What if biological coordination were shown to be a self-organized phenomenon? Might that be a springboard to finding laws of coordination? In the sense of T.S. Kuhn [131] such questions appear to call out for a new paradigm, special entry points where irrelevant details may be pruned away exposing the essential aspects one is trying to understand. Inspired by synergetics (and paradoxical though it may seem) the key to determining if coordination as a self-organized phenomenon is to focus on *qualitative change*, places where abrupt switches or bifurcations in coordination occur. Qualitative change is crucial because it affords a clear distinction between one coordination pattern and another, thereby enabling one to identify the key *collective variables or order parameters* that define coordination states and their coordination dynamics. If a complex system is changing smoothly and linearly it is hard to distinguish the variables that matter, so-called state variables, from the ones that don't. Qualitative change may also be used to infer relevant quantities in more naturalistic settings. In situations where many variables may be changing in uncontrolled ways, the one(s) that change(s) abruptly are likely to be the most meaningful, both for the phenomena themselves and our understanding of them [96]. Likewise, any parameter that induces qualitative behavioral change qualifies as a *control parameter*. This is the reason why stability is so important. As a control parameter crosses a critical value the previously stable pattern becomes unstable and the system switches to a different pattern that is now stable beyond the critical point. The quite general predictions of nonequilibrium phase transition theory are a strong enhancement of fluctuations (critical fluctuations) and a strong increase in the pattern's relaxation time (critical slowing down) as the transition is approached. Obviously, if nonequilibrium phase transitions are a basic mechanism of self-organization and if, as hypothesized, the forces of evolution and self-organization form the core of biological order and coordination, it should be possible to discover nonequilibrium phase transitions and their signature features in real experiments. If not, the theory that coordination in living things is due fundamentally to self-organization must go the way of all beautiful theories that are negated by the facts.

Empirical Foundations of Coordination Dynamics: Pattern Generation, Stability and Phase Transitions

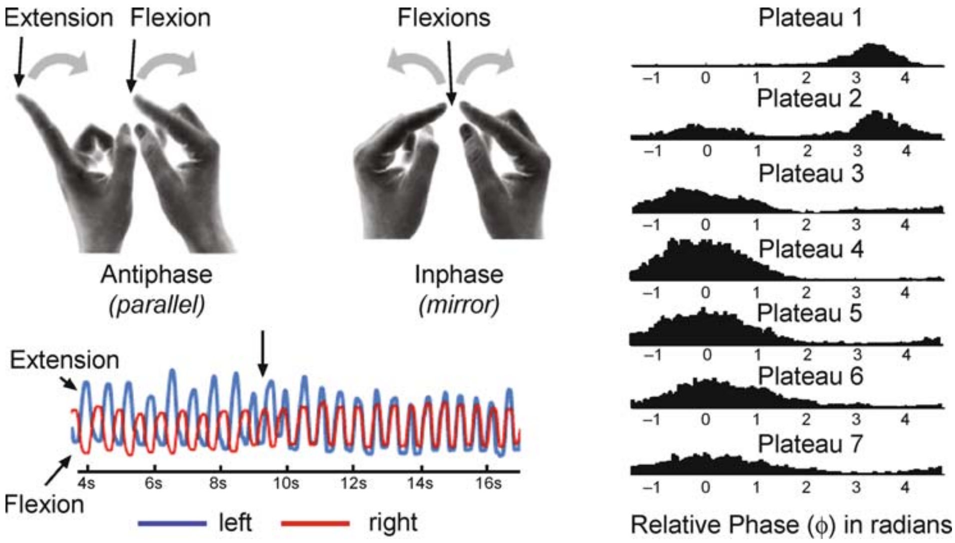
In coordination dynamics, the payoff of knowing collective variables and control parameters is high: they enable one to obtain the dynamical rules of behavior on a chosen level of description. By adopting the same strategy "one level down", the individual components and their dynamics may be studied and identified. It is the nonlinear interaction between the parts that creates coordinative patterns of the whole thereby building a bridge across levels of description (Table 1). This ability to derive phenomena from lower levels of description is at the core of what scientists usually mean by the word "understanding". In general, in complex living systems it is difficult to isolate the components and study their dynamics. The reason is that the individual components seldom exist outside the context of the functioning whole, and have to be studied as such.

If phase transitions hold the key to finding laws of coordination, where should we look for them? A central criterion for a law-based approach to coordination is reproducibility of the phenomenon in question. Although not everything is rhythmic, rhythms represent a wide variety of coordinated behaviors in a very large number of different biological systems at very many levels [24,70,71,97,119,174,212,215] and seem like an obvious entry point. One only has to look at the extensive field of so-called "central pattern generators" (CPGs) in invertebrate and vertebrate neurobiology to find remarkable similarities in the patterns that living creatures produce. Terms such as "swimming" CPG, "flight" CPG, and "locomotor" CPG reflect the reproducibility of patterns and their functional significance. Synchronization and desynchronization, frequency- and phase-locking are ubiquitous features of such patterns reflecting a high degree of neural and behavioral coordination (see Sects. "History of Coordination Dynamics: Synergy and Rhythmic Order" and "Coordination of Multiple Components: From Quadrupeds to Brains").

What then of phase transitions? And what connection exists, if any, between rhythms and phase transitions? It is well-known that quadrupeds and indeed many creatures including birds and fish exhibit characteristic gaits and may switch flexibly between them depending on circumstances. In the neurobiology literature, a key question is always "where are the switches in this thing"? [1]. Rather than assume the existence of switches, a priori, the scientific approach of coordination dynamics is to investigate the necessary and sufficient conditions that give rise to switching. Inspired by theories of self-organization in nature, coordination dynamics asks if switching may take the form of a nonequilibrium phase transition. The idea is not so far fetched as it seems. Many years ago, order-order transitions were hypothesized by Erwin Schrödinger [178] to be a crucial principle of biological organization and hypothesized to be the "new laws in the organism" [109].

Three Deceptively Simple Experiments

To investigate order-order transitions experimentally, consider an experimental paradigm introduced some years ago in which human beings are asked to move their two index fingers back and forth rhythmically [94,95]. In one condition (call it parallel, Fig. 1) they are told to alternate finger movements at a comfortable rate, one finger flexing in time as the other extends. In another separate condition (call it mirror) they are told to flex both fingers together and extend both fingers together at the same time. The key part of the experiment is that participants are instructed to increase the speed at which they perform these movements. For better experimental control a pacing metronome whose frequency can be systematically increased (say every 10 cycles called a plateau) may be used for subjects to follow. The main results are shown in Fig. 1 and described in the figure's caption.



Coordination Dynamics, Figure 1

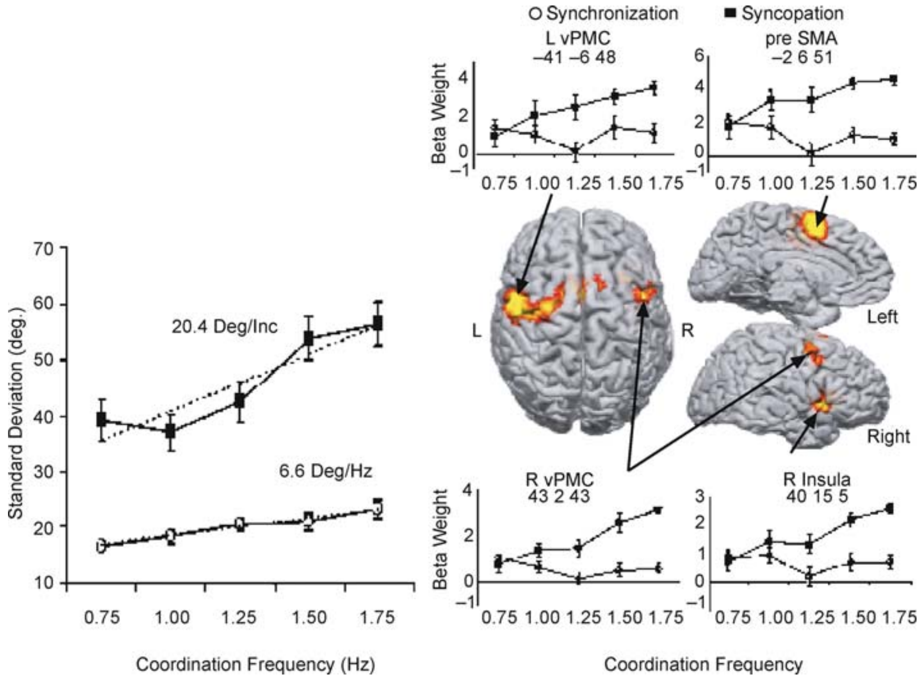
Phase transitions in bimanual movements. *Left side*. On the top are the two experimental conditions (parallel, antiphase and mirror, in phase) in the Kelso paradigm. The lower plot shows the time series of the finger movements in a representative run. As rate increases, trials initiated in the antiphase pattern spontaneously switch to the in-phase mirror pattern. The critical frequency is identified with an arrow. In contrast, trials initiated in the in-phase pattern do not switch as frequency increases (not shown). *Right side*. Distributions of relative phase between finger movements for plateaus of increasing frequency of movement. Initially the relative phase is concentrated at π radians, indicating antiphase is a stable pattern. On *plateau 2*, relative phase is concentrated around 0 and π radians, showing the bistability of antiphase and inphase coordination. For higher frequency plateaus the relative phase is concentrated at 0 radians, indicating that inphase is the only stable pattern of coordination (adapted from [7] with permission)

Experimental studies of bimanual rhythmic movement demonstrate that humans in the absence of learning procedures are able to produce two patterns of coordination at low frequency values, but only one – the symmetrical, in-phase mode – as frequency is scaled beyond a critical value. This is a remarkable result given the complexity of the nervous system, the body and their interaction with the world.

Consider another example, this time involving a human coordinating with an environmental signal [115,218]. In this experimental setup a single limb or finger is moved such that peak flexion occurs in between the beats of a pacing metronome, i. e. in a syncopated fashion. When the metronome frequency is increased, once again a critical value is reached where participants switch spontaneously to coordinating peak flexion on the beat, i. e. in a pattern of synchronization with the metronome. No such switching occurs when subjects begin in the synchronized mode of coordination. We may refer to these effects as a very basic example of *coordination between an organism and its environment*.

Now, consider the case of two people interacting with each other, an elementary form of interpersonal or *social coordination*. In this situation, each individual is instructed to oscillate a limb (the lower leg in this case) in the same or opposite direction to that of the other person [170]. In order to do the task, there must be a medium of interaction (vision, sound, touch, smell…) through which humans can couple. In this case, the two people watch each other (for details of this and other work see ► Social Coordination, from the Perspective of Coordination Dynamics). Then, either by an instruction from the experimenter or by following a metronome whose frequency is systematically increased, the social dyad speeds up their movements. When moving their legs up and down in the same direction, the two members of the dyad remain synchronized across a broad range of speeds. However, when moving their legs in the *opposite* direction (one person's leg extending at the knee while the other's is flexing), such is not the case. Once again at a certain critical rate participants change their behavior spontaneously so that their legs now move in the *same* direction.

The 'nonlinear' paradigm of coordination dynamics as illustrated in these three simple experiments has led to a wide range of investigations in many fields and a surprising variety of contexts (see Sect. "Collective Minds" for brief summary; also Books and Reviews) including detailed studies of underlying brain mechanisms using the full armamentarium of imaging technologies. Although



Coordination Dynamics, Figure 2

A pattern of generic results from combined brain and behavioral studies of coordination (adapted from [81]). On the *left* are behavioral results showing how relative phase variability is initially higher and increases more rapidly with the control parameter of frequency for syncopated antiphase (*filled squares*) than synchronized inphase coordination (*open circles*) with an external event. On the *right* are corresponding brain activations that comprise a network that is exquisitely sensitive to the stability of antiphase coordination. Areas depicted are left and right ventral premotor cortex (vPMC), pre supplementary motor area (pre-SMA) and right insula. The X Y Z Talairach coordinate of the peak voxel for each region is provided. Notice how the behavioral and brain data track each other

the findings would take us too far afield for present purposes ([19,20,191]; for reviews see [59,81]) two particular results are worth noting. First is that the basic paradigm has led to the first direct evidence of phase transitions in the human brain seen using both large scale electrode EEG [143,216] and SQuID arrays [35,61,62,108,123,124]. Second, and even more telling, is that fMRI evidence indicates that regardless of whether one is coordinating the two hands or coordinating with an external signal, a common network concerned with the *stability* of coordination is involved (see [81,156] for reviews).

The pattern of experimental findings described in this section illustrates an important conceptual distinction between coordination dynamics and other theories of self-organization [163]. In the latter, at bifurcation points or phase transitions, the system switches to a new, higher level of organization called a *dissipative structure*. Dissipative structures are so named because, compared with the "simpler" structures or patterns they replace, they require more energy to sustain them (ibid., p.xv). Not so in the order-order transitions of coordination dynamics. In coordination dynamics, the new organization that appears at bifurcation points is 'simpler' than the one it replaces and requires less energy. For example, brain electrical activity actually drops across the antiphase to inphase transition even though the system is being driven faster [124]. In Fig. 2, blood oxygen level dependent (BOLD) activity in certain brain regions is shown to increase as the stability of the antiphase pattern decreases. It is obvious that the increasing metabolic energy demands of the brain for antiphase relative to inphase coordination will diminish once the transition to in phase occurs. Thus, the key principle behind the 'simpler' self-organizing structures that emerge in coordination dynamics are based, not (or not only) upon energy per se as in the theory of dissipative structures, but on the system's *information processing demands*. Intuitively, the antiphase pattern is more difficult to coordinate as rate or frequency is increased causing the system to switch to a pattern that is easier to perform under the current conditions. Importantly, coordination dynamics replaces vague terms such as 'task difficulty' and 'task complexity' by quantitative behavioral measures of stability and quantitative brain measures of BOLD and neuroelectric activity.

