likely to be in disequilibrium, all the time, or even classed as far-from-equilibrium continually reinforcing the move away from equilibrium, is comparatively new but consistent with the speed of change and volatility in cities observed during the last fifty years.

The notion to that change is nowhere smooth but discontinuous, often chaotic, has become significant. Equilibrium structures are renewed from within as unanticipated innovations, many technological but some social, change the way people make decisions about how they locate and move within cities. Historical change is important in that historical accidents often force the system onto a less than optimal path with such path dependence being crucial to an understanding of any current equilibria and the dynamic that is evolving. Part of this newly emerging paradigm is the idea that new structures and behaviors that emerge are often unanticipated and surprising. As we will show in this chapter, when we look at urban morphologies, they are messy but ordered, self-similar across many scales, but growing organically from the bottom up. Planned cities are always the exception rather than the rule and when directly planned, they only remain so for very short periods of time.

The new complexity sciences are rewriting the theory of general systems but they are still founded on the rudiments of structures composed of elements, now often called actors or agents, linked through interactions which determine the processes of behavior which keep the system in equilibrium and/or move it to new states. Feedback is still central but recently has been more strongly focused on how system elements react to one another through time. The notion of an unchanging equilibrium supported by such feedbacks is no longer central; feedback is now largely seen as the way in which these structures are evolved to new states. In short, system theory has shifted to consider such feedbacks in positive rather than negative terms although both are essential. Relationships between the system elements in terms of their interactions are being enriched using new ideas from networks and their dynamics [56]. Key notions of how the elements of systems scale relative to one another and relative to their system hierarchies have become useful in showing how local actions and interactions lead to global patterns which can only be predicted from the bottom up [54]. This new view is about how emergent patterns can be generated using models that grow the city from the bottom up [37], and we will discuss all these ideas in the catalog of models that we present below.

We begin by looking at models of cities in equilibrium where we illustrate how interactions between key system elements located in space follow certain scaling laws reflecting agglomeration economies and spatial competition. The network paradigm is closely linked to these ideas in structural terms. None of these models, still important for operational simulation modeling in a policy context, have an internal dynamic and thus we turn to examine dynamics in the next section. We then start with simple exponential growth, showing how it can be capacitated as logistic growth from which nonlinear behaviors can result as chaos and bifurcation. We show how these models might be linked to a faster dynamics built around equilibrium spatial interaction models but to progress these developments, we present much more disaggregate models based on agent simulation and cellular automata principles. These dynamics are then generalized as reaction-diffusion models.

Our third section deals with how we assemble more integrated models built from these various equilibrium and dynamic components or sub-models. We look at large-scale land use transport models which are equilibrium in focus. We then move to cellular automata models of land development, concluding our discussion with reference to the current development of fine scale agent-based models where each individual and trip maker in the city system is simulated. We sprinkle our presentation with various empirical applications, many based on data for Greater London showing how employment and population densities scale, how movement patterns are consistent with the underling infrastructure networks that support them, and how the city has grown through time. We show how the city can be modeled in terms of its structure and the way changes to it can be visualized. We then link these more abstract notions about how cities are structured in spatial-locational terms to their physical or fractal morphology which is a direct expression of their scaling and complexity. We conclude with future directions, focusing on how such models can be validated and used in practical policy-making.

Cities in Equilibrium

Arrangements of Urban Activities

Cities can usually be represented as a series of n locations, each identified by i, and ordered from $i = 1, 2, \ldots, n$. These locations might be points or areas where urban activity takes place, pertaining either to the inter-urban scale where locations are places not necessarily adjacent to one another or at the intra-urban scale where a city is exhaustively partitioned into a set of areas. We will use both representations here but begin with a generic formulation which does not depend on these differences per se.

It is useful to consider the distribution of locations as places where differing amounts of urban activity can take place, using a framework which shows how different arrangements of activity can be consistently derived. Different arrangements of course imply different physical forms of city. Assume there is N amount of activity to be distributed in n locations as $N_1, N_2, \ldots$ Beginning with N_1, there are $N!/[N_1!(N - N_1)!$ allocations of

N_1, $(N-N_1)!/[N_2!(N-N_1-N_2)!$ allocations of N_2, $(N-N_1-N_2)!/[N_3!(N-N_1-N_2-N_3)!$ of N_3 and so on. To find the total number of arrangements W, we multiply each of these quantities together where the product is

$$W = \frac{N!}{\prod_i N_i!} \,. \tag{1}$$

This might be considered a measure of complexity of the system in that it clearly varies systematically for different allocations. If all N activity were to be allocated to the first location, then $W = 1$ while if an equal amount of activity were to be allocated to each location, then W would vary according to the size of N and the number of locations n. It can be argued that the most likely arrangement of activities would be the one which would give the greatest possibility of distinct individual activities being allocated to locations and such an arrangement could be found by maximizing W (or the logarithm of W which leads to the same). Such maximizations however might be subject to different constraints on the arrangements which imply different conservation laws that the system must meet. This would enable different types of urban form to be examined under different conditions related to density, compactness, sprawl and so on, all of which might be formalized in this way.

To show how this is possible, consider the case where we now maximize the logarithm of W subject to meaningful constraints. The logarithm of Eq. (1) is

$$\ln W = \ln(N!) - \sum_i \ln(N_i!) \,, \tag{2}$$

which using Stirling's formula, simplifies to

$$\ln W \approx N + \ln(N!) - \sum_i N_i \ln N_i \,. \tag{3}$$

N_i which is the number of units of urban activity allocated to location i, is a frequency that can be normalized into a probability as $p_i = N_i/N$. Substituting for $N_i = Np_i$ in Eq. (3) and dropping the constant terms leads to

$$\ln W \propto -\sum_i p_i \ln p_i = H \,, \tag{4}$$

where it is now clear that the formula for the number of arrangements is proportional to Shannon's entropy H. Thus the process of maximizing $\ln W$ is the well-known process of maximizing entropy subject to relevant constraints and this leads to many standard probability distributions [66]. Analogies between city and other social systems with statistical thermodynamics and information theory were developed in the 1960s and represented one of the first formal approaches to the derivation of models for simulating the interaction between locations and the amount of activity attracted to different locations in city, regional and transport systems. As such, it has become a basis on which to build many different varieties of urban model [74].

Although information or entropy has been long regarded as a measure of system complexity, we will not take this any further here except to show how it is useful in deriving different probability distributions of urban activity. Readers are however referred to the mainstream literature for both philosophic and technical expositions of the relationship between entropy and complexity (for example see [42]). The measure H in Eq. (4) is at a maximum when the activity is distributed evenly across locations, that is when $p_i = 1/n$ and $H = \ln n$ while it is at a minimum when $p_i = 1$ and $p_j = 0, j = 1, 2, \ldots, n, i \neq j$, and $H = 0$. It is clear too that H varies with n; that is as the number of locations increases, the complexity or entropy of the system also increases. However what is of more import here is the kind of distribution that maximizing entropy generates when H is maximized subject to appropriate constraints. We demonstrate this as follows for a simple but relevant case where the key constraint is to ensure that the system reproduces the mean value of an attribute of interest. Let p_i be the probability of finding a place i which has P_i population residing there. Then we maximize the entropy

$$H = -\sum_i p_i \ln p_i \,, \tag{5}$$

subject to a normalization constraint on the probabilities

$$\sum_i p_i = 1 \,, \tag{6}$$

and a constraint on the mean population of places $\bar{P}$ in the system, that is

$$\sum_i p_i P_i = \bar{P} \,. \tag{7}$$

The standard method of maximizing Eq. (5) subject to constraint Eqs. (6) and (7) is to form a Langrangian L – a composite of the entropy and the constraints

$$L = -\sum_i p_i \ln p_i - \beta \left(\sum_i p_i - 1 \right) - \vartheta \left(\sum_i p_i P_i - \bar{P} \right) \tag{8}$$

where β and ϑ are multipliers designed to ensure that the constraints are met. Maximizing (8) with respect to p_i gives

$$\frac{\partial L}{\partial p_i} = \ln p_i - 1 - \beta - \vartheta P_i = 0 \,, \tag{9}$$

leading directly to a form for p_i which is

$$p_i = \exp(-\beta - 1)\exp(-\lambda P_i) = K \exp(-\vartheta P_i) \,. \quad (10)$$

K is the composite constant of proportionality which ensures that the probabilities sum to 1. Note also that the sign of the parameters is determined from data through the constraints. If we substitute the probability in Eq. (10) into the Shannon entropy, the measure of complexity of this system which is at a maximum for the given set of constraints, simplifies to $H = \beta + 1 + \vartheta \bar{P}$. There are various interpretations of this entropy with respect to dispersion of activities in the system although these represent a trade-off between the form of the distribution, in this case, the negative exponential, and the number of events or objects n which characterize the system.

Distributions and Densities of Population

The model we have derived can be regarded as an approximation to the distribution of population densities over a set of n spatial zones as long as each zone is the same size (area), that is, $A_i = A, \forall_i$ where nA is the total size (area) of the system. A more general form of entropy takes this area into account by maximizing the expected value of the logarithm of the density, not distribution, where the 'spatial' entropy is defined as

$$S = -\sum_i p_i \ln \frac{p_i}{A_i} \,, \quad (11)$$

with the probability density as p_i/A_i. Using this formula, the procedure simply generalizes the maximization to densities rather than distributions [10] and the model we have derived simply determines these densities with respect to an average population size $\bar{P}$. If we order populations over the zones of a city or even take their averages over many cities in a region or nation, then they are likely to be distributed in this fashion; that is, we would expect there to be many fewer zones or cities of high density than zones or cities of low density, due to competition through growth.

However the way this method of entropy-maximizing has been used to generate population densities in cities is to define rather more specific constraints that relate to space. Since the rise of the industrial city in the 19th century, we have known that population densities tend to decline monotonically with distance from the center of the city. More than 50 years ago, Clark [29] demonstrated quite clearly that population densities declined exponentially with distance from the center of large cities and in the 1960s with the application of micro-economic theory to urban location theory following von Thünen's [68] model, a range of urban attributes such as rents, land values, trip densities, and population densities were shown to be consistent with such negative exponential distributions [5]. Many of these models can also be generated using utility maximizing which under certain rather weak constraints can be seen as equivalent to entropy-maximizing [6]. However it is random utility theory that has been much more widely applied to generate spatial interaction models with a similar form to the models that we generate below using entropy-maximizing [20,46].

We will show how these typical micro-economic urban density distributions can be derived using entropy-maximizing in the following way. Maximizing S in Eq. (11) or H in Eq. (5) where we henceforth assume that the probability p_i is now the population density, we invoke the usual normalization constraint in Eq. (6) and a constraint on the average travel cost $\bar{C}$ incurred by the population given as $\sum_i p_i c_i = \bar{C}$ where c_i is the generalized travel cost/distance from the central business district (CBD) to a zone i. This maximization leads to

$$p_i = K \exp(-\mu c_i) \quad (12)$$

where μ is the parameter controlling the rate of decay of the exponential function, sometimes called the 'friction' of distance or travel cost.

Gravitational Models of Spatial Interaction

It is a simple matter to generalize this framework to generate arrangements of urban activities that deal with interaction patterns, that is movements or linkages between pairs of zones. This involves extending entropy to deal with two rather than one dimensional systems where the focus of interest is on the interaction between an origin zone called $i, i = 1, 2, \ldots, I$ and a destination zone $j, j = 1, 2, \ldots, J$ where there are now a total of IJ interactions in the system. These kinds of model can be used to simulate routine trips from home to work, for example, or to shop, longer term migrations in search of jobs, moves between residential locations in the housing market, as well as trade flows between countries and regions. The particular application depends on context as the generic framework is independent of scale.

Let us now define a two-dimensional entropy as

$$H = -\sum_i \sum_j p_{ij} \ln p_{ij} \,. \quad (13)$$

p_{ij} is the probability of interaction between origin i and destination j where the same distinctions between distribution and density noted above apply. Without loss of generality, we will assume in the sequel that these variables p_{ij} covary with density in that the origin and destination zones all have the same area. The most constrained system is where we assume that all the interactions originating from any zone i must sum to the probability p_i of originating in that zone, and all interactions destined for zone j must sum to the probability p_j of being attracted to that destination zone. There is an implicit constraint that these origin and destination probabilities sum to 1, that is

$$\sum_i \sum_j p_{ij} = \sum_i p_i = \sum_j p_j = 1 \,, \tag{14}$$

but Eq. (14) is redundant with respect to the origin and destination normalization constraints which are stated explicitly as

$$\left.\begin{array}{l} \sum\limits_j p_{ij} = p_i \\ \sum\limits_i p_{ij} = p_j \end{array}\right\} . \tag{15}$$

There is also a constraint on the average distance or cost traveled given as

$$\sum_i \sum_j p_{ij} c_{ij} = \bar{C} \,. \tag{16}$$

The model that is derived from the maximization of Eq. (13) subject to Eqs. (15) and (16) is

$$p_{ij} = K_i K_j p_i p_j \exp(-\gamma c_{ij}) \tag{17}$$

where K_i and K_j are normalization constants associated with Eq. (15), and γ is the parameter on the travel cost c_{ij} between zones i and j associated with Eq. (16). It is easy to compute K_i and K_j by substituting for p_{ij} from Eq. (17) in Eq. (15) respectively and simplifying. This yields

$$\left.\begin{array}{l} K_i = \dfrac{1}{\sum\limits_j K_j p_j \exp(-\gamma c_{ij})} \\ K_j = \dfrac{1}{\sum\limits_i K_i p_i \exp(-\gamma c_{ij})} \end{array}\right\} , \tag{18}$$

equations that need to be solved iteratively.

These models can be scaled to deal with real trips or population simply by multiplying these probabilities by the total volumes involved, T for total trips in a transport system, P for total population in a city system, Y for total income in a trading system and so on. This system however forms the basis for a family of interaction models which can be generated by relaxing the normalization constraints; for example by omitting the destination constraint, $K_j = 1, \forall_j$, or by omitting the origin constraint, $K_i = 1, \forall_i$ or by omitting both where we need an explicit normalization constraint of the form $\sum_{ij} p_{ij} = 1$ in Eq. (14) to provide an overall constant K. Wilson [74] refers to this set of four models as: *doubly-constrained* – the model in Eqs. (17) and (18), the next two as *singly-constrained*, first when $K_i = 1, \forall_i$, the model is origin constrained, and second when $K_j = 1, \forall_j$, the model is destination constrained; and when we have no constraints on origins or destinations, we need to invoke the global constant K and the model is called *unconstrained*. It is worth noting that these models can also be generated in nearly equivalent form using random utility theory where they are articulated at the level of the individual rather than the aggregate trip-maker and are known as discrete choice models [20].

Let us examine one of these models, a singly-constrained model where there are origin constraints. This might be a model where we are predicting interactions from work to home given we know the distribution of work at the origin zones. Then noting that $K_j = 1, \forall_j$, the model is

$$p_{ij} = K_i p_i p_j \exp(-\gamma c_{ij}) = p_i \frac{p_j \exp(-\gamma c_{ij})}{\sum\limits_j p_j \exp(-\gamma c_{ij})} \,. \tag{19}$$

The key issue with this sort of model is that not only are we predicting the interaction between zones i and j but we can predict the probability of locating in the destination zone p'_j, that is

$$p'_j = \sum_i p_{ij} = \sum_i p_i \frac{p_j \exp(-\gamma c_{ij})}{\sum\limits_j p_j \exp(-\gamma c_{ij})} \,. \tag{20}$$

If we were to drop both origin and destination constraints, the model becomes one which is analogous to the traditional gravity model from which it was originally derived prior to the development of these optimization frameworks. However to generate the usual standard gravitational form of model in which the 'mass' of each origin and destination zone appears, given by P_i and P_j respectively, then we need to modify the entropy formula, thus maximizing

$$H = -\sum_i \sum_j p_{ij} \ln \frac{p_{ij}}{P_i P_j} \,, \tag{21}$$

subject to the normalization

$$\sum_i \sum_j p_{ij} = 1 \,, \tag{22}$$

and this time a constraint on the average 'logarithmic' travel cost $\overline{\ln C}$

$$\sum_i \sum_j p_{ij} \ln c_{ij} = \overline{\ln C} . \tag{23}$$

The model that is generated from this system can be written as

$$p_{ij} = K \frac{P_i P_j}{c_{ij}^{\eta}} , \tag{24}$$

where the effect of travel cost/distance is now in power law form with η the scaling parameter. Besides illustrating the fact that inverse power forms as well as negative exponential distributions can be generated in this way according to the form of the constraints, one is also able to predict both the probabilities of locating at the origins and the destinations from the traditional gravity model in Eq. (24).

Scaling, City Size, and Network Structure: Power Laws

Distance is a key organizing concept in city systems as we have already seen in the way various urban distributions have been generated. Distance is an attribute of nearness or proximity to the most accessible places and locations. Where there are the lowest distance or travel costs to other places, the more attractive or accessible are those locations. In this sense, distance or travel cost acts as an inferior good in that we wish to minimize the cost occurred in overcoming it. Spatial competition also suggests that the number of places that have the greatest accessibilities are few compared to the majority of places. If you consider that the most accessible place in a circular city is the center, then assuming each place is of similar size, as the number of places by accessibility increases, the lower the accessibility is. In short, there are many places with the same accessibility around the edge of the city compared to only one place in the center. The population density model in Eq. (12) implies such an ordering when we examine the frequency distribution of places according to their densities.

If we now forget distance for a moment, then it is likely that the distribution of places at whatever scale follows a distribution which declines in frequency with attributes based on size due to competition. If we look at all cities in a nation or even globally, there are far fewer big cities than small ones. Thus the entropy-maximizing framework that we have introduced to predict the probability (or frequency) of objects of a certain size occurring, is quite applicable in generating such distributions. We derived a negative exponential distribution in Eq. (10) but to generate a power law, all we need to do is to replace the constraint in Eq. (7) with its logarithmic equivalent, that is

$$\sum_i p_i \ln P_i = \overline{\ln P} , \tag{25}$$

and then maximize Eq. (5) subject to (6) and (25) to give

$$p_i = K P_i^{-\varphi} = \exp(-\beta - 1) \exp(-\varphi \ln P_i) , \tag{26}$$

where φ is the scaling parameter. Equation (26) gives the probability or frequency – the number of cities – for a zone (or city) with P_i population which is distributed according to an inverse power law. It is important to provide an interpretation of the constraint which generates this power law. Equation (25) implies that the system conserves the average of the logarithm of size which gives greater weight to smaller values of population than to larger, and as such, is recognition that the average size of the system is unbounded as a power function implies. With such distributions, it is unlikely that normality will prevail due to the way competition constrains the distribution in the long tail. Nevertheless in the last analysis, it is an empirical matter to determine the shape of such distributions from data, although early research on the empirical distributions of city sizes following Zipf's Law [81] by Curry [34] and Berry [21] introduced the entropy-maximizing framework to generate such size distributions.

The power law implied for the probability p_i of a certain size P_i of city or zone can be easily generalized to a two-dimensional equivalent which implies a network of interactions. We will maximize the two-dimensional entropy H in Eq. (13) subject to constraints on the mean logarithm of population sizes at origins and destinations which we now state as

$$\left.\begin{array}{l} \sum_i \sum_j p_{ij} \ln P_i = \sum_i p_i \ln P_i = \bar{P}_{\text{origins}} \\ \sum_i \sum_j p_{ij} \ln P_j = \sum_j p_j \ln P_j = \bar{P}_{\text{destinations}} \end{array}\right\} , \tag{27}$$

where $p_i = \sum_j p_{ij}$ and $p_j = \sum_i p_{ij}$. Note however that there are no constraints on these origins and destination probabilities p_i and p_j per se but the global constraints in Eq. (14) must hold. This maximization leads to the model

$$p_{ij} = K P_i^{-\lambda_i} P_j^{-\lambda_j} = \frac{P_i^{-\lambda_i}}{\sum_i P_i^{-\lambda_i}} \frac{P_j^{-\lambda_j}}{\sum_j P_j^{-\lambda_j}} , \tag{28}$$

where it is clear that the total flows from any origin node or location i vary as

$$p_i' \propto P_i^{-\lambda_i} , \tag{29}$$

and the flows into any destination zone vary as

$$p'_j \propto P_j^{-\lambda_j} , \tag{30}$$

with the parameters λ_i and λ_j relating to the mean of the observed logarithmic populations associated with the constraint Eq. (27). Note that the probabilities for each origin and destination node or zone are independent from one another as there is no constraint tying them together as in the classic spatial interaction model where distance or travel cost is intrinsic to the specification.

These power laws can be related to recent explorations in network science which suggest that the number of in-degrees – the volume of links entering a destination in our terms – and the number of out-degrees – the volume emanating from an origin, both follow power laws [2]. These results have been widely observed in topological rather than planar networks where the focus is on the numbers of physical links associated with nodes rather than the volume of traffic on each link. Clearly the number of physical links in planar graphs is limited and the general finding from network science that the number of links scales as a power law cannot apply to systems that exist in two-dimensional Euclidean space [24]. However a popular way of transforming a planar graph into one which is non-planar is to invoke a rule that privileges some edges over others merging these into long links and then generating a topology which is based on the merged edges as constituting nodes and the links between the new edges as arcs. This is the method that is called space syntax [47] and it is clear that by introducing order into the network in this way, the in-degrees and out-degrees of the resulting topological graph can be scaling. Jiang [48] illustrates this quite clearly although there is some reticence to make such transformations and where planar graphs have been examined using new developments in network science based on small worlds and scale-free graph theory, the focus has been much more on deriving new network properties than on appealing to any scale-free structure [33].

However to consider the scale-free network properties of spatial interaction systems, each trip might be considered a physical link in and of itself, albeit that it represents an interaction on a physical network as a person making such an interaction is distinct in space and time. Thus the connections to network science are close. In fact the study of networks and their scaling properties has not followed the static formulations which dominate our study of cities in equilibrium for the main way in which such power laws are derived for topological networks is through a process of preferential attachment which grows networks from a small number of seed nodes [8]. Nevertheless, such dynamics appear quite consistent with the evolution of spatial interaction systems.

These models will be introduced a little later when urban dynamics are being dealt with. For the moment, let us note that there are various simple dynamics which can account not only for the distribution of network links following power laws, but also for the distribution of city sizes, incomes, and a variety of other social (and physical) phenomena from models that grow the number of objects according to simple proportionate growth consistent with the generation of lognormal distributions. Suffice it to say that although we have focused on urban densities as following either power laws or negative exponential functions in this section, it is entirely possible to use the entropy-maximizing framework to generate distributions which are log-normal, another alternative with a strong spatial logic. Most distributions which characterize urban structure and activities however are not likely to be normal and to conclude this section, we will review albeit very briefly, some empirical results that indicate the form and pattern of urban activities in western cities.

Empirical Applications: Rank-Size Representations of Urban Distributions

The model in Eq. (26) gives the probability of location in a zone i as an inverse power function of the population or size of that place which is also proportional to the frequency

$$f(p_i) \propto p_i = KP_i^{-\varphi} . \tag{31}$$

It is possible to estimate the scaling parameter φ in many different ways but a first test of whether or not a power law is likely to exist can be made by plotting the logarithms of the frequencies and population sizes and noting whether or not they fall onto a straight line. In fact a much more preferable plot which enables each individual observation to be represented is the cumulative function which is formed from the integral of Eq. (31) up to a given size; that is $F_i \propto P_i^{-\varphi+1}$. The counter-cumulative $F - F_i$ where F is the sum of all frequencies in the system – that is the number of events or cities – also varies as $P_i^{-\varphi+1}$ and is in fact the rank of the city in question. Assuming each population size is different, then the order of $\{i\}$ is the reverse of the rank, and we can now write the rank r of i as $r = F - F_i$. The equation for this rank-size distribution (which is the one that is usually used to fit the data) is thus

$$r = GP_r^{-\varphi+1} \tag{32}$$

where G is a scaling constant which in logarithmic form is $\ln r = G - (\varphi - 1) \ln P_r$. This is the equation that is implicit in the rank-size plots presented below which reveal evidence of scaling.

First let us examine the scaling which is implicit in urban size distributions for the largest world city populations over 1 million in 2005, for cities over 100,000 in the USA in 2000, and for the 200 tallest buildings in the world in 2007. We could repeat such examples ad nauseum but these provide a good selection which we graph in rank-size logarithmic form in Fig. 1a, noting that we have normalized all the data by their means, that is by $<P_r>$ and $<r>$, as $P_r/<P_r>$ and $r/<r>$. We are only examining a very small number at the very top of the distribution and this is clearly not definitive evidence of scaling in the rest of the distribution but these plots do show the typical distributions of city size activities that have been observed in this field for over 50 years. As we will imply later, these signatures are evidence of self-organization and fractal structure which emerge through competition from the bottom up [15].

To illustrate densities in cities, we take employment and working population in small zones in Greater London, a city which has some 4.4 million workers. We rank-order the distribution in the same way we have done for world cities, and plot these, suitably normalized by their means, logarithmically in Fig. 1b. These distributions are in fact plotted as densities so that we remove aerial size effects. Employment densities $e_i = E_i/A_i$ can be interpreted as the number of work trips originating in employment zones $e_i = \sum_j T_{ij}$ – the volume of the out-degrees of each employment zone considered as nodes in the graph of all linkages between all places in the system, and population densities $h_j = P_j/A_j$ as the destination distributions $h_j = \sum_i T_{ij}$ – the in-degrees which measure all the trips destined for each residential zone from all employment zones. In short if there is linearity in the plots, this is evidence that the underlying interactions on the physical networks that link these zones are scaling. Figure 1b provides some evidence of scaling but the distributions are more similar to lognormal distributions than to power laws. This probably implies that the mechanisms for generating these distributions are considerably more complex than growth through preferential attachment which we will examine in more detail below [15].

Lastly, we can demonstrate that scaling in city systems also exists with respect to how trips, employment and population activities vary with respect to distance. In Fig. 1c, we have again plotted the employment densities $e_i = E_i/A_i$ at origin locations and population densities $h_j = P_j/A_j$ at destination locations but this time against distances $d_{\text{CBD}\to i}$ and $d_{\text{CBD}\to j}$ from the center of London's CBD in logarithmic terms. It is clear that there is significant correlation but also a very wide spread of values around the log-linear regression lines due to the fact that the city is multi-centric. Nevertheless the relationships appears to be scaling with these estimated as $e_i = 0.042 d^{-0.98}_{\text{CBD}\to i}$, $(r^2 = -0.30)$, and $h_j = 0.029 d^{-0.53}_{\text{CBD}\to j}$,

Employment, population and accessibilities in Greater London (greatest extent is 55kms east to west; 45kms north to south)

($r^2 = -0.23$). However more structured spatial relationships can be measured by accessibilities which provide indices of overall proximity to origins or destinations, thus taking account of the fact that there are several competing centers. Accessibility can be measured in many different ways but here we use a traditional definition of potential based on employment accessibility A_i to populations at destinations, and population accessibility A_j to employment at origins defined as

$$\left.\begin{aligned} A_i &\propto \sum_j \frac{h_j}{c_{ij}} \\ A_j &\propto \sum_i \frac{e_i}{c_{ij}} \end{aligned}\right\} , \tag{33}$$

where c_{ij} is, as before, the generalized cost of travel from employment origin i to population destination j. In Fig. 2a, b, we compare the distribution of employment densities e_i with accessibility origins A_i and in Fig. 2c, d, population densities h_j with accessibility destinations A_j. Each set of maps is clearly correlated with higher associations than in Fig. 1c which take account of only the single CBD. Regressing $\{\ln e_i\}$ on $\{\ln A_i\}$ and $\{\ln p_j\}$ on $\{\ln A_j\}$ gives an approximate scaling with 31% of the variance accounted for in terms of origin accessibility and 41% for destination accessibility. These relations appear linear but there is still considerable noise in the data which undoubtedly reflects the relative simplicity of the models and the fact that accessibility is being measured using current transport costs without any reference to the historical evolution of the city's structure. It is, however, building blocks such as these that constitute the basis for operational land use transport models that have developed for comparative static and quasi-dynamic forecasting that we will discuss below.

Urban Dynamics

Aggregate Development

Models of city systems have largely been treated as static for at first sight, urban structure in terms of its form and to some extent its function appears stable and long-lasting. During the industrial era, cities appeared to have a well-defined structure where land uses were arranged in concentric rings according to their productivity and wealth around a central focus, usually the central business district (CBD), the point where most cities were originally located and exchange took place. Moreover data on how cities had evolved were largely absent and this reinforced the focus on statics and equilibria. Where the need to examine urban change was urgent, models were largely fashioned in terms of the simplest growth dynamics possible and we will begin with these here.

The growth of human populations in their aggregate appears to follow an exponential law where the rate of change σ is proportional to the size of the population itself $P(t)$, that is

$$\frac{\mathrm{d}P(t)}{\mathrm{d}t} = \sigma P(t) . \tag{34}$$

It is easy to show that starting from an initial population $P(0)$, the growth is exponential, that is

$$P(t) = P(0)\exp(\sigma t) , \tag{35}$$

which is the continuous form of model. When formulated discretely, at time steps $t = 1, 2, \dots, T$, Eq. (34) can be written as $P(t) - P(t-1) = \beta P(t-1)$ which leads to

$$P(t) = (1+\beta)P(t-1) . \tag{36}$$

Through time from the initial condition $P(0)$, the trajectory is

$$P(t) = (1+\beta)^t P(0) . \tag{37}$$

$1+\beta$ is the growth rate. If $\beta > 0$, Eq. (37) shows exponential growth, if $\beta < 0$, exponential decline, and if $\beta = 0$, the population is in the steady state and simply reproduces itself.

This simple growth model leads to *smooth change*, and any discontinuities or breaks in the trajectories of growth or decline must come about through an external change in the rate from the outside environment. If we assume the growth rate fluctuates around a mean of one with β varying randomly, above -1, then it is not possible to predict the trajectory of the growth path. However if we have a large number of objects which we will assume to be cities whose growth rates are chosen randomly, then we can write the growth equation for each city as

$$P_i(t) = [1+\beta_i(t)]P_i(t-1) , \tag{38}$$

which from an initial condition $P_i(0)$ gives

$$P_i(t) = \prod_{\tau=1}^{t} [1+\beta_i(\tau)]P_i(0) . \tag{39}$$

This is growth by proportionate effect; that is, each city grows in proportion to its current size but the growth rate in each time period is random. In a large system of cities, the ultimate distribution of these population sizes will be lognormal. This is easy to demonstrate for the logarithm of Eq. (39) can be approximated by

$$\ln P_i(t) = \ln P_i(0) + \sum_{\tau=1}^{t} \beta_i(\tau) , \tag{40}$$

where the sum of the random components is an approximation to the log of the product term in Eq. (39) using Taylor's expansion. This converges to the lognormal from the law of large numbers. It was first demonstrated by Gibrat [43] for social systems but is of considerable interest here in that the fat tail of the lognormal can be approximated by an inverse power law. This has become the default dynamic model which underpins an explanation of the rank-size rule for city populations first popularized by Zipf [81] and more recently confirmed by Gabaix [41] and Blank and Solomon [23] among others. We demonstrated this in Fig. 1a for the world city populations greater than 1 million and for US city populations greater than 100,000. As such, it is the null hypothesis for the distribution of urban populations in individual cities as well as population locations within cities.

Although Gibrat's model does not take account of interactions between the cities, it does introduce diversity into the picture, simulating a system that in the aggregate is non-smooth but nevertheless displays regularity. These links to aggregate dynamics focus on introducing slightly more realistic constraints and one that is of wide relevance is the introduction of capacity constraints or limits on the level to which a population might grow. Such capacitated growth is usually referred to as logistic growth. Retaining the exponential growth model, we can limit this by moderating the growth rate σ according to an upper limit on population $P_{\max}$ which changes the model in Eq. (34) and the growth rate σ to

$$\frac{\mathrm{d}P(t)}{\mathrm{d}t} = \left[\sigma\left(1 - \frac{P(t)}{P_{\max}}\right)\right] P(t)\,. \tag{41}$$

It is clear that when $P(t) = P_{\max}$, the overall rate of change is zero and no further change occurs. The continuous version of this logistic is

$$P(t) = \frac{P_{\max}}{1 + \left(\frac{P_{\max}}{P(0)} - 1\right)\exp(-\sigma t)}\,, \tag{42}$$

where it is easy to see that as $t \to \infty$, $P(t) \to P_{\max}$.