The Theoretical Modeling Strategy of Coordination Dynamics: Symmetry and Bifurcations

The three pieces of experimental evidence described above cut across entirely different kinds of things and events (auditory, visual and proprioceptive sensations, finger and leg movements, people and brains, etc.). The common denominator is that all these things and processes are meaningfully coupled together in time under particular boundary conditions (task instructions, environmental context, manipulated parameters, etc.). The phenomena observed hint at an aspect that any basic law should exhibit, namely that although the patterns of coordination observed are realized by different physical structures and physicochemical processes, laws and regularities are abstract and relational.

How then do we go about identifying the actual underlying laws? More specifically, how do we explain the coordinative phenomena observed experimentally? As stressed above, in contrast to certain physical systems like the laser, in biological coordination the path from the microscopic level to collective order parameters is not known and cannot (yet?) be derived from first principles like conservation laws. In coordination dynamics we have to: a) identify the order parameters or coordination variables and their low-dimensional dynamics empirically; b) determine the key control parameters that move the system though its coordinative states; and c) relate different levels though a study of the individual subsystems and their nonlinear interaction.

Determining the dynamics of coordination variables is non-trivial. In all three experimental situations, the relative phase ϕ or phase relation between the component elements appears to qualify as a suitable order parameter or coordination variable. The reasons are as follows: ϕ characterizes the patterns of spatiotemporal order observed, in phase and anti-phase; ϕ changes far more slowly than the variables that describe the individual coordinating components (e. g., position, velocity, acceleration, electromyographic activity of contracting muscles, neuronal ensemble activity in particular brain regions, etc.); ϕ changes abruptly at the transition and is only weakly dependent on parameters outside the transition; and ϕ appears to obey a dynamics in which the patterns may be characterized as *attractors* or *attractive states* of some underlying dynamical system. Since in all cases the frequency or rate clearly drives the system through different coordination patterns without actually prescribing them, frequency qualifies as a control parameter.

Determining the coordination dynamics means mapping observed, reproducibly stable patterns onto attractors of the dynamics. A general strategy is to assume sufficiently higher order dynamics and expand the vector field of these dynamics in a Fourier series:

$$\dot{\phi} = f(\phi) = a_0 + a_1 \sin(\phi) + a_2 \sin(2\phi) + \dots \\ + b_1 \cos(\phi) + b_2 \cos(2\phi) + \dots \,. \quad (1)$$

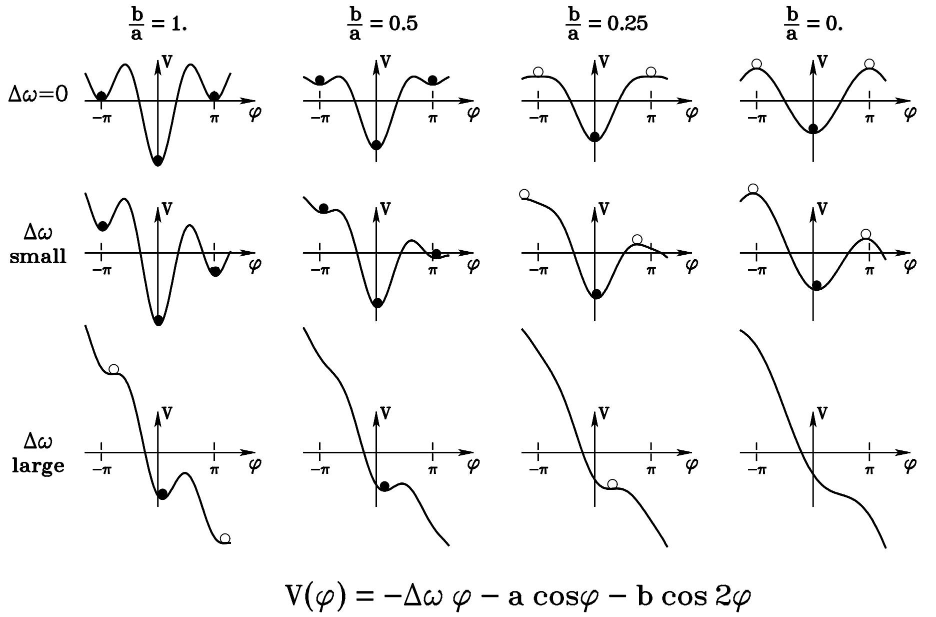
Symmetry may be used to classify patterns and restrict the functional form of the coordination dynamics. Symmetry means "no change as a result of change": pattern symmetry means a given pattern is symmetric under a group of transformations. A transformation is an operation that maps one pattern onto another, e. g. in the first experimental case, left-right transformation exchanges homologous limbs within a bimanual pattern. If all relative phases are equivalent after the transformation, then the pattern is considered invariant under this operation. Symmetry serves two purposes. First it serves as a pattern classification tool allowing for the identification of basic coordination patterns that can be captured theoretically. Given a symmetry group, one can determine all invariant patterns. Second, imposing symmetry restrictions on the dynamics itself limits possible solutions and allows one to arrive at a coordination dynamics that contains the patterns as *different* stationary states of the *same* nonlinear dynamical system. In other words basic coordination patterns correspond to attractors of the relative phase for adequate parameter values. For example, left-right symmetry of homologous limbs leads to invariance under the transformation $\phi \to \phi$ so that the simplest dynamical system that accommodates the experimental observations is:

$$\dot{\phi} = f(\phi) = -a \sin(\phi) - 2b \sin(2\phi) \quad (2)$$

where ϕ is the relative phase between the movements of the two individuals, $\dot{\phi}$ is the derivative of ϕ with respect to time, and the ratio b/a is a control parameter corresponding to the movement rate in the experiment. An equivalent formulation of Eq. (1) is

$$\dot{\phi} = -\partial V(\phi)/\partial\phi \quad \text{with } V(\phi) = -a \cos\phi - b \cos 2\phi \,. \quad (3)$$

In the literature, Eqs. (2) and (3) are the equations at the collective level of the HKB model of coordinated behavior, after Haken, Kelso and Bunz [76,106,139]. Figure 3 (top) allows one to develop an intuitive understanding of the behavior of Eqs. (2),(3), as well as to connect the key concepts



Coordination Dynamics, Figure 3

The potential, $V(\phi)$ of Eq. (3) (with $\Delta\omega = 0$) and Eq. (5) (with $\Delta\omega \neq 0$). *Black balls* symbolize stable coordinated behaviors and *white balls* correspond to unstable behavioral states (see text for details)

of stability and instability in self-organized dynamical systems to the observed experimental facts.

The dynamics can be visualized as a particle moving in a potential function $V(\phi)$. The minima of the potential are points of vanishing force, giving rise to stable solutions of the elementary coordination dynamics. As long as the speed parameter (b/a) is slow, meaning the cycle period is long, Eq. (3) has two stable fixed point attractors, coordinative states at $\phi = 0$ and $\phi = \pm\pi$ rad. Thus, two coordinated behavioral patterns coexist for exactly the same parameter values, the essentially nonlinear feature of *bistability* (Table 1). Such bi- and in general multi-stability is the dynamical signature of *multifunctionality* which can be seen at many levels in living things. As the ratio b/a is decreased, meaning that the cycle period gets shorter as the system speeds up, the formerly stable fixed point at $\phi = \pm\pi$ rad becomes unstable, and turns into a *repellor* (open circles). Any small perturbation will now kick the system into the *basin of attraction* of the stable fixed point corresponding to an in-phase coordination pattern at $\phi = 0$. Notice also that once there, the system's behavior will stay in the in-phase attractor, even if the direction of the control parameter is reversed. This is called *hysteresis*, a basic form of memory in nonlinear dynamical systems.

What about the individual components? Research has established that these take the form of self-sustaining oscillators, archetypal of all time-dependent behavior [12,14,47,92,93]. The particular functional form of the oscillator need not occupy the reader here (see ▶ Movement Coordination which uses empirical facts and symmetry arguments to restrict and thereby identify the component dynamics). More important is the nature of the nonlinear coupling that produces emergent coordination. The simplest, perhaps fundamental biophysical coupling that guarantees all the observed emergent properties of coordination: multistability, flexible switching among coordination states and primitive memory, is:

$$K_{12} = \left(\dot{X}_1 - \dot{X}_2\right)\left\{\alpha + \beta(X_1 - X_2)^2\right\} \,, \qquad (4)$$

where X_1 and X_2 are the individual components and α and β are coupling parameters. Notice that the 'next level up', the level of coordinated behavioral patterns and the dynamical rule that governs them (Eqs. (2) and (3)), can be *derived* from the level below, the individual components and their nonlinear interaction. One may call this *constructive reductionism*: by focusing on adjacent levels, under the boundary constraints of the task, the individual parts can be put together to create the behavior of the whole.

The basic self-organized dynamics, Eqs. (2) and (3) have been extended in numerous ways, only a few of which are mentioned here.

- *Critical slowing down* and *enhancement of fluctuations*. Introducing stochastic forces into Eqs. (2) and (3) ([175,210,211] see Chap. 11 in [74] and [101,121] for a thorough discussion) allows key predictions of coordination dynamics to be tested and quantitatively evaluated [113,121,172]. Critical slowing is easy to understand from Fig. 3 (top). As the minima at $\phi = \pm\pi$ become shallower and shallower, the time it takes to adjust to a small perturbation takes longer and longer. Thus, the local relaxation time is predicted to increase as the instability is approached because the restoring force (given as the gradient of the potential) becomes smaller. Likewise, the variability of ϕ is predicted to increase due to the flattening of the potential near the transition point. Both predictions have been confirmed in a wide variety of experimental systems, including recordings of the human brain ([81,100,174] for review).

- *Symmetry breaking*. Notice that Eqs. (2) and (3) are *symmetric*: the dynamical system is 2π periodic and is identical under left-right reflection (ϕ is the same as $-\phi$). This assumes that the individual components are identical, which as remarked upon earlier, is seldom the case in living things where symmetries are broken all the time.

In terms of the development of the theory, an important experimental example of symmetry breaking is the case of coordinating movement with a visual stimulus: visual stimuli and limb movement are obviously not equivalent. Thus $\phi \rightarrow \phi$ symmetry cannot be assumed. This means that symmetry partners of coordination patterns with systematic phase leads or lags do not coexist at the same parameter values. To accommodate this fact, a term $\Delta\omega$ is incorporated into the dynamics [115]:

$$\begin{aligned} &\dot{\phi} = \Delta\omega - a\sin\phi - 2b\sin 2\phi\,, \quad \text{and} \\ &V(\phi) = -\Delta\omega\phi - a\cos\phi - b\cos 2\phi \end{aligned} \tag{5}$$

for the equation of motion and the potential respectively.

Note that Eq. (5) falls out naturally from an analysis of the oscillators, ω_1 and ω_2, viz.

$$\dot{\phi} = \frac{\omega_1^2 - \omega_2^2}{2\Omega} + (\alpha + 2\beta R^2)\sin\phi - \beta R^2 \sin 2\phi \tag{6}$$

for

$$\Delta\omega = \frac{\omega_1^2 - \omega_2^2}{2\Omega} \approx \omega_1 - \omega_2 \tag{7}$$

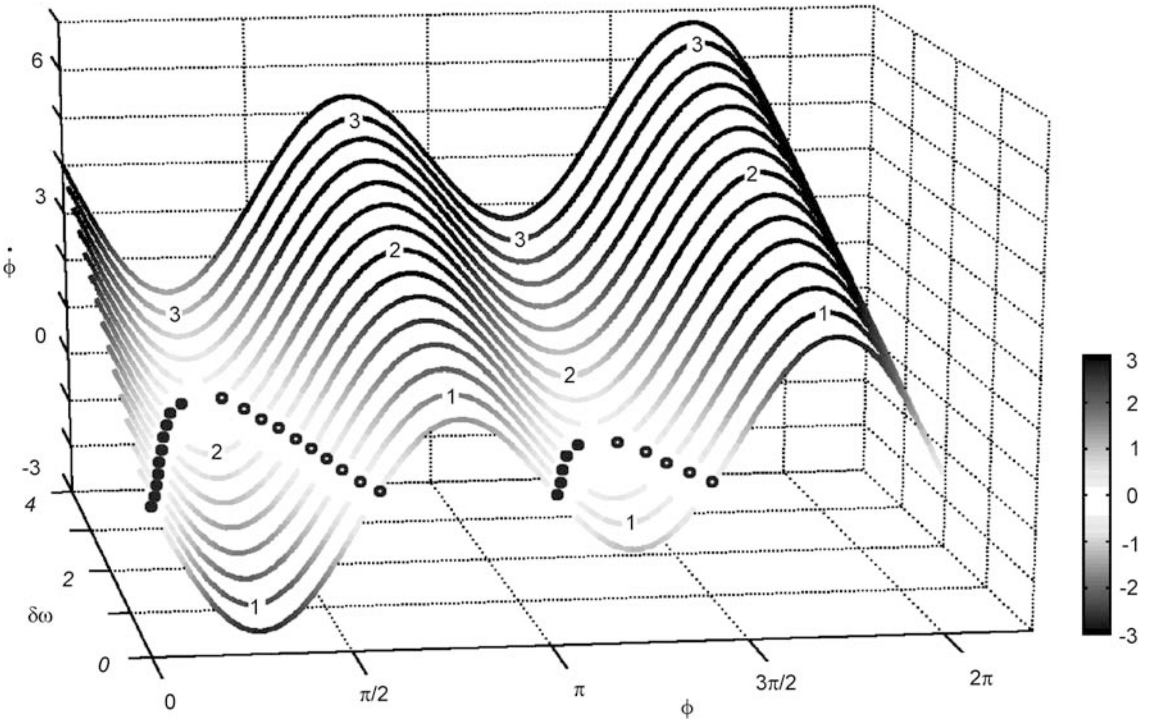
with

$$\begin{aligned} a &= -(\alpha + 2\beta R^2) \\ b &= \tfrac{1}{2}\beta R^2\,. \end{aligned} \tag{8}$$

Small values of $\Delta\omega$ shift the attractive fixed points (Fig. 3 middle) in an adaptive manner. For larger values of $\Delta\omega$ the attractors disappear entirely (Fig. 3 bottom) causing the relative phase to drift: no coordination between the components appears to be possible. Note, however, that the dynamics still retain some curvature (Fig. 3 bottom right): even though there are no attractors there is still attraction to where the attractors used to be. The reason is that the difference ($\Delta\omega$) between the individual components is sufficiently large that they do their own thing, while still retaining a *tendency* to cooperate. The introduction of the symmetry breaking term $\Delta\omega$ in Eq. (5) changes the entire coordination dynamics (layout of the fixed points, bifurcation structure) of the original HKB system in which $\Delta\omega = 0$. This is important to realize because it is the subtle interplay between the coupling ($k = b/a$) and the symmetry breaking term $\Delta\omega$ in Eq. (5) that gives rise to *metastability*.