The discrete equivalent of this model in Eq. (41) follows directly from $P(t) - P(t-1) = \beta[1 - (P(t-1)/P_{\max})]P(t-1)$ as

$$P(t) = \left[1 + \beta\left(1 - \frac{P(t-1)}{P_{\max}}\right)\right] P(t-1)\,, \tag{43}$$

where the long term dynamics is too intricate to write out as a series. Equation (43) however shows that the growth component β is successively influenced by the growth of the population so far, thus preserving the capacity limit through the simple expedient of adjusting the growth rate downwards. As in all exponential models, it is based on proportionate growth. As we noted above, we can make each city subject to a random growth component $\beta_i(t)$ while still keeping the proportionate effect.

$$P(t) = \left[1 + \beta_i(t)\left(1 - \frac{P(t-1)}{P_{\max}}\right)\right] P(t-1)\,. \tag{44}$$

This model has not been tested in any detail but if $\beta_i(t)$ is selected randomly, the model is a likely to generate a lognormal-like distribution of cities but with upper limits being invoked for some of these. In fact, this stochastic equivalent also requires a lower integer bound on the size of cities so that cities do not become too small [14]. Within these limits as long as the upper limits are not too tight, the sorts of distributions of cities that we observe in the real world are predictable.

In the case of the logistic model, remarkable and unusual discontinuous nonlinear behavior can result from its simple dynamics. When the β component of the growth rate is $\beta < 2$, the predicted growth trajectory is the typical logistic which increases at an increasing rate until an inflection point after which the growth begins to slow, eventually converging to the upper capacity limit of $P_{\max}$. However when $\beta \cong 2$, the population oscillates around this limit, bifurcating between two values. As the value of the growth rate increases towards 2.57, these oscillations get greater, the bifurcations doubling in a regular but rapidly increasing manner. At the point where $\beta \cong 2.57$, the oscillations and bifurcations become infinite, apparently random, and this regime persists until $\beta \cong 3$ during which the predictions look entirely chaotic. In fact, this is the regime of 'chaos' but chaos in a controlled manner from a deterministic model which is not governed by externally induced or observed randomness or noise.

These findings were found independently by May [52], Feigenbaum [38], Mandelbot [51] among others. They relate strongly to bifurcation and chaos theory and to fractal geometry but they still tend to be of theoretical importance only. Growth rates of this magnitude are rare in human systems although there is some suggestion that they might occur in more complex coupled biological systems of predator-prey relations. In fact one of the key issues in simulating urban systems using this kind of dynamics is that although these models are important theoretical constructs in defining the scope of the dynamics that define city systems, much of these dynamic behaviors are simplistic. In so far as they do characterize urban systems, it is at the highly aggregate scale as we demonstrate a little later. The use of these ideas in fact is much more applicable to extending the static equilibrium models of the last section and to demonstrate these, we will now illustrate how these models might be enriched by putting together logistic behaviors with spatial movement and interaction.

One way of articulating urban dynamics at the intra-urban level is to identify different speeds of change. In particular we can define a fast dynamics that relates to how people might move around the city on daily basis, for example, in terms of the journey to work, and a slower dynamics that relates to more gradual change that relates to the size of different locations affected by residential migrations. We can model the fast dynamics using a singly-constrained spatial interaction which distributes workers to residential locations which we define using previous notation where all variables are now time scripted by (t): $T_{ij}(t)$ trips between zones i and j, employment $E_i(t)$ at origin zone i, population $P_j(t)$ at destination zone j, the friction of distance parameter $\gamma(t)$, and the travel cost $c_{ij}(t)$ between zones i and j. The model is defined as

$$T_{ij}(t) = E_i(t)\frac{P_j(t)\exp[-\gamma(t)c_{ij}(t)]}{\sum_j P_j(t)\exp[-\gamma(t)c_{ij}(t)]}\,, \tag{45}$$

from which we can predict residential population $P'_j(t)$ as

$$\begin{aligned} P'_j(t) &= \sum_i T_{ij}(t) \\ &= \sum_i E_i(t) \frac{P_j(t) \exp[-\gamma(t) c_{ij}(t)]}{\sum_j P_j(t) \exp[-\gamma(t) c_{ij}(t)]} \,. \end{aligned} \tag{46}$$

This is the fast dynamics but each zone is capacitated by an unchanging upper limit on population where the zonal population changes slowly in proportion to its existing size through internal migration and in response to the upper limit $P_{j\max}$. The change in terms of this slower dynamic from t to $t+1$ is modeled as

$$\Delta P_j(t+1) = \beta[P_{j\max} - P'_j(t)] P'_j(t) \tag{47}$$

with the long term trajectory thus given as

$$P_j(t+1) = \left(1 + \beta[P_{j\max} - P'_j(t)]\right) P'_j(t) \,. \tag{48}$$

Clearly $P_j(t)$ will converge to $P_{j\max}$ as long as $P'_j(t)$ is increasing while the fast dynamics is also updated in each successive time period from

$$\begin{aligned} P'_j(t+1) &= \sum_i T_{ij}(t+1) \\ &= \sum_i E_i(t+1) \frac{P_j(t+1) \exp[-\gamma(t+1) c_{ij}(t+1)]}{\sum_j P_j(t+1) \exp[-\gamma(t+1) c_{ij}(t+1)]} \,. \end{aligned} \tag{49}$$

We may have an even slower dynamics relating to technological or other social change which changes $P_{j\max}$ while various other models may be used to predict employment for example, which itself may be a function of another fast dynamics relating to industrial and commercial interactions. The time subscripted variables travel $c_{ij}(t+1)$ and the friction of distance parameter $\gamma(t+1)$ might be changes that reflect other time scales. We might even have lagged variables independently introduced reflecting stocks or flows at previous time periods $t-1$, $t-2$ etc. Wilson [75,76] has explored links between these spatial interaction entropy-maximizing models and logistic growth and has shown that in a system of cities or zones within a city, unusual bifurcating behavior in terms of the emergence of different zonal centers can occur when parameter values, particularly the travel cost parameter $\gamma(t+1)$, cross certain thresholds.

There have been many proposals involving dynamic models of city systems which build on the style of nonlinear dynamics introduced here and these all have the potential to generate discontinuous behavior. Although Wilson [75] pioneered embedding dynamic logistic change into spatial interaction models, there have been important extensions to urban predator-prey models by Dendrinos and Mullaly [36] and to bifurcating urban systems by Allen [3,4], all set within a wider dynamics linking macro to micro through master equation approaches [45]. A good summary is given by Nijkamp and Reggiani [57] but most of these have not really led to extensive empirical applications for it has been difficult to find the necessary rich dynamics in the sparse temporal data sets available for cities and city systems; at the macro-level, a lot of this dynamics tends to be smoothed away in any case. In fact, more practical approaches to urban dynamics have emerged at finer scale levels where the agents and activities are more disaggregated and where there is a stronger relationship to spatial behavior. We will turn to these now.

Dynamic Disaggregation: Agents and Cells

Static models of the spatial interaction variety have been assembled into linked sets of sub-models, disaggregated into detailed types of activity, and structured so that they simulate changes in activities through time. However, the dynamics that is implied in such models is simplistic in that the focus has still been very much on location in space with time added as an afterthought. Temporal processes are rarely to the forefront in such models and it is not surprising that a more flexible dynamics is emerging from entirely different considerations. In fact, the models of this section come from dealing with objects and individuals at much lower/finer spatial scales and simulating processes which engage them in decisions affecting their spatial behavior. The fact that such decisions take place through time (and space) makes them temporal and dynamic rather through the imposition of any predetermined dynamic structures such as those used in the aggregate dynamic models above. The models here deal with individuals as agents, rooted in cells which define the space they occupy and in this sense, are highly disaggregate as well as dynamic. These models generate development in cities from the bottom up and have the capability of producing patterns which are emergent. Unlike the dynamic models of the last section, their long term spatial behavior can be surprising and often hard to anticipate.

It is possible however to use the established notation for equilibrium models in developing this framework based on the generic dynamic $P_i(t) = P_i(t-1) + \Delta P_i(t)$ where the change in population $\Delta P_i(t)$ can be divided into two components. The first is the usual proportionate effect, the positive feedback induced by population on itself which is defined as the *reactive* element of change $\omega P_i(t-1)$. The second is the *interactive* element, change that is generated from some action-at-a-distance which is often regarded as a diffusion of population from other locations in the system. We can model this in the simplest way using the traditional gravity model in Eq. (24) but noting that we must sum the effects of the diffusion over the destinations from where it is generated as a kind of accessibility or potential. The second component of change is $\phi P_i(t-1)K\sum_j P_j(t-1)/c_{ij}^{\eta}$ from which the total change between t and $t-1$ is

$$\Delta P_i(t) = \omega P_i(t-1) + \phi P_i(t-1)K\sum_j \frac{P_j(t-1)}{c_{ij}^{\eta}} + \varepsilon_i(t-1). \tag{50}$$

We have also added a random component $\varepsilon_i(t-1)$ in the spirit of our previous discussion concerning growth rates. We can now write the basic reaction-diffusion equation, as it is sometimes called, as

$$\begin{aligned} &P_i(t) \\ &= P_i(t-1) + \Delta P_i(t) \\ &= P_i(t-1)\left(1+\omega+\phi K\sum_j \frac{P_j(t-1)}{c_{ij}^{\eta}} + \varepsilon_i(t-1)\right). \end{aligned} \tag{51}$$

This equation looks as though it applies to a zonal system but we can consider each index i or j simply a marker of location, and each population activity can take on any value; for single individuals it can be 0 or 1 while it might represent proportions of an aggregate population or total numbers for the framework is entirely generic. As such, it is more likely to mirror a slow dynamics of development rather than a fast dynamics of movement although movement is implicit through the diffusive accessibility term.

We will therefore assume that the cells are small enough, space-wise, to contain single activities – a single household or land use which is the cell state – with the cellular tessellation usually forming a grid associated with the pixel map used to visualize data input and model output. In terms of our notation, population in any cell i must be $P_i(t) = 1$ or 0, representing a cell which is occupied or empty with the change being $\Delta P_i(t) = -1$ or 0 if $P_i(t-1) = 1$ and $\Delta P_i(t) = 1$ or 0 if $P_i(t-1) = 0$. These switches of state are not computed by Eq. (51) for the way these cellular variants are operationalized is through a series of rules, constraints and thresholds. Although consistent with the generic model equations, these are applied in more ad hoc terms. Thus these models are often referred to as automata and in this case, as cellular automata (CA).

The next simplification which determines whether or not a CA follows a strict formalism, relates to the space over which the diffusion takes place. In the fast dynamic equilibrium models of the last section and the slower ones of this, interaction is usually possible across the entire space but in strict CA, diffusion is over a local neighborhood of cells around i, Ω_i, where the cells are adjacent. For symmetric neighborhoods, the simplest is composed of cells which are north, south, east and west of the cell in question, that is $\Omega_i = n, s, e, w$ – the so-called von Neumann neighborhood, while if the diagonal nearest neighbors are included, then the number of adjacent cells rises to 8 forming the so-called Moore neighborhood. These highly localized neighborhoods are essential to processes that grow from the bottom up but generate global patterns that show emergence. Rules for diffusion are based on switching a cell's state on or off, dependent upon what is happening in the neighborhood, with such rules being based on counts of cells, cell attributes, constraints on what can happen in a cell, and so on.

The simplest way of showing how diffusion in localized neighborhoods takes place can be demonstrated by simplifying the diffusion term in Eq. (50) as follows. Then $\phi K\sum_j P_j(t-1) = \phi K\sum_j P_j(t-1)c_{ij}^{-\eta}$ as $c_{ij} = 1$ when $\Omega_i = n, s, e, w$. The cost is set as a constant value as each cell is assumed to be small enough to incur the same (or no) cost of transport between adjacent cells. Thus the diffusion is a count of cells in the neighborhood i. The overall growth rate is scaled by the size of the activity in i but this activity is always either $P_i(t-1) = 1$ or 0, presence or absence. In fact this scaling is inappropriate in models that work by switching cells on and off for it is only relevant when one is dealing with aggregates. This arises from the way the generic equation in (51) has been derived and in CA models, it is assumed to be neutral. Thus the change Eq. (50) becomes

$$\Delta P_i(t) = \omega + \phi K\sum_j P_j(t-1) + \varepsilon_i(t)\,, \tag{52}$$

where this can now be used to determine a threshold $Z_{\max}$ over which the cell state is switched. A typical rule might be

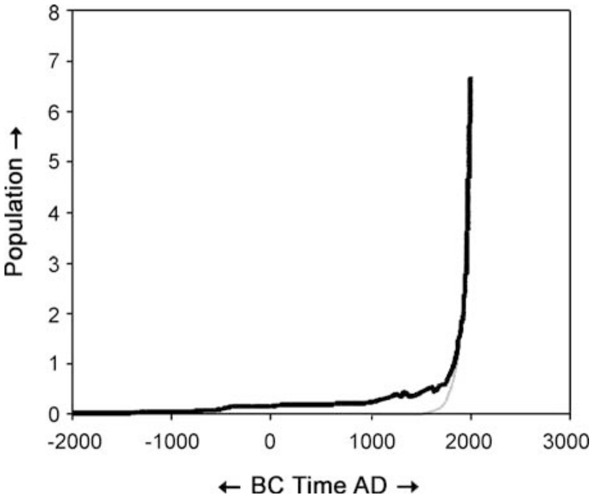
$$P_i(t) = \begin{cases} 1, & \text{if } [\omega + \phi K\sum_j P_j(t-1) + \varepsilon_i(t)] > Z_{\max} \\ 0, & \text{otherwise}\,. \end{cases} \tag{53}$$

It is entirely possible to separate the reaction from the diffusion and consider different combinations of these effects sparking off a state change. As we have implied, different combinations of attributes in cells and constraints within neighborhoods can be used to effect a switch, much depending on the precise specification of the model.

In many growth models based on CA, the strict limits posed by a local neighborhood are relaxed. In short, the diffusion field is no longer local but is an information or potential field consistent with its use in social physics where action-at-distance is assumed to be all important. In the case of strict CA, it is assumed that there is no action-at-a-distance in that diffusion only takes place to physically adjacent cells. Over time, activity can reach all parts of the system but it cannot hop over the basic cell unit. In cities, this is clearly quite unrealistic as the feasibility of deciding what and where to locate does not depend on physical adjacency. In terms of applications, there are few if any urban growth models based on strict CA although this does rather beg the question as to why CA is being used in the first place. In fact it is more appropriate to call such models cell-space or CS models as Couclelis [32] has suggested. In another sense, this framework can be considered as one for agent-based modeling where the cells are not agents and where there is no assumption of a regular underlying grid of cells [12,13]. There may be such a grid but the framework simply supposes that the indices *i* and *j* refer to locations that may form a regular tessellation but alternatively may be mobile and changing. In such cases, it is often necessary to extend the notation to deal with specific relations between the underlying space and the location of each agent.

Empirical Dynamics: Population Change and City Size

We will now briefly illustrate examples of the models introduced in this section before we then examine the construction of more comprehensive models of city systems. Simple exponential growth models apply to rapidly growing populations which are nowhere near capacity limits such as entire countries or the world. In Fig. 3, we show the growth of world population from 2000 BCE to date where it is clear that the rate of growth may be faster than the exponential model implies, although probably not as fast as double exponential. In fact world population is likely to slow rapidly over the next century probably mirroring global resource limits to an extent which are clearly illustrated in the growth of the largest western cities. In Figs. 4a, b, we show the growth in population of New York City (the five boroughs) and Greater London from 1750 to date and it is clear that in both cases, as the cities developed, population grew exponentially only to slow as the upper density limits of each city were reached.



Cities as Complex Systems: Scaling, Interaction, Networks, Dynamics and Urban Morphologies, Figure 3
Exponential world population growth. The *fitted exponential curve* is shown in *grey* where for the most part it is coincident with the observed growth, except for the very long period before the Industrial Revolution (before 1750)

Subsequent population loss and then a recent return of population to the inner and central city now dominate these two urban cores, which is reminiscent of the sorts of urban dynamic simulated by Forrester [39] where various leads and lags in the flow of populations mean that the capacity limit is often overshot, setting up a series of oscillations which damp in the limit. Forrester's model was the one of the first to grapple with the many interconnections between stocks and flows in the urban economy although these relationships were predicated hypothetically in simple proportionate feedback terms. Together they generated a rich dynamics but dominated by growth which was capacitated, thus producing logistic-like profiles with the leads and lags giving damped oscillations which we illustrate from his work in Fig. 5 [11]. We will see that the same phenomena can be generated from the bottom up as indeed Forrester's model implies, using cellular automata within a bounded spatial system.

Dynamics which arise from bottom-up urban processes can be illustrated for a typical CA/CS model, DUEM (Dynamic Urban Evolutionary Model) originally developed by Xie [78]. In the version of the model here, there are five distinct land uses – housing, manufacturing/primary industry, commerce and services, transport in the form of the street/road network, and vacant land. In principle, at each time period, each land use can generate quantities and locations of any other land use although in practice only industry, commerce and housing can gener-

Oscillating capacitated growth in a version of the Forrester *Urban Dynamics* model (from [11])

ate one another as well as generating streets. Streets do not generate land uses other than streets themselves. Vacant land is regarded as a residual available for development which can result from a state change (decline) in land use. The way the generation of land uses takes place is through a rule-based implementation of the generic Eq. (51) which enables a land use k, $P_i^k(t)$, to be generated from any other land use ℓ, $P_j^\ell(t-1)$. Land uses are also organized across a life cycle from initiating through mature to declining. Only initiating land uses which reflect their relative newness can spawn new land use. Mature remain passive in these terms but still influence new location while declining land uses disappear, thus reflecting completion of the life cycle of built form.

We are not able to present the fine details of the model here (see Batty, Xie and Sun [19], and Xie and Batty [79]) but we can provide a broad sketch. The way initiating land uses spawn new ones is structured according to rule-based equations akin to the thresholding implied in Eq. (53). In fact, there are three spatial scales at which these thresholds are applied ranging from the most local neighborhood through the district to the region itself. The neighborhood exercises a trigger for new growth or decline based on the existence or otherwise of the street network, the district uses the densities of related land uses and distance of the new land use from the initiating use to effect a change, while the region is used to implement hard and fast constraints on what cells are available or not for development. Typically an initiating land use will spawn a new land use in a district only if the cells in question are vacant and if they are not affected by some regional constraint on development with these rules being implemented first. The probability of this land use occurring in a cell in this district is then fixed according to its distance from the initiating location. This probability is then modified according to the density of different land uses that exist around each of these potential locations – using compatibility constraints – and then in the local neighborhood, the density of the street network is examined. If this density is not sufficient to support a new use, the probability is set equal to zero and the cell in question does not survive this process of allocation. At this point, the cell state is switched from 'empty' or 'vacant' to 'developed' if the random number drawn is consistent with the development probability determined through this process.

Declines in land use which are simply switches from developed to vacant in terms of cell state are produced through the life cycling of activities. When a mature land use in a cell reaches a certain age, it moves into a one period declining state and then disappears at the end of this time period, the cell becoming vacant. Cells remain vacant for one time period before entering the pool of eligible locations for new development. In the model as currently constituted, there is no internal migration of activities or indeed any mutation of uses but these processes are intrinsic to the model structure and have simply not been invoked. The software for this model has been written from scratch in *Visual C++* with the loosest coupling possible to GIS through the import of raster files in different proprietary formats. The interface we have developed, shown below, enables the user to plant various land use seeds into a virgin landscape or an already developed system which is arranged on a suitably registered pixel grid which can be up to 3K x 3K or 9 million pixels in size. A map of this region forms the main window but there are also three related windows which show the various trajectories of how different land uses change through time with the map and trajectories successively updated in each run.

A feature which is largely due to the fact that the model can be run quickly through many time periods, is that the system soon grows to its upper limits with exponential growth at first which then becomes logistic or capacitated. In Fig. 6, we show how this occurs from planting a random selection of land use seeds in the region and then letting these evolve until the system fills. Because there are lags in the redevelopment of land uses in the model due to the life cycle effects, as the system fills, land is vacated. This increases the space available for new development leading to oscillations of the kind reflected in Forrester's model shown in Fig. 5 and more controversially in the real systems shown for New York City and Greater London in Fig. 4. In this sense, a CA model has a dynamics which is equivalent to that of the more top-down dynamics where growth is modeled by exponential or logistic functions. CA models however generate this as an emergent phenomena from the bottom up.

Our last demonstration of CA really does generate emergent phenomena. This is a model of residential movement that leads to extreme segregation of a population classified into two distinct groups which we will call red R and green G. Let us array the population on a square grid of dimension 51 x 51 where we place an R person next to a G person in alternate fashion, arranging them in checker board style as in Fig. 7a. The rule for being satisfied with one's locational position viz a viz one's relationship to other individuals is as follows: persons of a different group will live quite happily, side by side with each other, as long as there are as many persons of the same persuasion in their local neighborhood. The neighborhood in this instance is the eight cells that surround a person on the checkerboard in the *n, s, e, w,* and *nw, se, sw,* and *ne* positions. If however a person finds that the persons of the opposing group outnumber those of their own group, and this would occur if there were more than 4 persons of the opposite persuasion, then the person in question would change their allegiance. In other words, they would switch their support to restore their own equilibrium which ensures that they are surrounded by at least the same number of their own group. There is a version of this model that is a little more realistic in which a person would seek another location – move – if this condition were not satisfied rather than change their support, but this is clearly not possible in the completely filled system that we have assumed; we will return to this slightly more realistic model below.

In Fig. 7a, the alternative positioning shown in the checker board pattern meets this rule and the locational pattern is in 'equilibrium': that is, no one wants to change their support to another group. However let us suppose that just six persons out of a total of 2601 (51 x 51 agents sitting on the checker board) who compose about 0.01 percent of the two populations, change their allegiance. These six changes are easy to see in Fig. 7a where we assume that four R persons of the red group, change in their allegiance to support the green group, and two Gs change the op-

posite way. What then happens is the equilibrium is upset in these locations but instead of being quickly restored by local changes, this sets off a mighty unraveling which quickly changes the locational complexion of the system to one where the Rs are completely and utterly segregated from the Gs. We show this in Fig. 7b. From a situation where everyone was satisfied and mixed completely, we get dramatic segregation which is a most unusual consequence. At first sight, one would never imagine that with so mild a balance of preferences, such segregation would take place. The ultimate pattern implies that Rs will live nowhere near Gs unless they really have to and there is nowhere else to live and vice versa. If an R or a G could not tolerate more than one person of a different kind living near them, then such segregation would be understandable but this is not the case: Rs are quite content to live in harmony with Gs as long as the harmony is equality.

This model was first proposed more than 30 years by Schelling [61,62]. In fact we can make this a little more realistic if we provide some free space within the system. In this case, we assume that 1/3 of the lattice is empty of persons of any kind, 1/3 composed of Rs, and 1/3 of Gs, and we mix these randomly as we show in Fig. 7c. Now the rule is slightly different in that if there are more opposition persons around a person of one persuasion, then that person will try to move his or her location to a more preferential position. This sets up a process of shuffling around the checker board but as we show in Fig. 7d, quite dramatic shifts take place in location which leads to the segregation shown. This is the kind of effect that takes place in residential areas in large cities where people wish to surround themselves with neighbors of their own kind. What is surprising about the phenomena which makes it 'emergent' is that for very mild preferential bias, dramatic segregation can take place. Of course if the preferences for like neighbors are very strong anyway, then segregation will take place. But in reality, such preferences are usually mild rather than strong, yet extreme segregation takes place anyway. The conclusion is that cities often look more segregated around racial and social lines than the attitudes of their residents might suggest.

Comprehensive System Models of Urban Structure

Integrated Land Use Transport Models

The various components used to model cities in equilibrium were quickly assembled into structures that attempted to simulate urban structure and growth from the 1960s onwards. These models were referred to as land use transport models in that their aim was to simulate the locations of different land uses and their consequent patterns of traffic generation, usually according to spatial interaction principles based on gravitational assumptions. But they usually represented cities as demographic and economic activities – population, households, employment and so on – rather than as residential, commercial or industrial land use. In short the city system was seen to operate at the level of the location of activities which then consumed space through land use from which traffic was generated, and once urban activities and their interactions were predicted, appropriate translations were made into land use. As we shall see, this is not as unproblematic as was originally thought.

The integration of urban activities and their interactions – land use and transport – can be accomplished using a variety of economic frameworks built around economic relationships between activities. Traditionally these have been represented as input-output models where one activity is linked to another and it is possible to predict the chain of linkages between all the activities using multipliers. We will illustrate this for two activities: we assume that employment E is divided into an unpredictable component, sometimes considered as employment that is *basic* B and export orientated in the economy, and employment that is *non-basic* S where $E = B + S$. Non-basic employment services the population P from which it is derived as $S = bP$. If we then consider that population can be generated by applying an activity rate a to employment as $P = aE$, we have the rudiments of a generative sequence that forms a structure for predicting activities and their locations which are highly interdependent. Simple manipulation of these relationships shows that $E = B(1 - ba)^{-1}$ where $(1 - ba)^{-1}$ is the multiplier central to traditional macro-economic theory.

If we now consider that employment and population are related spatially through their interactions, we model the relationship between employment as population using a singly-constrained sub-model

$$P_j = a \sum_i T_{ij} = a \sum_i E_i \frac{F_j c_{ij}^{-\psi}}{\sum_k F_k c_{ik}^{-\psi}} , \qquad (54)$$

where T_{ij} are work trips between i and j, F_j is some measure of attraction at residential location j, and ψ is the friction of distance/travel cost parameter. Employment is modeled in reverse direction as

$$E_i = b \sum_j S_{ji} = b \sum_j P_j \frac{F_i c_{ji}^{-\varpi}}{\sum_k F_k c_{ki}^{-\varpi}} , \qquad (55)$$

where S_{ji} are employment demands in j from i, F_i is some measure of attraction at residential location i, and ϖ is the friction of distance/travel cost parameter. These two equations for the two sectors are not usually solved simultaneously but the chain is broken in that we start with basic employment B in Eq. (54), predicting basic population, then using this basic population in Eq. (55) to produce an increment of non-basic employment which in turn is used to predict the next increment of non-basic population in Eq. (54). This iteration converges to the multiplier relationships $E = B(1 - ba)^{-1}$ and $P = bB(1 - ba)^{-1}$.

This kind of sequence can be disaggregated indefinitely with respect to population and employment types and linked demands to other sectors. Education, leisure and so on can be added to the framework making the model ever more comprehensive. This was the model first developed by Lowry [50]. It is still the most widely applied of all operational urban models and has been elaborated in various ways, some of them dealing with partial dynamics [11]. Their theoretical pedigree is rooted largely in regional economics, location theory and the new urban economics which represent the spatial equivalents of classical macro and micro economics. The most coherent recent statement in this vein is based on applications of trade theory to the urban economy as reflected in the work of Fujita, Krugman and Venables [40] but there is a long heritage of empirical models in the Lowry [50] tradition which continue to be built [71].

These models now incorporate the four-stage transportation modeling process of trip generation, distribution, modal split and assignment explicitly and they are consistent with discrete choice methods based on utility maximizing in their simulation of trip-making [20]. They have been slowly adapted to simulate dynamic change although they still tend to generate the entire activity pattern of the city in one go, and they remain parsimonious in that the assumption is that all the outcomes from the model can be tested in terms of their goodness of fit. They have also become more disaggregate and there are now links to physical land use although they still remain at the level of activity allocation despite their nomenclature as land use transport models. In short, this class of models is the most operational in that newer styles tend to be less comprehensive in their treatment of urban activities and transportation. Probably the most highly developed of these models currently is the UrbanSim model [69] although the MEPLAN, TRANUS and IRPUD models, whose most recent versions were developed in the EU Propolis [60] project, also represent the state-of-the-art.

Cities as Complex Systems: Scaling, Interaction, Networks, Dynamics and Urban Morphologies, Figure 8
Visualization of outputs from a Greater London land use transport model

To conclude this section, it is worth showing a visualization from one of these land use transport models which we have recently built for the London region as part of an integrated assessment of climate change in the metropolis. The component we show is a residential location model which predicts the flow of workers from employment locations to residential areas using four different modes of transport and disaggregated into five employment and five household types. In Fig. 8a, we show some outputs from the model – the observed employment distribution, the pattern of population density, and total work trips from the airport (Heathrow) zone in the base year simulation 2005. This kind of model assumes that employment and the travel cost network are exogenously determined and thus 'what-if' style questions can be thrown at the model to be evaluated in terms of the impact of changes in the transport network and employment volumes on the location of population. We illustrate such a scenario builder for changes in the transport routes and costs in Fig. 8b which provides some sense of how such complexity can be visualized. These are key issues in planning policy for the future growth of London, particularly with respect to flooding in the Thames Estuary which is likely to be affected by climate change. These kinds of models are hardly routine but they are being developed now in many places.

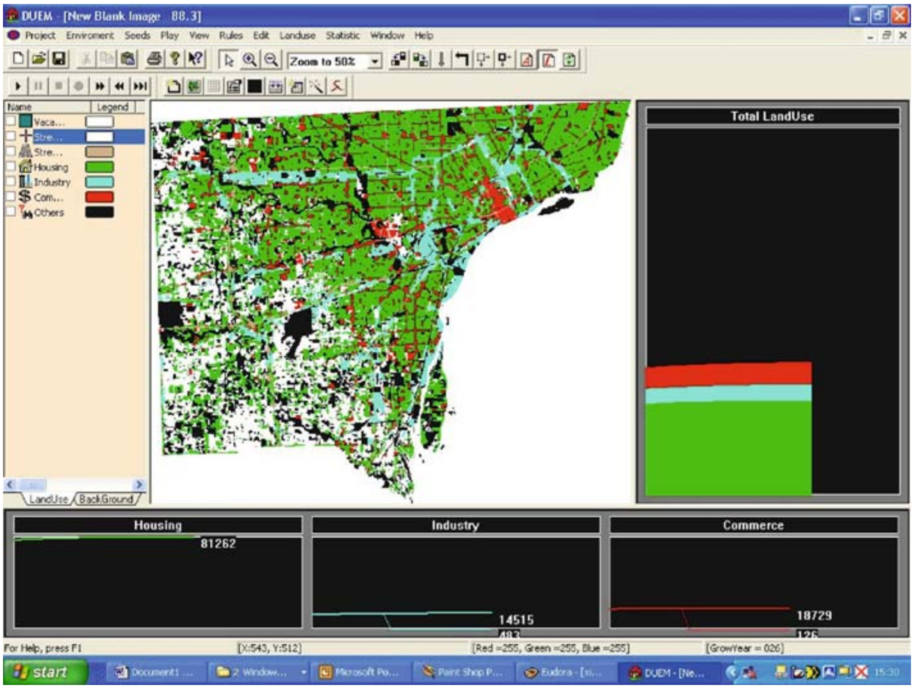
Agent-Based and Cellular Automata Models of Land Development

The first bottom-up CA models applicable to urban structure and growth can be traced back to the 1960s. Chapin and Weiss [27] used cell-space (CS) simulation whose locational attractions were based on linear regression, in their models of urban growth in Greensboro, North Carolina. Lathrop and Hamburg [49] used gravitational models to effect the same in simulating growth in the Buffalo-Niagara region while from a rather different perspective, Tobler [65] used CA-like simulation to generate a movie of growth in the Detroit region. All these applications were on the edge of the mainstream which 30 years ago was based not on formal dynamics but on cross-sectional equilibrium models of the variety presented above. In the intervening years, CA insofar as it was considered a simulation tool, was regarded as important mainly for its pedagogic and analytical value [32]. It was not until the early 1990s that models began to emerge which were considered to be close enough to actual urban growth patterns to form the basis for simulation and prediction. In fact, there still exists a recurrent debate about whether or not CA models are more important for their pedagogic value rather than for their abilities to simulate real systems. These require gross simplifications of model processes and spatial units, sometimes rendering them further from reality than the static cross-sectional models that came before.

The three earliest attempts at such modeling were geared to simulating rapid urban growth for metropolitan regions, medium-sized towns, and suburban areas. Batty and Xie [18] developed simulations of suburban residential sprawl in Amherst, New York, where a detailed space-time series of development was used to tune the model. Clarke and Gaydos [31] embarked on a series of simulations of large-scale metropolitan urban growth in the Bay Area and went on to model a series of cities in the US in the Gigalopolis project. White and Engelen [72] developed a CA model for Cincinnati from rather crude temporal land use data and in all these cases, the focus was on land development, suburbanization, and sprawl. Since then, several other groups have developed similar models focusing on suburbanization in Australian cities [70], 'desakota' – rapid urban growth in rural areas in China – specifically in the Pearl River Delta [80], diffused urban growth in Northern Italy [22], and rapid urbanization in Latin American cities [35]. Other attempts at modeling and predicting sprawl have been made by Papini et al. [58] for Rome and Cheng [28] for Wuhan, while Engelen's group at RIKS in the Netherlands has been responsible for many applications of their model system to various European cities [9].

There are at least four applications which do not focus on urban growth per se. Wu and Webster [77] have been intent on adding spatial economic processes and market clearing to such models, while Portugali and Benenson [59] in Tel-Aviv have focused their efforts on intra-urban change, particularly segregation and ghettoization. Semboloni [64] has worked on adding more classical mechanisms to his CA models reflecting scale and hierarchy as well as extending his simulations to the third dimension, while there have been several attempts by physicists to evolve a more general CA framework for urban development which links to new ideas in complexity such as self-organized criticality and power law scaling [7,63].

It is worth showing some graphics from such CA models as they are being applied to real cities. In Fig. 9, we show how the DUEM model can be used to simulate the pattern of development change in the Detroit region of South East Michigan. In a sense because we live in world dominated by a somewhat unhealthy interest in growth, it might be assumed that all the models we have presented here are only geared to simulating new development. In fact, each of these models can simulate decline or reproduce the steady state because CA models can solely deal with transitions and change in the existing fabric as we il-



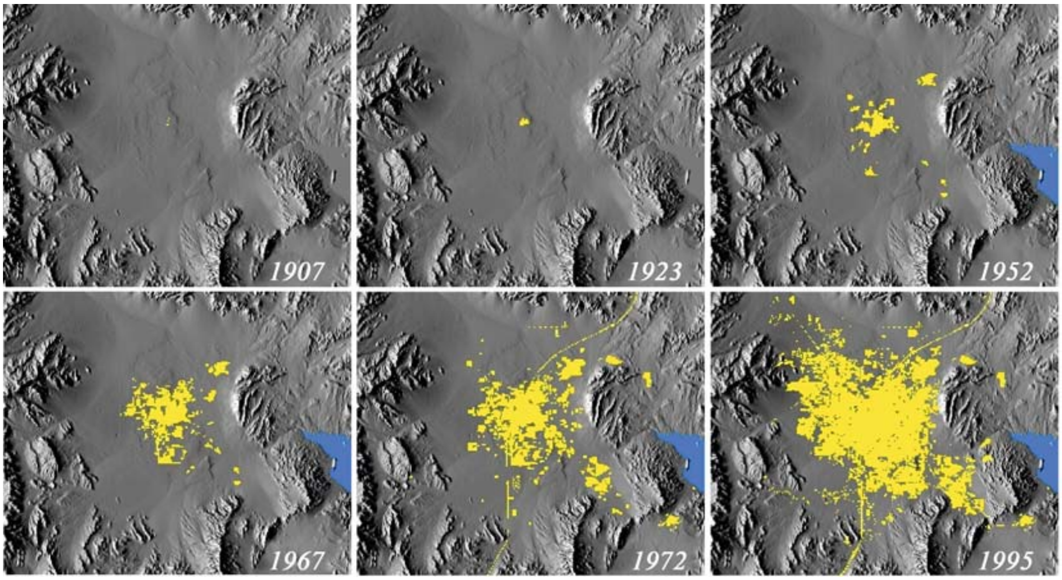
Cities as Complex Systems: Scaling, Interaction, Networks, Dynamics and Urban Morphologies, Figure 9
Simulating very slow growth and rapid decline in the Detroit region using the CA *DUEM* model

lustrated earlier in the Schelling segregation model. This is the case in Detroit where the population has rapidly adjusted and segregated its locations in the last 50 years but in a context where the overall growth has been extremely modest with many areas growing very fast in the suburbs but the central areas declining at similar rates. The profile in Fig. 9 is akin to a steady state rather than the overall exponential growth or decline shown in previous examples.

There are some agent-based models at the land use or activities level which enable predictions of future urban patterns but the main focus is at the very micro-level where local movements in terms of traffic are being simulated [25]. Several models that approach the agent-based ideal originate from other areas. TRANSIMS is a hybrid in that its roots are in agent-based simulation of vehicles but it has been scaled to embrace urban activities [55] and even UrbanSim can be interpreted through the agent paradigm. A parallel but significant approach to individualistic modeling is based on micro-simulation which essentially samples individual behavior from more aggregate distributions and constructs synthetic agent-based models linked to spatial location [30]. This is a rapidly changing field at the present time with no agreement about terminology. The term agent is being used to describe many different types of models with some focusing on unique objects ranging from cells or points in space where activities or individuals exist to models of institutions and groups with only implicit spatial positioning [44].

Models of Urban Morphology

The models introduced above do not capture many of the physical features of cities and regions in terms of their morphology. Cities are highly organized with respect to their form, displaying as we have already seen in terms of city size, clusters of activity on all scales, in short, fractals [16]. Insofar as static equilibrium models are able to reproduce this form and to an extent they are able to do so, this is largely because some of the structure of the city is input into these models through existing employment and population distributions which have already captured elements of the morphology. There are competitive effects in these models too that are intrinsic to these simulations with the dynamic models based on cellular automata closest to reflecting these processes in urban form. This is because the process of development is generated from the bottom up and agglomeration is a key feature of the processes of development that are simulated as in some of the



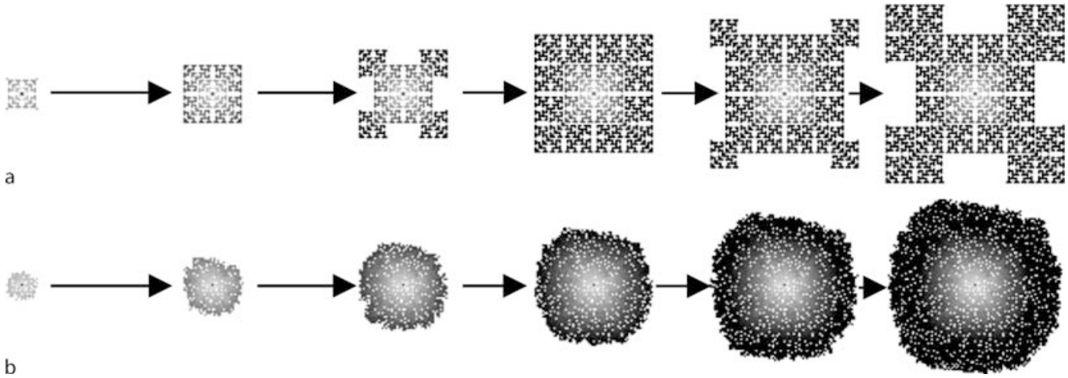
Cities as Complex Systems: Scaling, Interaction, Networks, Dynamics and Urban Morphologies, Figure 10
The growth of Las Vegas from 1907 to 1995 (from [1])

models discussed in the last section. Here we will simply illustrate some of the evolving forms that various combinations of the models already discussed are able to simulate. This shows how various processes of land development and travel behavior can come together to generate structures that are close to what we observe in the real world.

A good example of the urban growth which has been rapid over the last 50 years is Las Vegas, the fastest growing metropolitan area in the United States which is illustrated in Fig. 10 [1]. The sprawl does not look very different from time period to time period although it is clear that growth is clustered and these clusters tend to merge as the city grows. In this sense, the pattern always looks like more of the same from time period to time period but inside the city, things have changed rather more dramatically as the place has moved from desert oasis and staging post prior to 1950 to the entertainment and gambling capital of the US. Exponential growth of population, employment and tourism is implied by this volume of urban development mirroring the simplest 'un-capacitated' growth model in Eqs. (36) and (37). The fact that the city has grown in some directions rather than others is largely due to a combination of physical and accidental historical factors and does not imply any differences in the way growth has occurred from one time period to the next.

Cellular automata models can generate such growth where entirely local development rules are operated uniformly across the space to grow a city from a single seed. This can lead to fractal patterns, patterns that are self-similar in form with respect to scale, of the kind observed in real cities. In Fig. 11a, we show how the operation of deterministic rules where a cell is developed if there is one and only one cell already developed in its immediate neighborhood, leads to a growing structure. This is a typical example of a modular principle that preserves a certain level of density and space when development occurs but when operated routinely and exhaustively leads to cellular growth that is regular and self-similar across scales, hence fractal. In Fig. 11b, the shape of the structure generated is now circular in that development eventually occurs everywhere. The city fills up completely but the order in which this takes place is a result of development taking place at each time period with random probability. This is the effect of introducing 'noise' or 'diversity' into the model used to generate the sequence in Fig. 11a.

If urban growth is modular and scales in the simplistic way that is portrayed in these models of fractal growth, then it is not surprising that there is a tendency to explain such patterns generically, without regard to growth per se; to study these as if they represent systems with an equilibrium pattern that simply scales through time. But this is a trap that must be avoided. Dig below the surface, and examine the processes of growth and the activities that occupy these forms, disaggregate the scale and change the time interval, and this image of an implied stability changes quite radically. During the era pictured in



Cities as Complex Systems: Scaling, Interaction, Networks, Dynamics and Urban Morphologies, Figure 11
Growth from the bottom up. a deterministic growth based on developing cells if one and only one cell is already developed in their 8 cell adjacent neighborhood, and b stochastic growth based on developing cell if any cell is developed in the adjacent neighborhood according to a random probability

Cities as Complex Systems: Scaling, Interaction, Networks, Dynamics and Urban Morphologies, Figure 12
Greater London: self-similar clusters and the connectivity network within the sprawl

Fig. 10, technology has changed dramatically. Las Vegas did not acquire its gambling functions until the 1950s but by then it was already growing fast and the subsequent injection of cash into its local economy, the largest per capita in the western world for those who reside there, did little to change the pattern of explosive growth that followed. The manner in which people moved in the early Las Vegas was by horse and wagon but the city could only grow with the car, the plane and air-conditioning, not to say the incredible information technologies that now dictate how one gambles, wins, and loses.

Our six frame 'movie' of the growth of Las Vegas does reveal that the established pattern of adding to the periphery is not entirely the complete story for small blobs of development seem to attach themselves and then are absorbed back into the growing mass as growth catches them up. In this case, this is simply housing being constructed a little beyond the edge due to the mechanics of the development process. In older, more established settlement patterns such as those in Western Europe for example, this might be the absorption of older villages and freestanding towns into the growing sprawl. Consider the picture of population density in London recorded in 1991 and illustrated in Fig. 12a. Here there are many towns and villages that existed long before London grew to embrace them. If we define the metropolis as the connected network of settlement that fills an entire space where everyone can connect to everybody else either directly or indirectly, the picture is similar as we show in Fig. 12b.

One could envisage London being connected in this way with a much sparser network of links while at the other extreme the entire space could be filled. In fact, it would seem that the level of connectivity which has evolved with respect to the density of the space filled is just enough for the city to function as a whole. It is this morphology and degree of connectivity that marks the fact that the city has reached a level of self-organization which is regarded as critical. If connectivity were greater, more space would be filled and many more connections put in place but the structure would contain a certain degree of redundancy making it inefficient. Below this, the system would not be connected at all and it would not function as a metropolis. In fact there are strong relationships to this characterization of urban settlement as a porous media in which a phase transition might take place as the system fills up which in network terms, is like a percolation threshold [13]. The models that we have sketched above all provide ways of generating these kinds of morphology, albeit through somewhat different mechanisms than the obvious way in which growth in physical systems takes place. The forms generated constitute an essential check on the adequacy or otherwise of these system models.

Future Directions

The biggest problems facing the development of complex systems models in general and those applied to cities in particular involve validation. The move from articulating systems as organized entities structured from the top down based on some sort of centralized control mechanisms to systems that grow in an uncoordinated way from the bottom up have also shifted our perspective from developing systems model in a parsimonious way to developing much richer models requiring more detailed data. In short, complexity theory has changed the basis for theory and model selection from an insistence that all models must be testable against data to an acceptance that if there is a strong reason why some non-testable propositions should be included in a model (as models with very rich behaviors and processes imply), then these should be included even if they cannot be tested. This is consistent with the shift from aggregate to disaggregate modeling, from the focus on equilibrium to dynamics, and on processes and behaviors rather than simply outcomes.

This changes the entire basis of validation and combined with the difficulties of articulating processes which are clearly relevant but often unobservable, the way in which models might be useful in policy making in complex systems is changing too. Modeling is now much more contingent on context and circumstance than at any time in the past. The use of multiple models, counter modeling and the synthesis of different and often contradictory model structures is now taken for granted in systems where we consider there may be no optimal solutions and where there will always be dissent from what is regarded as acceptable. Many newer models such as those based on cellular and agent-based structures and those which postulate a dynamics that involves bifurcations that are often of only theoretical interest until one such dynamic is observed, are unlikely to meet the canons of parsimony in which unambiguous tests can be made against data. These limits to validation begin to suggest that complex system models need to be classified on a continuum of ways in which they can be tested and used in practice which will depend on the type of model, the context, and the users involved [17].

In terms of more substantive developments, the question of dynamics is still of burning importance in developing better models of cities. There is an intrinsic problem of articulating urban processes of change from sparsely populated data bases which often contain only the aggregate outcomes of multiple processes. The way in which our commonsense observations of decision making in cities can be linked to more considered outcomes represented in data has barely been broached in developing good models of urban spatial behavior. In agent-based modeling, the role of cognition is important while the question of defining agents at appropriate levels is a major research focus, particularly when it comes to aggregates which are of a more abstract nature, such as groups and institutions. However what is of clear importance is the fact that as our focus becomes finer and as we disaggregate to ever more detailed levels, we then begin to represent policy processes into which these models might be nested in more detailed ways, implying that policy making and planning itself might be simply one other feature of these system models.

In short in our quest for more detail and for embracing a wider environment, city models have come to encapsulate the control mechanisms themselves as intrinsic to their functioning. It is at this point that we need much better ways of showing how such models can be used in practice. To an extent, this implies that we need to link these system models to their wider context of use and application, showing how other conceptions, other systems models, might be related to them in less formal ways than in terms of the science we have presented here. This has always been a challenge for the application of complexity theory to human and social systems, and it will remain the cutting edge of this field whose rationale is the prediction and design of more efficient, equitable, and sustainable cities.

Article Outline

Glossary

Anthropogenic emissions Greenhouse gas emissions that are produced as a result of humans through such developments as industry or agriculture.

Greenhouse gases The gases of the atmosphere that create the greenhouse effect, which keeps much of the heat from the sun from radiating back into outer space. Greenhouse gases include, in order of relative abundance: Water vapor, carbon dioxide, methane, nitrous oxide, ozone, and CFCs. Greenhouse gases come from natural sources and human activity; present CO_2 levels are $\sim$380 ppmv, approximately 100 ppmv higher than they were in pre-industrial times.

Soybean cyst nematode *Heterodera glycines*, a plant-parasite that infects the roots of soybean, with the female becoming a cyst. Infection causes various symptoms, including a serious loss of yield.

El Niño-southern oscillation (ENSO) A phenomenon in the equatorial Pacific Ocean characterized by a positive sea-surface temperature departure from normal (for the 1971–2000 base period) in the Niño 3.4 region greater than or equal in magnitude to 0.5°C, averaged over three consecutive months.

North atlantic Oscillation (NAO) A hemispheric, meridional oscillation in atmospheric mass with centers of action near Iceland and over the subtropical Atlantic.

Vegetative index A simple numerical indicator used to analyze remote sensing measurements, often from space satellites, to determine how much photosynthesis is occurring in an area.

Soil organic carbon All the organic compounds within the soil without living roots and animals.

Introduction

The term climate change refers to an overall shift of mean climate conditions in a given region. The warming trend associated with anthropogenic emissions of greenhouse gases and the enhanced greenhouse effect of the atmosphere can and should be regarded as a "climate change" when viewed on the time scale of decades or a few centuries.

Climate change exacerbates concerns about agricultural production and food security worldwide. At global and regional scales, food security is prominent among the human concerns and ecosystem services under threat from dangerous anthropogenic interference in the earth's climate [17,29,50]. At the national scale, decision-makers are concerned about potential damages that may arise in coming decades from climate change impacts, since these are likely to affect domestic and international policies, trading patterns, resource use, regional planning, and human welfare.

While agro-climatic conditions, land resources and their management are key components of food production, both supply and demand are also critically affected by distinct socio-economic pressures, including current and projected trends in population and income growth and distribution, as well as availability and access to technology and development. In the last three decades, for instance, average daily per capita intake has risen globally from 2,400 to 2,800 calories, spurred by economic growth, improved production systems, international trade, and globalization of food markets [12]. Feedbacks of such growth patterns on cultures, personal tastes, and lifestyles have in turn led to major dietary changes – mainly in developing countries – where shares of meat, fat, and sugar in total food intake have increased significantly [13]. Thus, the consequences of climate change on world food demand and supply will depend on many interactive dynamic processes.

Agriculture plays two fundamental roles in human-driven climate change. It is one of the key human sectors that will be affected by climate change over the coming decades, thus requiring adaptation measures. Agriculture is also a major source of greenhouse gases to the atmosphere, including carbon dioxide (CO_2) due to land-use change and farm operations; methane (CH_4) from rice production and livestock husbandry, and nitrous oxide (N_2O) from application of nitrogen fertilizer. As climate changes as well as socio-economic pressures shape future demands for food, fiber and energy, synergies can be identified between adaptation and mitigation strategies, so that robust options that meet both climate and societal challenges can be developed. Ultimately, farmers and others in the agricultural sector will be faced with the dual task of contributing to global reductions of carbon dioxide and other greenhouse gas emissions, while coping with an already-changing climate.

A changing climate due to increasing anthropogenic emissions of greenhouse gases will affect both the productivity and geographic distribution of crop and pasture species. The major climate factors contributing to these responses include increasing atmospheric carbon dioxide, rising temperature, and increasing extreme events, especially droughts and floods. These factors in turn will affect water resources for agriculture, grazing lands, livestock, and associated agricultural pests. Effects will vary, depending on the degree of change in temperature and precipitation and on the particular management system and its location. Several studies have suggested that recent warming trends in some regions may have already had discernible effects on some agricultural systems [17].

Climate change projections are uncertain in regard to both the rate and magnitude of temperature and precipitation variation in the coming decades. This uncertainty arises from a lack of precise knowledge of how climate system processes will change and of how population growth, economic and technological developments, and land-use patterns will evolve in the coming century [16,17]. Despite these uncertainties, the ultimate significance of the climate change issue is related to its global reach, affecting agricultural regions throughout the world in complex ways. After approximately two decades of research, ten major conclusions may be drawn in regard to climate change and agriculture.

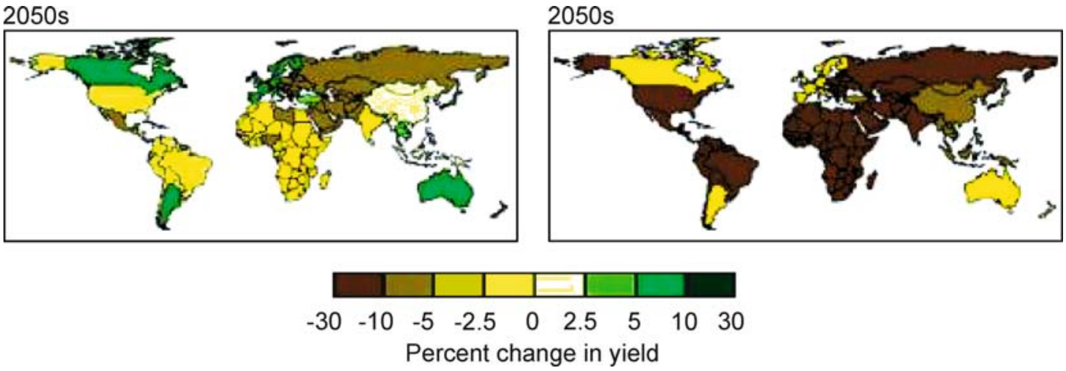
Effects on Agricultural Systems Will Be Heterogeneous

Global studies on projected climate change effects on agriculture show that negative and positive effects will occur both within countries and across the world. In large countries such as the United States, Russia, Brazil, and Australia, agricultural regions will likely be affected quite differently. Some regions will experience increases in production and some declines (see, e. g., [34]). At the international level, this implies possible shifts in comparative advantage for production of export crops. This also implies that adaptive responses to climate change will necessarily be complex and varied. Due to differences in global climate model projections and decadal variability, it is impossible to project exact effects in any one location for any given decade.

Developing Countries Are More Vulnerable

Despite general uncertainties about the rate and magnitude of climate change and especially about consequent hydrological changes, regional and global studies have consistently shown that agricultural production systems in the mid and high latitudes are more likely to benefit in the near term (to mid-century), while production systems in the low-latitudes are more likely to decline (Fig. 1) [17]. In biophysical terms, rising temperatures will likely push many crops beyond their limits of optimal growth and yield. Higher temperatures will intensify the evaporative demand of the atmosphere, leading to greater water stress, especially in semi-arid regions. Since most developing countries are located in lower-latitude regions (some which are indeed semi-arid) while most developed countries are located in the more humid mid- to high latitudes, this finding suggests a divergence in vulnerability between these groups of nations, with far-reaching implications for future world food security [31,37].

Furthermore, developing countries often have fewer resources with which to devise appropriate adaptation measures to meet changing agricultural conditions. The combination of potentially greater climate stresses and lower adaptive capacity in developing countries creates different degrees of vulnerability between rich and poor nations as they confront global warming. This difference is due in part to the potentially greater detrimental impacts of a changing climate in areas that are already warm (particularly if such areas are also dry), and in part to the generally lower levels of adaptive capacity in developing countries.



Climate Change and Agriculture, Figure 1

Potential changes (%) in national cereal yields for the 2050s (compared with 1990) under the HadCM3 SRES A1FI with (*left*) and without (*right*) CO_2 effects [31]

Development Path Matters

Since climate is not the only driving force on agriculture, researchers now conduct scenario analysis that include linked sets of population projections, economic growth rates, energy technology improvements, land-use changes, and associated emissions of greenhouse gases [31]. Regional patterns related to economic development and adaptive capacity contribute to differing levels of climate change impacts [17]. Scenarios with higher economic growth rates and less attention to environmental issues lead to high temperatures and reduced adaptive capacity, which in turn lead to pronounced decreases in yields both regionally and globally. Scenarios with lower greenhouse gas emissions and greater attention to environmental issues lead to lower amounts of temperature rise and crop production declines.

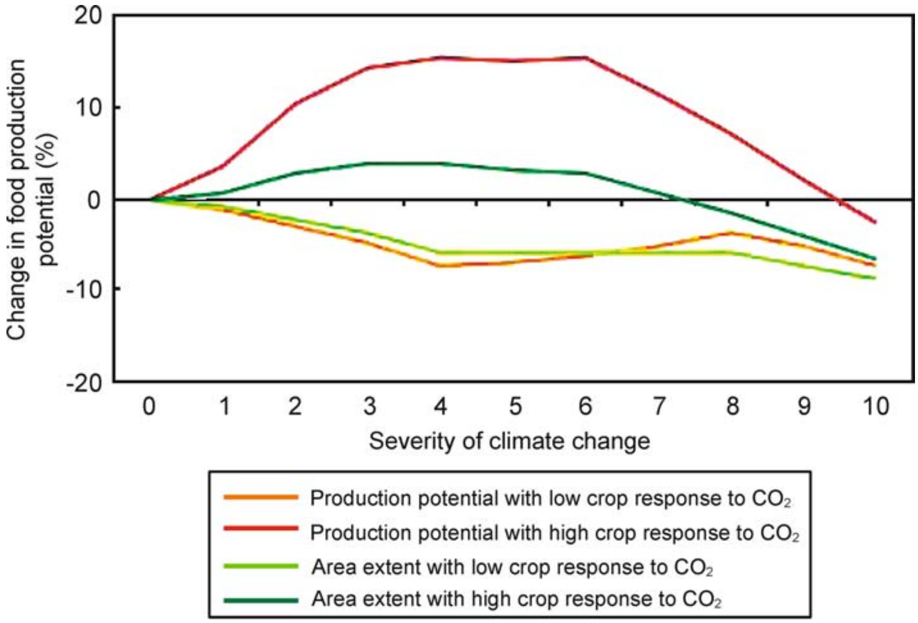
Long-Term Effects Are Negative for Both Developed and Developing Countries

If the effects of climate change are not abated, production in the mid- and high-latitudes is likely to decline in the longer term (i. e., above ~ 3°C warming) (Fig. 2) [16]. These results are consistent over a range of temperature, precipitation, and direct CO_2 effects tested, and are due primarily to the detrimental effects of heat and water stress as temperatures rise. While the beneficial effects of CO_2 may eventually level out, the detrimental effects of warmer temperatures and greater water stress are more likely to be progressive in all regions. Although the precise levels of CO_2 effects on crops and their contribution to global crop production are still active areas of research [47], global impacts are likely to turn negative in all regions sometime during the second half of the century, and perhaps before then for some major crops. For instance, by 2050 climate change is projected to have a downward pressure on yields of almonds, walnuts, avocados, and table grapes in California. Opportunities for expansion into cooler regions have been identified, but this adaptation would require substantial investments and may be limited by non-climatic constraints [24].

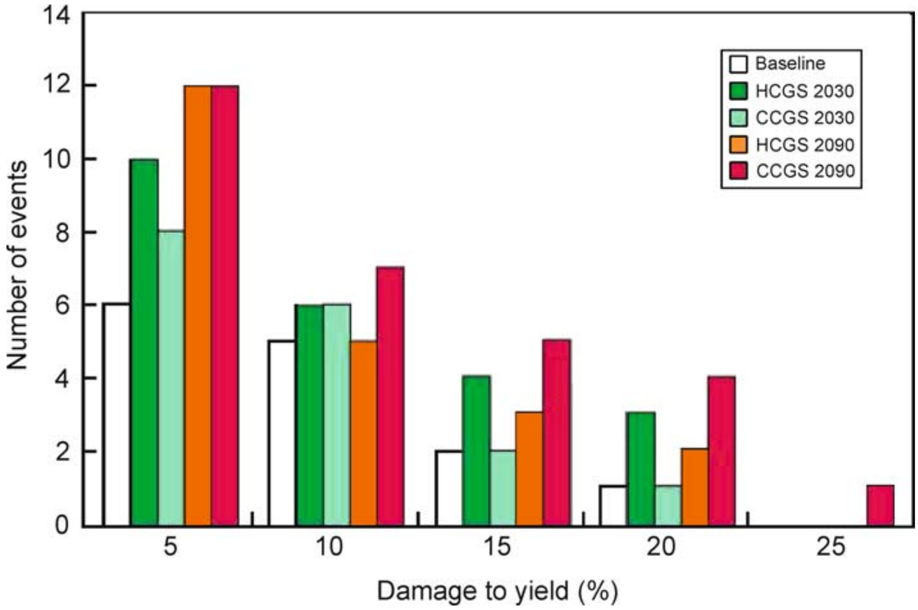
Water Resources Are Key

Recent flooding and heavy precipitation events in the US and worldwide have caused great damage to crop production. If the frequency of these weather extremes were to increase in the near future, as recent trends for the US indicate and as projected by global climate models [17,48], the cost of crop losses in the coming decades could rise dramatically. US corn production losses due to excess soil moisture, already significant under current climate, may double during the next thirty years, causing additional damages totaling an estimated $3 billion per year (Fig. 3) [41]. These costs may either be borne directly by those farmers affected or may need to be transferred to private or governmental insurance and disaster relief programs. There is also concern for tractability in the spring and water-logging in the summer in mid and high latitudes where precipitation is projected to increase.

Changes in crop water demand and water availability will affect the reliability of irrigation, which competes for growing municipal and industrial demands [42]. Studies link climate change scenarios with hydrologic, agricultural, and planning models to estimate water availability for agriculture under changing climate conditions, to explore changes in ecosystem services, and to evaluate adap-



Climate Change and Agriculture, Figure 2
Change in food production potential in relation to severity of climate change [13]



Climate Change and Agriculture, Figure 3
Number of events causing damage to maize yields due to excess soil moisture conditions, averaged over all study sites, under current baseline (1951–1998) and climate change conditions. The Hadley Center (HC) and Canadian Center (CC) scenarios with greenhouse gas and sulfate aerosols (GS) were used. Events causing a 20% simulated yield damage are comparable to the 1993 US Midwest floods [41]

tation strategies for the water resources and agriculture sectors. Major irrigated agricultural regions are very likely to be affected by changing supplies of and demands for water due a changing climate especially under conditions of expansion of irrigated lands [42].

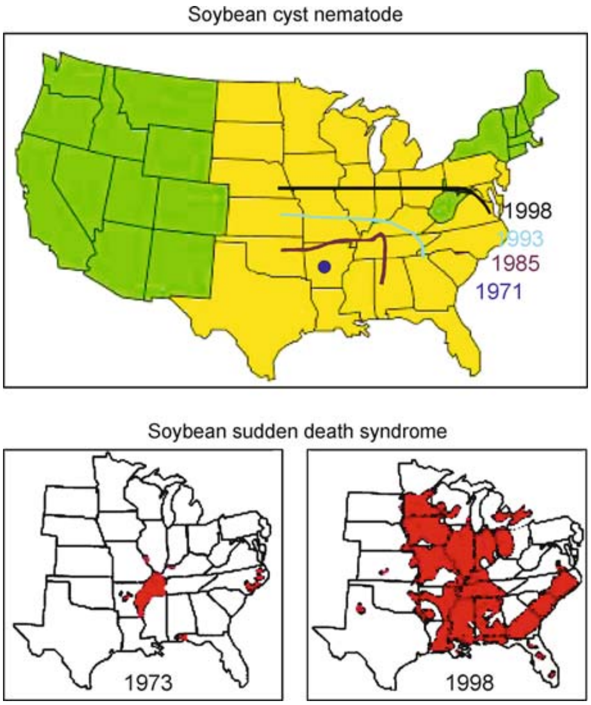
Cultivars are available for agricultural adaptation to the projected changes, but their demand for water may be higher than currently adapted varieties. Thus, even in relatively water-rich areas, changes in water demand due to climate change effects on agriculture and increased demand from urban growth will require timely improvements in crop cultivars, irrigation and drainage technology, and water management. In tropical regions, the use of agroforestry may be an economically feasible way to protect crop plants from extremes in microclimates and soil moisture [22].

Agricultural Pests and Diseases May Spread

Increased pest damage arises from changes in production systems, enhanced resistance of some pests to pesticides, and the production of crops in warmer and more humid climatic regions where crops are more susceptible to pests. Changes in crop management techniques, particularly the intensification of cropping, reduction in crop rotations, and increase in monocultures, have increased the activity of pests. The expansion of worldwide trade in food and plant products has also increased the impact of weeds, insects, and diseases on crops. The geographical ranges of several important insects, weeds, and pathogens in the US have recently expanded, including soybean cyst nematode (*Heterodera glycines*) and sudden death syndrome (*Fusarium solani* f. sp. *glycines*) (Fig. 4) [15,39,43].

Current climate trends and extreme weather events may be directly and indirectly contributing to the increased pest damage [17,39,52]. Downy mildew (*Plasmopara viticola*) epidemics on grape, the most serious grapevine disease in northern Italy, may increase under climate change, even though reduced precipitation may have a counterbalancing effect on disease pressure [44].

Such changes need to be put in the context of the global increases in pest-induced losses of crops in all regions since the 1940s [30,33] and the more than 33-fold increase in both the amount and toxicity of pesticide used over the same period [33]. Climate change thus may exacerbate environmental and public health issues related to agricultural chemicals [39], since increased applications of agricultural chemicals are likely to be needed in response to increasing disease pressure. Improved knowledge of the effects of climate on host–pathogen interactions will contribute to the adaptive capacity of agro-ecosystems.