Sometimes in the literature Eq. (5) is referred to collectively as the Haken–Kelso–Bunz equation. Though convenient, this is technically incorrect and fails to recognize both the intellectual contributions to its extension and the conceptual consequences thereof. For reasons of symmetry and simplicity, the original HKB equation did not contain the symmetry breaking term, $\Delta\omega$ [115] nor did it treat fluctuations explicitly [175] both of which are crucial for capturing the broad range of phenomena observed and testing further predictions. In particular, without $\Delta\omega$ there is: a) no fixed point shift, a sign of adaptation to changing circumstances, see Fig. 3 and 4; b) the bifurcation is a saddle node not, as in the original HKB equation, a pitchfork. These are different normal forms [98]; and c) most important of all, the original HKB equation does not and cannot exhibit metastability which is the key to understanding the complementary relationship between the synergic tendency of the elements to couple (integration) and at the same time to express their individual differences (segregation). The oscillators in the original HKB formulation were identical thereby excluding metastability. For these reasons, it seems wise to refer to Eq. (5) (with its stochastic aspect included) as the extended HKB equation.

Equation (5) is a bit strange. Even though it is an order parameter equation of motion that describes *coordinative* behavior (in words, phi dot is a function of phi), it includes also a parameter ($\Delta\omega$) that arises as a result of differences among the *individual components*. Equation (5) is thus a strange mixture of the whole and the parts, the global and the local, the cooperative and the competitive, the collective and the individual. Were the components identical, $\Delta\omega$ would be zero and we would not see component differences affecting the behavior of the whole (Fig. 3 top row). Equation (5) would simply reflect the behavior of the collective untarnished by component properties, a purely



Coordination Dynamics, Figure 4

Elementary coordination law (Eq. (5)). Surface formed by a family of flows of the coordination variable ϕ (in radians) as a function of its time derivative $\dot{\phi}$ for increasing values of $\Delta\omega$. For this example, the coupling is fixed: $a = 1$ and $b = 1$. When $\dot{\phi}$ reaches zero (*flow line becoming white*), the system ceases to change and fixed point behavior is observed. Note that the fixed points here refer to *emergent coordination states* produced by nonlinearly coupled elements. Stable and unstable fixed points at the intersection of the flow lines with the isoplane $\dot{\phi} = 0$ are represented as filled and open circles respectively. Three representative *lines labeled 1 to 3* illustrate the different régimes of the coordination dynamics. Following the *flow line 1* from left to right, two stable fixed points (*filled circles*) and two unstable fixed points (*open circles*) exist. This flow belongs to the multistable (here bistable) régime of dynamics. Following *line 2* from left to right, one pair of stable and unstable fixed points is met on the left, but notice the complete disappearance of fixed point behavior on the right side of the figure. That is, a qualitative change (bifurcation; phase transition) has occurred due to the loss of stability of the coordination state near antiphase, π rad. The flow now belongs to the monostable régime. Following *line 3* from left to right, no stable or unstable fixed points exist yet a subtle form of coordination – neither completely ordered (synchronized) nor completely disordered (desynchronized) – still remains. This is the metastable régime

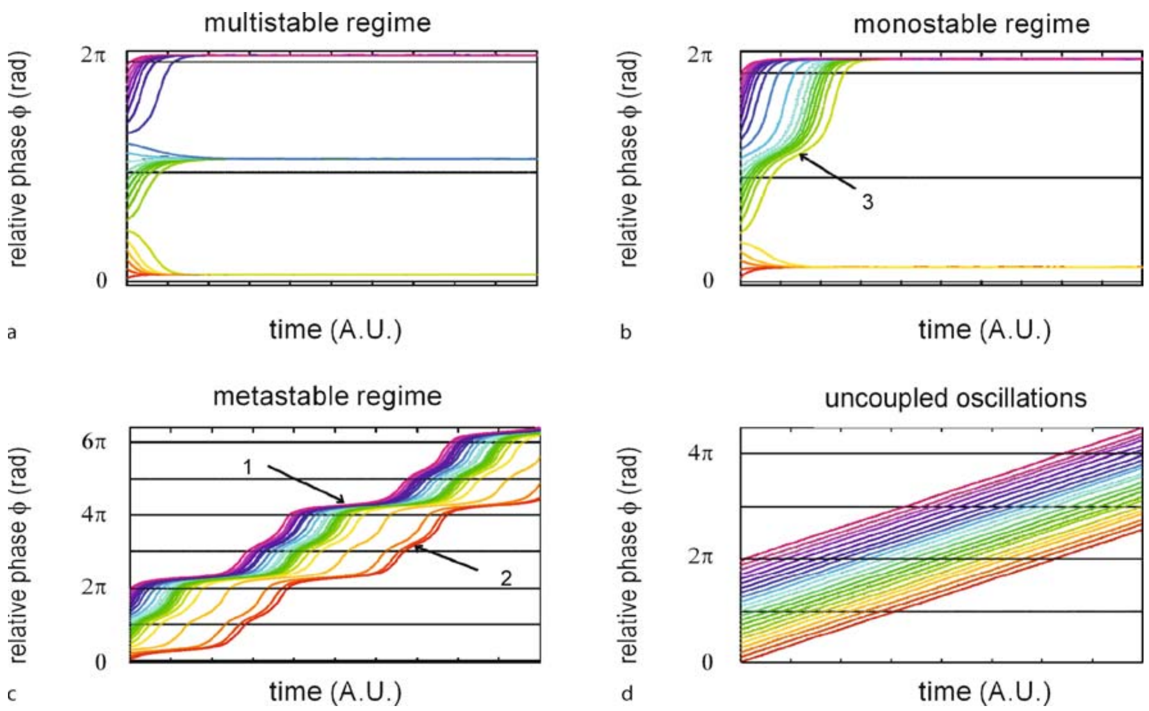
emergent interaction – the HKB equation. It is the fact that *both* the components *and* their (nonlinear) interaction appear at the same level of description that gives rise to the array of coexisting tendencies characteristic of metastability. The history of coordination (Sect. "History of Coordination Dynamics: Synergy and Rhythmic Order") may now be seen in a new light: Eq. (5) is a basic representation of a *synergy*, a low dimensional dynamic of a metastable organization in which the tendency of the parts to act together coexists with a tendency of the parts to do their own thing (see Chap. 4 in [100]). If indeed the synergy is a unit of life and mind as proposed in [105,107] then it is metastability that endows the synergy with robustness and flexibility, enabling the same parts to participate in multiple functions.

Metastable Coordination Dynamics

From States to Tendencies

Etymologically, 'metastability', comes from the latin '*meta*' (beyond) and '*stabilis*' (able to stand). In coordination dynamics, metastability corresponds to a régime near a saddle-node or tangent bifurcation in which stable coordination states no longer exist (e. g., in-phase synchronization where the relative phase between coordinating components lingers at zero), but attraction remains to where those fixed points used to be (see Fig. 3, bottom row). This gives rise to a dynamical flow consisting of *both* phase trapping and phase scattering.

To best visualize the emergence of metastability, Fig. 4 shows the flow of the dynamics for the elementary coor-



Coordination Dynamics, Figure 5

How the key coordination variable or order parameter of the elementary coordination law (Eq. (5)) behaves over time. Shown is a family of trajectories of the relative phase ϕ over time (in Arbitrary Units) arising from a range of initial conditions sampled between 0 and 2π radians, in the multistable (a), monostable (b) and metastable régimes (c) of Eq. (5). For the uncoupled case (d) the trajectories never converge indicating that the oscillations are completely independent of each other. Trajectories in the multistable régime (a) converge either to an attractor located slightly above $\phi = 0$ rad modulo 2π or to another attractor located slightly above $\phi = \pi$ rad modulo 2π. In the monostable régime (b), trajectories converge to an attractor located slightly above $\phi = 0$ rad modulo 2π. In the trajectories of relative phase for the metastable régime (c unwrapped to convey continuity), there is no longer any persisting convergence to the attractors, but rather a succession of periods of rapid drift (*escapes*) interspersed with periods inflecting toward, but not remaining on the horizontal (*dwells*). Note dwells near $\phi = 0$ rad modulo 2π in the metastable régime (e. g. dwell at about 4π rad annotated 1 in c) and nearby $\phi = \pi$ rad modulo 2π (dwell at about 3π rad annotated 2 in c) are reminiscent of the transient obtained for certain initial conditions in the monostable régime (Fig. 5b, annotation 3). The key point is that in the metastable régime the system's behavior is a blend of coupled and independent behavior

dination law (Eq. (5)) across a range of $\Delta\omega$ values with the coupling parameter, $k = b/a = 1$ fixed. Stable fixed points (attractors) are presented as filled circles and unstable fixed points (repellors) as open circles. Here, fixed points of the coordination dynamics correspond to phase- and frequency relationships between oscillatory processes.

The surface shown in Fig. 4 defines three regions under the influence of the symmetry breaking term $\Delta\omega$. In the first region present in the lower part of the surface, the system is multistable: two stable attracting fixed points (filled circles) represent possible alternative states. Which one the system settles in depends on initial conditions and the size of the basin of attraction. In an intermediate region, following the line labeled 2 from left to right, the weakest attractor near anti-phase (right side) disappears after it collides with its associated repellor somewhere near $\Delta\omega = 1.3$, but the strongest attractor (left side) is still present as well as its repellor partner. Finally in the third region in the upper part of the surface, the dynamics become metastable. Following the line labeled 3 from left to right, no fixed points exist anymore: this part of the surface no longer intersects the isoplane $\dot{\phi} = 0$ where the fixed points are located. Strictly speaking coordination *states* qua frequency- and phase-synchrony no longer exist in the metastable régime of the coordination dynamics. Metastability is thus a subtle blend of coupling and intrinsic tendencies in which behavior is neither completely ordered (synchronized) nor completely disordered (desynchronized). Both tendencies coexist.

How do individual and coordination behavior evolve in time in the metastable régime? A unique flow now exists in which the dynamics may be characterized by places where the trajectory of the coordination variable converges and pauses around the horizontal and places where the trajectory drifts or diverges from the horizontal. Let us define the former as a *dwell time*, and the latter as an *escape time*. In Fig. 5c we show two locations for the dwell times: one that lingers a long time before escaping (e. g. Fig. 5c, annotation 1) slightly above the more stable in-phase pattern near 0 rad (modulo 2π), and the other that lingers only briefly (e. g. Fig. 5c, annotation 2) slightly above π (modulo 2π). These inflections recur over and over again as long as the system self-organizes in the metastable régime, i. e. as long as it does not undergo a phase transition to a locked or unlocked state. Despite the complete absence of phase-locked attractors, the coordinating elements in the metastable régime do not behave totally independently. Rather, their interdependence takes the form of dwellings (phase gathering tendencies) nearby the remnants of the fixed points (cf. Fig. 3 bottom; Figs. 4, 5c) and may be nicely expressed by concentrations in the histogram of the relative phase (see Chap. 4 in [100]).

Recently metastability has been hailed as a "new principle" of coordination in the brain and has been embraced by a number of neuroscientists as playing a role in various cognitive functions, even consciousness itself (e. g. [44,45,57,58,111,127,187,212]). According to a recent review [49]:

> *Metastability is an entirely new conception of brain functioning where the individual parts of the brain exhibit tendencies to function autonomously at the same time as they exhibit tendencies for coordinated activity* [19,20,97,100].

For Coordination Dynamics, metastability's significance lies not in the word itself but in what it means for understanding coordination in living things. In coordination dynamics, as shown in its most elementary form (Eq. (5)), metastability is not a concept or an idea, but a direct result of the broken symmetry of a system of (nonlinearly) coupled (nonlinear) oscillators. Such a design principle for the brain seems highly plausible given that rhythms in the brain are ubiquitous, operate over a broad range of frequencies and are strongly associated with various sensory, motor and cognitive processes [10,24,100].

The Creation of Information

There is another reason for proposing metastable coordination dynamics as the essential way the brain and perhaps all complex organizations work. It concerns an analogy to how physicists understand how we know the universe we live in. According to Quantum Mechanics, out of a universe in which quantum indeterminacy rules – the wave function is spread out over all of space – nature selects an alternative. Information is thereby created. The way this is done in practice is that a device is built in which an interactive material is placed in a physically, electrically or chemically metastable state. According to the late quantum measurement theorist, H.S. Greene [69]:

> *It is the observable transition between this metastable state and a more stable state that conveys the essential information concerning a sub-microscopic event that would otherwise go undetected … The functional material of the detector must be macroscopic and in a metastable state which allows the quantal interaction to become manifest at the macroscopic level.* (see p. 173 in [69])

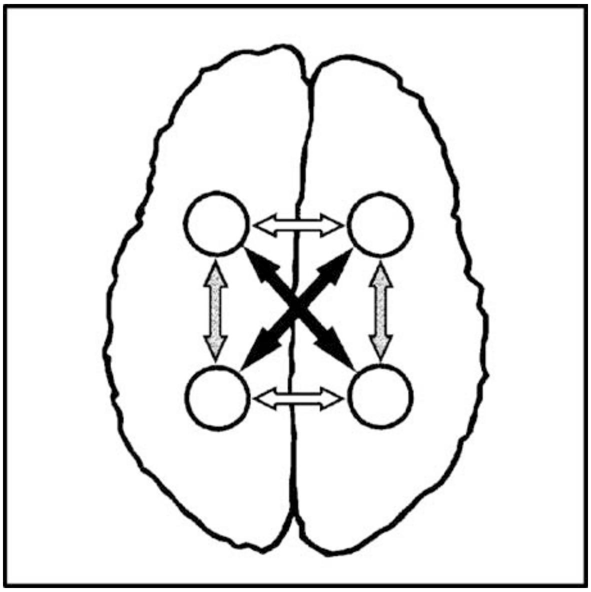
This is how some physicists view the creation of information: bit from it, as it were (in contrast to John Archibald Wheeler's 'it from bit'). Quantum Mechanics thus implies the creation of new information in the process of measurement and observation. Likewise, we have seen in the human brain that information (as a marginally coupled, phase-locked state) is created and destroyed in the metastable régime of the coordination dynamics, where tendencies for apartness and togetherness, individual and collective, segregation and integration, phase synchrony and phase scattering *coexist*. New information is created because the system operates in a special régime where the slightest nudge will put it into a new coordinated state. In this way, the (essentially nonlinear) coordination dynamics creates new, informationally meaningful coordination states that can be stabilized over time. The *stability of information over time* is guaranteed by the coupling between component parts and processes and may constitute a dynamic kind of (non-hereditary) memory. It does not seem a big step then to say that once created, this information can then guide, modify and direct the system's dynamics. As we shall see in Sect. "Modifying Coordination: Meaningful Information" studies of intentional change, environmental change, learning and so forth have demonstrated both empirically and theoretically that an intentional goal – as memorized information – acts in the same information space as the coordination dynamics ([114,173]; see also [141]).

Coordination of Multiple Components: From Quadrupeds to Brains

Phase- and frequency synchronization, the coupling among oscillatory processes, are an example, par excellence, of self-organization in natural systems [76,119,132,161,219]. Think of the famous clocks on the wall, no two exactly the same in frequency, but somehow ticking perfectly in time with each other. The weakest of coupling, whether through vibration in the wall or displacement of the air, enables the clocks to be mutually coordinated without any coordinator at all. Similar phenomena have been seen in the brain and have been hypothesized to play a key role in "binding": oscillations in the brain appear to be coupled or "bound" together into a coherent network when people attend to a stimulus, perceive, think and act (e. g., [34,43,67,184,214]). For example, synchronization in the so-called gamma band (approx. 30–50 Hz) has been proposed as a neural correlate of consciousness. The Journal *Science* announced the synchronization effects observed in monkey cortex as "The Mind Revealed" (see also [34]).

The brain, it seems, has latched on to phase synchrony as a principle of self-organization. Though the connection is seldom made, phase- and frequency- synchronization is typical of central pattern generators (CPGs), neural circuits in vertebrates and invertebrates that generate timing sequences without feedback from the periphery or the help of reflexes (see Sect. "Empirical Foundations of Coordination Dynamics: Pattern Generation, Stability and Phase Transitions"; [70,71]). Indeed, it is the temporal order observed that allows us to talk about 'pattern generators' in the first place. Though the specific mechanisms are obviously different between the visual cortex of the monkey and the stomatogastric ganglion of the lobster, the dynamic patterns are the same, hinting at the source of an underlying principle [97,100,174]. But what form might the coordination dynamics of the brain take?

Obviously when it comes to the brain there are, in principle, very many regions to coordinate. In practice, however, only a restricted set of regions appear to be functionally connected during particular tasks (see, e. g. Fig. 2). The idea, then, is that one could use the Central Pattern Generator (CPG) design for quadrupedal locomotion [32,66,176] as a basic model of interaction among cortical pattern generators. This is not as far fetched as it seems. It is likelier than not that the precursors to the structure and function of the cerebral cortex are self-contained circuits in the spinal cord and brainstem that generate intrinsic patterns of rhythmic activity [70,71,220]. Such CPGs typically work by transforming tonic driving inputs into detailed spatiotemporal patterns of (usually oscillatory) activity. Several of the properties of CPGs are conserved throughout evolution rendering them a likely candidate for the basic building blocks of the brain [72]. The hypothesis proposed here is that cortical pattern generators may underlie the coordination that is needed for everything the brain is purported to do – think, feel, remember, act, socialize, etc.



Coordination Dynamics, Figure 6
A schematic of brain coordination dynamics among four brain regions. Each *circle* represents an area of the brain capable of intrinsic oscillation and the *arrows* correspond to connections among brain areas giving rise to cortical pattern generation (see text)

Following the footsteps of basic coordination dynamics, in the quadruped analogy each "limb" corresponds to a neural region capable of intrinsic oscillatory activity and the patterns emerge from (broken) symmetries and changes in coupling between neural regions. For example, Fig. 6 shows a cartoon of the neuroanatomical connections underlying the anterior-posterior coordination of the hemispheres of the brain.

The relevant variables are four phase variables, ϕ_{ij} (with $i \in \{\text{right, left hemisphere}\}$, $j \in \{\text{anterior, posterior}\}$ characterizing the oscillatory behavior of each brain area with respect to its timing. Much research on coordination dynamics shows that the *relative phase* is a key coordination variable or order parameter although it is quite possible that amplitudes and frequencies are important variables too [4,57,111]. For the sake of simplicity, we stick to the case of interareal cortical coordination between 4 brain regions, where a set of 3 relative phases suffices to characterize any pattern uniquely.

As already illustrated, a key notion is to use symmetry to classify patterns and restrict the functional form of the coordination dynamics. Here, pattern symmetry means a given cortical pattern is symmetric under a group of transformations. As we have noted, a transformation is an operation that maps one pattern onto another, e. g. the anterior-posterior (a-p) transformation exchanges anterior and posterior regions within a cortical pattern. If all relative phases are equivalent after the transformation, then the pattern is considered invariant under this operation.

Symmetry serves as a pattern classification tool allowing for the identification of basic cortical patterns that can be captured theoretically. Given a symmetry group, one can determine all invariant patterns. For example, certain idealized cortical patterns are invariant under the symmetry group generated by the following operations: exchange of anterior and posterior, exchange of left and right, and inversion of all phases (inversion of time). A good way to illustrate these patterns is with phase pictograms.

Imposing symmetry restrictions on the dynamics itself limits possible solutions and allows one to arrive at a coordination dynamics that contains the patterns as *different* stationary states of the *same* nonlinear dynamical system. In other words basic cortical patterns correspond to attractive states of the relative phase for adequate parameter values:

$$\begin{aligned}\dot{\phi}_{ij} = \sum_{n=1}^{\infty}\{&A_n \sin(n(\phi_{ij} - \phi_{\hat{i}j}))\\ &\text{Homologous contralateral coupling (white arrows)}\\ &+ C_n \sin(n(\phi_{ij} - \phi_{i\hat{j}}))\\ &\text{Ipsilateral coupling (gray arrows)}\\ &+ E_n \sin(n(\phi_{ij} - \phi_{\hat{i}\hat{j}}))\}\\ &\text{Nonhomologous contralateral coupling (black arrows)}\end{aligned} \tag{9}$$

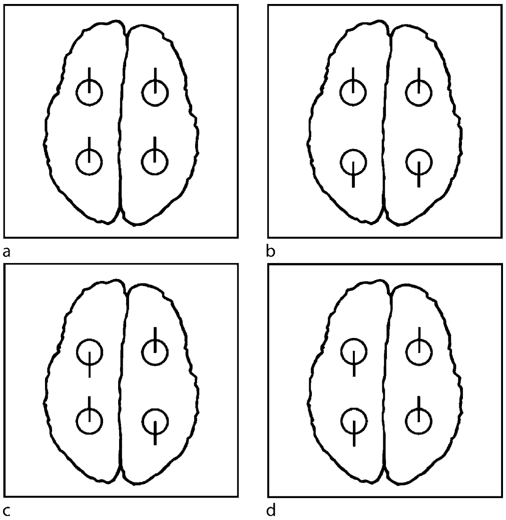
where A_n, C_n and E_n are parameters and a hat over an index means that the opposite value is taken, e. g. if $i = \text{right}$, then $\hat{i} = \text{left}$.

To analyze the solutions to the phase dynamics, for the sake of simplicity the coordination dynamics may be restricted to second order. Higher orders generate parameter régimes where many patterns may coexist; first order removes the possibility that some patterns may coexist. Also, diagonal coupling (black arrows in Fig. 6) may be neglected by setting $E_n = 0$. Notice that an effective diagonal coupling still exists because two couplings are sufficient to stabilize any pattern of activity among 4 cortical areas. Moreover, it is easier to generalize a system with contralateral and ipsilateral couplings to systems in which more areas are involved.

In sum, following exactly the basic theoretical modeling strategy (Eq. (1)) the dynamical system takes the following form:

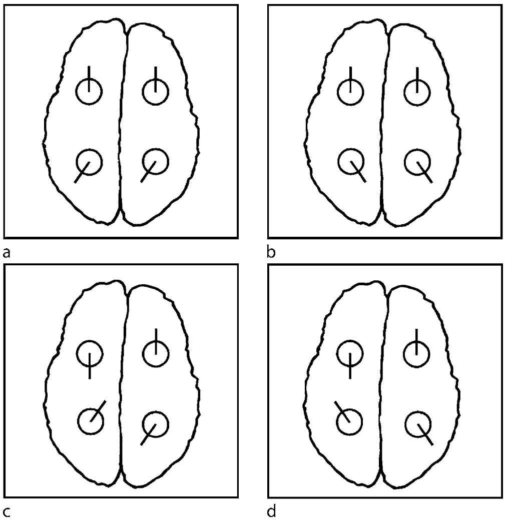
$$\begin{aligned}\dot{\phi}_{\mathrm{rp}} &= A_1[\sin(\phi_{\mathrm{rp}} - \phi_{\mathrm{lp}}) + \sin(\phi_{\mathrm{la}})]\\ &\quad + A_2[\sin(2(\phi_{\mathrm{rp}} - \phi_{\mathrm{lp}})) + \sin(2\phi_{\mathrm{la}})]\\ &\quad + 2C_1 \sin(\phi_{\mathrm{rp}}) + 2C_2 \sin(2\phi_{\mathrm{lp}})\\ \dot{\phi}_{\mathrm{lp}} &= A_1[\sin(\phi_{\mathrm{lp}} - \phi_{\mathrm{rp}}) + \sin(\phi_{\mathrm{la}})]\\ &\quad + A_2[\sin(2(\phi_{\mathrm{lp}} - \phi_{\mathrm{rp}})) + \sin(2\phi_{\mathrm{la}})]\\ &\quad + C_1[\sin(\phi_{\mathrm{lp}} - \phi_{\mathrm{la}}) + \sin(\phi_{\mathrm{rp}})]\\ &\quad + C_2[\sin(2\phi_{\mathrm{lp}} - \phi_{\mathrm{la}})) + \sin(2\phi_{\mathrm{rp}})]\\ \dot{\phi}_{\mathrm{la}} &= 2A_1 \sin(\phi_{\mathrm{la}}) - \phi_{\mathrm{lp}}) + 2A_2 \sin(2\phi_{\mathrm{la}})\\ &\quad + C_1[\sin(\phi_{\mathrm{la}} - \phi_{\mathrm{lp}}) + \sin(\phi_{\mathrm{rp}})]\\ &\quad + C_2[\sin(2(\phi_{\mathrm{la}} - \phi_{\mathrm{lp}})) + \sin(2\phi_{\mathrm{rp}})]\ .\end{aligned} \tag{10}$$

Solving $\dot{\phi}_{ij} = 0$ yields stationary solutions that correspond to idealized cortical "gaits". Trot, pace, gallop and jump patterns may be identified as multistable or monostable solutions in various parameter régimes. Patterns of lower symmetry can also be captured. Obviously the foregoing analysis is intended for illustrative purposes only. The examples provided in Fig. 7 and 8 are only a few of very many possible cortical patterns that can be obtained by further symmetry groups. It is important to empha-



Coordination Dynamics, Figure 7
Brain phase pictograms. Each brain area is represented as a *circle*. The spatial arrangement of the circles viewed from looking down on the top of the head represents the brain's hypothesized anterior-posterior and left-right functional organization. Phase is represented by the angle the stick makes on each circle, with the reference phase being zero for the right frontal region. If all phases are rotated by the same amount in the same direction, the cortical coordination pattern remains the same. The patterns in a, b, c and d are those idealized cortical patterns that remain invariant under anterior-posterior, left-right and time inversion operations. Notice that the relative phase between any two brain regions is either inphase or antiphase

size that not all patterns in a given symmetry group are observable. Which ones are actually observed is dictated by the coordination dynamics, in particular a given pattern's *stability* which, as we have seen, can be measured (cf. Sect. "Empirical Foundations of Coordination Dynamics: Pattern Generation, Stability and Phase Transitions"). As in the simpler cases of coordination dynamics described above, *switching* among cortical patterns is due, not to switches per se but to instabilities – phase transitions or bifurcations in the phase dynamics. Neuromodulators are candidate control parameters capable of sculpting cortical patterns by leading the system through instabilities [130]. Moreover, when the oscillatory frequencies in the anterior and posterior regions of the brain are slightly different, a kind of partial coordination among cortical regions may occur. This is exactly the *metastable* coordination dynamics of the brain as described in the previous section. Here again, the key point is that the rules of the game appear to be run by principles of coordination dynamics and symmetry. As always, experiments are now needed to test this hypothesis. EEG measures of cross-frequency phase synchrony of the human brain may reflect a start in this direction (e. g., [84,158]). More direct attempts are underway in our laboratory [199].