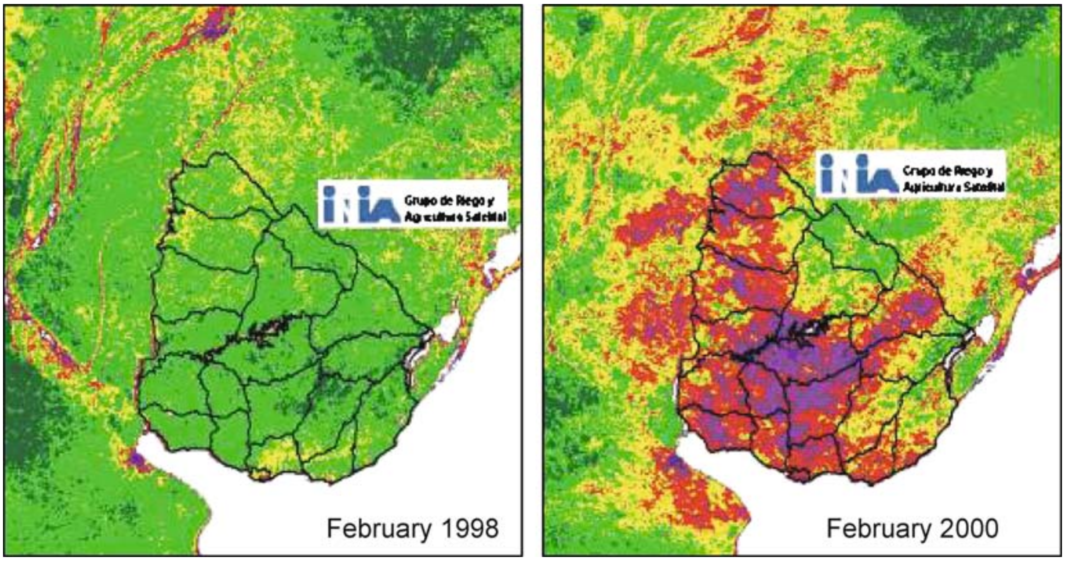


Climate Change and Agriculture, Figure 4
Range expansion of soybean cyst nematode (*Heterodera glycines*) from 1971 to 1989 (*top*) and soybean sudden death syndrome (*Fusarium solani f. sp. Glycines*) from 1973 to 1998 (*bottom*) in North America [40]

Current Climate Stress Is a Key Entry Point for Climate Change

There is an important interplay between current and future climate stresses. Since farmers have dealt with climatic fluctuations since the advent of agriculture, improving strategies for dealing with present climate extremes – such as droughts, floods, and heatwaves – is an important way to prepare for climate change. Many agricultural regions are affected by the major climate variability systems, including the processes known as the El Niño-Southern Oscillation (ENSO) and the North Atlantic Oscillation (NAO) [36]. The El Niño phase of the ENSO cycle tends to bring rainfall to Uruguay, while La Niña brings drought, as shown in Fig. 5 for 1998, an El Niño year, and 2000, the following La Niña.

In terms of prediction tools, ENSO models provide the opportunity for testing and validation of climate prediction and assessment on shorter seasonal-to-interannual time-scales. Skill in predicting climate changes on shorter time-scales, particularly the ENSO periods of the last twenty years when good observations exist, may lend credence to projections of global warming over the longer-term. As global climate models are further developed with



Climate Change and Agriculture, Figure 5
Vegetative Index (NDVI) for El Niño (1998) and La Niña (2000) years in Uruguay. *Green* = adequate water conditions; *red*/*purple* = drought conditions [2]

improved parametrizations and higher spatial resolution, they are likely to improve simulations of ENSO and other large-scale variability processes. The interaction of these systems with underlying anthropogenic trends caused by increasing greenhouse gas concentrations in the atmosphere is an active area of contemporary climate science. For regions directly affected by ENSO and other systems, such changes, if they do indeed occur, may become important manifestations of global warming.

Adaptation Is Necessary

'Coping range' is a useful paradigm for improving responses to climate stresses of today and preparing for the climate changes of tomorrow [20]. An agricultural system may currently exist within a 'coping range' of climate variability that may be exceeded as incidence of extreme events increases under changing climate conditions (Fig. 6). The goal is to increase the coping range over which an agricultural system may thrive under such changes through the process of adaptation.

Adaptation can help farmers to minimize negative impacts of climate on human activities and ecosystems and to take advantage of potential beneficial changes. *Adaptation* to climate change can be defined as the range of actions taken in response to changes in local and regional climatic conditions [45]. Adaptation responses include both *autonomous adaptation* actions (i. e., those taken spontaneously and independently by individual farmers), and *planned adaptation* actions (i. e., those facilitated by climate-specific regulations and incentives put in place by regional, national and international policies) (see Table 1) [17]. In terms of the multiple factors impinging on agriculture, however, system responses to socio-economic, institutional, political or cultural pressures may outweigh response to climate change alone in driving the evolution of agricultural systems. The *adaptive capacity* of a system, in the context of climate change, can be viewed as the full set of system skills – i. e., technical solutions available to farmers in order to respond to climate stresses – as determined by the socio-economic and cultural settings, plus institutional and policy contexts, prevalent in the region of interest [17].

While current agronomic research confirms that at the field level crops would respond positively to elevated CO_2 in the absence of climate change (e. g., [1,17,19,21], the associated impacts of high temperatures, altered patterns of precipitation, and possibly increased frequency of extreme events (such as drought and floods) are likely to require a range of adaptation responses, some of which are listed in Table 2.

Mitigation Reduces Long-Term Risk

Agriculture has an important role to play in mitigation of climate change. *Mitigation* is defined as intervention aimed at reducing the severity of climate change by reducing the atmospheric concentration of greenhouse gases, ei-

Climate Change and Agriculture, Table 1
Adaptation approaches to climate impacts on agriculture

Approach	Definition	Operation
Autonomous	Adaptation that does not constitute a conscious response to climatic stimuli but is triggered by ecological changes in natural systems and by market or welfare changes in human systems. Also referred to as spontaneous adaptation.	Crop calendar shifts (planting, input schedules, harvesting) Cultivar changes Crop-mix changes
Planned	Adaptation that is the result of a deliberate policy decision, based on an awareness that conditions have changed or are about to change and that action is required to return to, maintain, or achieve a desired state.	Land-use incentives Irrigation infrastructure Water pricing Germplasm development programs

Climate Change and Agriculture, Table 2
Key agronomic impacts and adaptation responses

Agricultural impacts	Adaptation response
Biomass increase under elevated CO_2	Cultivar selection and breeding to maximize yield
Acceleration of maturity due to higher temperature	Cultivar selection and breeding of slower maturing types
Heat stress during flowering and reproduction	Early planting of spring crops
Crop losses due to increased droughts and floods	Changes in crop mixtures and rotations; warning systems; insurance
Increased pest damage	Improved management; increased pesticide use; biotechnology

ther by reducing emissions or by enhancing sinks. There are several major ways that the agricultural sector can contribute to climate change mitigation.

Soil Carbon Sequestration Of the approximately 150 GT of carbon that were lost in the last century due to land conversion to agriculture and subsequent production, about two thirds were lost due to deforestation and one-third, roughly 50 GT, due to cultivation of current agricultural soils and exports as food products [50]. The latter figure represents the maximum theoretical amount of carbon that could be restored in agricultural soils. In practice, as long as 40–50% of total above-ground grain or fruit production is exported as food to non-agricultural areas, the actual carbon amount that can be restored in agricultural soils is much lower.

Efforts to improve soil quality and raise soil organic carbon (SOC) levels include crop management and conservation tillage techniques. These practices have evolved as means to enhance sustainability and resilience of agricultural systems, rather than with soil carbon sequestration as primary motivation. They include so-called "best practice" agricultural techniques, such as use of cover crops and/or nitrogen fixers in rotation cycles, judicious use of fertilizers and organic amendments, soil water management improvements to irrigation and drainage, and improved varieties with high biomass production.

Conventional tillage is defined [27] as the mechanical manipulation of the topsoil that leaves no more than 15% of the ground surface covered with crop residues. In contrast, no-till management is defined as the avoidance of mechanical manipulation of the topsoil so as to leave it undisturbed and covered with surface residues from harvesting the prior crop to planting the new crop.

Best agricultural practices can result in a net augmentation of soil carbon and in enhanced productivity due to better soil structure and soil moisture management. The relevant practices include precise and timely applications and spatial allocation of fertilizers, use of slow-release fertilizers, prevention of erosion, shortening or elimination of fallow periods, use of high-residue cover crops and green-manure crops, and minimized mechanical disturbance of soil (e. g., zero tillage). Altogether, such practices may lead to partial or even complete restoration of the soil's organic carbon content where it had been depleted. In some cases, it might even be possible to store more carbon than had originally been present in the "virgin" soil. Where the soils had been severely degraded and their agricultural productivity greatly impaired, they may be converted to grassland or afforested so as to serve as carbon sinks.

The overall potential for carbon storage depends in each case on such factors as climate, type of vegetation, topography, depth and texture of the soil, past use (or abuse), and current management.

Along with sequestering carbon, these practices have the potential to improve soils in developing countries. In areas such as West Africa, soil fertility depletion has been described as the single most important constraint to food security [4]. Studies in smallholder agricultural farms in Africa have already illustrated significant increases in system carbon and productivity through organic-inorganic resources management (Roose and Barthes [35])

Biofuels Agriculture may help to mitigate anthropogenic greenhouse emissions through the production of biofuels. As has been demonstrated by ethanol based on corn production, issues involved with biofuel production include potential competition with food production, increased pollution from fertilizers and pesticides, and loss of biodiversity. Biofuels derived from low-input high-diversity mixtures of native grassland perennials can provide more usable energy, greater greenhouse gas reduction, and less agrichemical pollution per hectare than corn grain ethanol or soybean biodiesel [46]. The higher net energy results arise because perennial grasses require lower energy inputs and produce higher bioenergy yield. Furthermore, all aboveground biomass of the grasses can be converted to energy, rather than just the seed of either corn or soybean. These perennial grasses also sequester carbon at significant rates [46].

Other Greenhouse Gases Because of the greater global warming potential (GWP) of methane (21) and nitrous oxide (310) compared to carbon dioxide (1), reductions of non-CO_2 greenhouse gas emissions from agriculture can be quite significant and achieved via the development of more efficient rice (for methane) and livestock production systems (for both methane and nitrous oxide). In intensive agricultural systems with crops and livestock production, direct CO_2 emissions are predominantly connected to field crop production and are typically in the range of 150–200 kg C ha^{-1} yr^{-1} [14,51]. Recent full greenhouse gas analysis of different farm systems in Europe showed that such CO_2 emissions represent only 10–15% of the farm total, with emissions of CH_4 contributing 25–30% and emissions of N_2O accounting for as much as 60% of total CO_2-equivalent greenhouse gas emissions from farm activities. The N_2O contribution arises from substantial nitrogen volatilization from fertilized fields and animal waste, but it is also a consequence of its very high GWP.

In Europe, methane emissions are mostly linked to cattle digestive pathways; its contribution also dominates that of CO_2, due in part to methane's high GWP. Mitigation measures for methane production in livestock include improved feed and nutrition regimes, as well as recovery of bio-gas for on-farm energy production. Effective reduction of N_2O emissions is more difficult, given the largely heterogeneous nature of emissions in space and time and thus the difficulty of timing fertilizer applications and/or manure management. Large uncertainties in emission factors also complicate the assessment of efficient N_2O-reduction strategies. Current techniques focus on reduction of absolute amounts of fertilizer nitrogen applied to fields, as well as on livestock feeding regimes that reduce animal excreta.

Climate Change Effects on Agriculture Are Occurring Already

Agricultural effects of observed climate changes are being documented in many regions of the world (Fig. 7). Changes in crop phenology provide important evidence of responses to recent regional climate change. Such changes are apparent in perennial crops, such as fruit trees and wine-making varieties of grapes, which are less dependent on yearly management decisions by farmers than annual crops and are also often easier to observe.

Phenological changes are often observed in tandem with changes in management practices by farmers. Between 1951 and 2004 in Europe, agricultural crops have advanced 2.1 days/decade in response to recent warming in spring [28]. In Sahelian countries, increasing temperature in combination with rainfall reduction has led to

🟦 <-1.2C to >1.2C 🟥

Climate Change and Agriculture, Figure 7
Locations of observed changes in agriculture in response to climate changes

a reduced length of vegetative period, no longer allowing present varieties to complete their cycle [5].

A negative effect of warming for local rice production has been observed by the International Rice Research Institute (IRRI) in the Philippines (yield loss of 15% for 1°C increase of growing-season minimum temperature in the dry season) [32]; a similar effect has been noted on hay yield in the UK (1°C increase in July–August led to a 0.33 t/ha loss) [6]. At the county level, US maize and soybean yields are demonstrating a positive effect of cooler and wetter years in the Midwest and hotter and drier years in the North-west plains [23]. In the case of the Sahel region of Africa, warmer and drier conditions have served as a catalyst for a number of other factors that have accelerated a decline in groundnut production [49]. For livestock, one study in Tibet reports a significant relationship of improved performance with warming in high mountainous conditions [9], while pasture biomass in Mongolia has been negatively affected by the warmer and drier climate, as observed at a local station [3] or at the regional scale by remote sensing [10].

Conclusions

Climate change brings both challenges and opportunities to agriculture. Farmers and researchers are being called on to simultaneously adapt to and mitigate climate change through a myriad of activities involving management practices, crop breeding, and new production systems. Some of these can be mutually re-enforcing, especially in view of the projected increased climate variability under climate change. This is because, most mitigation techniques currently considered in agriculture, including reduced tillage, were originally designed as “best practice” management strategies, aimed at enhancing the long-term stability and resilience of cropping systems in the face of climate variability or of increased cultivation intensity. By increasing the ability of soils to hold soil moisture and to better withstand erosion, and by enriching ecosystem biodiversity through the establishment of more diversified cropping systems, mitigation techniques implemented locally for soil carbon sequestration may also help cropping systems to better withstand droughts and/or floods, both of which are projected to increase in frequency and severity in future warmer climates. As climate change progresses, agriculture will continue to play a leading role in responding to a dynamic environment.

Future Directions

The time has come to incorporate climate as an essential factor in development planning and implementation. In the past, responses to climate variability were often too narrowly focused and lacking in institutional fit. Development programs are now beginning to include recommendations to mainstream responses to climate variability and change.

Magalhães [25] gave as an example of the need for a broad focus when considering climate in planning the early drought policies in Northern Brazil. Responses had focused on improving the water-supply infrastructure (e. g. building dams and digging wells) rather than on redressing the social and economic vulnerabilities and the need to build human capital by means of education, institutions, and market incentives for sustainability. Adaptive policies should be broadly conceived so as to increase and secure household entitlements, to change land-use patterns that lead to degradation, and to develop means of support for inhabitants that are less sensitive to the vagaries of climate.

At what levels or scales of organization (national, regional, household, and individual) can the variability of climate and the sustainability of agricultural production be addressed effectively? Because many nations encompass several and often most numerous climatic zones, the challenge faced by national agricultural managers and policy make is to foster sustainability at the regional level while building a foundation from the bottom-up at the individual as well as at the household and community levels. Dilley [8] believes that greater benefits of food security could be realized if knowledge were made more readily available at the household level, thereby improving the ability of more people to make even small adjustments based on anticipated climatic conditions. Multiple-scale efforts are clearly needed, with pathways of communication among the various levels and sectors of society.

Regions do not exist in isolation, as evidenced by the effects that extreme climate events occurring along the Atlantic coast of South America have on the sustainability of the inland Amazon rainforest. At least part of the pressure to deforest the Amazon region arises from the westward migration of farmers from Northern Brazil who suffer from ENSO-related droughts there (Magalhães [25]). Thus, policies related to sustainability and climate issues need to take regional interactions and their direct and indirect linkages into account.

Beyond interconnections among regions within a nation, there are the larger national concerns of economics, finance, and international relations that may affect the range of climate-adaptation policy choices. Engaging with the international community on issues of climate variability and change can lead to capacity building in both developed and developing countries, as climate and societal processes are studded and as improved understanding is incorporated into policies. This can be accomplished through interactions with international bodies dealing with climate variability and change, such as the World Meterological Organization and the United Nations Framework Convention on Climate Change. There is a growing realization that climate plays an important role in sustainable development: It is a component of natural capital, an occasional trigger to socio-economic crises caused by extreme events, and a long-term component of global environmental change.

Article Outline

Glossary

Direct costs The direct cost equals quantity times price.

Discount factor The discount factor t years into the future equals one over one plus the discount rate, raised to the power t.

Discount rate The discount rate is the annual rate of decline of the value of consumption. It is roughly equal to the rate of interest, or the opportunity cost of capital. The discount rate consists of two components: the rate at which consumers get better off, and the rate of pure time preference (or impatience). The discount rate is not related to the rate of inflation, which is the annual rate of decline of the value of money.

Economics Economics is the social science which studies human behavior with regard to the relationship between ends and scarce means which have alternative uses.

Equity weights Equity weights are applied to aggregate national impacts to a global total. Equity weights are often set to unity, but sometimes equity weights equal the ratio of nationally average per capita income over global average per capita income.

Indirect costs The indirect costs equal all costs that are not direct costs. This includes the price change induced by the change in quantity (partial equilibrium effects), the changes in other markets (general equilibrium effects), and the changes at later times (dynamic effects).

Marginal costs The marginal cost of greenhouse gas emissions equals the first partial derivative of the net present value of the total costs of climate change to emissions.

Monetary valuation Monetary valuation is a set of techniques and their application that attempts to express in monetary terms the value to humans of changes in environmental goods and services. Negative impacts are typically expressed as an income loss that would give an equivalent loss in welfare.

Neo-classical economics Although historians would refer to neo-classical economics as the dominant form of economic research between 1860 and 1910, common usage has neo-classical economics as a synonym for mainstream or orthodox economics. In that sense, neo-classical economics is a style of research, characterized by empirical rigour, mathematical rigour, and micro-founded macro-relationships.

Net present value The net present value is the sum of all future costs and benefits, weighted by the discount factor.

Total costs The total cost of climate change equals the direct and the indirect costs of climate change, that is, the difference in welfare between a scenario with climate and a scenario without.

Definition of the Subject

The economic costs of climate change include all positive and negative impacts of the enhanced greenhouse effect and the resulting changes in the atmosphere and ocean on all human consumers and producers. Total costs refer to the difference in human welfare between a scenario with climate change and a scenario without climate change.

Marginal costs refer to the difference in human welfare between two scenarios with a slightly different climate, normalized by the amount of greenhouse gas emissions that would induce that difference. Estimates of the economic costs of climate change are important to assess the size of the climate problem relative to other problems, and to compare the costs of climate change to the costs of greenhouse gas emission reduction.

Introduction

Calls for greenhouse gas emission reduction are often phrased as a moral imperative. While tempting, this is wrong. Firstly, there is no moral agreement. Emission reduction could save polar bears but it would cost coal miner's jobs and raise the price of food for the malnourished. Moral imperatives are easy if a policy has only benefits. As soon as a policy has both costs and benefits, one has to make trade-offs and choose the lesser evil. Secondly, there is no avoiding dangerous interference with the climate system. Emission reduction would slow down the melting of the Greenland ice cap, and reduce the probability of a collapse of the West-Antarctic Ice Sheet – but it would not stop the melting or bring the change to zero. Thirdly, we have no obligations to future generations or poor people. Such duties are self-imposed. And even if we choose to help others, there are many ways to do this. Would our grandchildren prefer a richer but warmer world, or a poorer but colder one? Would the grandchildren of the Bangladeshis like us to reduce greenhouse gas emissions, help them to adapt to climate change, or help their grandparents grow rich?

This chapter looks into such questions. It is written from the thoroughly relativistic perspective of a neo-classical economist. The basic principles of the economic theory of climate change are quite simple. Greenhouse gas emissions are an externality. Externalities are unintended – we burn coal to make electricity, not to emit carbon dioxide – and uncompensated – carbon dioxide is freely dumped in the atmosphere – consequences of economic activity. Externalities should be internalized, that is, emitters should pay for their emissions. The price of emissions should equal the damage done by the emissions. That is all.

There is now a vast literature on the economics of climate change – started by Nordhaus [73,74]. A large part of that literature is about the deviation between the simple policy prescription of economic theory and the complexities of actual policy. Another large part of the literature is about the costs of greenhouse gas emission reduction. The literature on the economic costs of climate change is only a small one. It is reviewed here.

Section "Issues" discusses the methodological, conceptual, and moral issues one has to confront when estimating the economic impacts of climate change. Section "Total Costs" reviews estimates of the total economic impact. Section "Marginal Costs" surveys estimates of the marginal impacts. Section "Policy Implications" concludes by assessing the policy implications.

Issues

Scenarios

A scenario is a set of assumptions on future conditions that is coherent, internally consistent, and not implausible [70]. Climate scenarios are usually derived from modeling experiments with General Circulation Models (GCM). Climate scenarios include simple statistics such as the global mean surface air temperature, and complex results such as spatial patterns of rainfall extremes. Climate scenarios may also include low-probability events, such as a disruption of the thermohaline circulation in the Atlantic Ocean, or the collapse of the West Antarctic Ice Sheet.

Scenarios also include population, economic activity, greenhouse gas emissions, and land use. Besides driving the climate models, these components are also important as they determine the vulnerability of social and economic systems to climate change over time. Although poorer societies are generally believed to be more vulnerable to climate change, this is by no means a simple relationship. Some impacts tend to fall with economic growth. The impacts of climate change on infectious diseases are a prime example. Malaria does not kill middle income people, because they can afford prevention and (if necessary) cure. Some impacts tend to rise with economic growth. The impact of climate change on biodiversity and species loss is one example. People tend to care more about these matters as their income grows, and further developed economies put more pressure on nature. Other impacts may rise first and then fall with economic growth. Urban air quality is one example. The very poor have nothing to foul the air with, and the very rich do not like foul air and have the wherewithal to prevent it. Climate change is likely to increase malaria, reduce biodiversity and worsen air quality. In some case, climate change and economic growth work together to increase the impacts, while in other cases they pull in opposite directions.

Valuation Approach

There are various techniques for the monetary valuation of climate change impacts. Some values of impacts are directly based on observed prices. Agriculture and dike building are examples. Other values can be indirectly measured on the basis of observed market prices for surrogate products or services. One example is human health, which is not traded directly but indirectly through safety measures, labor markets, and health care. The challenge in these instances is to model future market prices that are consistent with the underlying socioeconomic scenario. For yet other impacts, no market values exist, and hypothetical prices are needs. Notable impacts are on non-commercial ecosystems and biodiversity.

Because it is practically impossible to estimate each exposure-response relationship or value at the respective geographical location of a climate change impact, data from previous studies focusing on different locations and different policy contexts are inevitable. Furthermore, most climate change impacts will take place in the future, for which by definition no data are available. Therefore it is important to know when data from other studies can be used and under what conditions, and how to extrapolate values from today to tomorrow.

The majority of recent studies still adopt benefit transfer methods for the evaluation of climate impacts. However, benefit transfer is not very reliable [91]. For this reason, more attention should be given to original valuation research in the context of climate change.

An example of such a study is Li et al. [54] who analyze the willingness-to-pay (WTP) of American citizens for climate policy by means of the contingent valuation method. They find that the median American citizen is willing to pay about $ 15/tC. Berrens et al. [7] find a willingness-to-pay between $ 200 and $ 1760 per US household per year (0.2–2.3% of income) for US ratification of the Kyoto Protocol. (Manne and Richels [60] estimate that the costs of US ratification would be 0.75% of GDP in 2010.) Hersch and Viscusi [46] find that Europeans are willing to pay up to 3.7% more for petrol if that helps combat climate change. Viscusi and Zeckhauser [117] find that Harvard students are willing to pay $ 0.50/gallon (a 25% price increase) or 3% of their expected annual income for greenhouse gas emission reduction. (This study also showed that these students underestimate projected warming in Boston by about 50%, while the authors made them believe that carbon dioxide emission reduction would be effective for slowing climate change in the next 30 years.) There is scope for similar applications of WTP techniques, mainly to account for spatial and socio-economic differences in individuals' preferences.

Direct and Higher Order Impacts

Most studies to date have estimated the direct costs of climate change. Direct costs equal the physical change (e. g., the dikes to be reinforced) times their price (in this example, the costs per dike length and dike height). Direct costs are easy to compute (but see Subsect. "Valuation Approach"), but probably underestimate the real economic costs.

The higher order impacts come in three kinds. Firstly, climate change may impact the market under consideration. For example, if dikes are being reinforced everywhere, then the costs of dike building is likely to go up as materials, machinery, and skilled labour is difficult to get. Secondly, the impact of climate change on one market may spill over into other markets. For example, dike building may increase the costs of construction, as the same materials and skills are used. Dike building is capital intensive and may drive up the interest rate. Thirdly, the impact of climate change may affect economic growth. For example, money invested in dike building is not invested elsewhere.

A number of recent studies have examined the economy-wide implications of sea level rise [10], tourism [8], and health [9]. While it is perhaps too early to draw firm conclusions from this body of research, the studies suggest that the indirect effects of climate change impacts can both enlarge and diminish the direct economic impacts of climate change. The distribution of gains and losses is another difference between direct costs and general equilibrium effects. Whereas direct costs are limited to those directly affected, markets would spread the impact to their suppliers, clients, and competitors as well as to financial markets.

Fankhauser and Tol [35] show that the economic growth impact of climate change is as large as the direct impact of climate change. Acemoglu et al. [1] and Masters and McMillan [62] show that differences in climate explain part of observed differences in economic development. Easterly and Levine [28] show that the link is at most weak and indirect, and it is not clear whether the mechanisms that may have been active in the past, still hold for present and future.

Adaptation

One cannot study the costs of climate change impact without also studying, or at least making assumptions about the costs of adaptation [109]. Studies focusing on costs of the impacts make widely differing assumptions about the amount of adaptation that will take place. While some studies completely ignore adaptation, other studies consider arbitrary levels of adaptation, or assume optimal adaptation. No studies use realistic models of adaptation [109]. There is little research that shows how adaptation costs compare to the potential damages of not adapting. The impacts of climate change and the capacity to adapt would be affected with the level of development and flexibility of the economy [123]. Hence, the future success and nature of adaptation depends on the assumed socio-economic scenario.

Aggregation: Temporal

Climate change is a slow process. Today's emissions will affect the climate for decades to centuries, and sea level for centuries to millennia. As cause and effect are separated in time, so are costs (of emission reduction) and benefits (of avoided climate change). The procedure to make commensurate costs and benefits at different points in time is called discounting. Discounting is as common as it is controversial. See [3] for an excellent discussion.

Individuals discount future gains or losses because of two reasons. (People may also discount the future because it is more uncertain than the present, but in this case discounting is used as a shortcut for an uncertainty analysis.) First, money earns interest. Second, people are impatient. The first reason is widely accepted. Davidson [26] is one of the few exceptions. On the second reason, there is virtual consensus too. All ethical arguments show that people should not discount (e. g., [12]). All empirical evidence shows that people do nonetheless (e. g., [79,80]).

Climate change is a large-scale problem. Therefore, the discount rate of society is more relevant than the individual discount rate. The appropriate measure of the growth rate of money is the average growth rate of per capita consumption. Again, there is little dispute on this. But should the social rate of discount also include a measure of impatience? Again, philosophers agree: Impatience is immoral. However, this implies that a government would deviate from the will of the people. This may be defended with the argument that the government is the guardian of future, yet unborn people. However, the empirical evidence is clear in this case too: Governments are impatient [31].

Discounting is more profound over long periods than over short ones. Discounting implies that climate change damages that occur in a century or so are largely irrelevant. This realization has led people to rethink the fundamental principles of discounting, particularly

(a) the notion that the procedure of discounting results from the intertemporal allocation of resources of an individual agent; and
(b) the assumption that discounting is exponential.

To start with the individual perspective, Lind [56] and Lind and Schuler [55] argue that *earmarked* investment is a crucial assumption in discounting. The discount factor measures the trade-off between consumption now and consumption later, where consumption later is contingent on a specific investment plan. As the current generation cannot commit near-future generations to maintain their investments for the benefit of far-future generations, discounting breaks down between generations. Schelling [95] agrees. The alternative is to decide explicitly on the resource allocation between generations. Chichilnisky [19] shows that discounting coincides with a dictatorship of the present generation over future generations. Gerlagh and Keyzer [38] show that discounting is equivalent to the present generation owning all future resources. This is objectionable from a moral standpoint, but it is reality. This line of research has not led to practical alternatives to discounting.

Conventional discounting is exponential: The discount factor is $(1+r)^{-t}$, where r is the discount rate and t is time. Some people argue that the functional specification of conventional discounting is wrong. The first component is empirical. Conventional exponential discounting has that the relative difference between two years is always equal, regardless of their distance from the present. That is, the difference between year 10 and 11 is the same as the distance between year 100 and 101. However, many people would in fact argue that the difference between year 10 and 11 is equal to the difference between year 100 and 110. Such hyperbolic discounting [22] is very similar to exponential discounting for short periods, but the difference is substantial for long periods. The similarity between exponential and hyperbolic discounting in the short run is important, because a switch to hyperbolic discounting would imply a drastic overhaul of long-term decisions only.

There are two further arguments for hyperbolic discounting cf. Dasgupta and Maskin [25]. The first is due to Weitzman [118]. He shows that, if one is uncertain what discount rate to use, then the lowest discount rate becomes increasingly dominant over time. The certainty-equivalent discount rate falls with time, and the difference between years shrinks in the more distant future. Consider the following example. After one year, the average of a 1% and a 10% discount rate is

$$1-\left(\frac{\left(1.01^{-1}+1.10^{-1}\right)}{2}\right)^{1/1}=5.0\,\%$$

(and not 5.5%). After 100 years,

$$1-\left(\frac{\left(1.01^{-100}+1.10^{-100}\right)}{2}\right)^{1/100}=1.7\,\%\,.$$

That is, the average approaches the minimum as time progresses. One may criticize this as a short cut for a full uncertainty analysis. However, Gollier [39,40] shows that the same is true if a government somehow aggregates the individual discount rates of its citizens. In the long run, the preferences of the person with the lowest discount rate become increasingly important, and the discount rate declines over time.

Guo et al. [41] and Newell and Pizer [71] show that hyperbolic discounting leads to higher estimates of the social cost of carbon. However, the quantitative effect is limited by the fact that hyperbolic discount rates are high for the first decades.

Aggregation: Spatial

Climate change is a global problem. Carbon dioxide and other greenhouse gases mix uniformly in the atmosphere. This implies most of the impacts of one country's emissions fall on other countries. The same is true for the benefits of emission reduction. The impacts on different countries need to be aggregated somehow.

Two methods dominate the literature. In the first and oldest method, regional impacts are quantified in local currencies, converted to dollars, say, and added up [33,103]. This is simple, but the disadvantage is that similar impacts are treated differently. Most disturbingly, climate-change-induced deaths in rich countries receive a greater weight than climate-change-induced deaths in poor countries. The second method, known as equity weighing, corrects for this [6,36]. Rather than simply adding regional estimates, the regional utility-equivalents are added and then converted back to money according to an assumed global welfare function. A big disadvantage of this method is that climate-change-induced deaths are treated differently than deaths by other, national causes. The reason for this discrepancy is that equity weighing, as practiced in the literature, explicitly assumes a global decision maker.

In the meta-analysis of Tol [107], the median estimate of the marginal damage costs of carbon dioxide is $ 10/tC without equity weights, and $ 54/tC with equity weights. So, equity weighing is obviously important. The reason is simple. Poor countries are more vulnerable to climate change. Poor countries have little economic weight. Equity weights correct for this.

Morally, this may be the right thing to do. However, national governments also have a certain obligation to defend the interests of their citizens. A narrow interpretation of self-interest would suggest that impacts abroad be ignored (unless they spill over, e. g., through international migration). Then, climate change policy would be very limited, as most impacts will be abroad. However, the principle of good neighborhood is well established, both morally and legally. This entails that one should avoid doing harm to others; and should pay compensation if harm is done nonetheless (e. g., [113]).

A rational actor would avoid doing harm if that is cheaper than the compensation paid. From a national perspective, the relevant damages are then the impacts on the own country plus the compensation paid to other countries. Schelling [93] forcefully argues that compensation should equal the welfare loss of the victim rather than the welfare loss that the culprit would have experienced had she been the victim. This argues for aggregation of monetized impact estimates without equity weighing.

However, compensation would need to be paid only once. Furthermore, a country would also reasonably expect to be compensated itself. This implies that the damage to a country equals the global damage times its share in causing the problem. Defining the latter is a thorny issue, as the cause-effect chain is long, complex, and uncertain. One would need to make arbitrary decisions on cause, effect and their connection.

Uncertainty

Climate change is plagued by uncertainty [16]. Partly, this is because our understanding of climate change and its impacts is incomplete. For the larger part, however, this is because climate change will take place in the future, partly driven by future emissions, and impacting a future world. Future research and observations may reduce the uncertainty, although surprises may increase the uncertainty just as well, but uncertainty will never disappear. Learning and irreversibility play a crucial role in how to deal with uncertainty. Events that may or may not occur in some distant future, but whose consequences can be alleviated once it becomes clear if they would occur, should not worry us too much. On the other hand, if an effect is irreversible (e. g., species extinction), we may want to prevent it regardless of how uncertain it is and regardless of what future research will show (according to the "precautionary principle"). Another crucial part of dealing with uncertainty is risk aversion. Essentially, this determines how much weight we place on negative surprises. A risk neutral decision maker would cancel negative surprises against positive ones, but a risk adverse decision maker would not. Recent work has shown that the marginal damage costs of carbon dioxide are indeed very sensitive to the assumed degree of risk aversion. Although uncertainty and risk are often emphasized – often in a casual way – only few studies seek to quantify its implications (e. g., [51]).

In a recent paper, Weitzman [120] shows that, under a wide range of standard assumptions, the uncertainty about climate change is so large that the expected value of the social costs of climate change is infinite. Earlier, Tol [106] showed this for a specific model. This implies that uncertainty should take central stage in the analysis of climate policy. The Weitzman result throws up a number of methodological issues that will need to be resolved before the policy implications of this work become clear.