Coordination Dynamics, Figure 8
Representative brain phase pictograms corresponding to cortical patterns of lower symmetry. Here the anterior-posterior symmetry is dropped and the cortical patterns that remain form two one parameter families. One family consists of in-phase ordering *within* anterior and posterior areas and any fixed phase relation *between* anterior and posterior regions (a,b). The other family (c,d) consists of anti-phase relations within frontal and anterior regions and any fixed phase relations between them

"Collective Minds"

The basic coordination dynamics for two and four nonlinearly interacting components (Eqs. (2)–(10)) can readily be elaborated as a model of emergent coordinated behavior or "group cohesion" among very many anatomically different components (see, e. g. [5]). Self-organized behavioral patterns such as singing in a group or making a "wave" during a football game are common, yet unstudied examples. By virtue of information exchange nearest neighbors adjust their motions to each other generating, and being influenced by, their social environment. Recently, Néda and colleagues [148,149] have examined a simpler group activity: applause in theater and opera audiences in Romania and Hungary. After an exceptional performance, initially thunderous incoherent clapping gives way to slower, synchronized clapping. Measurements indicate that the clapping period suddenly doubles at the onset of the synchronized phase, and slowly decreases as synchronization is lost. This pattern is a cultural phenomenon in many parts of Europe: a collective request for an encore. Increasing frequency (decreasing period) is a measure of the urgency of the message, and culminates in the transition back to noise when the performers reappear. These results are readily explained by a model of a group of globally coupled nonlinear oscillators [132]:

$$\frac{\mathrm{d}\phi_k}{\mathrm{d}t} = \omega_k + \frac{K}{N}\sum_{j=1}^{N}\sin(\phi_j - \phi_k) \tag{11}$$

in which a critical coupling parameter, K_c determines the different modes of clapping behavior. K is a function of the dispersion (D) of clapping frequencies:

$$K_c = \sqrt{\frac{2}{\pi^3}}\mathrm{D}\,. \tag{12}$$

During fast clapping, synchronization is not possible due to the large dispersion of clapping frequencies. Slower, synchronized clapping at double the period arises when small dispersion appears. Period doubling rhythmic applause tends not to occur in big open-air concerts where the informational coupling among the audience is small. K can also be societally imposed. In Eastern European communities during communist times, synchronization was seldom destroyed because enthusiasm was often low for the "great leader's" speech. For people in the West, the cultural information content of different clapping patterns may be quite different. Regardless, the mathematical descriptions for coordinated behavior – of social dyads and the psychology of large groups – are remarkably similar.

Modifying Coordination: Meaningful Information

Unlike the behavior of inanimate things, the self-organizing dynamics of animate behavior is based on information (Table 1), though not in the standard sense of data communicated across a channel [180]. In coordination dynamics, *collective or coordination variables are context-dependent and intrinsically meaningful*. Context-dependence does not imply subjectivity and lack of reproducibility. Nor does it mean that every new context requires a new collective variable or order parameter. As we have seen already, for example, within- and between-person coordinated behaviors are described by the same self-organizing coordination dynamics. One of the consequences of identifying the latter is that in order to *modify or change* the system's behavior, new information (in the form say, of an environmental input, a task to be learned, or an intention to change behavior) is expressed in terms of parameters acting on system-relevant collective dynamics. On the one hand, the benefit of identifying collective variables is that they embrace the full complexity of the system and hence provide the relevant information about *what* to modify. On the other, the collective variable dynamics – prior to the introduction of any new information – influences how that information can be used. The upshot is that information is not lying out there as mere data: information is meaningful to the extent that it modifies, and is modified by, the collective variable dynamics.

A minimum mathematical form for the full coordination dynamics which encompasses both spontaneous self-organizing tendencies and specific parametric influences is

$$\dot{\phi} = f(\phi) + f\,\mathrm{inf}(\phi) \qquad (13)$$

where the first term is the typical so-called "intrinsic dynamics" e. g., of Eq. (5) or Eq. (10) and the second term represents 'informational forcing', i. e., a perturbation of the vector field of the dynamics attracting the system toward a required coordination pattern. It is important to emphasize that the plus sign in Eq. (13) is for operational purposes only, affording the measurement of the complementary contributions to the coordination dynamics of both spontaneous and directed (parametric) influences. The conceptual advantage of Eq. (13) is that information acts in the same space as the collective variables that define the intrinsic coordination patterns, i. e., those patterns that characterize spontaneous coordination tendencies. Thus, information is not arbitrary with respect to the dynamics. A corollary of this formulation is that information has no meaning outside its influence on the intrinsic dynamics. They are cut, as Sheets-Johnstone [182] remarks, from the same dynamic cloth.

Intentional Dynamics

Self-organizing processes, in the manner of Haken's synergetics, provide a theoretical foundation for all forms of coordination. However, we do not want to throw the baby out with the bathwater. Coordinated behavior often has a goal-directedness to it as well. We humans, for example, have no doubt whatsoever that it is us, and us alone, that direct the motions of our own bodies. Where do agency and directedness come from? A clue comes from considering the elementary spontaneous movements we are born with which consist of a large repertoire of spontaneous (thus self-organized) movements – making a fist, kicking, sucking, etc. etc. Only at some point does the child realize – through his own movements and the kinaesthetic sensations they give rise to – that these movements are his own. If one attaches the string of a mobile to his foot, he comes to realize that it is *his* kicking movements that are causing the mobile to move in ways that *he* likes. The pre-existing repertoire enables activities to happen before we make them happen. Evolutionarily constrained self-organizing coordination tendencies ('intrinsic dynamics') thus appear to lie at the origins of conscious agency. They are, in the words of the philosopher Maxine Sheets-Johnstone, "the mother of all cognition", presaging every conscious mind that ever said "I". From spontaneous self-organized behavior emerges the self – "I am" "I do" and from there a huge range of potentialities ('I can do'). "I-ness" arises from spontaneity, and it is this "I" that directs human action. As Sheets-Johnstone [182] cogently remarks, we literally discover ourselves in movement. In our spontaneity of movement, we discover arms that extend, mouths that open, knees that flex and so forth. We make sense of ourselves as living things.

Following these insights, consider briefly how Coordination Dynamics addresses the role of intentional information in bringing about behavioral change. How is the process of intentionally switching among patterns of coordination to be understood? According to the theory, the relative stability of the intrinsic patterns plays a role in determining how easily the system can switch in and out of coordination states. As defined previously, "intrinsic dynamics" expresses the fact that the system (which may include the brain) – prior to any specific input – already possesses a repertoire of behavioral patterns that are unique to each individual. Theoretically, intention parametrizes the intrinsic dynamics in two ways: (i) by destabilizing an ongoing pattern and stabilizing a target pattern [114,137,171]; and (ii) by stabilizing an intrinsically unstable pattern that under the current circumstances might otherwise become unstable and switch (see

Chap. 5 in [100], [114]). Measurement of switching time shows that intention both acts upon and is constrained by the intrinsic dynamics of coordination. First, the system switches far faster from less stable to more stable patterns (as measured by variability) than vice-versa. Second, the data show that it is possible to intentionally stabilize intrinsically unstable patterns under conditions in which they would normally switch. Both results are in excellent agreement with theory [114,171,173].

The neural basis of the interaction between intrinsic brain dynamic activity and *intentional* pattern selection and switching is just beginning to be studied and the results look very promising [39]. *Spontaneous* switching between patterns is known to be associated with increased activity in prefrontal, premotor and parietal regions [3,37,146], a network that is compatible with the stability dependent circuits described in Fig. 2 (see also Jantzen & Kelso, 2007). Increased activity reported in specific brain regions appears to reflect the loss of pattern stability that precedes spontaneous pattern switching. New results from our laboratory show that there is greater activity in the basal ganglia (BG) – a region known to be crucial for starting and controlling voluntary movements [68] – when moving from a more to a less stable pattern [39]. The heightened level of activity in BG may be related to the stability of the original pattern, the stabilization of the selected pattern switched into or both. Regardless, this intriguing result suggests that the basal ganglia play a key role in parametrizing the coordination dynamics.

Stimulus (Parametric) Stabilization and Change

Not only internally generated information is able to stabilize and destabilize coordination states under suitable circumstances: coupling sound, vision or touch conditions to specific aspects of an individual movement have been shown, not only to modify the movement but to *globally* stabilize coordination [25,50,122,133]. Thus the role of 'stimuli' in Coordination Dynamics is much more than to trigger preset motor commands or provide feedback to the motor system. To account for these kinds of effects, Jirsa and colleagues [89] introduced the notion of *parametric stabilization*: coupling specific sensory input parametrically to a set of limit cycle oscillators (see also [4,91]):

$$\begin{aligned}\ddot{x}_1 + f(x_1, \dot{x}_1)\dot{x}_1 + \omega^2 x_1 &= g(x_1, \dot{x}_1, x_2, \dot{x}_2) + \varepsilon(t)x_1\\ \ddot{x}_2 + f(x_2, \dot{x}_2)\dot{x}_2 + \omega^2 x_2 &= g(x_2, \dot{x}_2, x_1, \dot{x}_1) + \varepsilon(t)x_2\end{aligned} \tag{14}$$

where *f* is a nonlinear oscillator function, *g* represents the HKB coupling (Eq. (4)), ω is the eigenfrequency of the oscillator and $\varepsilon(t)$ represents sensory information. Here again in Eq. (14) we see a key aspect of coordination dynamics, namely that perception and action, sensory information and the dynamics of movement are inextricably linked. Notice the linkage in this case is of a parametric, multiplicative nature which is necessary to account for both the local changes to component trajectories produced by sensory information (called 'anchoring') and the global stabilization effects on the coordination dynamics. Fink et al. [50] for example, were able to show that such localized and specific sensory information was capable of shifting (and thereby delaying) the critical point at which phase transitions occurred.

A Brief Survey of Applications and Elaborations of Coordination Dynamics

The foregoing discussion pertains to just two of the many kinds of adaptive modification of coordination dynamics that have been investigated in the literature. Here only a flavor can be provided. The sample includes, but is by no means limited to: the processes underlying the ability of biological systems to stabilize intrinsically unstable systems [26,54,199]; the initiation (including 'false starts') and coordination of discrete, discontinuous behaviors [52,80,86,112,188,189] including neurally-based comparisons with those of a continuous, rhythmic nature [166,185]; the spontaneous recruitment and annihilation of biomechanical degrees of freedom to accomplish task and environmental conditions [21,23,51,118]; the coordination dynamics of trajectory formation [22,38] and cursive handwriting [6]; the important role that perception [145] and attention [2,27,147,190,193,194] play in modulating coordinative stability; how practice and learning alter the entire coordination repertoire by reshaping the landscape of the coordination dynamics using competitive and cooperative mechanisms [53,140,151, 177,222,223]; the stabilization and consolidation of new memorized states of coordination and the dynamics of the forgetting process [128,129]; how handedness amplifies asymmetries in the coordination dynamics [2,201], and so forth. The same concepts and methods have been applied to problems ranging from maintaining posture and stabilizing postural sway [8,9,42,83] to understanding how concurrent cognitive tasks modulate coordination dynamics [159,183].

Theoretical research at the neural level has progressed from phenomenological modeling at behavioral (e. g. [60,76,89,115,118,175,201]) and brain levels [88,205] to neurobiologically-grounded accounts of both unimanual [56,63,125] and bimanual coordination [87] that are based on known cellular and neural ensemble properties of the cerebral cortex. Recent work [85] has extended this neural theory to include the heterogeneous connectivity between neural ensembles in the cortex. Once general laws of coordination at behavioral and brain levels have been identified, it has proved possible to derive them from a deeper theory founded on neuroanatomical and neurophysiological facts, thereby causally connecting different levels of description [117] for review). The neural theory, in turn, poses a number of challenges to experiment, such as how synaptic and cellular properties are influenced by learning, arousal and attention [103].

Remarkable applications of coordination dynamics have occurred in expected directions (though none the less remarkable for all that) including many physical activities and sports such as the relation between respiration and locomotion [36], juggling [13,79], gymnastics [142], running [41], tennis [157], swimming [179], boxing [135], skiing [154], golf [125] and even riding horses [134] to name only a few, as well as in entirely unexpected directions, such as modeling coordination of infant breathing as a way to understand the effects of premature birth [65], studies of coordination dynamics in children with Developmental Coordination Disorder [213] and the introduction of coordination dynamics therapy to treat a wide variety of CNS disorders and diseases (e. g. [167,168,169]; see also [207]). Principles of coordination dynamics have been shown to apply to perceptual grouping as nicely illustrated by the classic bistable properties of reversible figures such as the Necker cube (e. g. [100]), pattern recognition [77], the visual perception of spatiotemporal inphase and antiphase moving stimuli [18,40,78,221] and speech categorization [28,202]. In many cases the foregoing research findings have expanded, if not overturned, conventional explanations of phenomena that have seldom considered dynamics.

Increase in research activity using the concepts and methods of coordination dynamics has been such that the term has taken on a life of its own in different fields. Thus, it is commonplace in the literature to hear the words 'cognitive', 'brain', 'neural', 'social', 'behavioral', 'developmental' 'multimodal', 'postural', etc., qualify and precede the words *coordination dynamics*. The dynamical approach is currently center stage in a number of fields, for example, dynamical neuroscience (e. g., [90,160]), dynamical cognitive science (e. g., [16,162,186,209]), behavioral [217] and task [165] dynamics, dynamical social psychology (e. g., [15,155,206]), dynamical systems accounts of development (e. g., [135,149,191,192,204]; see also [195]) and its implications are under careful consideration in philosophical circles (e. g. [11,29,30,31,198]).

Future Directions and Conclusions: The Complementary Nature of Coordination Dynamics

General laws and principles of biological coordination – to the extent they exist – are, by definition, abstract and mathematical. Yet, these laws are always conditioned by and realized by specific mechanisms and contexts. Over the last twenty-five years, often using the field of animate movement as an entry point it has been shown that the same coordination dynamics applies to functional coordination in a wide variety of situations. Although the basic laws for a quantitative description of the phenomena observed when human beings (and human brains) move, interact with the environment and with each other are the same, the anatomical, mechanical and physiological mechanisms realizing these dynamics are obviously not. Laws and mechanisms are complementary aspects of coordination dynamics.

Current research and theory views coordination as arising from the mutual interplay of constraints on multiple levels of description – ranging from the intrinsic properties and modes of interaction among cells and cellular ensembles in brain circuitry to biomechanical influences at the behavioral level all the way to cognitive and task constraints. Coordination dynamics is not only a theoretical framework, but also a research program that explicitly attempts to incorporate and connect known constraints at multiple levels of description. For instance, coordination dynamics successfully identified and later quantified the form of the nonlinear coupling among interacting components. In showing that the stability and change of coordination is due to nonlinear interactions among individual components coordination dynamics removes some of the mysticism behind the contemporary terms "emergence" and "self-organization". At the same time, coordination dynamics expands and modifies the concept of self-organization in non-living systems by introducing new concepts to account for the fact that coordination is not only characterized by self-organization but also by directed or supervised forms of coordination. The two origins or cornerstones of coordination dynamics may be reconciled by showing how meaningful information originates from self-organizing processes and may in turn modify them.

In studies of coordinated movement, the field to which coordination dynamics owes its origins, it has proven useful to try to isolate the role of various constraints and how they are mediated by the central nervous system. On the one hand, this strategy has helped identify different factors that serve to stabilize coordination under conditions in which it may otherwise become unstable and susceptible to change. On the other hand, a focus on isolating particular constraints can lead, albeit unwittingly, to dichotomies (e. g., coordination principles versus neuromuscular-skeletal mechanisms of implementation) that may not be so useful. In reality it seems safe to conclude that a coalition of constraints – acting on multiple levels – impinges upon the stability of coordination depending on task and environmental context and the mover's intent. For example, the multilevel theory offered by Kelso [100] connects task goals (Level 1) to constraints on nonlinear oscillators (Level 3), the interactions among which determine the coordinative patterns observed (Level 2). Thus, rather than pose "abstract laws of coordination dynamics" against "neuromuscular-skeletal determinants of coordination", more important is to understand how the balance between identified constraints plays itself out in the course of any coordinated activity. Situations in which constraints are placed in competition with each other often prove to be highly revealing [122].

Throughout this article, every effort has been made to articulate the key notions of coordination dynamics, both conceptual and technical, and to present them in close proximity in order to help both the novice and the expert reader. The behavioral simplicity of the basic coordination patterns studied in the laboratory is deceptive; their understanding, however, requires recent advances in physics and mathematics. The theoretical concepts and methods of coordination dynamics are likely to play an ever greater role in the social, behavioral, economic, cognitive and neurosciences, especially as the interactions among disciplines continues to grow. Up to now, the use of nonlinear dynamics is still quite restricted, and often metaphorical. One reason is that the tools are difficult to learn, and require a degree of mathematical sophistication. Their implementation in real systems is nontrivial, requiring a different approach to experimentation and observation. Another reason is that the dynamical perspective is often cast in opposition to more conventional theoretical approaches, instead of as an aid or complement to understanding. The former tends to emphasize decentralization, collective decision-making and cooperative behavior among many interacting elements. The latter tends to focus on individual psychological processes such as intention, perception, attention, memory and so forth. Yet there is increasing evidence that intending, perceiving, attending, deciding, emoting and remembering have a dynamics as well. The language of dynamics serves to bridge individual and group processes. In each case, dynamics must be filled with content, with key variables and parameters obtained for the systems under study. A beauty about coordination dynamics is that the coordination variables or order parameters are semantic, relational quantities that "enfold" different aspects together thereby reducing often arbitrary divisions. Every system is different, but what we learn about one may aid in understanding another. What may be most important of all is to see animated living things in the light of a theory – coordination dynamics – that embraces both spontaneous self-organizing and directed processes, the complementary nature.

Glossary

ABS Automated Bond System. The original automated limit-order market for bonds operated by the NYSE that executed orders according to strict price/time priority. ABS was replaced by the NYSE Bonds Platform in 2007.

Agency trade A bond transaction executed by a broker-dealer on behalf of another party. A broker-dealers is compensated by a commission on an agency trade.

Broker A firm that acts as an intermediary by executing agency trades.

Broker-dealer A firm that engages in both agency trades and principal trades.

Broker's broker A broker-dealer that exclusively executes agency trades of municipal bonds with other broker-dealers. Broker's brokers do not execute principal trades and they do not trade directly with public investors.

Commission A form of compensation that a customer pays a broker-dealer for executing an agency trade. Broker-dealers must explicitly disclose the commission to the customer as a separate item on the customer's trade confirmation.

Dealer A firm that engages in principal trades for its own account.

FINRA Financial Industry Regulatory Authority. The self-regulatory organization (SR0) created in July 2007 from the consolidation of NASD and the member regulation, enforcement and arbitration functions of the NYSE. FINRA rules are approved by the SEC and enforced by themselves.

FIPS Fixed Income Pricing Service. The electronic system operated by the National Association of Securities Dealers (NASD) from 1994 through 2002 to collect and disseminate real-time quotations and hourly trade reports for a subset of high-yield corporate bonds. FIPS was retired in July 2002 with the implementation of TRACE.

Market maker A specific designation made by a regulatory authority for a broker-dealer that holds itself out to trade securities by publishing regular or continuous quotations to buy (bid) or sell (offer). Currently, there are no broker-dealers regulated as market makers in the US corporate or municipal bond markets.

Mark-up and mark-down A form of compensation that a customer pays a broker-dealer for executing a principal trade. Customers pay a mark-up when they buy a bond from a broker-dealer; they pay a mark-down when they sell a bond to a broker-dealer. Unlike commissions, mark-ups and mark-downs do not need to be disclosed on customer trade confirmations.

MSRB Municipal Securities Rulemaking Board. The self-regulatory organization (SRO) charged with primary rulemaking authority over broker-dealers in connection with their municipal bond transactions. MSRB rules are approved by the SEC and enforced by FINRA (formerly NASD).

NASD Formerly known as the National Association of Securities Dealers. The self-regulatory organization (SRO) charged with, among other things, primary rulemaking authority over broker-dealers in connection with their corporate bond transactions. In July 2007, NASD and the member regulation, enforcement and arbitration functions of the NYSE consolidated to form FINRA.

NYSE New York Stock Exchange. Operates the NYSE Bonds Platform (formerly ABS) trading system for exchange-listed corporate bonds.

OTC securities Over the-counter securities. Securities that are not traded on an organized exchange.

Principal trade A bond transaction executed by a broker-dealer for its proprietary account. The broker-dealer is compensated by a mark-up or mark-down on a principal trade.

Riskless principal trade A principal trade in which a broker-dealer purchases a bond to satisfy a previously received order to buy, or a broker-dealer sells a bond to satisfy a previously received order to sell. The transaction is riskless to the broker-dealer because the firm does not bear any inventory (price) risk.

RTTRS (or TRS) (Real-Time) Transaction Reporting System. MSRB's municipal bond transaction reporting and dissemination system.

Serial offering A bond issuance in which several different bonds are offered with different, often consecutive, maturities. Municipal bonds are typically issued in serial offerings.

SRO Self-regulatory Organization. A non-governmental industry association that has statutory authority to regulate members through the promulgation and enforcement of rules and regulations governing business practices. The SEC oversees SRO activities and approves SRO rules.

SEC US Securities and Exchange Commission. The primary governmental overseer and regulator of US securities markets, including the corporate and municipal bond markets. Broker-dealers and SROs are overseen by the SEC's Division of Trading and Markets (formerly Division of Market Regulation).

TRACE (formerly NASD TRACE) Transaction Reporting and Compliance Engine. FINRA's corporate bond transaction reporting and dissemination system.

Definition of the Subject

The subject of this article is the microstructure of the US corporate and municipal bond markets. ▶ Treasury Market, Microstructure of the U.S. provide a complementary discussion of the microstructure of the US Treasury bond market.

Market microstructure is broadly defined as the study of the economics of markets and trading. Market microstructure research covers a wide range of interrelated topics including market structure and design issues (e. g., trading systems and rules); price formation and price discovery; strategic trading behavior; market quality, liquidity, and trading costs (explicit and implicit); information, disclosure, and transparency; and consequences of regulatory policy (intended and unintended).

While much has been written on the microstructure of equity markets since the mid-1980s, the bond markets have only recently started receiving attention from academic researchers. The development of research in both markets can largely be attributed to the availability of quality intraday trade, quote, and/or order data ("tick" data) to empirical researchers.

The seminal theoretical work in market microstructure was conducted contemporaneously with the early equity market microstructure research, and much of the underlying economics is general enough to be appropriate for the bond markets. As a result, the significant contributions of bond market research so far have been almost exclusively empirical in nature. The last study featured in this article by Green, Hollifield, and Schurhoff [23] is a notable exception.

Conversely, the empirical methods developed specifically for the structure and design of equity markets are not well-suited for the bond markets. Accordingly, many of the important contributions of bond market microstructure research stem from not only the results and conclusions, but also from the development of new empirical methods. This article will provide details on some of these methods as well as discuss the important results, conclusions, and policy implications.

But, before moving on to a detailed discussion of bond market microstructure research, an important question needs to be answered. Why should we care about the bond markets? We should care because the bond markets provide an important source of capital for issuers and an important source of securities for investors. In other words, the bond markets are large. How large are they? The answer to this question depends on one's definition of size.

Figure 1 shows that an astonishingly large number, approximately 1.5 million, corporate and municipal bonds are outstanding. The vast majority of these are municipal bonds, which are typically issued in serial offerings consisting of a set of up to 20 (or more) bonds issued at the same time with different maturities. Thus, the number of bonds dwarfs the number of equities.

In terms of total dollar amounts outstanding, Fig. 1 shows that US corporate and municipal bond markets combined are roughly half the size of the US equity markets. The average daily trading volume in these bond markets is about $36 billion, which is about 1/3 of the average daily trading volume of $115 billion in the equity markets. While the discussion of the microstructure of the Treasury bond markets is left to ▶ Treasury Market, Microstructure of the U.S., it is worth noting that total US bond market trading volume (corporate, municipal, and Treasury) exceeds US equity market trading volume. Thus, no matter what measure is used, it is apparent that the bond markets offer important sources of capital for issuers and securities for investors.

The remainder of this article proceeds as follows. Section "Introduction" provides a historical overview of the US corporate and municipal bond markets. Section "Early Corporate and Municipal Bond Market Microstructure Research" through "The Links Between Bond Market Microstructure Research and Other Finance and Economics Research" review the significant contributions to the bond

Section "Transaction Reporting and Compliance Engine (TRACE) Research" reviews the research enabled by the NASD's Transaction Reporting and Compliance Engine (TRACE) system that began in July 2002. Section "The Links Between Bond Market Microstructure Research and Other Finance and Economics Research" provides examples of how bond market microstructure research is linked to other areas of finance and economics research.

Introduction

Today, virtually all US corporate and municipal bond trading occurs in over the-counter (OTC) dealer markets with transparent prices. But, that was not always the case. In the early 20th century there were active and transparent markets for both corporate bonds and municipal bonds on the New York Stock Exchange (NYSE). Then, bond trading began migrating to opaque OTC dealer markets. In the late 20th century, post-trade transparency was added to the both the corporate and municipal bond OTC markets.

What factors are responsible for the evolution of the bond markets over the past century? What caused the migration of trading in the early 20th century? How (and why) was post-trade transparency added to the bond markets in the late 20th century? The brief history of US corporate and municipal bond markets below provides answers to these questions.

The Early 20th Century

Biais and Green [9] provide a fascinating historical overview of the US corporate and municipal bond markets. Early 20th century NYSE bond trading took place among the "bond crowd". Bond trading originally took place in the same trading room as stock trading, with the bond crowd organizing around three trading booths in the "bond corner" of the Exchange. In 1928, the NYSE opened a separate trading room, the "bond room", in response to increases in trading volumes. Trading in the bond room was separated into four different crowds. US corporate and municipal bonds were traded in either the "active" crowd or the "inactive" crowd. The inactive crowd was also known as the "cabinet" crowd because bond orders were written on slips of paper and filed in the bond cabinets. Foreign bonds and Government securities each had their own bond crowds. A small number of active bonds were traded on the floor in an open outcry market.

NYSE bond trading was "order-driven". The exchange collected, posted, and matched public customer orders.

Public investors paid commissions to brokers to facilitate their NYSE bond trades. All NYSE bond brokers could observe the book of available orders and the recent trades, and inform their customers about them. Thus, NYSE bond trading enjoyed a very high level of "pre-trade transparency" and "post-trade transparency". Pre-trade transparency refers to the dissemination of information about trading interests. Pre-trade information can include price (bid and ask) and depth quotations, as well as limit order prices and sizes. Post-trade transparency refers to the dissemination of information about past trades. While post-trade information includes not only prices, such as trade execution times and volumes, post-trade transparency in the bond markets is sometimes referred to as simply "price transparency". Madhavan [38] and Harris [24] provide excellent discussions all the different dimensions of transparency as well as the related market microstructure literature.

In the late 1920s, municipal bond trading migrated to the over the-counter (OTC) market. Corporate bond trading migrated to the OTC market in the 1940s. Biais and Green [9] examine a number of potential explanations for the decline in municipal and corporate bond trading on the NYSE. They find that the decline of exchange trading in bonds was not due to a decline in the supply of bonds outstanding or a decline in listings in response to costly rules and regulations promulgated by the newly created SEC.

Biais and Green [9] find that the migration of bond trading from the NYSE to the OTC markets coincided with changes in the investor base. In the late 1920s, retail investor interest in municipal bonds waned, as they became more attracted to the higher returns on equities. As retail interest in municipal bonds waned, institutions became the dominant investor in the market. During the 1940s, a similar shift in the relative importance of retail investors and institutional investors occurred in the corporate bond market. Biais and Green [9] conclude that the migration of bond trading from the NYSE to the OTC markets was an evolution in response to the changing investor base.

Biais and Green [9] provide evidence that institutions fared better in OTC bond markets and argue that the dealers were happy to accommodate this new class of dominant investors. Because liquidity was no longer concentrated on a centralized transparent exchange, retail investors were effectively forced into trading with dealers in these decentralized opaque OTC markets. Not surprisingly, retail investors faredjt worse in these markets. Both municipal and corporate bond transaction costs increased significantly for retail investors.

The Late 20th Century and Early 21st Century

While the most significant change in the bond markets in the early 20th century was a migration of trading from the exchange to OTC, the most significant change in the late 20th century was the introduction of price transparency. Unlike trading migration, bond market transparency was not caused by market forces. Rather, transparency was added to the bond markets by direct regulatory intervention.

The Municipal Securities Rulemaking Board (MSRB) introduced price transparency to the municipal bond market. The MSRB was created by Congress in 1975 as the self-regulatory organization (SRO) charged with primary rule-making authority over broker-dealers in connection with their municipal bond transactions.