Completeness

The impacts of climate change that have been quantified and monetized include the impacts on agriculture and forestry, water resources, coastal zones, energy consumption, air quality, and human health. Obviously, this list is incomplete. Also within each impact category, the assessment is incomplete. Studies of the impacts of sea level rise on coastal zones, for instance, typically omit saltwater intrusion in groundwater [72]. Furthermore, studies typically compare the situations before and after climate change, but ignore that there will be a substantial period during which adaptation is suboptimal – the costs of this are not known.

Some of the missing impacts are most likely negative. Diarrhoea impacts have been quantified recently [57]. Like malaria, diarrhoea is a disease that is driven by poverty but sensitive to climate. Including diarrhoea tightens the link between development and climate policy. Increasing water temperatures would increase the costs of cooling power plants [101]. Redesigning urban water management systems, be it for more or less water, would be costly [4], as would implementing the safeguards against the increased uncertainty about future circumstances. Roads and bridges would suffer from weather conditions for which they were not designed; this would imply either disruption of traffic or expensive retrofits. Extratropical storms may well increase, leading to greater damage and higher building standards [27]. Expenditures on these things are relatively small. Even if climate change would double or triple the cost, the impact would be small. Ocean acidification would reduce marine biodiversity, and may well harm fisheries [52]. Ocean fisheries are only a small, and declining fraction of GDP, while there are ready substitutes for wild fish protein (notably fish farming). The value of biodiversity is unclear (see below).

Other missing impacts are probably positive. Higher wind speeds in the mid-latitudes would decrease the costs of wind and wave energy [11,44]. Less sea ice would improve the accessibility of arctic harbours, would reduce the costs of exploitation of oil and minerals in the Arctic, and may even open up new transport routes between Europe and East Asia [121]. Warmer weather would reduce expenditures on clothing and food, and traffic disruptions due to snow and ice [15]. Also in these cases, the impact of climate change is likely to be small relative to the economy.

Some missing impacts are positive in some places, and negative in others. Tourism is an example. Climate change may well drive summer tourists towards the poles and up the mountains [42,43]. People, however, are unlikely to change the time and money spent on holiday making. The effect is a redistribution of tourist revenue [8]. The global impact is close to zero, but regional impacts are measured in tens of billions of dollars – positive in temperate, rich countries, and negative in tropical, poor countries. This exacerbates the already skewed distribution of climate impacts. Some ski resorts may go out of business, and others would need expensive snowmaking equipment [29,97]. Other ski resorts would profit from the reduced competition. Although regional impacts may be substantial, at the global scale positives and negatives cancel.

Other impacts are simply not known. Some rivers may see an increase in flooding, and others a decrease [53]. At the moment, only a limited number of rivers have been studied in detail, and it is unclear how to extrapolate to other rivers. It is clear though, that land use and water management may greatly increase or reduce impacts. Although river floods wreak substantial havoc and damages of a single event can reach substantial numbers, average flood damage is in fact small relative to the economy [112]. Tropical storms do more damage, although a substantial share of the impact is due to bad planning rather than bad weather [14]. Nonetheless, tropical storms may prevent capital accumulation and the plantation of lucrative crops such as banana [30,69]. Unfortunately, it is not known how climate change would alter the frequency, intensity, and spread of tropical storms [63,89].

The missing impacts discussed above are probably small. There are also bigger gaps in the coverage of climate change impact studies. Climate change is likely to have a profound impact on biodiversity, but quantitative predictions are rare [13]. Although the economic impact of a small change in biodiversity is known to be small [88], the value of large biodiversity changes is unknown but could well be substantial [18]. There is a small but unknown chance that climate change will be more dramatic than is typically assumed in the impacts literature. This may be because of shutdown of the thermohaline circulation [61], a collapse of the Greenland or West-Antarctic Ice Sheet [84], or a release of large amounts of methane [45]. The economic analysis of such scenarios has only just begun [57]. It may be that climate change would lead to large-scale migration [64] and violent conflict, although there is only weak empirical support for this [49,124]. Finally, climate change impact studies stop at the end of the 21st century. In 2100, impacts are negative, and getting more negative at an accelerating pace. It is not known how rapidly things would get worse in the 22nd century without emission abatement.

Although the sign of the aggregate unknown impacts is not known, risk aversion would lead one to conclude that greenhouse gas emission reduction should be more stringent than suggested by a cost-benefit analysis based on the quantified impacts only. However, the size of the bias is unknown too – so the main policy implication is that more research is needed.

Total Costs

The first studies of the welfare impacts of climate change were done for the USA [21,74,98,102]. Although Nordhaus [74] (see also Ayres and Walter [5]) extrapolated his US estimate to the world, the credit for the first serious study of the global welfare impacts goes to Fankhauser [32,33], although Hohmeyer and Gaertner [48] earlier published some low quality estimates. Other global estimates include those by Nordhaus [76,77], Tol [103], Nordhaus and Yang [82], Plambeck and Hope [90], Nordhaus and Boyer [81], Mendelsohn et al. [66,68], Tol [105], Maddison [59], Hope [50], Rehdanz and Maddison [92] and Nordhaus [78]. Note that Stern et al. [100] is based on Hope [50].

This is a rather short list of studies, and an even shorter list of authors. This problem is worse if one considers that Nordhaus and Mendelsohn are colleagues; that Fankhauser, Maddison and Tol are students of Pearce; and that Rehdanz is a student of Maddison and Tol; while Hope's (and Stern's) estimates are averages of Fankhauser's and Tol's. Although most fields are dominated by a few people, dominance is here for want of challengers. The effect of this is hard to gauge. The reasons are lack of funding (this work is too applied for academic sources, while applied agencies do not like the typical results and pre-empt this by not funding it), lack of daring (this research requires making many assumptions, and taking on well-entrenched incumbents), and lack of reward (the economics profession frowns on the required interdisciplinarity). In addition, many people, including many economists, would argue that climate change is beyond cost-benefit analysis and that monetary valuation is unethical.

Table 1 shows some characteristics of these studies. A few insights emerge. First, the welfare impact of a doubling of the atmospheric concentration of carbon dioxide on the current economy is relatively small. Although the estimates differ, impacts are not more than a few percent of GDP. The estimates of Hope [50], Mendelsohn et al. [66,68] and Tol [105] even point to initial benefits of climate change. (Studies published after 1995 all have regions with net gains and net losses due to global warming, whereas earlier studies only find net losses.) With such estimates, it is no surprise that cost-benefit analyses of climate change recommend only limited greenhouse gas emission reduction – for instance, Nordhaus [75] argues that the optimal rate of emission reduction is 10–15%, one of the more contentious findings of the climate economics literature.

Second, although the impact is relatively small, it is not negligible. A few per cent of GDP in annual damage is a real concern.

Third, climate change may initially have positive impacts. This is partly because the higher ambient concentration of carbon dioxide would reduce water stress in plants and may make them grow faster – although this effect is now believed to be weaker [58]. Another reason is that the global economy is concentrated in the temperate zone, where a bit of warming may well be welcomed because of reductions in heating costs and cold-related health problems. At the same time, the world population is concentrated in the tropics, where the impacts of initial climate change are probably negative. Even though initial *economic* impacts are positive, it does not necessarily follow that greenhouse gas emissions should be subsidized. The climate responds rather slowly to changes in emissions, so the initial impacts cannot be avoided. Impacts start falling – that is, additional climate change reduces global welfare – roughly at the same time as climate change can be influenced by present and future emission reduction [47].

The fourth insight is that relative impacts are higher in poorer countries (see also Yohe and Schlesinger [122]). This is because poorer countries have a lower adaptive capacity [2], particularly in health [108], and have a greater exposure to climate change, particularly in agriculture and water resources. Furthermore, poorer countries tend to be hotter and therefore closer to temperature limits and short on spatial analogues should it get warmer still. At the same time, there are fewer studies on the impacts of climate change on developing countries than on developed countries. Although research is scarce [83], there is little reason to assume that climate change impacts would be homogeneous within countries; certainly, certain economic sectors (e. g., agriculture), regions (e. g., the coastal zone) and age groups (e. g., the elderly) are more heavily affected than

Climate Change, Economic Costs of, Table 1

Econonic impact estimates of climate change; numbers in brackets are either standard deviations or confidence intervals

Study	Warming	Impact	Minimum	Region	Maximum	Region
Nordhaus [76]	3.0	−1.3				
Nordhaus [77]	3.0	−4.8 (−30.0 to 0.0)				
Fankhauser [33]	2.5	−1.4	−4.7	China	−0.7	Eastern Europe and the former Soviet Union

[a] Note that the global results were aggregated by the current author.
[b] The top estimate is for the "experimental" model, the bottom estimate for the "cross-sectional" model.
[c] Note that Mendelsohn et al. only include market impacts.
[d] Note that the national results were aggregated to regions by the current author for reasons of comparability.
[e] Note that Maddison only considers market impacts on households.

others. This has two policy implications. Firstly, recall that greenhouse gas mix uniformly in the atmosphere. It does not matter where they are emitted or by whom, the effect on climate change is the same. Therefore, any justification of stringent emission abatement is an appeal to consider the plight of the poor and the impacts imposed on them by the rich [94,95]. While this makes for wonderful rhetoric and fascinating research (e. g., [104]), reality shows little compassion for the poor by the rich. Secondly, if poverty is the root cause for vulnerability to climate change, one may wonder whether stimulating economic growth or emission abatement is the better way to reduce impacts. Indeed, Tol and Yohe [115] argue that the economic growth foregone by stringent abatement more than offsets the avoided impacts of climate change, at least for malaria, while Tol [108] shows that development is a cheaper way of reducing climate-change-induced malaria than is emission reduction. Moreover, richer countries may find it easier and cheaper to compensate poorer countries for the climate change damages caused, than to reduce greenhouse gas emissions. Such compensation may be explicit and financial, but would more likely take the shape of technical and financial assistance with adaptation (cf. [85]).

The agreement between the studies is remarkable if one considers the diversity in methods. The studies of Fankhauser, Hope, Nordhaus, and Tol all use the enumerative method: 'physical' impact estimates are obtained one by one, from 'natural science' papers based on 'process-based' models or 'laboratory experiments'. These physical impacts are multiplied with their respective prices, and added up. The 'prices' are obtained by benefit transfer. In contrast, Mendelsohn's work is based on direct, empirical estimates of the welfare impacts, using observed variations in prices and expenditures to discern the effect of climate (e. g., [67]). Mendelsohn estimates are done per sector and then added up, but physical modelling and benefit transfer are avoided. Nordhaus [78] uses empirical estimates of the *aggregate* climate impact on income, while Maddison [59] looks at patterns of *aggregate* household consumption. Like Mendelsohn, Nordhaus and Maddison rely exclusively on observations, but they assume that all climate effects are aggregated by the economy into incomes and expenditures. Rehdanz and Maddison [92] also empirically estimate the aggregate impact, but use self-reported happiness as an indicator; their approach is similar to that of Nordhaus and Maddison, but the indicator is subjective rather than objective. The enumerative studies of Fankhauser etc rely on controlled experiments (albeit with detailed, process-based models in most cases). This has the advantages of ease of interpretation and physical realism, but the main disadvantage is that certain things are kept constant that would change in reality; adaptation is probably the key element. The statistical studies of Mendelsohn etc rely on uncontrolled experiments. This has the advantage that everything varies as in reality, but the disadvantages are that the assessment is limited to observed variations (which may be small compared to projected changes, particularly in the case of carbon dioxide concentration) and that effects may be spuriously attributed to climate. Therefore, the variety of methods enhances confidence, not in the individual estimates, but in the average.

The shortcomings of the estimates are at least as interesting. Welfare losses are approximated with direct costs, ignoring general equilibrium and even partial equilibrium effects (see below). In the enumerative studies, impacts are assessed independently of one another, even if there is an obvious overlap as between water resources and agriculture. Estimates are often based on extrapolation from a few detailed case studies, and extrapolation is to climate and levels of development that are very different from the original case study. Valuation is based on benefit transfer, driven only by difference in per capita income. Realistic modelling of adaptation is problematic, and studies either assume no adaptation or perfect adaptation. Many impacts are unquantified, and some of these may be large (see below). The uncertainties are unknown – only 4 of the 14 estimates in Table 1 have some estimate of uncertainty. These problems are gradually solved, but progress is slow. Indeed, the above list of caveats is similar to that in Fankhauser and Tol [34].

Marginal Costs

Although the number of studies of the *total* costs of climate change is small, a larger number of studies estimate the *marginal* costs. The marginal damage cost of carbon dioxide is defined as the net present value of the incremental damage due to an infinitesimally small increase in carbon dioxide emissions. If this is computed along the optimal trajectory of emissions, the marginal damage cost equals the Pigou tax. Marginal damage cost estimates derive from total cost estimates – the fact that there are more estimates available, does not imply that we know more about the marginal costs than we do about the total costs. In fact, some of the total cost estimates [59,66,68,78,92] have yet to be used for marginal cost estimation, so that the empirical basis is actually smaller.

Tol [110] gathers 211 estimates of the SCC from 47 studies. The studies were grouped in those that were peer-reviewed and those that were not. Some studies are based on original estimates of the total costs of climate change, while other studies borrow total costs estimates from other studies. Most studies use incremental or marginal calculus to estimate the SCC, as they should, while a few others use average impacts or an unspecified method. Some studies assume that climate changes but society does not, while other studies include a dynamic model of vulnerability. A few studies use entirely arbitrary assumptions about future climate change, while most studies are based on internally consistent scenarios. These classifications are used as quality indicators. More recent studies were given a higher weight. Many studies report multiple estimates. Most of the estimates are sensitivity analyses around a central estimate, and some estimates are only included to (approximately) reproduce an earlier study. Tol [110] introduces additional weights to account for this.

Tol [110] adjusts a Fisher–Tippett kernel density estimator to 211 data points, weighted as describe above. The 211 estimates provide the modes. Only a few of the studies provide an estimate of the uncertainty. Therefore, the standard deviation is set equal to the sample standard deviation.

Table 2 shows selected characteristics of the kernel distribution for the whole sample and selected sub-samples.

Splitting the sample by discount rate used has the expected effect: A higher discount rate implies a lower estimate of the SCC and a thinner tail. Table 2 also shows that estimates in the peer reviewed literature are lower and less uncertain than estimates in the gray literature.

Splitting the sample by publication date, shows that the estimates of the SCC published before AR2 [87] were larger than the estimates published between AR2 and AR3 [99], which in turn were larger than the estimates published since. Note that these differences are not statistically significant if one considers the means and standard deviation. However, the kernel distribution clearly shifts to the left. Therefore, AR4 [96] were incorrect to conclude that the economic estimates of the impact of climate change have *increased* since 2001. In their words (pp. 781): "There is some evidence that initial new market benefits from climate change will peak at a lower magnitude and sooner than was assumed for the TAR, and it is likely that there will be higher damages for larger magni-

tudes of global mean temperature increases than was estimated in the TAR.” It is unclear how Schneider et al. [96] reached this conclusion, but it is not supported by the data presented here.

The SCC estimate by Stern et al. [100] is almost an outlier in the entire sample (excluding, of course, the Stern estimate itself). Depending on the kernel density, the Stern estimate lies between the 90th and the 94th percentile. It fits in better with estimates that use a low discount rate and were not peer-reviewed – characteristics of the Stern Review – but even in comparison to those studies, Stern et al. [100] are on the high side. The Stern estimate also fits in better with the older studies. This is no surprise, as the PAGE model (e. g., [50]) is calibrated to [87] and [99]. Other criticism of the Stern Review can be found in [24,65,79,80,115,119,120].

Policy Implications

The policy implications of the above findings are several, and not necessarily in line with the conceived wisdom of climate policy. First and foremost, the economic impacts literature points out that climate change is a problem. Initial climate change may be beneficial, but it cannot be avoided. This is a sunk benefit. The avoidable part of climate change is in all likelihood negative. This justifies greenhouse gas emission reduction.

Second, the estimates of the marginal damage costs justify some emission abatement, but not too much. For instance, the future price of carbon dioxide emission permits in the European Trading System is around $ 100/tC. Using the market rate of discount, the expected social cost of carbon is only $ 24/tC. This climate policy has a benefit-cost ratio of 0.24. EU climate policy is therefore too stringent. Of course, European climate policy does pass the cost-benefit test according to CEC [17], but this study does not meet conventional standards of academic quality [111]. Earlier, Pearce [89] similarly concluded that the UK cost-benefit analysis [20] is deficient, while also the *Stern Review* [100] has been criticized in the academic literature (e. g., [80,119]).

Third, climate policy is about ethics rather than about economics [37,116]. The judgment what to do about greenhouse gas emissions rests on the values one attaches to far-flung countries and distant futures. The ethics are not straightforward, however. If one places a lot of weight on the future, one should make a trade-off between increasing investment in capital goods, education, emission reduction, or technology. If one places a lot of weight on people in poor countries, one should make a trade-off between adaptation, development, emission reduction, and trade reform.

Fourth, the uncertainties about the economic impact of climate change are profound. Partly, this is because the subject is complex. A large share of the uncertainty can be explained, however, by the dearth of research funding. Although climate change is often said to be the largest (environmental) challenge of our times, very few researchers are funded to substantiate or refute that claim.

Future Directions

Further research is therefore needed. Several problems with past and present research are identified above. Firstly, research into the economic impact of climate change is rightly classified as “applied research”. This implies, however, that research funding comes from bodies with a stake in the result, and that quality and independence are not necessarily overriding concerns. The *Stern Review* is the most prominent example in the recent past of a study that started with the conclusions and worked back to identify the required assumptions. The new *Centre for Climate*

Change Economics and Policy at the *London School of Economics* may fall into the same trap. Because the stakes in climate policy are large, academic quality of research must be guaranteed.

Secondly, there are only two groups of independent academics who study the economic impact of climate change. These groups are not sufficiently funded. More importantly, these groups are rarely challenged. Combined with the first problem, it is therefore important to establish a third group of independent, academic economists to study the impact of climate change.

Thirdly, research on the impact of climate change, economic and otherwise, has been lamp-posting. After the groundbreaking work in the early 1990s, researchers have refined previous estimates. Little attention has been paid to those impacts for which no previous estimates exist. While this is the normal procedure of gradual progress in scientific research, the study of the impact of climate change is still in its formative stages. Not just *more*, but particularly *different* research is needed – into the economic effects of climate change on biodiversity, on violent conflict, on ice shelves and ocean current, and on economic development in the long term.

Acknowledgments

My thoughts on this subject were shaped by discussions with Hadi Dowlatabadi, Tom Downing, Sam Fankhauser, David Maddison, Rob Mendelsohn, Bill Nordhaus, David Pearce, Steve Schneider, Joel Smith, and Gary Yohe.

Article Outline

Glossary

Health As defined by the World Health Organization (WHO) health is the state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.

Human bioclimate The fundamental issue in human biometeorology is the assessment of the direct health effects of the atmospheric environment from heat exchange, to solar radiation and air pollution.

Climate change related direct health effects Climate change always impacts on human bioclimate, presently it leads to increased heat stress and heat stress frequency, higher ultraviolet radiation doses especially in summer, longer allergic pollen seasons and new allergens as well as intensified photo-smog.

Thermal stress and mortality Summer heat waves in mid-latitudes and elsewhere increase without doubt mortality; hence also highlight lack of correct adaptive measures, i. e. heat waves impact most strongly in societies with lack of social cohesion.

Global expansion of tropical diseases The observed recent global warming has increased the incidence and enlarged the distribution of some tropical diseases due to the expansion of suitable conditions for both vectors and pathogens. A northward spread has been observed for West Nile fever, Leishmaniasis and Chikungunya fever and a climate-driven spread has in parts also been recorded for malaria, dengue fever and other vector-borne infectious diseases.

Vector-borne diseases In epidemiology a vector is an organism transmitting a pathogen from one of its reservoirs (e. g. ruminants, birds) to another one (e. g. human) without falling ill. Such vectors for tropical diseases are: mosquitoes, biting flies, bugs, lice, flea's and mites. Typical vector-borne diseases are malaria, yellow fever, dengue fever, West Nile fever, Leishmaniasis, Chikungunya fever. For some of these diseases global warming is the cause of the observed expansion or intensification. The complex web of reservoir organism, pathogens, vectors and infected organisms with different dependence on climate parameters often hinders a full understanding. Hence, surprises are and will be common.

Arbo viruses Arbo viruses are transmitted by arthropods (**ar**thropod-**bo**rne) to vertebrates and hence in parts also to humans. Besides yellow fever, tick borne encephalitis and dengue fever about 150 other diseases are due to virus infections by insects and spiders (arthropods). In very complex transmission cycles climatic conditions play a central role. The occurrence of unusual arbo virus infections is often related to changes in climatic conditions. Therefore, the partly dramatic global increase of some arbo virus infections is also driven at least in part by the ongoing global anthropogenic climate change.

Arbo viruses transmitted by Aedes mosquitoes Aedes mosquitoes and Aedes-transmitted arbo viruses such as the dengue and yellow fever viruses are a growing global threat. The primary vector of these diseases, *Aedes aegypti*, has re-emerged throughout the tropics, but also *Aedes albopictus* has emerged as one of the worst invasive species taking the role of *Aedes aegypti*. Direct human activities like global trade are mainly responsible for the spread of these vectors and global warming – indirectly anthropogenic as well – cannot be ruled out as a contributor. With further warming temperate regions like Central Europe could also become areas for *Aedes albopictus*.

Malaria and global warming Although the Anopheles mosquitoes transmitting the protozoae (e. g. *Plasmodium falciparum*) causing malaria are strongly dependent on temperature and suitable small water reservoirs for the larvae, the spread of malaria in recent years is more a consequence of deficiencies in public health systems of many countries rather than due to the observed global warming and concomitant precipitation changes.

Blue-tongue disease in Europe Since August 2006 the blue-tongue-disease of cattle and sheep (serotype 8 from South Africa) spread within months from the Netherlands to Belgium, Luxembourg, France and Germany alone at the end of 2006. The vector carrying the virus is the ceratopogonid, biting midge, *Culicoides obsoletus*. The new disease for ruminants in Western and Central Europe is primarily a consequence of globalization but the extremely warm winter 2006/2007 in Western and Central Europe supported further spreading.

Carbon dioxide fertilization and quality of food From field experiments at elevated carbon dioxide concentrations (close to a doubling of preindustrial values) it is known that agricultural yield increases for C3 plants by 10 to 30 percent; however, frequently also reduced nitrogen content in plant tissue including seeds is observed. Hence, food quality may be lowered.

Changes in the pollen season and new pollen The onset of flowering of plants in mid and high latitudes is mainly triggered by temperature. Therefore, warming in recent decades has caused an earlier start of pollen in the air, often also leading to a longer pollen season and for some pollen also to higher abundance stimulated by higher carbon dioxide concentration. Hence, susceptible individuals will suffer from pollen allergy longer and even perennial allergic symptoms may become possible.

Introduction

The basis of our life is energy from the sun, water from the skies and biomass production by plants on land and in the oceans. If we ask for the key climate parameters – given the size of the planet and its mean distance to the sun – we get a very similar answer: energy flux density of the sun, precipitation and land surface parameters, mostly determined by vegetation. Hence, climate is the key natural resource. If this resource changes rapidly, as it does now, life in all its forms is affected as well. Therefore, it is a must for decision makers to deal with climate change. Here only one facet of climate change is discussed: the health of humans. It is rather astonishing that it has not already been studied intensively since the beginning of the climate change debate, as other environmental policy decisions were nearly totally driven by health consequences for humans [12].

The consequences of climate change for the health of humans, animals and plants are complex with direct and indirect relations between causes and impacts. As any organism on land is in permanent struggle with the local weather a rather strong capacity for adaptation exists; however, the organisms are trained only with existing weather and climate variability during the life-time of an organism. For new weather extremes accompanying any climate change this adaptation capability is no longer given. Hence, a changing climate will often become a threat to health. As several health related factors may change simultaneously, "multiplying" impacts, which – if alone – would not have gone beyond existing adaptive capability, may do so. An example is heat stress during heat waves accompanied not only by high ultraviolet radiation levels but also by high near surface concentrations of the strong oxidant ozone, exacerbating the heat stress.

According to the World Health Organization (WHO) "Health" is defined as "the state of complete physical, mental and social well being and not merely the absence of disease or infirmity". This comprehensive and also ambitious understanding of the term health can also be applied to animals and plants as well as ecosystems (the terms ecosystem health and environmental health have been used very often in recent literature). Therefore, consequences of climate change on health are not confined to diseases but also include reduced well-being or reduced strength of an organism as well as weakened functions in an ecosystem or a socio-economic system.

This contribution to the Encyclopedia of Complexity does not focus exclusively on climate change and human health (see Sect. "Climate Change Impact on Human Health") because climate change impacts on animals and plants (see Sect. "Climate Change Impacts on Plants with Consequences for Human Health") also have consequences for human well-being and human health. An example of the complexity is the changed composition of nutrients in grains as a consequence of higher carbon dioxide levels in the atmosphere, in addition modulated by changed climate parameters that may in turn enhance infestations of plant diseases with consequences for the composition of our food. The section on Climate Change Impacts on Plants with Consequences for Human Health tries to collect known knowledge, reports on potential threats and chances for political reactions as well as pointing out major open research questions.

Climate Change Impact on Human Health

Whenever climate changes all ecosystems have to react, i. e. they try to adapt to changed climate that must also include new weather extremes. Typical reactions are shift of biomes, altered ecosystem composition, new geographical patterns of animal and plant diseases, new relations between predator and prey. As major so-called natural climate changes have occurred also in the recent few million years the first major question in the present anthropogenic climate change era is: Can earlier so-called abrupt climate changes be used as an example for projections into the future? The answer is no, because the mean global temperature change rate to occur in the 21st century exceeds by far even the most rapid natural ones. The largest and most rapid *global* mean temperature change rates in the recent few million years have been the collapses of the large northern hemisphere ice sheets that have led to a mean global warming of up to 5°C and a sea level rise of about 120 m in roughly 10,000 years. Projections for the 21st century without stringent climate policy [4] range between 1.5°C and about 4°C, i. e. an acceleration of at least a factor 30. Hence, the past cannot be used as an analogue. In other words: The key goal of the United Nations Framework Convention on Climate Change (UNFCCC) that speaks of avoidance of a dangerous interference with the climate system, cannot be met without globally coordinated climate policy. It requests, in addition, a climate policy helping to stabilize greenhouse gas concentrations within a time frame that firstly natural ecosystems are able to adapt to climate change, secondly food production is not generally threatened and a sustainable economic development remains possible.

In this situation with ill-adapted forests, rapidly changed patterns of infectious diseases for plants, animals and humans looking back through climatic history does also not help directly. Besides intensified research on changed disease patterns in the very recent past a stringent globally coordinated climate policy under UNFCCC is the best insurance against massively altered disease patterns.

This paper will concentrate on climate change impacts on human health but will not exclude totally impacts on food production. Major points will be "thermal stress" before "vector-borne diseases" and also prolonged allergen seasons and new allergens are discussed.

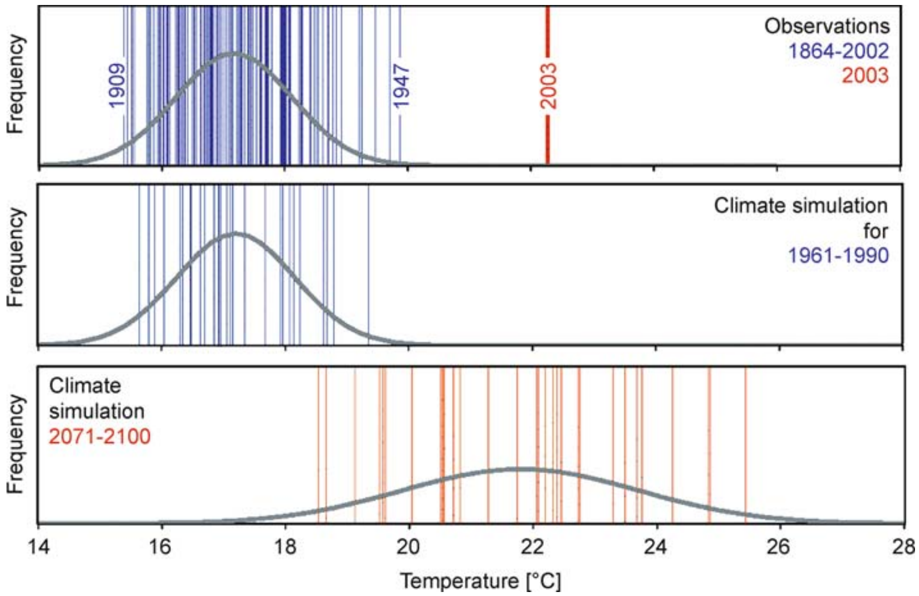
Changed Thermal Stress

Heat or cold stress forces our body to adapt to keep the core body temperature within a narrow temperature interval of about five degrees centigrade (35 to a maximum of slightly above 40°C). While extreme cold stress events have diminished and will further diminish as a consequence of ongoing global warming, extreme heat stress will increase dramatically (see Fig. 1), when the frequency distributions of temperature at a certain location are shifted by only a few degrees centigrade and may be broadened. Up to now only very few places on the Earth's surface exist where survival of a human being is nearly impossible. This would certainly happen if the wet bulb temperature (roughly equivalent to a ventilated sweating naked body) surmounts about 35°C. Under present climate conditions such areas do not exist, but coastal areas of the Red Sea come closest to it during on-shore winds after a sunny day that was heating surface waters to about 35°C. Hence, heat strokes can in principle be avoided by adequate behavior, if buildings are well insulated and properly ventilated and if an individual behaves. Therefore, the huge death toll caused by major heat waves, namely about 55,000 people that died during the heat wave in summer 2003 in Europe [5] is rather an indication for "social freeze" and ill-adapted buildings in our industrialized or developing societies than for really intolerable thermal conditions. Many have died because of lack of care. New weather extremes always demask weaknesses in our security-related infrastructure. A famous example is the large difference in the number of people dying during a summer heat wave in 1995 in two US cities (Chicago and Philadelphia) just because of intensified public care in Philadelphia where the weak and poor citizens where brought by the city administration to the cooled malls during daytime.

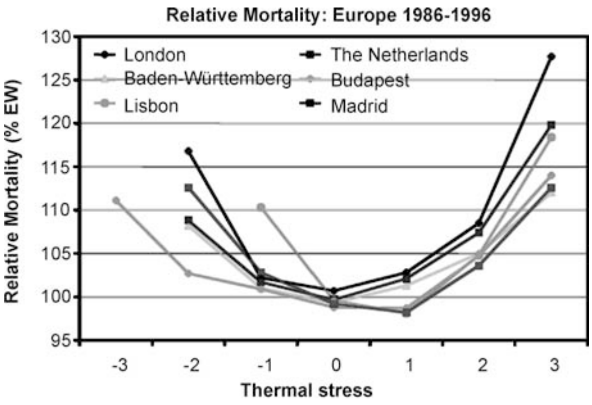
As Fig. 2 clearly demonstrates the mortality anomaly caused by heat waves is a fact observed over several decades (here in a developed country). Lowering the anomaly means not only investment in better warning systems but also enhanced social care in general.

Both heat and cold stress increase mortality as underlined by Fig. 3 for European countries. In the future heat stress category 3 will occur much more often and the lowering of the increased mortality will also be a sign of an improved public health system.

A further point to be made with respect to enhanced thermal stress as a consequence of climate change is the rapidly mounting heat stress in the inner tropics, where



Climate Change and Human Health, Figure 1
Observed (*upper panel*) and modeled summer mean temperatures for the Swiss Plateau both for present climate (1961 to 1990) (*central panel*) and the last three decades of the 21st century for scenario A2. Please note that the exceptional summer 2003 would occur every second year, if globally coordinated climate policy would not exist. From [13]



Climate Change and Human Health, Figure 2
Mean relative mortality in percent for different thermal stress categories observed in Europe during 1986 to 1996. Please note that the mortality increases by more than a factor 2 when heat stress category 2 is replaced by category 3. From [5]

dew points of about 25°C will more often occur, if global warming also continues there. The ability to work with high efficiency is shrinking there rapidly with rising temperatures and dew points. As is well known economic development of developing countries needs a cooled or well-ventilated work place.

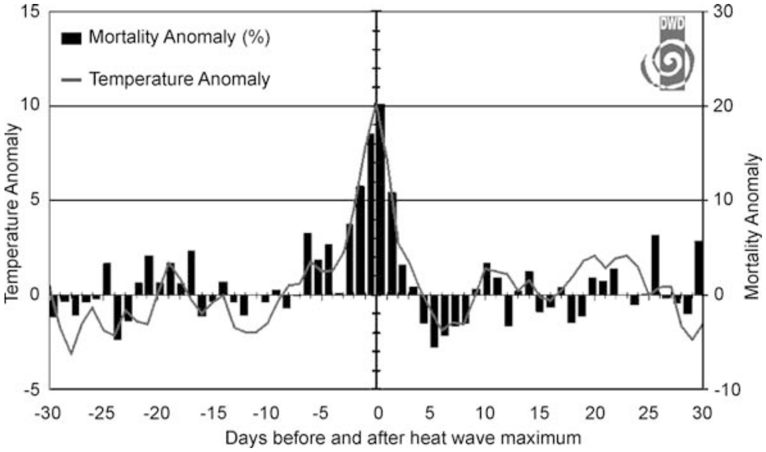
Impact on Photochemical Smog

Photochemical smog is formed if solar radiation stimulates chemical reactions in a polluted atmosphere. Emissions of non-methane hydrocarbons and nitrogen oxides ($NO + NO_2$) lead to the formation of ozone and other oxidizing toxic trace gases as well as aerosol particles. In mid-latitudes photochemical smog is typically strongest in late spring and summer and it has been the reason for some environmental policy making. Heat waves with intense solar radiation lead to major photochemical smog episodes. The higher frequency and longer duration of heat waves during recent and foreseen global warming will intensify health problems already existing during heat waves. As Tables 1 and 2 demonstrate the hot summer in Germany in 2003 has increased the number of days for both ozone and aerosol load (PM_{10}) where limit values have been surmounted in Germany dramatically [14,15], e. g. by a factor of 2 or more both for PM_{10} in rural areas and ozone in all areas.

Fighting against photochemical smog will become even more demanding in a warming world.

Changed Ultraviolet Radiation

Ozone protects us to a large extent from the dangerous part of ultraviolet solar radiation through absorp-



Climate Change and Human Health, Figure 3

tion in the ultraviolet (UV-B) range from 0.28 to 0.32 µm wavelength. The observed latitude-dependent reduction of stratospheric ozone (from 8 to 50 km height in high latitudes), which constitutes about 90% of the total ozone column content and which is caused by chlorine compounds stemming from decay products of chlorofluorocarbons (CFCs) and other halocarbons, has increased UV-B radiation especially in spring of both hemispheres at higher latitudes. This stratospheric ozone decrease is strongest in Antarctic spring in the so-called ozone hole. This ozone depletion has certainly increased and still will increase the skin cancer and cataract incidence that has dramatically grown in recent decades. However, the ozone depletion contribution is largely buried in the variability and change of exposure of our body to UV radiation, which is due to changed behavior, especially in developed countries. The key question for the forthcoming decades is: How fast will ozone column content recovery be after the banning of CFCs and other chlorine and bromine containing compounds? Present knowledge says: Full recovery after several decades with a chance of a super-recovery caused by a further increase of the greenhouse effect of the atmosphere, which lowers stratospheric temperatures.

Health Effects Caused by Other Changed Climate Parameters

Climate change shifts and reshapes frequency distributions of meteorological and hydrological parameters, thereby multiplying the occurrence of known extremes and leading to new ones (see Fig. 1, where this is demonstrated for temperature). Therefore, the health of many more millions is affected by intensified flooding, higher storm surges, and many other weather-related disasters.

While the highest death toll of weather-related disasters was – for thousands of years – due to droughts, with up to 10 million people dying per decade around 1930, the highest death toll is now caused by flooding and wind damage due to tropical cyclones and hurricanes (Red Cross, …). The main reason for this change is – besides more dwellings in flood-prone areas, often already lying slightly below mean sea level – the international aid bringing food and seeds into the drought-affected areas; as long as civil war does not prevent this help.

Hence, climate change also calls – irrespective of globally coordinated climate change mitigation policies – for a coordinated climate change adaptation policy in the coming decades, because we have to adapt to the already unavoidable climate change. Mitigation measures meant to avoid the un-tolerable climate change will only become effective in decades due to the inertia of the climate system caused by the slow reaction of oceans and ice sheets. In other words: If flooding is prevented by strengthened dikes, anticipating shifted frequency distributions of precipitation, cholera epidemics will not occur. Diking has to become an international activity, as the emitters in industrialized countries are causing more flooding and sea level rise on a global scale, co-financed by the already existing but strongly to be increased adaptation fund under the UNFCCC, its Kyoto Protocol and the follow-up protocol envisaged to be signed in 2009.

As an aside I will here report on reactions of our body to high carbon dioxide levels in the atmosphere. Very often if many people are gathered in the same closed room and breathe the same air some will ask for fresh air (i. e. they require more oxygen). The need for fresh air is because of too high carbon dioxide levels. Regulations in some German states concerning ventilation in classrooms provide ventilation rules to avoid carbon dioxide concentrations above 1,500 ppm, a level after which concentration diminishes and some students may even develop signs of a beginning headache. The oxygen content of air has fallen by a bit more than a tenth of a percent only to about 20.84 percent at which point ventilation by opening windows becomes a must. Hence, ventilation of our living rooms means pushing out carbon dioxide.

Transmission of Infectious Diseases from Birds to Humans

In recent years migratory birds have been named as a cause for the transmission of bird flu (avian influenza) to humans because they can in principle transmit the influenza virus to chickens, geese, turkeys and ducks in our farms from where the virus infects humans that come into close contact with the fowl or their products. However, very often the cause for the long-range transmission is global trade and tourism on the one hand plus industrialized animal husbandry in developed and emerging countries on the other. The latter has been found as the principal cause for the comparably rapid mutation of slightly pathogenic bird flu viruses to highly pathogenic ones (Bairlein and Metzger, 2008). These in turn can reach wild bird species which then can rapidly transmit them to new areas, if the viruses are only slightly pathogenic for them. But also pathogens, vectors or reservoir species can inadvertently be introduced by globalization to regions where no longer-term co-evolution could have taken place. Further global warming will intensify the shift of pathogens with the shift of (migratory) birds, but will only add to the further rapid distribution of pathogens caused by globalization (Smith et al., 2007).

Allergies Caused by Pollen

In most countries allergies have recently increased dramatically. In Germany, for example, 20 to 30% of the population suffers from allergies. Most abundant is the allergic rhino conjunctivitis (hay fever), often turning into asthma bronchiale, caused by allergic pollen in air. Climate change has led to longer pollen seasons, in parts to more pollen, changed pollen spectrum and also new pollen [9].

From studies in Europe, North America and Japan an earlier flowering of 1 to 3 days per decade has been reported during the recent decades [11]. For some species, especially the late flowering ones a prolonged pollen season has been found [2,3], in parts caused also by long-range transport of the pollen. Consequently, for many people in mid-latitudes suffering from several pollen the pollen season became longer, sometimes already starting in December and ending only in October after the flowering of the neophyte ragweed (*Ambrosia artemisiifolia*) for Europe.

From differences between cities and rural areas as well as from laboratory studies it became known that pollen abundance increases with carbon dioxide concentration for some species.

In combination with air pollution allergic reactions have been shown to intensify [3].

Invasion of Allergenic Neophytes With ongoing global warming two processes combine for the spread of neophytes: Firstly, global trade and tourism transmitting plants and their seeds within days and weeks around the globe to all inhabited places and into ocean basins and secondly, increased temperatures allowing more and more often establishment of exotic species in new areas. A famous example where both mentioned processes work in combination is the invasion of the strongly allergenic ragweed (*Ambrosia artemisiifolia*) from North America to Europe in the 19th century with a large spread after the Second World War. Ragweed flowers from late August to September and its pollen also undergo long-range transport [1]. In recent decades it spread strongly in Central Europe facilitated by agricultural practice and by inadvertent transport with bird food as well as higher temperatures.

Indirect Health Effects Caused by Climate Change

Many infectious diseases are transmitted by vectors, i. e. by animals (very often insects) transferring a pathogen from another animal and/or human without suffering from the pathogen themselves. The complicated web of hosts, pathogens, reservoirs and vectors is dependent on many factors, among them climate variables, foremost temperature and precipitation. Therefore, distribution patterns and incidence of infectious diseases will also be modified by climate change; however, disentangling the cause and effect relationships is often extremely difficult. Since tropical infectious diseases are the most common of these diseases and especially temperature sensitive they will be a focus in this section. The World Health Organization (WHO) points to a highly probable increase of morbidity and mortality due to higher prevalence and a pole-ward shift of tropical infectious diseases due to further global warming.

Increase of Vector-Borne Tropical Infectious Diseases As always in scientific investigations it is especially difficult to derive long-term trends of certain variables influenced by many parameters like changes in land use, socio-economic conditions and climate or weather patterns. This is also true for tropical infectious diseases. Hence, only few trend analyses exist, e. g. for malaria reaching higher elevations in Africa.

The main vectors for infectious diseases are mosquitoes, biting flies, bugs, lice, fleas, and mites. Of about more than a million insect species roughly 17,000 have adapted to a blood-sucking mode of life. A small minority of these are vectors of pathogens. The pathogens are viruses, bacteria, protozoa or filarioses. Pathogens are either multiplied within the vectors without change of form (Arboviruses, Rickettsiae, Bacteria), multiplied with change of form (Protozoa) or changed without multiplication (Filaria). From uptake of a pathogen during a blood meal until the infective stage temperature is *the* factor determining duration, hence, higher temperatures can lead to enhanced spread of vector-borne diseases as for example observed for dengue fever.

According to number of people infected by blood-sucking insects *malaria* comes first with 300 to 500 million cases per year of which 1 to 2 million die, especially children. About 70 mosquito species of the genera Anopheles transmit four different protozoa (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*). The mosquito *Anopheles gambiae* in Africa is the most important vector. Because malaria has been eradicated in many developed countries in Europe an enhanced potential for malaria must not lead to a re-introduction there. However, in countries with a weak public health system higher prevalence and new malaria infected areas are highly probable.

About 120 million people in Asia, Africa, South and Central America are infected by *lymphatic filariasis* (elephantiasis) transmitted by different genera of mosquitoes. The larvae of the worm develop (from 0.4 to about 1.5 mm) in the vector and can be transmitted during the next blood meal to humans. The development period is temperature-dependent. Hence, a potential for a further spread exists, but the Global Program to Eliminate Lymphatic Filariasis (WHO, 2006) may reduce incidence strongly.

Dengue fever affects about 50 million persons per year and it is a clearly growing threat to human health in about 100 tropical and subtropical countries. The virus belonging to the flaviviruses is transmitted mainly by the *Aedes aegypti* mosquito. Vector and virus show strong temperature dependence in their development. But the disappearance of *Aedes aegypti* from Europe around 1950 points to the probably strong application of the insecticide DDT. As often, measures taken against infectious diseases can easily off-set climate influences.

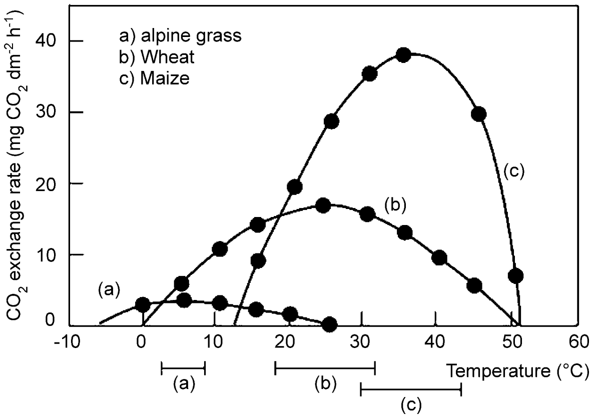
Onchocerciasis (in severe cases leading to river blindness) affects about 37 million persons, mainly in Africa, the microfilaria of the worm "*Onchocerca volvulus*" are taken up from the human skin by the vector, a simuliidae species, during a first blood meal, they develop through two skinnings within the vector and are transmitted back to a human being during a further blood meal after about 7 to 10 days. Whether the vector, developing in running water and sucking blood during daylight, is already reacting to climate change is not known although a temperature and precipitation dependence clearly exists.

Many other tropical vector-borne infectious diseases exist, like loiasis affecting about 13 million people in tropical Africa, "Schlafkrankheit" with about 60,000 new cases per year or West Nile fever that has reached the USA. In all cases it is a complex mix of influencing factors with positive and negative feedbacks, which inhibits a clear separation of a climate contribution to changed patterns and severity. Hence, there will be many surprises often based both on transport of vectors by growing trade and tourism and better survival conditions in higher latitudes due to higher temperatures and/or changed moisture conditions.

The best means to cope with changed disease distribution patterns is a strong public health system and links between the systems in different countries.

Climate Change Impacts on Plants with Consequences for Human Health

Our food is produced by plants on land and in the ocean, even if we eat meat or fish because animals also feed ultimately on plants. Hence, a climate change impact on plants may have strong indirect effects on human health. However, even if the climate change impact were small on certain plants, their way of reacting to enhanced CO_2 concentration could still have consequences for food production. In reality climate change and elevated CO_2 concentration act together and both have largely different impacts on plant types and species. The temperature dependence of photosynthesis rate as presented in Fig. 4 for very different plants, shows the rather steep decline of this rate for maize, a C4-plant, at high temperatures above about 40°C. Adding to this finding that there is nearly no positive feedback to higher CO_2 levels for C4-plants, yield in tropical areas would be reduced if plants have to assimilate at leave temperatures of about 40°C. Therefore, Working Group II of IPCC concluded [4]: "Crop productivity is projected to increase slightly at mid- to high latitudes for local mean temperature increases of up to 1–3°C depending on the crop, and then decrease beyond that in some regions. At lower latitudes, especially seasonally dry and tropical latitudes, crop productivity is projected to decrease for even small local temperature increases (1–2°C), which would increase the risk of hunger."



Climate Change and Human Health, Figure 4
Temperature dependence of photosynthesis rate for an alpine grass, wheat and maize. Please note the strongly differing optimal temperature ranges. From [10]

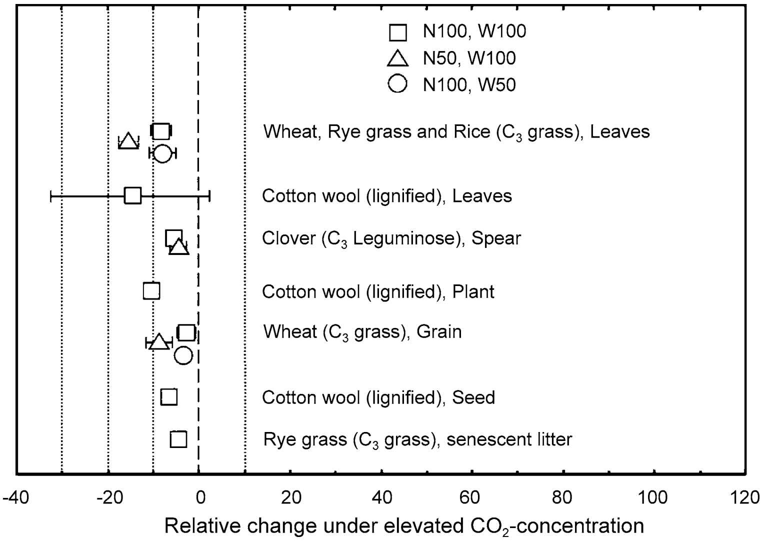
If C3-plants (e. g. wheat, rice, potato, sugar beet) live at higher CO_2-concentrations their photosynthesis rate increases rather linearly with CO_2-concentration, if water stress and nutrient scarcity are not limiting their photosynthesis rate. Consequently, the delay of decades between CO_2-concentration rise and full expression of the warming, to which we are already committed, is a "window of opportunity" for high crop yields of C3-plants. This may in the long-term also have global consequences, because the CO_2-concentration could rise additionally if the (high latitude) forests (C3-plants), acting as a sink for anthropogenic CO_2 presently, would lose this capacity under higher climate change stress. Whether and when this will occur is not yet known.

Changes in Food Composition for Main Crops at Elevated CO_2-Concentration

An important consequence of elevated CO_2-concentration would be changed composition of plant tissue, and especially of seeds, as it could have immediate health consequences for animals and humans eating them. The sparse body of published studies is nearly unanimously pointing to a loss of nitrogen content in leaves and stems as well as in seeds (see Fig. 5 and [6] for an overview). The results of so-called **F**ree **A**ir **C**arbon Dioxide **E**nrichment (FACE) studies at roughly doubled CO_2-concentrations ($\sim$ 550 ppm) are all reporting higher nitrogen content for plant tissue and a bit less for seeds. This negative consequence for our food is not yet fully acknowledged in the public, because of the very different impacts for different parts of society. For a grain-producing farmer the CO_2 fertilization effect leads to higher yields of C3-plants, a dampening of photo-smog yield reductions, higher water use efficiency for both C3- and C4-plants and thus less drought impact while for the baker the wheat quality for baking bread declines, and the cattle as well as the consumer get less healthy food.

Shift of Biomes and Migration

As already observed, precipitation is redistributed due to rather different warming patterns. And projections of precipitation changes in the 21st century, as published in the Fourth Assessment Report of [4], can be summarized in the following sentence: Rather humid areas will on average get more precipitation, especially in high latitudes, while semi-arid areas will get on average less (with strongly lowered soil moisture at higher temperatures). This is bad news for many millions of people in semi-arid zones of the tropics and subtropics. The main impact on plants is water stress, hence lower crop yields. But also less food for cat-



Climate Change and Human Health, Figure 5
Changes in nitrogen content in plant tissue under elevated CO_2-concentration (∼ 550 ppm) depending on nitrogen fertilizer and water availability (50 or 100%). From [16]

tle in pasture lands, continued or enhanced malnutrition for the poor, aggravation of existing deficiencies in public health care systems in these areas will be the negative consequences of climate change impact on the biomes of these areas. In other words: Undermined public health systems, loss of livelihoods and finally migration will be the dire consequences of anthropogenic climate change. The socio-economic and political reactions to this threat cannot be foreseen in detail. However, the international economic cooperation between developing and industrialized countries has to take as a priority adaptation to unavoidable climate change as the best means to lower impacts on public health.

Concluding Remarks

Although threat to human health was often the cause for environmental policy making, e. g. in the case of desulfurization of power plant exhaust, the manifold threats to human health as a consequence of global anthropogenic climate change have rarely been named as a key reason for climate change policy measures. What else is the partly still growing mal-nutrition of subsistence farming communities in the desertification-prone semi-arid tropics and subtropics than a threat to human health? On the other hand most new threats to our health caused by the spread of vector-borne infectious diseases due to higher temperatures or those caused by new weather extremes can be strongly reduced by proper health system up-grading and pre-cautionary measures that strengthen security-related infrastructure. However, this will probably not be the case in developing countries already suffering from (very) weak public health systems; unless the preliminary decisions of the 13th Conference of the Parties to the UNFCCC lead to a new international and binding protocol in 2009 as a follow-on to the Kyoto Protocol that then stipulates that a fixed portion of the revenues of international greenhouse gas emission trading should be used for adaptation measures in developing countries. A large share has to be invested in public health systems in poor developing countries in order to help the poorer parts of societies typically suffering most from epidemics and weather-related catastrophes.

If earlier tropical vector-borne infectious diseases, like the West Nile fever, reach developed countries, research to get proper vaccines will be stimulated within large pharmaceutical companies. If the threat remains confined to the poor South, this research effort will often not exist, because developing countries' normal population cannot afford the expensive new drugs or vaccines that remain property right protected for years. It is high time that political summits deal with this problem and WHO helps to circumvent this barrier as pointed out recently by the Nobel Prize laureate for economics (Stiglitz, 2006).

Climate Modeling, Global Warming and Weather Prediction, Introduction to

HARTMUT GRASSL
Max Planck Institute for Meteorology,
Hamburg, Germany

All systems operating away from thermodynamic equilibrium develop structures. The planet Earth will always be far away from thermodynamic equilibrium because of the strongly differing solar radiation input as a function of latitude and season. Hence, the differential heating of the surface and also the atmosphere must lead to temperature gradients, in turn causing pressure gradients that create currents in the ocean and the wind in the atmosphere. On a rotating sphere (in reality the geoid, which is close to a rotational ellipsoid) these flows form low and high pressure systems both in the ocean and the atmosphere which are able to reduce latitudinal gradients but never come close to thermodynamic equilibrium because of continuing differential heating. The average temperatures and flow fields, as well as their strong spatial and temporal variability, are a function of land/sea distribution and atmospheric composition, especially depending on water and ice in clouds. The strongly climatically relevant gases in the atmosphere are, to a large extent, a consequence of life on Earth.

Ranking all radiatively active gases in the atmosphere according to their influence on weather and climate shows the exceptional composition of the atmosphere: Water vapor (H_2O) in all three phases but largely as a gas, carbon dioxide (CO_2), ozone (O_3), nitrous oxide (N_2O) and methane (CH_4) constitute only three thousandths of the atmospheric mass, yet they largely determine how much solar radiation reaches the surface, e. g., through clouds, and how much thermal or terrestrial radiation leaves from there to space, again a strong function of clouds and the above-mentioned gases. The average surface temperature is thus strongly depending on the concentration of the gases mentioned, which are all greenhouse gases. They do not strongly absorb solar radiation but do absorb terrestrial radiation, thereby forcing the surface and the lower atmosphere to warm in order to reach nearly equilibrium between absorbed and emitted energy. Any growth or reduction of greenhouse gas concentrations increases or decreases average surface temperature and thus changes climate.

The climate system, i. e., its interacting components atmosphere, ocean, land, vegetation, soils and crust, shows both a remarkable stability and high sensitivity. Over many million years the greenhouse effect of about 30 K has varied only by about +/ − 5 K with respect to present interglacial temperatures, thus has been stable in terms of temperature varying only from 283 to 293 K. +5 K however meant melting of all inland ice sheets and −5 K a new strong glaciation with major ice sheets reaching 40 to 50° N (see ► Cryosphere Models).

The observed strong increases of all long-lived naturally occurring greenhouse gases (+35% for CO_2, +120% for methane, and +10% for N_2O since 1750) have stimulated a mean global warming which now has emerged from strong climate variability. In 2007, the Fourth Assessment Report of the Intergovernmental Panel on Climate Change concluded: "The understanding of anthropogenic warming and cooling influences has improved ... leading to very high confidence that the global average net effect of human activities since 1750 has been one of warming". On the other hand, the high sensitivity of the climate system is demonstrated in so called abrupt climate change events (see ► Abrupt Climate Change Modeling).

The strongest global one of these – besides the impact of celestial bodies – is deglaciation after an intense glaciation in about 5000 to 10 000 years with a concomitant temperature increase of 4 to 5 K, caused by the slow latitudinal redistribution of solar radiation due to Earth orbit parameter changes as a consequence of slowly changing gravitational forcing by the neighboring planets, mainly Venus, Jupiter and Saturn. Because climate is a key natural resource for plants, animals and humans, any rapid climate change threatens life on Earth. Therefore agriculture (see ► Climate Change and Agriculture), forestry and all economic activities (see ► Climate Change, Economic Costs of) will be impacted by anthropogenic climate change in the 21st century, leading to strong consequences in societal behavior vis-a-vis this challenge, e. g., the one caused by growing inequity between those societies causing climate change, the industrialized countries, and those suffering first or more strongly such as subsistence farmers in semi-arid tropical areas. Climate Models developed so far include many physical processes (see ► Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface as an example), parts of atmospheric chemistry, and vegetated land surface atmosphere interactions, but still lack reaction of ocean biomass production to enhanced CO_2 levels. Finally, it is apparent that global warming will have an effect on human health and that this will include effects on food crops and animals (see ► Climate Change and Human Health).

The low horizontal resolution of global climate models has stimulated nested regional climate models (see ► Regional Climate Models: Linking Global Climate Change to Local Impacts) delivering enhanced output in areas with strong topography or sea/land contrasts. The slowly emerging Earth System Models are no longer driven by changed atmospheric composition alone but by emissions, i. e., they can calculate resulting greenhouse gas concentrations. However they are still not advanced enough to answer the question: When will growing climate change stress turn the present uptake of anthropogenic CO_2 into forests through the CO_2-fertilization into an additional CO_2 source for the atmosphere due to a generally weakened vegetation? It is common knowledge that weather, for example the passage of a coldfront at a certain location, can be forecast only for up to two weeks because of the intrinsically chaotic behavior of atmospheric flow. The accuracy of present day weather forecast models, which are very similar to the atmospheric component of climate models, has advanced strongly, driven by higher spatial resolutions and better parametrizations of sub-grid scale processes in the models, assimilation of more (and especially satellite data) into the models and ensemble forecasting. This has recently led to the same forecast accuracy up to about 10 days in the southern hemisphere, where an in situ observing system for the starting fields of the model is largely lacking.

The increased attention the topic climate change has finally attracted in the political arena will certainly accelerate progress in this field, despite the complex nature of the functioning of the Earth system.

There are two additional articles on climate change which were recruited for other sections. These articles are: ► Dynamic Games with an Application to Climate Change Models and ► System Dynamics Models of Environment, Energy and Climate Change.

Cognitive Robotics

[2] Cybernetics, The University of Reading, Reading, UK

Article Outline

Glossary

Amygdala Amygdala consists of almond-shaped groups of neurons located within the limbic lobe in the brain. The amygdale performs primary roles in the formation and storage of memories associated with emotions and is said to have a substantial role in mental states.

Basal ganglia Basal Ganglia are a collection of subcortical neuronal group and have a significant role in the control of movement.

Central executive agent (CEA) CEA is a cognitive or compound agent responsible for high-level executive control, such as reasoning, task switching and realization of internal rehearsal, e. g. within the ISAC cognitive architecture.

Chinese room argument
John Searle developed a thought experiment called the "Chinese Room" argument against what he calls "strong AI". Searle describes a scenario in which a person who knows no Chinese is locked in a room full of boxes of Chinese symbols together with a book of instructions for manipulating symbols. This person receives questions in Chinese from under the door. If the person in the room is able to pass out Chinese symbols using the instruction book to produce correct answers to the questions, he passed the Turing Test for intelligence in Chinese, but he does not understand a word of Chinese.

Connectionist models Connectionist models of cognition are structured on the concept of neural networks. Connectionist networks provide an account for the complex behavior in a way parallel distributed processing (PDP) does. There is no way to distinguish between simple and complex representations in connectionist models. In this sense, they are considered to be subsymbolic.

Cortex Cortex (or cerebral cortex) is a surface structure in the brain responsible for many brain functions including attention, sensory processing, motor functions, awareness, language processing and arguably consciousness. The human cortex is 2–4 mm thick and consists of large sheets of mostly layered neurons.

First-order cybernetics First-order cybernetics considers control and communication in the animal and machine, where the agent receives feedback, including utility of its actions, from the environment.

Cartesian theater A centered locus in the brain called *Cartesian materialism*, because it is the view one arrives at when one discards Descartes' dualism, but fails to discard the associated imagery of a central (but material) theater where it all comes together.

Global workspace Multiple parallel *specialist* processes compete and co-operate for access to a *global workspace*. If granted access to the global workspace, the information a process has to offer is *broadcast* back to the entire set of specialists.

Humanoid robots There is no universally accepted definition for a humanoid robot today. However, it is widely accepted that a humanoid robot must have a body somewhat resembled to a human body, exhibit human-like behavior, and be able to interact with humans using human-level intelligence. As of today, no existing humanoid robots satisfy all these requirements.

ISAC ISAC stands for Intelligent Soft Arm Control. The name arises from the fact that the arm is highly compliant and safe for working with and around people. In its multiagent architecture called the Intelligent Machine Architecture (IMA), human and many modules within the humanoid are represented as distinct agents within a common computational framework.

Minimum robust representationalism (MRR) MRR is a notion, rather than a formal definition, put forward by Clark and Grush that addresses the problem of internal representation when addressing cognitive phenomena. The emphasis on emulators differs from the classical ideas of cognitivism and representationalism. Transparent (i. e. analytically traceable) emulator circuitry is the minimal needed to usefully consider representations of external states.

Multiagent systems (MAS) A multiagent system (MAS) is a software system composed of multiple agents and collectively capable of reaching goals that are difficult to achieve by an individual agent. An agent within MAS can be autonomous in the sense that it has own decision-making capability or non-autonomous like a simple input-output device. MAS agents can include human agents like the case study in this section.

Neural networks Neural networks, or artificial neural networks, are a class of networks of simple processing units which can exhibit complex behavior. They were inspired by the way biological nerve systems, such as the brain, process information. Simple neural networks consist of three layers, input, hidden and output.

Production systems Production systems are symbolic artificial intelligence systems, i. e. they manipulate symbols, instead of numbers. Production systems are composed three parts: a global database, production rules and a control structure. Production rules (or productions) are called if-then rules.

Second-order cybernetics Second-order cybernetics recognizes that the agent has an important effect back on the environment and the two systems affect each other.

Definition of the Subject

Cognitive Robotics is an emerging field of robotics, which will continue to evolve for the years to come. The field of cognitive robotics generally comprises the design and use of robots with human-like intelligence in perception, motor control and high-level cognition. To realize cognitive robots many overlapping disciplines are needed, e. g. robotics, artificial intelligence, cognitive science, neuroscience, biology, philosophy, psychology, and cybernetics. Thus attempting to tightly define the subject is not constructive as often its nature is amorphous, growing and a strict definition could exclude future relevant work.

Work by Clark and Grush [1] towards a cognitive robot definition is well respected. We quote some important considerations below:

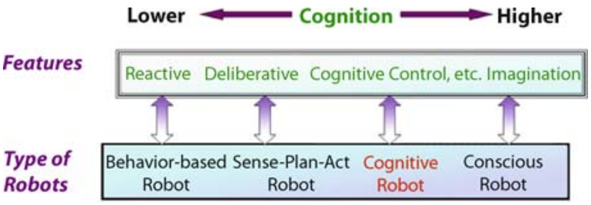
- We hold that fluent, coupled real-world action-taking is a necessary component of cognition.
- Cognition, we want to say, requires both fluent real-world coupling and the capacity to improve such engagements by the use of de-coupled, off-line reasoning.
- Cognizers, on our account, must display the capacity for environmentally decoupled thought and the contemplation of options. The cognizer is thus a being who can think or reason about its world without directly engaging those aspects of the world that its thoughts concern.

In 2006 international researchers representing many of the above disciplines attended the Cognitive Robotics, Intelligence and Control Workshop (COGRIC) [2], which discussed the future of cognitive robotics. Important concepts in cognitive robotics were held to be the ability to form internal states or models for reasoning and decision making (consequently planning), learning from experience, self reflection, embodiment and situatedness, perception to measure world, external behavior/internal representation and importing ideas from human cognition including perception and learning (the entire system) whilst understanding brains and minds. From discussions, it was concluded that it was not worth debating boundaries between consciousness, cognition and intelligence. Future opportunities included lifelong adaptability and developmental learning.

Other researchers have considered this topic, with different list of key features that a cognitive robot should/would possess. Key features that participants identified in the workshop are:

- Ability to perceive the world in a similar way to humans (or better) (e. g., "active perception", Dana Ballard [3], "ecological approach to perception", JJ Gibson [4])
- Ability to communicate with humans using natural language and mental models (robust human-robot interaction, such as overcoming the frame of reference problem, Alan Schultz [5])
- Ability to develop cognition through sensory-motor coordination (e. g., "morphological computation", Rolf Pfeifer [6])
- Ability to have a sense of self awareness (internal states, machine consciousness: Igor Alexander [7], Owen Holland [8] vs. Kevin O'Reagan [9])
- Ability to use attention and emotion (not in a sense of social robots) to control behaviors (K. Kawamura [10])

Robots may be justified in terms of ameliorating a labor shortage, working in hazardous environments, and undertaking repetitive tasks. However, the importance of cognitive robotics is in enabling robots to work autonomously in real-world environments. Currently, robots are not intelligent enough to operate without supervision in real-world situations, e. g. due to difficulties in applying existing knowledge to new situations, selecting between competing goals, coping with multiple sensory input and completing multiple tasks each with subtle variations. Deliberative robots may be able to weld a car, but higher order cognition (Fig. 1) is needed to care for the elderly as the environment is much more unstructured, dynamic, sensory rich, noisy, multitask, varied input/communication, emotive and interactive.



Cognitive Robotics, Figure 1
A spectrum of cognition in robotics. Adapted from [11]

Finally we quote Pentti Haikonen, Nokia Research Center:

"The next big push in robotics may well be machine cognition. Cognitive robotics, that are able to perceive and move as well as we humans do, are the focus of several national and international research programs in EU, Japan and USA. The emerging cognitive technology (as opposed to cognitive science) tries to emulate human information processing and in doing so utilizes experience, affordance (in terms of meaning), attention and even emotion" [2].