The MSRB began publicly disseminating municipal bond price information in January 1995. "Interdealer Daily Reports" provided statistics on total interdealer market activity reported for the previous day, as well as information about price and volume for each security that was "frequently traded" on that day. The MSRB defined frequently traded securities to be securities with four or more interdealer transactions on a particular day. The Interdealer Daily Report included the total par value traded, the daily high and low price, and the average price of trades having a par value between $100,000 and $1 million for each frequently traded issue. Transaction price information on securities with three or fewer interdealer transactions on a particular day ("infrequently traded" securities) was not disseminated.

In August 1998, the MSRB began producing "Combined Daily Reports". The Combined Daily Reports merged information from customer and interdealer transactions and provided daily high, low, and average prices for frequently traded securities of municipal securities on a one-day delayed basis. The frequently traded threshold was four transactions per day, taking into account both customer and interdealer transactions.

In January 2000, the MSRB began publicly disseminating transaction details on individual trades in frequently traded securities through "Daily Transaction Reports". Trade information on infrequently traded securities was still not disseminated until October 2000, when the MSRB began producing "Monthly Comprehensive Reports". These reports provided information on a one-month delayed basis for all transactions from the previous month, including infrequently traded issues.

By June 2003, the MSRB was publicly disseminating transaction details for all trades in all securities (frequently traded and infrequently traded) on a one-day lag basis through "T+1 Daily Reports". In January 2005, the MSRB began disseminating prices on a real-time basis through its Real-Time Transaction Reporting System (RTTRS or TRS).

The National Association of Securities Dealers (NASD) introduced price transparency to the corporate bond market. NASD (now FINRA) is the self-regulatory organization (SRO) charged with primary rulemaking authority over broker-dealers in connection with their corporate bond transactions. Regulatory concern for price transparency spiked in the late 1980s and early 1990s.

At that time, the high-yield corporate bond market faced unprecedented instability, highlighted by insider trading scandals and the ultimate collapse of the dominant dealer and underwriter Drexel Burnham Lambert. Concern over future market instability, along with the recognition of a need for better monitoring, led to regulatory intervention that provided a small degree of transparency in this market segment. The Fixed Income Pricing Service (FIPS) began in 1994. FIPS was the result of the SEC encouraging NASD to develop an electronic reporting and dissemination facility for non-convertible high-yield corporate bonds.

But, FIPS only provided partial transparency for this particular segment of the corporate bond market. While every trade in FIPS-eligible bonds was reported to FIPS, only summary information on a small subset (50 bonds) of the most active bonds was disseminated to the public. Alexander, Edwards, and Ferri [2] point out that some members of the SEC staff at that time feared that adding price transparency to less active bonds could possibly harm the market. FIPS added both pre-trade transparency and post-trade transparency to the market by disseminating quotations and hourly trade summaries, respectively. The hourly trade summaries contained high and low prices as well as total trading volume.

Many bond market participants and some SEC staff felt that FIPS added a sufficient amount of transparency to the corporate bond market. SEC Chairman Arthur Levitt disagreed. In 1998, he gave a speech entitled *The Importance of Transparency in America's Debt Market* in which he famously quipped "The sad truth is that investors in the corporate bond market do not enjoy the same access to information as a car buyer or a homebuyer or, dare I say, a fruit buyer". To address the lack of price transparency in the corporate bond market, he called on NASD to take several related actions. He called on NASD to adopt rules requiring dealers to report all corporate bond transactions; to develop a system to receive all corporate bond transaction information; to create a database of the transactions, and in conjunction, create a surveillance program to better detect fraud in corporate bonds; and, to disseminate the bond transaction prices to the public in order to help them make better investment decisions.

NASD responded by developing the Transaction Reporting and Compliance Engine (TRACE) system, which began operation in July 2002. Corporate bond dealers were required to report all transaction in TRACE-eligible securities. TRACE-eligible securities included investment grade and high-yield debt, convertible and non-convertible debt, and publicly issued debt and privately issued (Rule 144A) debt. While all TRACE-eligible transactions were reported to TRACE from the beginning of its operation, the dissemination of the trade information was phased-in over time. The phase-in approach was adopted by NASD, and approved by the SEC, because of industry concerns that adding transparency to the bond market would somehow harm liquidity.

The TRACE phase-in approach began with the dissemination of trade information on the largest, highest-rated bonds first. Price transparency was introduced to smaller and lower-rated bonds over time. By February 2005, prices were transparent on effectively 99% of trades, and by the end of that year, pricing information on all TRACE-eligible trades was being disseminated on a real-time basis to the public.

By the beginning of the 21st century, investors (and market microstructure researchers) were able to access an unprecedented amount of information about the OTC municipal and corporate bond markets from the post-trade transparency brought by TRS and TRACE, respectively. It is worth noting that bond trading never completely migrated to the OTC markets. The NYSE continues to list and trade some bonds. The NYSE developed the Automated Bond System (ABS), a computerized limit-order market for bonds, in an effort to encourage the migration of trading back to the exchange. The displayed public limit orders on ABS provided pre-trade transparency for some bonds.

However, the vast majority of bonds are not listed on the NYSE ABS or any other exchange, so all of the trading in these bonds occurs in the OTC markets. Moreover, for many of the bonds that are listed on the NYSE ABS, a majority of their trades still occur over the-counter. Therefore, the early 21st century bond markets can be characterized as dealer markets with a high degree of post-trade transparency, but with virtually no pre-trade transparency. It remains to be seen whether market forces, regulatory initiatives, or some combination of the two will eventually lead to the introduction of some form of pre-trade transparency, the emergence of bond market-makers, and/or a migration of trading back to an order-driven market in the US corporate and municipal bond markets.

Early Corporate and Municipal Bond Market Microstructure Research

Early bond market microstructure researchers were forced to rely on data sources that covered only certain segments of the market because comprehensive bond market data simply did not exist. Bond dealers kept their own trading records because there was no central reporting facility. Bond dealers were not required to publicly disseminate their trades. Researchers, as well as investors and regulators, were able to see snapshots of parts of the bond markets, but no one was able to see the complete picture.

But, even with the data limitations, early bond market researchers found creative ways to tease out useful information. Their initial findings shed the first light on the opaque bond markets. For example, Schultz [42] provides indirect evidence that higher bond market trading costs may be attributable to the lack of transparency. Variants of their original empirical methods continue to be used by more recent researchers.

Any encyclopedic article on corporate bond market microstructure research would be incomplete if it did not mention the efforts of the Fixed Income Research Program (FIRP), and more importantly its founder Professor Arthur Warga, in promoting early bond market research. Art Warga's influence on the development of the bond market microstructure literature extends beyond his own research. He collected, consolidated, cleaned, and organized various fragmented sources of bond market data to create the Fixed Income Securities Database (FISD), which he made accessible to academic and regulatory researchers. Many within the market microstructure research community informally refer to the FISD as simply the "Warga database".

Warga (1991)

Warga [44] uses an econometric model to investigate bond pricing discrepancies that arise when researchers (and commercial bond pricing services) use data from the two different sources that were generally available in 1990. The one source was exchange data in the form of actual transaction prices from the NYSE Automated Bond System (ABS). The other source was OTC dealer data in the form trader-quoted prices.

Warga [44] denotes the unobserved, true value of bond i as P_i^* and the unobserved, true bid-ask spread as BA_i. He assumes that P_i^* is the midpoint of BA_i. He also assumes that the prices/quotes observed in both markets are unbiased in the sense that they deviate from the true unobserved prices/quotes by a random error term. Then, for month-end NYSE transaction prices (P_{NY}):

$$P_{NY_i} = P_i^* + u_i \ ,$$

and, for month-end Lehman Brothers bid quotes (P_B):

$$P_{B_i} = P_i^* - \frac{1}{2} BA_i + \zeta_i \ .$$

Combining these two equations and letting $\varepsilon_\iota = \zeta_\iota + \mu_\iota$ yields:

$$P_{B_i} - P_{NY_i} = -\frac{1}{2} BA_i + \varepsilon_i \ .$$

Squaring both sides results in:

$$\left(P_{B_i} - P_{NY_i}\right)^2 = \frac{1}{4} (BA_i)^2 - (BA_i)\,\varepsilon_i + \varepsilon_i^2 \ .$$

Assuming the random error terms are orthogonal to prices/quotes, the expected squared price discrepancies is:

$$E\left[\left(P_{B_i} - P_{NY_i}\right)^2\right] = \frac{1}{4} (BA_i)^2 + \sigma_{\varepsilon i}^2 \ ,$$

where σ_ε^2 equals the variance of the discrepancy.

Warga [44] regresses the squared price discrepancies on six observable liquidity-related variables – bond rating, duration, NYSE dollar trading volume, bond age, issue amount outstanding, and the time of trade of the last trade price on the NYSE – with the following equation:

$$\begin{aligned}\left(P_{B_i} - P_{NY_i}\right)^2 &= \alpha_0 + \alpha_1 MOODYS + \alpha_2 DURTN \\ &+ \alpha_3 OUTSTD + \alpha_4 DVOL + \alpha_5 AGE + \alpha_6 TIME + \omega \ .\end{aligned}$$

Warga [44] finds that squared discrepancies are larger for bonds with lower credit ratings, higher duration, smaller issue sizes, lower trading volume, and trade prices that occurred earlier in the day. While he finds that these variables are capable of explaining some of the observed variation in price discrepancies, he also concludes that commingling exchange and dealer bond pricing data does not induce any biases.

Hong and Warga (2000)

Hong and Warga [29] use a benchmark method to estimate average daily effective spreads with newly available trade data. They obtain exchange market data from the NYSE ABS and OTC dealer market data from the Capital Access International (CAI) database. CAI obtains trading data on insurance companies, mutual funds, and pension funds from various regulatory filings.

They calculate the effective spread for a given bond on a given day as the dollar-volume-weighted average price transacted at the ask minus the dollar-volume-weighted average price transacted at the bid:

$$\sum_{i=1}^{N} P_i^{\mathrm{A}} W_i^{\mathrm{A}} - \sum_{j=1}^{M} P_j^{\mathrm{B}} W_j^{\mathrm{B}} ,$$

where P_i^{A} is the price of transaction i occurring at the ask, W_i^{A} is the dollar-value weight of transaction i, and N is the number of transactions occurring at the ask for a given bond on a given day. Similarly, P_j^{B} is the price of transaction j occurring at the bid, W_j^{B} is the dollar-value weight of transaction j, and M is the number of transactions occurring at the bid for a given bond on a given day.

Hong and Warga [29] find that the average daily effective spreads for corporate bond transactions occurring on the NYSE ABS that involve at least 10 bonds is about $0.21 for investment grade bonds and about $0.19 for high-yield bonds. For corporate bond trades occurring in the OTC dealer market, they find that the average daily effective spreads is about $0.13 for investment grade bonds and about $0.19 for high-yield bonds. They note that these spread estimates are smaller than previous estimates based on data from an earlier period, which is consistent with evidence that corporate bond spreads may have declined over time.

Hong and Warga [29] also find that OTC dealer market spreads exhibit much larger dispersion than NYSE ABS spreads. The standard deviations of daily effective spreads for the dealer market are two to three times larger than those for the exchange market. This result suggests that investors, particularly uninformed retail investors, could benefit from more transparency in the OTC markets.

Schultz (2001)

Schultz [42] also uses CAI institutional trade data. He develops an econometric model similar to Warga [44] to estimate average round trip corporate bond trading costs from institutional trade data and estimated contemporaneous bid quotes.

Schultz [42] estimates daily corporate bond bid quotes from the month-end bid quotes available from the Warga database. He develops a threestep estimation procedure that uses daily Treasury bond bid quotes, based on the observation that most of the day-to-day changes in investment grade corporate bond prices are explained by changes in the level of risk-free interest rates.

The first step is to calculate a predicted month-end quote for each corporate bond by taking its previous month-end quote and multiplying it by the change in the price of Treasury bonds of similar duration. The second step is to subtract the predicted month-end quote from the actual month-end quote. This calculation yields the monthly pricing error from predicting that the change in the corporate bond prices is exactly the same as the change in Treasury bond prices. The monthly pricing error is converted to an average daily pricing error by dividing it by the number of trading days in the month. The third step is to estimate the bid quote for a particular within-month trade date by starting with the previous end-of-month quote and adding on the average daily pricing error times the number trading days since the previous month end.

Schultz [42] finds that his bid quote estimates are accurate for investment grade bonds, but not for high-yield bonds. This is not surprising, since changes in high-yield prices are more often due to changes in firm-specific factor than changes in Treasury bond prices. Therefore, he does not attempt to estimate trading costs for high-yield bonds with this methodology.

For investment grade bonds, Schultz [42] estimates round-trip transactions costs by regressing the difference between the CAI trade prices and his estimate of the contemporaneous bid quote on a dummy variable that takes the value of 1 for buys and 0 for sells:

$$\Delta_i = \alpha_0 + \alpha_1 D_i^{\mathrm{Buy}} + \varepsilon_i ,$$

where Δ_i is the price of trade i minus estimated bid price and D_i^{Buy} equals one if trade i is a buy and zero otherwise. The coefficient α_i is an estimate of the average round-trip transaction costs. His estimate of the average round-trip transaction costs across all trades is about $0.27 per $100 of par value.

Schultz [42] also examines the determinants of corporate bond trading costs with the following regression:

$$\begin{aligned}\Delta_i &= \alpha_0 + \alpha_1 D_i^{\mathrm{Buy}} + \alpha_2 S_i + \alpha_3 D_i^{\mathrm{Inst}} + \alpha_4 D_i^{\mathrm{Deal}} \\ &\quad + \alpha_5 D_i^{\mathrm{Inst}} D_i^{\mathrm{Deal}} + \alpha_6 D_i^{\mathrm{Inst}} S_i + \alpha_7 D_i^{\mathrm{Deal}} S_i + \varepsilon_i ,\end{aligned}$$

where S_i is the signed (positive for buys, negative for sells) natural logarithm of the dollar trade size, D_i^{Inst} is a dummy variable that takes a value of one for buys and negative one for sells by one of the 20 most active institutions and a value of zero otherwise, and D_i^{Deal} is a dummy variable that takes a value of one for buys and negative one for sells if the trade involves one of the 12 active dealers and a value of zero otherwise. For the interactive term for active institutions and dealers, $D_i^{\text{Inst}} D_i^{\text{Deal}}$, the product of the dummies is positive for buys and negative for sells when the trade involves both an active institution and an active dealer and a value of zero otherwise.