Introduction

Humans have sought to create human-like artificial creatures for menial tasks, for coworkers and for the intellectual challenge. Historical stories of Golems raised by religious rituals from mud have lead to the science-fiction of androids assisting or terrorizing the human race. Fiction has now been replaced by increasingly serious attempts by industry and academics, which is treated here as it relates to complexity.

Complexity covers systems where the interaction of multiple components leads to behaviors unachievable by any individual component alone. Cognitive robots require multiple components to function, often in parallel and in harmony, with the goal to produce intelligent human-like behavior and skills.

The origin of modern cognitive robotics comes from the field of cybernetics, the study of control and communication in living organisms, machines and organizations. The term cybernetics was popularized by Norbert Wiener in his 1948 book [12]. Cybernetics had a crucial influence on many important concepts, such as goal-directed behavior generation, self organization and situated nature of intelligence, which are now commonly used in the intelligent robotics community.

In the 1960s, researchers in artificial intelligence (AI) pursued the concept of intelligence from a more deterministic point of view. AI, or commonly known as strong AI, was predicated on the presumption that intelligence or knowledge can be represented as production systems and stored inside of a machine, i. e. computer. However, researchers in cybernetics claim that intelligence is an attribute of an interaction with the environment rather than a commodity stored in a computer and must be actively constructed by a machine itself (e. g., [13]).

The concept of strong AI is that a machine's processors can become a mind, exhibiting many aspects of intelligent behavior, especially sapience and insight into its inner workings. Weak AI, on the other hand, maintains that machines can only reproduce human attributes through the interaction with the environment, which sets constraints on cognitive robots. The best known example of a counter argument to claims made by the strong AI approach is the Chinese Room argument made by John Searle [14]. The debate Searle caused continues today.

In 1999, Clark and Grush [1] pointed out the problem with the notion of internal knowledge or world representation (a part of strong AI argument) and offered a solution called the Minimal Robust Representationalism (MRR). According to MRR, "Cognition, we want to say, requires both fluent real-world coupling and the capacity to improve such engagements by the use of de-coupled, off-line reasoning" ([1], p. 13). We will revisit this notion later in Sect. "Case Study".

As the opening paragraph stated, building a humanoid robot with which to embody human-level intelligence has been a dream of many AI and robotic researchers. In 1993, Rodney Brooks began to work on a first generation cognitive robot [15], which was an upper-torso humanoid and used to generate human-like behaviors. His effort led to a number of government and commercial humanoid development projects in Japan, such as Honda's ASIMO [16] and Toyota's personal assistant humanoid robot [17] during the 1990s and early 2000s. One of the strong arguments for humanoid robot development was that there is a strong desire to replicate human behavior within embedded artificial agents and humanoid robots are the best embedded system to do so. Other researchers consider the field too new to draw this conclusion, thus the jury is still out, e. g. no one knows whether an elderly person prefers a human-like robotic companion to a robotic wheelchair that provides specific needs for the person.

Recently, a number of international projects aimed to develop humanoid robot capabilities that can be used to test developmental theories of cognitive development and language acquisition were initiated (e. g. RoboGroup [18], RobotCub [19], Synergistic Intelligence [20]). The overall objectives of these projects are to study the perceptual, representational, reasoning and learning capabilities of embodied systems in human-centered environments. In particular, these projects propose to use humanoid robots to study mental development processes through robots' interaction with the environment similar to children's mental development processes. For example, RobotCub project, one of the most ambitious among them, aims to develop a set of fully functional humanoid cub robots the size of a 2-year old child.

The aim of this chapter is to provide an overview of the emerging field of cognitive robotics that will evolve over the years into a truly interdisciplinary field. The organization of the rest of the chapter is: Sect. "What Is Cognition?" covers the concept and definition of cognition. Section "Cognitive Architectures" covers major approaches to cognition: symbolic, connectionist and hybrid. Section "Cognitive Robotics" gives an overview of various cognitive robots in terms of important aspects and formative examples. Section "Case Study" summarizes Kawamura's attempt to realize a humanoid robot emphasizing the cognitive task of internal rehearsal. Finally Sect. "Future Directions" provides future directions for the field of cognitive robotics.

What Is Cognition?

This section explores cognition in its influence on constructing advanced robots, rather than debating philosophical insights into its nature. By investigating the brain's functionality, we can gain insight into how to form an artificial cognitive mind.

A goal of advanced/cognitive robots is to endow a level of intelligence and cognitive skills typically associated with people or animals. Although the goal may be based on nature, the methods do not have to be naturally inspired. Much of the early classical symbolic AI-type cognition work (details in Sect. "Cognitive Architectures") were based on computer science techniques, such as production rules, finite state machines and functional programming. Due to issues with scalability, generality, robustness, disturbance rejection and coping with environmental properties (such as uncertainty, noise, nonlinearities, non-determinism and epistasis), biologically inspired methods, such as connectionism became popular in the 1980s.

Although robotic cognition often takes inspiration from biological evidence, it does not guarantee that the outcomes will be equivalent due to discrepancies in evidence and implementation. Investigative techniques, from cell straining to functional magnetic resonance imaging or fMRIs, have been used to 'map' the brain. However, there is much debate on the accuracy and interpretation of the results, with the caveat that the brain's structure/functionality is "not as simple as it appears" often stated. It is argued that a boxology (where functional boxes are connected by lines), which may be easily represented in a computer program, could not replicate the biological evidence.

Mapping brain activity in awake, functioning animals is considered more valuable for cognitive research than when the animal is sleeping, e. g. sensory–motor coordination requires interaction with an environment. Insight can also be gained into self organizing and self reflection during sub-conscious processes using modern neuroscience methods.

Tests for cognition have a tradition in animal as well as human studies, e. g. maze exploration (path planning), T-maze latent learning, mirror test, and relational studies. These are being adapted for robots, e. g. recognition of own mirror image by a small robot [21].

The above tests identify key features and attributes for cognition, but individually do not represent a definition for recognizing cognition. Cognition may be considered as ill-defined due to many alternative definitions. A simple definition came from the foresight initiative by the United Kingdom Department of Trade and Industry (UKDTI) that states:

"Cognitive systems are natural or artificial information processing systems, including those responsible for perception, learning, reasoning and decision-making and for communication and action" [22].

Applying definitions is also controversial, e. g. at what point does something stop being cognitive? (e. g. are ants cognitive as an individual and/or do they display collective cognition?).

Cognitive Architectures

The task of developing a general cognitive architecture and subsequent computational models is greatly complicated by the lack of a clear definition of cognition as discussed in Sect. "What is Cognition?". Nevertheless, cognitive architectures are designed to propose structural properties of the modeled cognitive systems such as humans. Cognitive architectures are classified as symbolic, connectionist, or hybrid (i. e. symbolic-connectionist). As John Anderson, one of the pioneers of the unified theory of cognition, observed, "it is difficult to answer a question regarding which (architecture) might be the correct one or the most correct one since these architectures are often quite removed from empirical phenomena that they are supposed to account for" [23]. Nonetheless, cognitive architectures generally implement cognition as a whole as opposed to cognitive models (the topic of Sect. "Cognitive Robotics"), which focus on particular problems or applications. The aim of this section is to provide the reader a short summary and the important aspects of symbolic, connectionist and hybrid approaches using representative cognitive architectures in the fields of cognitive science, artificial intelligence, cognitive neuroscience, and machine cognition.

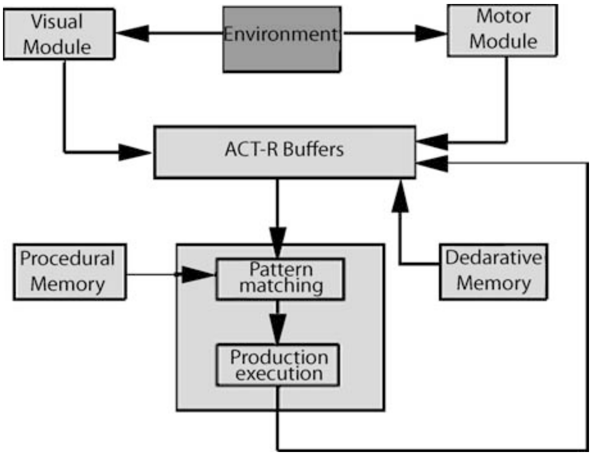
Symbolic Approach to Cognition

The symbolic approach to cognition can be best seen in Newell and Simon's physical-symbol system hypothesis [24] which states that "a physical symbol system has the necessary and sufficient means of general intelligent action". It means that any system that manipulates symbols is sufficient for producing intelligent behavior, and further that all intelligent systems are necessarily implementations of physical-symbol systems. The symbolic approach to cognition dominated the filed of cognitive science and artificial intelligence during the 1970s and 80s. Well-known examples of architectures that fall within this paradigm include ACT-R, Soar and EPIC.

ACT-R (Adaptive Character of Thought-Rational) ACT-R is a cognitive architecture for analyzing human cognitive performance which was developed by John R. Anderson and his group at Carnegie Mellon University [25]. ACT-R has been inspired by the work of Allen Newell and also inspired by the progresses of cognitive neuroscience. It is not a computational model, rather it is a framework for modeling specific human cognitive abilities whose predictions can be compared with human performance. That is, models of assumptions in cognitive processes can be created using ACT-R, allowing results to be easily observed, visualized, and compared with human performance data.

ACT-R makes use of symbolic processing and a sub-symbolic network. Symbolic processing is done through a set of production rules of the classic IF … THEN form. The sub-symbolic level runs concurrently with the symbolic level and consists of parallel processes that influence the performance of the symbolic system, such as conflict resolution, data retrieval, and rule execution. This allows the designer to have extra control over various conditions that affect the system performance without having to create explicit production rules. The central feature of the architecture is that all processing depends upon the current goal of the system. Functionally, ACT-R consists of three basic components: modules, buffers, and a pattern matcher as shown in Fig. 2.

There are two types of modules: perceptual-motor, and memory modules. Perceptual-motor modules (i. e., Visual and Motor Modules in Fig. 2 Declarative Memory) interface with the real world by perceiving environment and generating actions. Memory modules represent ACT-R's most important assumption, i. e. human knowledge can be divided into two kinds of representations: declarative and procedural. Declarative memory consists of facts which can be used to represent goals. Procedural memory describes tasks in the form of production rules. Each production rule consists of a condition in which it should be executed, and an instructional component describing what to do.



Cognitive Robotics, Figure 2
Functional structure of ACT-R. Adapted from [25]

Buffers hold declarative memory modules to be used by ACT-R and are somewhat analogous to the human working memory system [26]. Declarative information that is relevant to that goal is activated and considered to be in the focus of attention. The contents of the buffers are analyzed and a production rule is matched by the Pattern Matching module. A production rule is selected based on how well the conditions of execution associated with the production rule are met. The reader is referred to the ACT-R web site [25] for further information on the architecture and useful links.

SOAR (State, Operator And Result) Soar is another example of a production system-based cognitive architecture that implements goal-directed human behavior. It was created by John Laird, Allen Newell, and Paul Rosenbloom at Carnegie Mellon University [27]. Soar has been widely used by AI researchers to model different aspects of human behavior. Initially, Soar had been presented as a problem-solving architecture for artificial intelligence. Since then, Soar has been applied both within artificial intelligence and psychology for modeling human cognition.

Similar to ACT-R, underlying the Soar architecture is that knowledge representations can be made in forms of

procedural, declarative and episodic. Also Soar tries to address a collection of mechanisms of mind. Figure 3 illustrates a high-level Soar architecture showing major mechanisms.

Soar represents all tasks as collections of problem spaces, following Newell's problem space principle [29]. Problem spaces are made up of a set of states and operators that manipulate the states. Soar begins work on a task by choosing a problem space, then an initial state in the space. Soar represents the goal of the task as some final state in the problem state. There is a single current state that represents the information about the problem or task being processed, including information about the current situation, the current state of the model, the goal toward which the model is working, and information relevant to that goal. This information is brought into the Soar's dynamic memory (SDM). All productions that match the current contents of dynamic memory then fire in parallel. The results usually cause changes in the dynamic memory, so other productions may now match. Those productions are then allowed to fire causing further matching. This process continues until no new productions fire. At this time, there may be a set of possible actions available as results from the productions firing. Action decision is processed by the *preference system*. When an action is performed, this usually results in a new state, and thus the operation can be repeated.

All learning in Soar occurs through the "chunking" mechanism, which is a form of explanation-based learning and a by-product of impasse resolution [30]. When an impasse is resolved and results in a change in the contents of dynamic memory, information about the resolution is stored as a new production rule. Impasses occur frequently during problem solving in Soar therefore, so does learning. The reader is referred to the Soar web site [28] for complete documentations and useful inks.

EPIC (Executive-Process/Interactive-Control) EPIC is a cognitive architecture developed by David E. Kieras and David E. Meyer at the University of Michigan [31]. While ACT-R and Soar focus primarily on the internal information processing of humans, EPIC extends to include the perceptual and motor aspects of human cognition. A schematic overview of the EPIC architecture is shown in Fig. 4. It consists of a cognitive processor in the form of a production system, a set of perceptual and motor processors and a simulated task environment allowing interaction with the surroundings. EPIC has three types of simulated sensory organs: visual, auditory, and tactile. For each sensory organ, there is a perceptual processor that works in parallel to each other. These processors receive information from the sensory organs, convert it into a symbolic form, and send the symbolic representation into working memory.

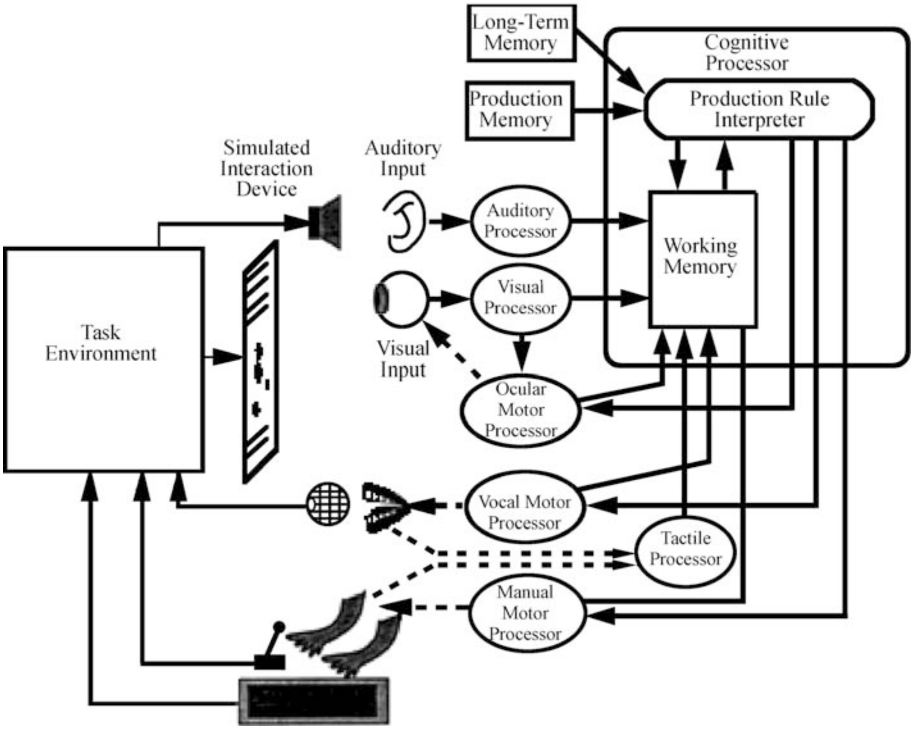
There are motor processors for each of the three sensory processors: ocular, vocal, and manual. The inputs to the motor processors are abstract symbolic representations of responses, which are then translated into explicit responses and passed to the motor processors. Information from the motor processors is passed to the working memory as a feedback.

Overall control of this architecture is attained through the use of task-specific control processes. There is no central control structure. Instead, production rules are used that are of the same form, but functionally separate from those used to encode information. Limitations in the EPIC architecture are postulated to be in the capacity of perceptual-motor processes.

The most important issue being pursued with EPIC is said to be the nature of human multiple-task performance. Major applications are user interface design to telephone operator workstations and cockpit systems, in which operation speed is critical and multiple perceptual and motor modalities are involved. The reader is referred to the EPIC web site [33] for complete documentations and useful inks.

Connectionist Approach

The connectionist approach to cognition provides an alternative theory of mind to the symbolic approach. It be-



Cognitive Robotics, Figure 4
EPIC architecture. Adapted from [31,32] with kind permission from Professor David Meyer

came popular in the 1980s and its popularity has not been diminished. The connectionist approach differs from the symbolic approach in almost all major dimensions. Connectionist (or parallel distributed processing) models offer many attractive features when compared with standard symbolic models. They include a level of biological plausibility, parallel distributed representations, pattern generalization performance, and adaptive learning.

Connectionist models represent information throughout a network of simple, but highly interconnected units or nodes. In some connectionist networks, each unit has a particular meaning. In others, such as neural networks, the nodes are individually meaningless and information is represented as a function of the simultaneous activation of multiple nodes. Neural networks [34] are one of the most popular connectionist models used in many fields, including artificial intelligence and robotics. The number of different connectionist architectures available today is large; to discuss them all is beyond the scope of this section. Instead, this section will focus on two unique architectures, which the authors believe generic enough to give the reader a good sense how to design connectionist-based cognitive robots. For more general discussion of connectionist approach, the reader is referred to an excellent review [35]. For more technical details, the reader is referred to, e. g. the Handbook on Parallel and Distributed Processing [36].

Connectionist Cognitive Machine Architecture Pentti Haikonen of Nokia Research Center takes a connectionist approach to build an embodied cognitive architecture. Instead of creating specialized models that reproduce cognitive processes directly at higher representational level like ACT-R, Haikonen proposes a cognitive architecture based on a distributed signal representation as a building block as shown in Fig. 5. In Fig. 5, “the preprocessed sensory information in the form of distributed signal representation is forwarded to feedback neurons, which also accept feed-

Haikonen's cognitive machine architecture. Reprinted from [37] with kind permission from Dr. Pentti Haikonen

back signals from the system". The feedback and the sensory information are compared with each other and the eventual match, mismatch and novelty conditions are indicated by respective signals. The internal feedback indicates also the intended act that is to be executed subsequently by the effector and will therefore be expected as the corresponding sensory percept. In that case, "the feedback signal is comparable to the so-called corollary discharge which is forwarded from the motor area to sensory areas in the brain" [37].

Figure 6 illustrates a schematic diagram of Haikonen's cognitive architecture. The cognitive architecture determines the cross-connections between the sensory perception/response loop modules of the Fig. 5. The architecture allows the association of complex additional meanings with percepts and also allows the generation of emotional significance, the "emotional soundtrack" to be associated with memorized entities and episodes. This emotional significance is then used to control attention. Each module works on its own and produces streams of percepts about environment and the module's own internal states. This output is then fed back to the feedback neurons and via this route becomes a percept.

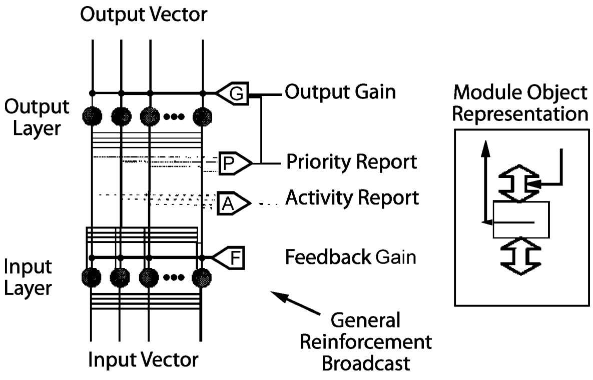
Typical neuronal unit model used in SNMs. Reprinted from [40] with kind permission from Dr. Jeffrey Krichmar

Synthetic Neural Modeling The synthetic neural modeling approach is a general method of testing theories of brain function at the system level [38]. It was developed by a group of researchers at the Neurosciences Institute over the last two decades. These models are designed to demonstrate the theory of neuronal group selection (TNGS) proposed by Edelman [39]. That is, it is based on the premise that neuronal circuits in the brain, formed with functional properties, the value of which is not knowable a priori, compete with one other to participate in the determination of behavior via strengthening of their connections with other brain circuits. Basic unit of selection in the TNGS are neuronal group, collections of dozens, or hundreds of neurons that are strongly connected to each other via synapses. A synthetic neural model (SNM) comprises a device, an environment and a neural system simulation [40]. Figure 7 shows a typical SNM unit (a) and its output (b). In (a), neuronal unit i receives input from N neuronal units via synaptic connections labeled c_{ij}, $j = 1, 2, \ldots, N$. Each connection has a relative strength that can be either excitatory (e. g. c_{i1} and c_{iN} are positive) or inhibitory (e. g. c_{i2} is negative). In (b), the output of a neuron is subject to a function based on its current activity and the input from other neurons. Below a specific threshold φ_i, the output is 0. SNMs have been embedded in a series of mobile robots called Darwin [38]. Section "Cognitive Robotics" includes a short description of such a Darwin model.

Hybrid Approach

The hybrid architecture is intended to capitalize on the complementary strengths of production-systems and connectionist architectures to implement a human dual processing theory of controlled and automatic processing.

CAP2 (Controlled and Automatic Processing 2) CAP2 is a hybrid cognitive architecture, incorporating both sym-



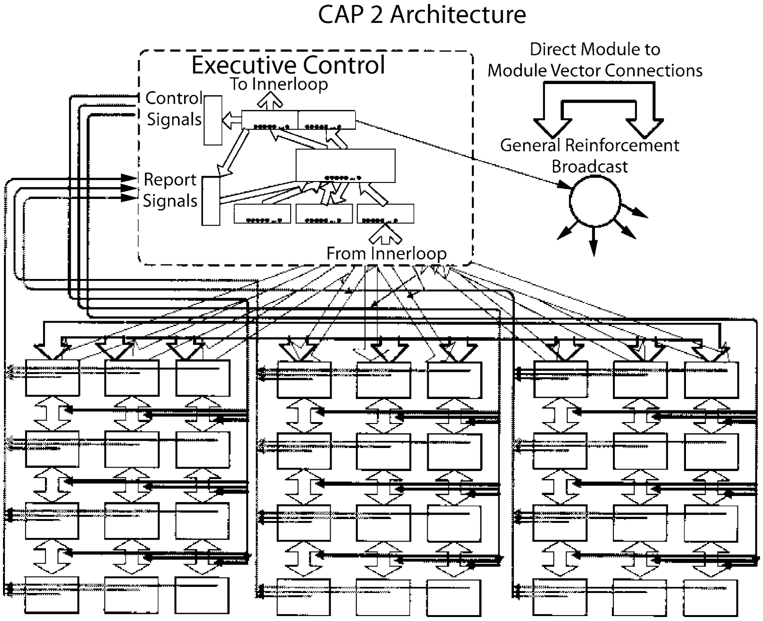
Cognitive Robotics, Figure 8
Microstructure of a CAP2 module. Reprinted from [41] with kind permission from Professor Walter Schneider

bolic (e. g., ACT-R) and connectionist (e. g., PDP) elements. It was developed by Walter Schneider and others at the University of Pittsburgh [41]. It is based on a human dual processing theory of automatic and controlled processing [42]. The CAP2 architecture is implemented with entirely connectionist components, but has networks that operate as sequential control structures to behave like a production system. The basic module of the CAP2 architecture is shown in Fig. 8. It involves two layers of units and five control signals. It is modeled after the cortical columns in the human cortex. An input vector of activation enters the module from below, passes through a connection matrix that reflects prior learning and evokes a new activation pattern in the input layer. The input layer then activates the output layer through a second connection matrix and sends a vector of activation to other modules.

A schematic overview of the CAP2 architecture, which implements a hierarchy of modules or modular processors is shown in the Fig. 9. At the top of this hierarchy is an executive control network, which is responsible for the control of the flow of information between modules. This control of information flow is conducted according to the current goal of the system, thus making it conceptually similar to the ARC-R architecture.

Cognitive Robotics

Now that the relevant aspects of cognition have been identified and the formative architectures in the field have been outlined, this section explores cognitive robotics. It does not attempt to provide necessary and sufficient measures for determining if a device is a cognitive robot as the field is still maturing and such definitions are likely to prove limiting when exploring the still somewhat unknown nature of cognition. Nor will this section present a history of cognitive robots as it is more insightful to detail important aspects of the field illustrating concepts with features of individual robots.



Cognitive Robotics, Figure 9
The CAP2 architecture showing three regions with four levels in each region. Reprinted from [41] with kind permission from Professor Walter Schneider

The first aspect is that a cognitive robot is embodied, which is commensurate with the situated nature of intelligence. It is noted that most robots have self-contained processing relating to a single environment often with a single objective. Increased wireless data transfer rates have resulted in the possibility of the processing being remote from the sensing and action. Furthermore, a single processor could now be embodied in multiple locations simultaneously, whilst communicating with other embodied and remotely embodied processes. Note: a disembodied processor has no online environmental interaction, which is employed occasionally where an offline agent is used to quickly develop promising strategies based on the model of the real environment built or learnt from embodied interactions.

Arguably the first robots exploring cognition were built by the cyberneticist Grey Walter in the late 1940s. The idea of cognitive robotics had not been developed in 1948 when the first tortoise was designed. The legacy of Grey Walter [43] is such that some of his ideas have influenced biologically inspired robotics and are still relevant today. The tortoises were based on analogue electronics as digital electronics barely existed at the time. They relied on relays – threshold devices – to implement behavioral transitions. Phototaxis behaviors were obtained as well as touch-controlled behavior and results were reported on the mirror test [44].

Walter was also an eminent neuroscientist, a field that continues to have much input and importance into cognitive robotics. This highlights the equal support of all the associated fields. This support is a two-way process, e. g. the intellectual challenge of creating cognitive robotics includes testing insights into natural cognition. One unique robot, or a design study, along this line is CRONOS robot (Fig. 10) being developed by Owen Holland [45]. Holland calls his approach *anthropomimetric robotics*.

Cybernetics arose from the realization that many seemingly diverse fields share similar properties; namely the importance of feedback from the environment to a system. This feedback is central to communication and control in order to achieve efficacy of action. The theoretical insight from cybernetics into dynamical systems is very relevant to cognitive robots.

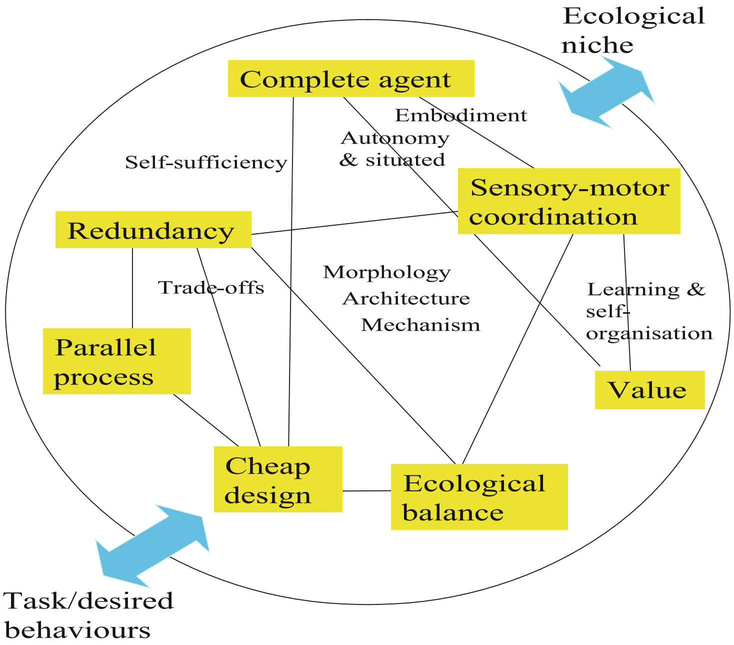
First-order cybernetics considers the effect of the environment through feedback on the robot, whilst second-order cybernetics acknowledges that the robot can also affect the environment and thus the meta-system must be taken into account. Consequently, the environment can determine the level of cognition that any robot can display. An example is where an exploratory robot has to learn only not to collide with obstacles, so the robot learns to stay away from obstacles by staying still. Braitenberg, a cybernetician and a neuroanatomist, originated the Braitenberg Vehicles as a thought experiment to "illuminate the key issues of what we may call cybernetics or artificial intelligence or cognitive science" [46] based on adjusting the morphology of a vehicle in order to respond differently to similar environmental stimuli [47].

Cognitive Robotics, Figure 10
CRONOS robot. Reprinted with kind permission from Professor Owen Holland

Morphological computation is an important modern research field where the robot is designed to complement the environment. Whereas evolution has had millennia to adapt creatures to their environment in order to exhibit cognition, robots must be designed to fit their environment. An example is the robot Puppy designed by Iida and Pfeifer [48], where stable gates are obtained through efficient mechanical design and simple processing rather than convoluted cognitive learning. A morphological design guide, adapted from Pfeifer and Scheier [49], is shown in Fig. 11.

Perception interfaces with the environment, so the sensor set-up of the robot is core to cognition. Human eyes are tuned to the wavelengths of primary colors so will have a stronger reaction to these colors (e. g. red) than a robot with a CCD camera that treats visible frequencies equally. Humans have multiple types of sensors (more than the anecdotal five), whilst robots may have many more (such as laser range finding). Thus robot cognition of an environment will differ, subtly or significantly, from human cognition.

Even if a human and a robot could be instantaneously given the same perceptions there is the *explanatory gap*, where the quality of the experience is important. Smelling



Cognitive Robotics, Figure 11
Morphological design guide. Adapted from [49]

a red rose will bring a deeper quality of experience to a human due to past associations. Humans also utilize *active perception*, where the perception of an object is deliberately manipulated in order to experience it to a greater extent. Thus a cognitive robot will need to perceive by exercising a skill, rather than passively receiving information.

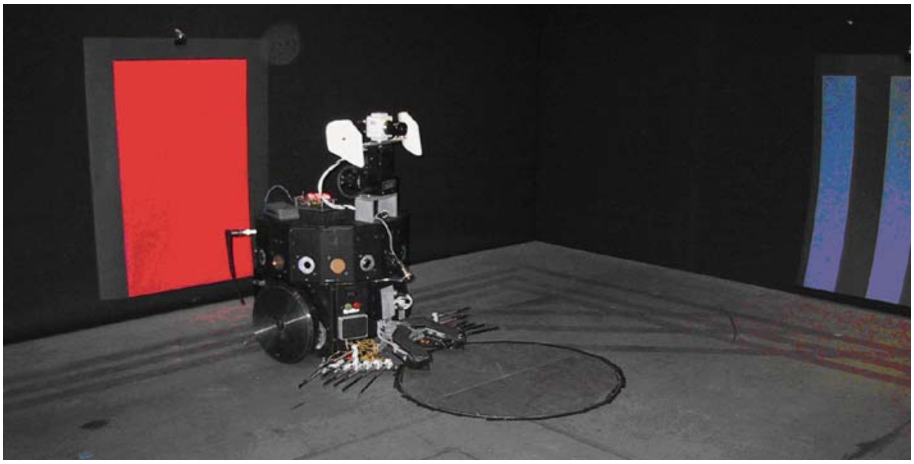
The perceptions need to be represented internally within a robot in order to manipulate them to determine the appropriate action. Either connectionist or symbolic representations may be utilized. Connectionist approaches reputedly mimic the representation in the human brain, which is difficult to understand. Symbols have proved useful when transparency for human readability and understanding of cognitive processing is required. The *symbolic grounding problem* [50] addresses how symbols get their meaning and in a deeper sense, what it is to experience the symbol. The word 'red' is very emotive to humans, but storing the letter sequence 'r e d' in a memory address does not have the same connotations. The more symbols are experienced, the greater the grounding.

A connectionist architecture based on the biological evidence has been successfully used by Krichmar [40] to replicate the behavior of rats in a Morris Water Maze (a simple water-based maze where a rat is required to use memory and path planning in order to locate a safe platform) (Fig. 12). Through much post processing of the learned artificial neuronal links an additional artificial pathway was deemed necessary, which was subsequently found to exist in nature. This is an example where cognitive studies can be enhanced through cognitive robotics.

Although it is possible to perceive and represent a multitude of external information it would be too slow and take too much memory if every detail was processed and stored. Thus a cognitive robot must have *attention* on the salient features of the domain, whilst ignoring others. This reasoning continues as the actions are available to the agent (*affordances*) within a domain must be determined for analysis/selection. Classical search is too slow so key feature selection is required. Once an action has been selected the *frame problem* (Frame Problem in Artificial Intelligence) occurs as the cognitive robot must determine what to update dependent on the results of effecting this action.

It has been argued that the mind has a central executive that acts as a librarian for memories [51]. Although this may provide a practical solution, it is undetermined what tells the central executive how to act. As an alternative approach, Noelle proposes that:

"Since working memory is employed extensively during cognitive processing in humans and animals, it is reasonable to conjecture that robots could benefit from the capabilities provided by a working memory system. Benefits could include the focusing of attention on the most relevant features of the current tasks" [52].



Cognitive Robotics, Figure 12
Darling robot exploring dry version of Morris Water Maze. Reprinted with kind permission from Dr. Jeffrey Krichmar

It is worth noting here that memory is not considered uniform in humans, with types such as episodic, procedural and semantic being identified [53]. Episodic memory encodes individual events, whilst semantic memory expresses the essence of memories. It is argued that a mechanism, such as abstraction, is required to transfer between episodic and semantic memory. Memory is also temporal in nature, which has caused much debate into its categorization. Long-term, short-term and working memory are hypothesized, but it is the ability to recall appropriate past events/lessons in a timely manner and compare these with prescient events that is important to cognitive robotics.

Learning from feedback encompasses one of the most active areas of AI research, so it will not be detailed here. Instead, a few important aspects for cognitive robotics are highlighted. To map the vast world into memory requires compactness as well as the recall of salient features. States, actions and feedback can be *imprinted*, which although reliable is memory intensive. The ability to *generalize*, i. e. remove irrelevant information, improves performance but more steps are necessary. *Abstraction* is where patterns, both spatial and temporal, are identified independent of their associations, e. g. the concept of a tree without recalling specific instances. The ability to scale learning is a main challenge in the field of AI.

Many advanced robotic platforms exist or are emerging, such as ASIMO [16] and iCub [19]. Unfortunately, many modern actuators require much power, space and advanced control. Lack of compliance, which is inherent in most animals and other material properties, can limit the behavior in a cognitive robot. CRONOS [45] is an example of a platform with natural actions to mimic human cognition. Thus a new 'breed' of robots will require new control methods as their nonlinear nature results in many existing control methods being invalid.

Now that we have considered an embodied robot with the rudiments of cognition, there are aspects of cognition, behavior and social interaction that need to be considered.

A cognitive robot will need to plan a series of actions over time. This will require a series of state-action links, an internal world model, or a method that utilizes the world itself as a model. Cartesian theater, global workspace [54] and other architectures have been proposed for such a model.

Despite the ability to memorize and learn from situations, a robot will need to react to unknown/unfamiliar situations. Interpolation and extrapolation are popular techniques, but are often hard to compute and cannot be guaranteed to be effective. Instead, artificial emotions are being considered as action modifiers, goal setters and decision makers. Emotions are also useful to aid human robotic interaction, but their cognitive uses are much wider [55].

Most previous robots were designed to achieve a single or limited number of similar tasks and goals. Increasing the range of competencies of a robot will require it to select between goals, so a value system will be needed on which to base decision-making. Science fiction may suggest hard-coded laws for robotics [56], but this could lead to conflicts and contradictions. Debates have begun on the ethics and legal aspects of giving robots autonomy in goal setting, especially if this enables new goals to be determined.

Robots operating in a domestic or social setting will need to assess the intentions of others to aid collaboration and prevent destructions/accidents. Humans have inherited neural circuitry to recognize faces and use body language/gestures as important communication tools. Much work is required in this field and it is unproven on how humans will react to robots in a social setting [5].

Work in the 1970s by Masahiro Mori on the Uncanny Valley hypothesizes that a robot must appear and behave very humanlike to be acceptable [57]. Alternatively it is better to make the robot mechanical in appearance, so it would be acceptable as a mechanoid.

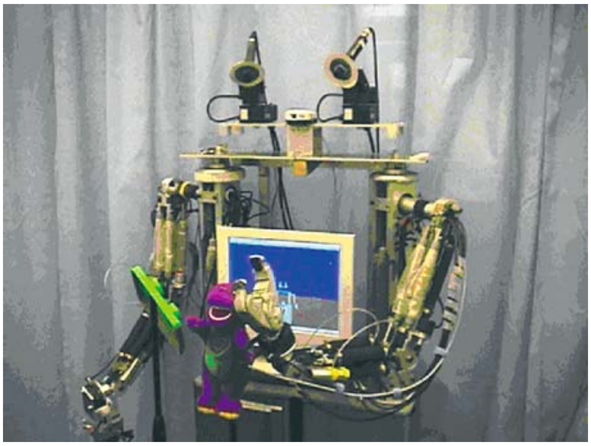
After considering what future cognitive robots may need it is worth noting that their processing is unlikely to be serial, silicon-based digital systems. Parallel systems are more timely when processing large quantities of data. Analog systems could encompass non-linear and possibly nondeterministic behavior. Finally, biological substrates, which exhibit both the above properties, are being developed for use in robot control [58].

Case Study

Introduction

This section presents a case study on the humanoid robot ISAC [59] that one of the authors (Kawamura) is developing. Specifically, the task of reaching for a named object involving internal rehearsal is explored as sense, memory and planning are all required and the implementation of an 'inner sense' where sensory experiences and consequences of different behaviors may be anticipated is developed.

The first lesson is that humanoid robots are indeed complex systems due to the number of components that must interact. Figure 13 shows ISAC that is an upper bodied humanoid robot incorporating stereo vision, audio and touch sensors with pneumatic actuation for multiple arm and hand movement. Sensing inputs are mapped to non-linear and flexible actuators through parallel, distributed processing that represent perception, reasoning and learning.



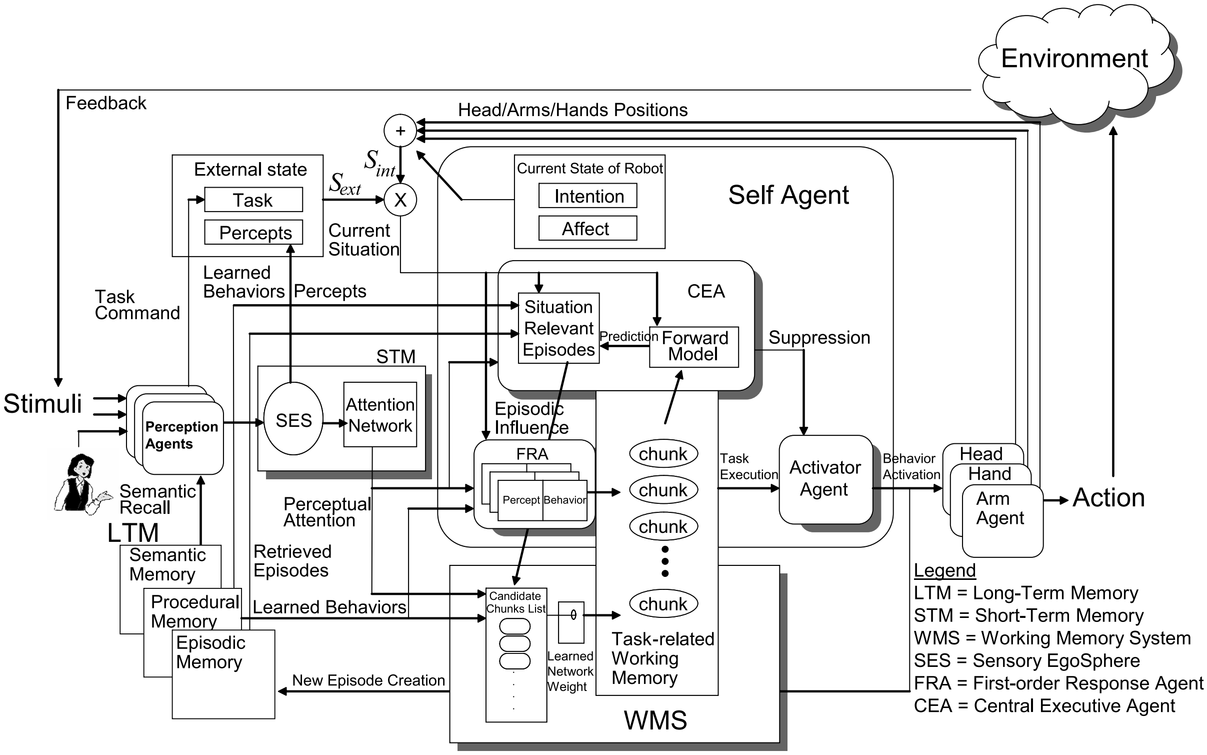
Cognitive Robotics, Figure 13
ISAC reaching to Barney with left arm

Architecture

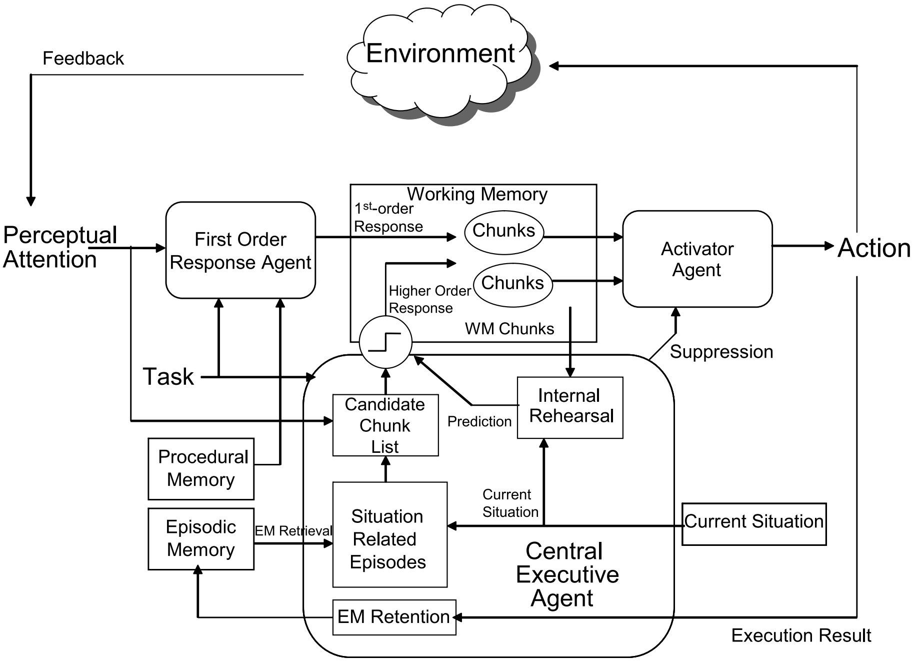
During earlier development it was realized that enhancement and maintenance of such robotic software systems could benefit from domain-specific guidelines that promote code reuse and integration through software agents. This led his group to develop a multiagent-based robot control architecture based on the Intelligent Machine Architecture (IMA) [60,61]. IMA allows for modular design and the development of subsystems from perception modeling to behavior control through the collections of software agents and associated memories. Figure 14 was configured using IMA agents and associated memory structures. It consists of a number of IMA agents and a set of memory structures. Within the cognitive architecture, the Self Agent represents the robot's self [62] and is responsible for multiple aspects of cognition including internal rehearsal.

In the ISAC architecture, the Self Agent handles the dual sensory-motor loops as shown in Fig. 15. The First–Order Response Agent (FRA) is responsible for the reactive and routine responses of the system while the Central Executive Agent (CEA) is responsible for the cognitive response. The Internal Rehearsal System (IRS) takes the working memory chunks as the motor commands, the current situation as the external state and sends a rehearsed result to CEA. If IRS produces a poor prediction, CEA will suppress the Activator Agent, replace the working memory chunks, and tell the Activator Agent to switch action.

It is known that humans are able to have sensory experiences in the absences of external stimuli as illustrated by experimental results of, e. g. Lee and Thompson [63]. It thus seemed reasonable to assume the existence of an 'inner sense' where sensory experiences and consequences of different behaviors may be anticipated. The idea of the existence of such an inner sense (or model) does not necessary go against the theory of embedded intelligence advocated by a number of researchers e. g., Brooks [64], Clancy [65], Clark [66], Pfeifer [49] who de-emphasize the role of internal world models and instead emphasize the situated and embodied nature of intelligence. An alternative to internal world models is the 'simulation hypothesis' by Hesslow [67] which accounts for the 'inner world' in terms of internal simulation of perception and behavior. Kawamura's approach may be termed as a "grounded



Cognitive Robotics, Figure 14
IMA-based cognitive robot architecture

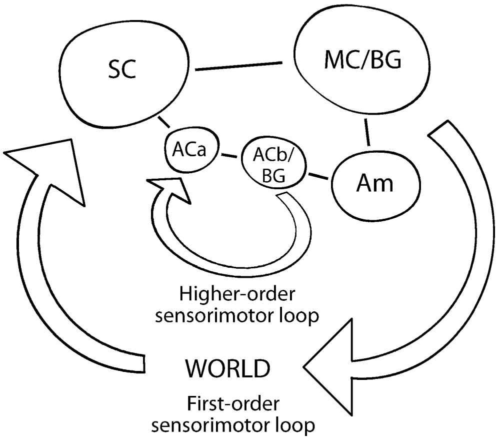


Cognitive Robotics, Figure 15
ISAC self agent cognitive cycle

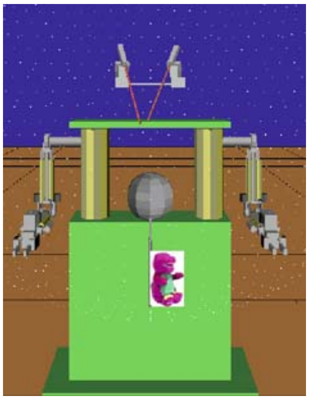
internal simulation" utilizing one type of internal representation of perception and behavior.

Design of the Internal Rehearsal System (IRS)

Brain-inspired internal simulation research has now moved into the robotics field. For example, Shanahan [68] proposed a cognitive architecture for a mobile robot, shown in Fig. 16, involving two sensory-motor loops: the reactive or first-order loop and the cognitive or higher-order loop. The first-order loop involves the sensory cortex (SC), motor cortex (MC), and basal ganglia (BG). This loop directly maps sensory input to motor actuation. The higher-order loop internally rehearses the decision from the first-order loop and changes the output of the system based on the observation of this rehearsal through the Amygdala (Am) or the emotion system.



Cognitive Robotics, Figure 16
A top-level schematic diagram of two interacting sensory-motor loops in the brain. Adapted from [68]



Cognitive Robotics, Figure 17
ISAC simulator displaying a Barney doll as a sphere

When IRS is invoked by CEA, it takes the current behavior chunk as the motor command and the current environment ISAC is in as the current state. After CEA selects a behavior to perform the skill described by the task, IRS internally rehearses the behavior with the percept corresponding to the current. If a collision occurs with the percept during the rehearsal, IRS returns the percept, the step in interpolation where the collision occurred, and the total number of joint steps in the interpolated motion to CEA.

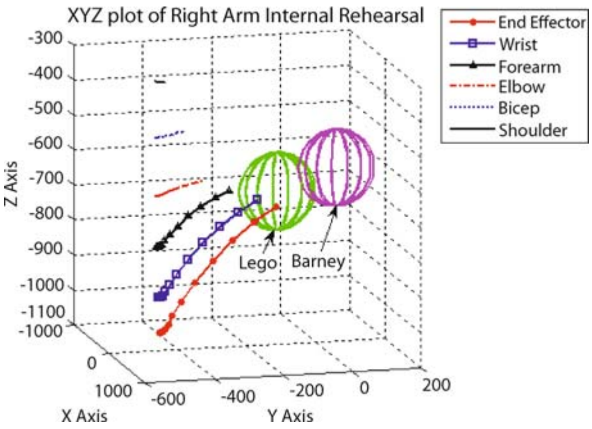
The following experiment is designed to evaluate how FRA, CEA, and IRS work together. The experiment involves two percepts: Barney (target) and a Lego toy (obstacle) (Fig. 17).

1. A task to *reach-to-Barney* is given to ISAC. FRA immediately places ReachRight and Barney into the working memory (WM) as chunks.
2. Using the chunks, IRS will try to reach to the Barney with the right arm, but predicts a collision with the Lego toy.
3. CEA will suppress the Activator Agent based on this prediction from IRS.
4. CEA will use the episodic retrieval technique and replace the chunk ReachRight to ReachLeft.
5. IRS will reach to the Barney with the virtual left arm. This reach will be successful.
6. CEA will let the Activator Agent proceed to reach to the Barney using the left arm.

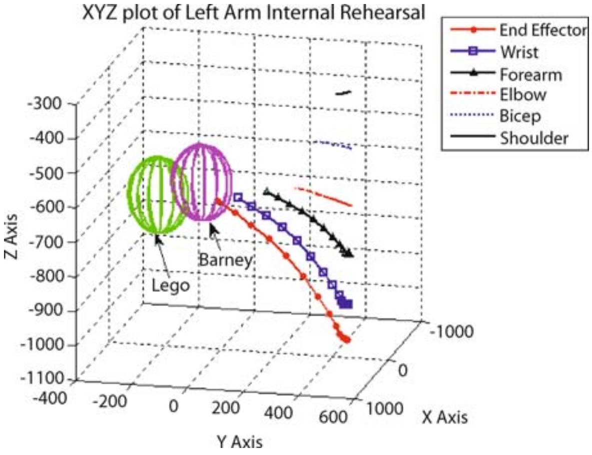
Performance

When ISAC was given a command to reach to the Barney, FRA placed two chunks "ReachRight" and "Barney" into the working memory (Note: ISAC normally begins with its right arm). Both the Activator Agent and IRS began to process these chunks. IRS completed the computation within 3.2 s and sent its results to CEA. At the same time, the Activator Agent sent a motion command to the Right Arm Agent to perform the reaching motion. The Right Arm Agent would take 11 s to perform this type of reach if no obstacle exists. When IRS finished, the following output was sent to CEA: [15 68 lego_toy]. This means that during the simulation, IRS determined a collision with the Lego toy in the fifteenth step of the interpolated *reach* behavior out of the total of 68 interpolated steps. Figure 18 shows the trajectories of the right arm collision points during the rehearsal. CEA took this result and determined that it did not reach to the Barney. CEA then suppressed the Activator Agent and prevented the right arm from further action.

CEA then decided to use the left arm and replaces the working memory chunks with "ReachLeft" and "Barney".



Cognitive Robotics, Figure 18
Right arm internal rehearsal



Cognitive Robotics, Figure 19
Left arm internal rehearsal

IRS and the Activator Agent were once again initiated, and IRS internally rehearsed the reach skill and determined no collision with the Lego toy (Fig. 19). Both the wrist and end effector points entered the Barney percept sphere on the sixteenth step out of the total of 69 interpolation steps. CEA determines this as a success and did not impede the Activator Agent thus allowing ISAC to reach to Barney using the left arm (Fig. 13).

Summary

This section illustrated how dual mechanisms of coupled real world of action-taking loop and off-line inner reasoning loop can work together to improve cognitive skills for a robot using internal rehearsal.

Future Directions

Cognitive robotics is still an evolving field with many possible and exciting future directions. To date, much progress has been made in architecture, perception, mobility, reasoning, learning from environmental embodiment, and advanced actuators. However, it will take years before we will see truly integrated cognitive robots in everyday life.

A few of the challenges to cognitive robots are listed below:

- Developing flexible systems, with ability to cope with multiple tasks, environments and disturbances
- Design strategies for learning by taking into account morphological and material constraints
- Cognitive skills development through social interaction
- Robots with mental states and emotions
- Modeling consciousness and its interaction with cognition
- Built in sensation and communication.

As robotic technology continues to penetrate every aspect of human society, the importance of social acceptance, such as trustworthiness and ethics, will become important. The field of cognitive robotics is expected to play a leading role in this area in the future. It is our hope that within decades, we will see true cognitive robots that will be accepted by the general public.

Article Outline

Glossary

Elastic manifold An elastic manifold is a spatially extended object whose energy is given by a quadratic function of the gradients of its transverse displacements. In statistical physics, it is used as a coarse-grained description of the low-energy modes in an ordered structure.

Pinning Pinning is a common phenomenon in condensed systems where the relevant degrees of freedom are trapped to an energy minimum and hence respond dynamically only when the external driving exceeds a certain threshold. Pinning is often caused by defects or impurities in the system but it may also be due to intrinsic properties such as the existence of a periodic lattice that breaks the translational symmetry of space.

Scaling Scaling describes power-law relationships among two or more physical quantities. Physical systems at continuous phase transitions are often found to exhibit scale invariance, i. e., structural and dynamic properties on different length and time scales can be mapped onto each other through suitable scale transformations. Such properties are characterized by a set of scaling exponents. The renormalization group theory, through its flow equations under a scale transformation, provides a systematic method to compute these exponents.

Universality Universality is a key concept in the classification of systems which exhibit scale invariance. Models in the same universality class have identical scaling properties and are described by the same set of scaling exponents. Therefore the identification of possible universality classes is one of the key issues in the study of, e. g., critical phenomenon at continuous phase transitions. The origin of universality is best illustrated by the fixed-point structure of the renormalization group flow equations. Studies have shown that dimensionality, symmetry, and conservation laws are the key factors that determine a particular universality class. There is, however, a great deal of theoretical interest to identify new principles that determine universality classes, or exceptions to the above rule, particularly in driven nonequilibrium systems.

Definition of the Subject

Collective transport takes place in systems which exhibit highly correlated response to external driving. This is in contrast to, e. g., electrical conduction in a normal metal, where free electrons drift independently under an applied electric field, leading to Ohm's law. Collective motion of microscopic degrees of freedom, on the other hand, often yields a nonlinear response or even threshold behavior, where steady-state transport sets in only when the driving exceeds a certain critical strength. In the subcritical regime, the collective modes are pinned by defects or impurities in the system. An increasing degree of correlation and corporation takes place as the threshold is approached. The subject plays an important role in the study of a broad class of solid state phenomena, including charge and spin density wave transport, hysteresis in dirty magnets, and nonlinear current-voltage characteristics in type-II superconductors. It has also found interesting applications outside physics, such as in crack propagation and earthquake modeling. Important theoretical developments that took place in the early 1990s culminated in the formulation of a functional renormalization group theory for the nonequilibrium depinning transition. The analytical framework enables systematic computation of the critical properties and, perhaps more importantly, elucidation of universality through its fixed point structures. Subsequent work by many research groups have established a close link between driven depinning and the sandpile models of self-organized criticality (SOC). This connection has been fruitfully explored to gain a better understanding of the long-range spatial correlations and intermittent temporal activities in the two classes of problems.

Introduction

The motion of a water drop down a glass window under gravity illustrates many salient features of collective transport and depinning, although the phenomenon itself is surprisingly rich in physics and chemistry when examined in microscopic detail [18,51,73]. The size of the drop is governed by the so called capillary length (typically of the order of a few millimeters) from elementary physics: On this scale the surface tension that makes a water drop spherical competes with the gravity which acts to deform the droplet. The actual descent of the droplet, which usually follows a zigzag path with an ever changing speed, is a result of many factors, not least the random force set by the local wettability of the glass surface. With a microscope, one may observe the hysteric advancement of the contact line separating wet and dry regions on the substrate. The interplay between the surface tension, the pinning force on the contact line, and the driving force provided by gravity gives rise to a complex and intermittent dynamical behavior encompassing a wide range of length and time scales.

Similar types of collective and intermittent transport exist in solids. In certain low-dimensional materials such as $NbSe_3$, periodic modulation of the electronic density, known as the charge-density-wave (CDW) [33], develops spontaneously at sufficiently low temperatures through the Peierls instability. An applied electric field in the direction of the charge modulation exerts a body force on the CDW much the same way as gravity does on the water droplet. However, in the presence of impurity atoms or crystal defects, the CDW does not move unless the electric field exceeds a certain threshold value, as seen in experiments [33,85]. The vortex lattice in type-II superconductors is another example of modulated electronic structures within a solid [44]. Pinning of the vortex lattice by intrinsic or artificial defects is essential for achieving a high critical supercurrent in these materials.

Yet another class of collective pinning phenomena in solids involves the dynamics of topological defects such as crystal dislocations [31] or magnetic domain walls [10]. These objects have internal dimensions lower than that of the embedding medium, and hence can explore inhomogeneities in the surrounding environment. The driven motion of these objects has a great effect on the physical properties of their host system, e. g. plastic deformation of a solid due to glide and climb motion of dislocations, and hysteresis effect [78,80,88] related to the pinning of domain walls separating regions of opposite magnetization.

The development of quantitative theories for impurity pinning and the driven depinning transition began in the 1970s after fundamental breakthroughs in many-body physics and equilibrium critical phenomena [29,44,45,50]. Research in this area has traditionally followed two separate approaches: The microscopic approach that attempts to explain the observed behavior starting from the fundamental laws of physics, and the phenomenological approach that focuses on the large-scale properties using the simplest models possible. The second approach, which is popular in the field of statistical physics, has the advantage of mathematical simplicity and clarity. It facilitates identification of the underlying symmetries of the original problem, and the establishment of universality classes through which model systems can be classified and compared. However, real physical systems often contain complications that prevent a direct comparison between model predictions and experimental observations (see, e. g. [85]). This is where the microscopic approach, popular among condensed matter theorists, comes to aid. In the best studied cases, a microscopic theory allows one to derive or estimate system-specific parameters and properties, and to suggest correct phenomenological models and possible improvements when discrepancies are found.

The present article focuses on the recent theoretical developments in the statistical physics of this class of problems. This is partly motivated by the significant progress that has been achieved in a quantitative characterization of the depinning transition over the past two decades. Similar to the critical phenomena in thermal equilibrium systems, static and dynamic fluctuations exhibit scaling properties with exponents that fall into well-defined universality classes determined by the symmetry and dimensionality of the problem. These concepts allow one to establish precise relationships among models proposed under different physical contexts. The successful application of the renormalization group methods to the depinning transition has led to a deeper analytical understanding of the observed critical phenomena. Our choice is also motivated by the close connection between depinning and the subject of self-organized criticality [5], which enjoys broad interest in the complexity community.

We shall start with a brief review of systems, mostly from solid state physics, where collective modes and depinning play an important role in the interpretation of the observed transport phenomenon. A generic mathematical formulation of this class of problems, known as the elastic manifold in a disordered potential, is introduced, along with a discussion of the complex energy landscape underlying its equilibrium and dynamic properties. This is followed by a description of the critical properties at the driven depinning transition and numerical results. The basic analytic structure of the threshold solution can be seen in a mean-field theory. We then summarize the main results of functional renormalization group calculations which provide a systematic and quantitative characterization of the depinning transition. The relationship between driven depinning and self-organized criticality is explained. The influence of medium anisotropy on the depinning transition is briefly discussed. Finally, we mention a few open problems in the field for future work.

Elastic Manifolds and Impurity Pinning

Elasticity, Order, and Symmetry Breaking

Although long-range spatial correlations that underlie collective transport can be generated dynamically under certain conditions, we shall focus on systems for which such correlations are already present before external driving is applied. In particular, we shall assume that the system is in a low temperature ordered state and responds elastically to external perturbations. This assumption allows us to concentrate on the large scale properties of the system in the depinning process, while leaving the microscopic, system-specific behavior to a separate discussion.

Elasticity is a familiar concept in macroscopic physics. An object is said to be *elastic* if it deforms under an applied force in a continuous and reversible manner. Microscopically, elasticity is intimately related to the existence of an ordered state that breaks a continuous symmetry [4]. This point can be appreciated with the example of a crystalline solid. Atoms in the solid form a periodic structure in space with energetically preferred unit cells and lattice constants. This state is said to break the translational symmetry of the particle system as the density of atoms is no longer uniform in space. A uniform translation of the structure does not lead to a change in the system energy. On the other hand, relative displacement of atoms distorts the unit cells and leads to an increase in energy which grows quadratically with the displacement. Thus, the system has acquired a form of rigidity by breaking a continuous symmetry to gain order. Elasticity is a manifestation of this rigidity when the ordered state is perturbed by external forces or internal impurities and defects.

Both charge-density waves and vortex lattices are periodic structures in space, and hence naturally their behavior is similar to a crystalline solid. There are, however, differences in the number of components needed to describe a generic deformation in each case. A CDW with a single modulation wave vector $\mathbf{Q}$ corresponds to an electron density $\rho(\mathbf{r}) = \rho_0 + \rho_1 \cos(\mathbf{Q} \cdot \mathbf{r} + \varphi)$, where ρ_0 is the average density and ρ_1 the modulation amplitude due to charge ordering. A uniform phase shift $\varphi \to \varphi + c$ moves the CDW uniformly against the underlying lattice. Weak deformation of the CDW is described by a spatially varying phase $\varphi(\mathbf{r})$. The elastic energy of a CDW depends quadratically on the phase gradient $\nabla\varphi$, with different elastic constants along and perpendicular to the modulation vector $\mathbf{Q}$ [29]. In the case of the vortex lattice, a two-component vector field $\mathbf{u}(\mathbf{r})$ perpendicular to the vortex lines is needed to describe a general distortion of the ideal structure. The construction of the elastic energy parallels that of a crystalline solid. In an isotropic medium, three elastic constants are needed to describe the energetics of a vortex line array [44,45].

Topological defects in an ordered structure also behave elastically when deformed from their ideal positions under a great variety of circumstances, though this form of elasticity has a different microscopic origin. A dislocation in a solid, for example, has a core where the atomic arrangement differs from elsewhere in the crystal. This gives rise to an excess amount of energy proportional to the length of the line. The interface between two bulk phases has an excess free energy (commonly known as the surface tension) proportional to the surface area for the same reason. This applies also to domain walls in a magnet.

Elastic Manifolds in a Disordered Potential

The energy of a topological defect is affected by the presence of impurities or point defects in the system. For example, an impurity atom sitting in the core of a dislocation has a different atomic environment and hence a different energy than when it resides in a normal region. This effect gives rise to a short-range and often attractive force between the impurity and the dislocation core. The tendency for the dislocation to distort itself in order to adapt to the impurity configuration is countered by the elastic energy cost. In general, the two competing forces lead to a large number of metastable conformations of the dislocation core, separated by energy barriers. The effect of impurities on interfaces and magnetic domain walls can be considered in a similar way.

A unified statistical mechanical description of impurity pinning can be formulated in terms of a D-dimensional elastic manifold embedded in d spatial dimensions [28,34,49]. Let $\mathbf{r} \in R^D$ be the internal coordinates of the manifold and $\mathbf{u}(\mathbf{r}) \in R^{d-D}$ be the transverse displacement of the manifold at point $\mathbf{r}$ with respect to a flat configuration. When the deformation is small, the excess volume of the manifold is a quadratic function of the gradient of $\mathbf{u}(\mathbf{r})$. The following energy function includes effects of both elasticity and impurities,

$$E(\{\mathbf{u}\}) = \int \mathrm{d}^D r \left[\frac{\gamma}{2} |\nabla \mathbf{u}|^2 + V_R(\mathbf{r}, \mathbf{u})\right] . \qquad (1)$$

Here γ is the stiffness constant of the manifold, and $V_R(\mathbf{r}, \mathbf{u})$ is a random potential arising from the interaction between the manifold and the impurities in the medium. In most theoretical treatments, the set of random variables $\{V_R(\mathbf{r}, \mathbf{u})\}$, which take particular values in a given sample, is assumed to be Gaussian distributed with the mean $\langle V_R(\mathbf{r}, \mathbf{u})\rangle = 0$ and the second moment $\langle V_R(\mathbf{r}_1, \mathbf{u}_1) V_R(\mathbf{r}_2, \mathbf{u}_2)\rangle = R(\mathbf{u}_1 - \mathbf{u}_2)\,\delta(\mathbf{r}_1 - \mathbf{r}_2)$. Here $\delta(\mathbf{r})$ is a short-ranged function which vanishes beyond a coarse-graining length $a_\parallel$.

The form of the disorder correlator $R(\mathbf{u})$ in the transverse directions is dictated by the symmetries of the original physical problem [28]. For contact interactions and randomly distributed impurities in the embedding space, $R(\mathbf{u})$ is short-ranged with a characteristic decay length $a_\perp$. A different situation is encountered when the manifold represents an interface that separates two bulk phases, each affected differently by the impurities which serve as a "random field" (i. e., the impurity atom has different chemical potential in the two bulk phases). The potential $V_R(\mathbf{r}, u)$ represents the cumulative effect of impurities swept by the interface when it is displaced to $u(\mathbf{r})$ from a reference configuration. Consequently $R(u) \sim |u|$ for large u.

A CDW in the presence of impurities can also be described by Eq. (1), where $u(\mathbf{r}) = \varphi(\mathbf{r})$ is a scalar field and $\mathrm{d} = D$. Since the impurity interacts with the local charge density which is a periodic function of the local phase, the potential $V_R(\mathbf{r}, \varphi)$ is also periodic in φ. Consequently, $R(\varphi)$ is periodic in φ as well.

Application of Eq. (1) to the vortex lattice requires special care. On scales smaller than the spacing between vortex lines, each vortex line behaves as an independent object. However, this description fails on large scales, where the periodicity of the lattice changes the nature of the problem [30,68].

Rugged Energy Landscape, Critical Dimension, and the Pinning Length