Schultz [42] finds that institutional corporate bond trading costs decline with trade size. He does not find any evidence that trading costs are related to credit rating. But, this is not surprising given the fact that his analysis is limited to the four investment grade rating classes (Aaa, Aa, A, Baa).

Schultz [42] finds that trading costs are lower when a large bond dealer is used. In other words, small bond dealers charge more than large ones. He also finds that inactive institutions pay more than twice as much as active institutions to trade the same bonds. Schultz [42] attributes this result to the lack of transparency in the corporate bond market during his sample period. In an opaque market, obtaining price information is costly, so only active institutions will find it worthwhile to bear them.

Chakravarty and Sarkar (2003)

Chakravarty and Sarkar [12] use CAI data and benchmark methods to calculate "traded bid ask-spreads" over one-day, two-day, and five-day windows in the corporate, municipal, and Treasury bond markets. Similar to Hong and Warga [29], they define the traded bid-ask spread per day as the difference between its mean daily selling price and its mean daily buying price.

To check the sensitivity of their estimates to the requirement of one buy trade and one sell trade for each bond day, Chakravarty and Sarkar [12] calculate spreads over non-overlapping two-day and five-day windows. Their two-day traded bid-ask spread is calculated as the difference between the two-day means of the selling prices and the buying prices.

Chakravarty and Sarkar [12] find that the mean traded bid-ask spread per day per \$100 par value is \$0.21 for corporate bonds, \$0.23 for municipal bonds, and \$0.08 for Treasury bonds. In all three markets, they find that spreads increase with longer time-to-maturity, lower credit ratings, and lower trading volume. These results suggest that spreads are positively related to interest rate risk and credit risk, and negatively related to trading activity. For corporate bonds, Chakravarty and Sarkar [12] find that spreads increase with age.

Chakravarty and Sarkar [12] pool observations across all three bond markets for cross-market comparisons. After controlling for credit risk, Chakravarty and Sarkar [12] find no significant difference in the spreads of corporate bonds and Treasury bonds, but they find that municipal bonds have higher spreads.

Fixed Income Pricing Service (FIPS) Research

FIPS provided new price and volume data that allowed market microstructure researchers to conduct studies that were not previously possible. Alexander, Edwards, and Ferri [1] use FIPS volume data to test various hypotheses about bond liquidity. Alexander, Edwards, and Ferri [2] use FIPS returns and equity returns to tease out new evidence on agency conflicts between stockholders and bondholders. Hotchkiss and Ronen [31] use FIPS returns and equity returns to examine the relative informational efficiency of the corporate bond market. Somewhat surprisingly, they find that that informational efficiency of the corporate bond market is similar to the stock market.

Alexander, Edwards, and Ferri (2000a)

Alexander, Edwards, and Ferri [1] examine the determinants of trading volume of FIPS high-yield bonds using a pooled time-series cross-sectional approach. They use the following linear specification:

$$\begin{aligned} \textit{Trading Volume}_{it} &= \beta_0 + \beta_1 \text{Ln}\,(\textit{Size}_{it}) + \beta_2 \textit{Age}_{it} \\ &\quad + \beta_3 \textit{Private Equity}_{it} + \beta_4 \textit{Credit Rating}_{it} \\ &\quad + \beta_5 \textit{Duration}_{it} + \beta_6 \textit{Price Variability} + \varepsilon_{it}\,, \end{aligned}$$

where the dependent variable, *Trading Volume*, is measured in three different ways for each bond *i* in each month *t*. The three trading volume measures are the natural log of the average daily number of trades (Ln*(Trades)*), the natural log of the average daily number of bonds traded (Ln*(Bonds)*), and average daily turnover (*Turnover*). Ln*(Size)* is the natural logarithm of the issue's par value outstanding, *Age* is a dummy variable equal to one if the issue has been outstanding for less than two years, *Private Equity* is a dummy variable equal to one if the issue has no public equity outstanding in any part of the month, *Credit Rating* is a dummy variable equal to one if the issue is rated below B- by Standard & Poor's at any point during the month, *Duration* is the bond's modified duration, and *Price Variability* is the monthly average absolute value of the daily percentage change in volume-weighted price.

They find consistent results for all three measures of trading volume. Larger issues and younger issues are more heavily traded. They point out that the age result extends earlier empirical results that found that the liquidity of Treasury securities drops off a few months after issuance.

Alexander, Edwards, and Ferri [1] also find that bonds of firms without public equity trade more frequently than bonds of firms with public equity. This last finding is inconsistent with a disclosure hypothesis that predicts that more relaxed disclosure rules for firms without public equity will lead lower liquidity, as measured by trading volume. However, it is consistent with the competing substitution hypothesis that predicts that high-yield bonds of private firms will attract trading volume that otherwise would have occurred in the equity.

Alexander, Edwards, and Ferri (2000b)

Alexander, Edwards, and Ferri [2] use equity data and FIPS bond data to investigate the relationship between a firm's stock return and its bond return. They examine the long-term co-movement between a firm's bond returns and its stock returns. They also examine stock and bond returns around events typically associated with agency conflicts to see whether their co-movements provide evidence of agency conflicts.

To examine the long-term co-movement between a firm's bond returns and its stock returns, Alexander, Edwards, and Ferri [2] use three regression approaches. The first approach is a time-series regression model:

$$\begin{aligned} RB_{it} = \beta_0 + \beta_1 XRS_{it} + \beta_2 XRS_{it-1} + \beta_3 RBIND_{it} \\ + \beta_4 RBIND_{it-1} + \varepsilon_{it} \,, \end{aligned}$$

where RB_{it} is the bond return for firm i on day t, XRS is the current (t) and lagged ($t-1$) excess stock return, and $RBIND$ is the current (t) and lagged ($t-1$) high-yield bond index return, and ε_{it} is the residual bond return for firm i on day t. The second approach is a pooled time-series cross-sectional model that uses the regression equation above and follows the pooling technique of Greene (1993). The third approach is a cross-sectional regression model that follows the approach of Fama and MacBeth. For each sample day, the excess bond returns are regressed on the current and lagged excess stock returns:

$$XRB_{it} = \beta_0 + \beta_1 XRS_{it} + \beta_2 XRS_{it-1} + \varepsilon_{it} \,.$$

The estimates of β_1 in each of the three regressions show whether the stock and bond returns tend to co-move together (positive), in the opposite direction (negative), or not at all (insignificant). Alexander, Edwards, and Ferri [2] find that all three regressions produce similar results. The β_1 estimates are positive and statistically significant, indicating that excess bond returns are positively correlated with excess stock returns. But, Alexander, Edwards, and Ferri [2] point out the that the magnitudes of the coefficients suggest that the correlation is economically small.

To examine the behavior of stock and bond returns around events typically associated with agency conflicts, Alexander, Edwards, and Ferri [2] look at cumulative excess stock and bond returns around announcements of corporate events that are typically associated with wealth transfers from bondholders to stockholders, or vice versa. Events include debt issuances and redemptions, stock issuances and repurchases, dividend changes, new credit agreements, and others. They use Wilcoxon rank-sum tests to determine whether the means of the cumulative excess bond returns around potentially wealth-transferring events are significantly different from the returns otherwise. They find that the means are significantly different and that the mean cumulative excess bond returns around the wealth-transferring events is negative, while the returns are at other times are positive.

Thus, Alexander, Edwards, and Ferri [2] show that wealth-transferring corporate events (from bondholders to stockholders, or vice versa) can cause a firm's bond returns to diverge from its typical positive (weak) co-movement with its stock returns. In addition, they point out that this result is a likely factor in the weak long-term time-series correlations observed between stock and bond returns.

Hotchkiss and Ronen (2002)

Hotchkiss and Ronen [31] use FIPS data for 55 high-yield bonds to examine the informational efficiency of the corporate bond market relative to the market for the underlying stock. They find that stocks do not lead bonds in reflecting firm-specific information. They also find that pricing errors for bonds are no worse than for the underlying stocks, even on an intraday level.

Hotchkiss and Ronen [31] use a vector autoregression (VAR) approach applied to daily and hourly returns with a return-generating process that includes an interest rate risk factor and an equity market (systematic) risk factor:

$$\begin{aligned} RB_t = \alpha_t + \sum_{i=1}^{nb} \beta_i^{\mathrm{B}} RB_{t-i} + \sum_{i=0}^{ni} \beta_i^{\mathrm{L}} RL_{t-i} \\ + \sum_{i=0}^{ns} \beta_i^{\mathrm{M}} RM_{t-i} + \varepsilon_t \,, \end{aligned}$$

where RB_t is the FIPS bond portfolio return, RL_t is the Lehman Intermediate Government Bond Index return, and RM_t is the S&P 500 Index return. The number of lags for the bond, interest rate, and stock returns are $nb = 3$, $ni = 0$, and $ns = 4$, respectively. Hotchkiss and Ronen [31] include lagged bond returns (RB_{t-i}) to consider autocorrelation-adjusted bond returns. They also consider a specification that replaces the Lehman index return with the default risk-free return, RD_t, as interest rate factor:

$$RB_t = \alpha_t + \sum_{i=1}^{nb} \beta_i^{\mathrm{B}} RB_{t-i} + \sum_{i=0}^{ni} \beta_i^{\mathrm{D}} RD_{t-i} + \sum_{i=0}^{ns} \beta_i^{\mathrm{M}} RM_{t-i} + \varepsilon_t \,.$$

Finally, they add the underlying stock (firm-specific) return, RS_t :

$$RB_t = \alpha_t + \sum_{i=1}^{nb} \beta_i^{\mathrm{B}} RB_{t-i} + \sum_{i=0}^{ni} \beta_i^{\mathrm{D}} RD_{t-i} + \sum_{i=0}^{ns} \beta_i^{\mathrm{M}} RM_{t-i} + \sum_{i=0}^{ns} \beta_i^{\mathrm{S}} RS_{t-i} + \varepsilon_t \,.$$

With these three regressions, Hotchkiss and Ronen [31] find that high-yield bond returns exhibit a very strong interest rate risk component and that this component is significantly greater for higher-rated bonds. They also find that high-yield bond returns exhibit a very strong systematic risk component and that this component is slightly weaker for higher-rated bonds.

To test whether stock returns lead bond returns, Hotchkiss and Ronen [31] conduct Granger causality tests at the daily and hourly levels. They estimate the VAR for the variable set $z_t = [RB_t, RS_t]'$ using the specification:

$$z_t = B_1 z_{t-j} + B_2 z_{t-j} + \mu_t \,,$$

where RB_t is the bond return and RS_t is the stock return, for day (hour) t, B_i are conformable matrices, and μ_t is a disturbance vector. To test whether stock returns Granger cause bond returns they estimate the following bivariate VAR model using ordinary least squares (OLS):

$$RB_t = c_1 + \sum_{i=1}^{j} a_i RB_{t-i} + \sum_{i=1}^{j} b_i RS_{t-i} + \nu_{1,t} \,,$$

where c is a constant, as and bs are coefficients, ν_t is the disturbance vector, and j is the lag length. The null hypothesis is that stock returns do not Granger cause bond returns, or that $H_0 = \left[b_i\right] = 0$, for all i. Tests of whether bond returns Granger cause stock returns are conducted in a similar way. F-tests indicate that lagged stock returns are not significant in explaining bond returns. Thus, stocks do not lead bonds in reflecting firm-specific information. The Granger causality test results also indicate that lagged bond returns are not significant in explaining stock returns.

Hotchkiss and Ronen's [31] interpretation of the Granger causality test results is that the contemporaneous correlations between stock returns and bond returns are best described as a joint reactions to common factors. This motivates an additional investigation of the comparative reaction of stocks and bonds to firm-specific information. To conduct this investigation, they examine how quickly firm-specific information contained in earnings announcements are incorporated into bond prices relative to stock prices. First, they compare reported earnings to the median of analysts' earnings forecasts and calculate the log forecast error:

$$FE_i = \ln\left(A_i / F_i\right) \,,$$

where FE_i is the log forecast error for firm i, A_i is the announced earnings per share, and F_i is the forecast earnings per share. Next, they run the following regressions to examine whether earnings information is reflected in bond returns or stock returns:

$$RB_{[-1,t]} = \alpha_0 + \alpha_1 * FE + \alpha_2 * RM_{[-1,t]} + \varepsilon$$
$$RS_{[-1,t]} = \alpha_0 + \alpha_1 * FE + \alpha_2 * RM_{[-1,t]} + \varepsilon \,,$$

where RB and RS are the bond and stock returns, respectively, for the period starting at day (hour) -1 prior to the announcement and ending at day $+7$ (hour $+14$) after the announcement, and RM is the market (S&P 500 Index) return. Both the daily and hourly regression results indicate that all information is quickly impounded into both bond prices and stock prices.

Finally, Hotchkiss and Ronen [31] compare the market quality for the high-yield FIPS bonds to the underlying stocks by examining whether price errors of different magnitudes are associated with the different markets. The estimate the following market quality measure:

$$MQ_i = 1 - 2 * \left(\sigma_{si}^2 / \sigma_{Ri}^2\right) \,,$$

where σ_{si}^2 is the variance of the pricing error described in Hasbrouck [27] and σ_{Ri}^2 is the variance of the return. The intuitive interpretation of this measure is the proportion of the total return variance that is due to fundamental variance. In general, they find that the market quality measure for bonds is no worse than for the underlying stocks.

Municipal Bond Market Research

With the MSRB's introduction of central reporting and price transparency to the municipal bond market, microstructure researchers were able to make use of a comprehensive source quality transaction-level municipal bond data for the first time. This new data provided researchers the opportunity to develop new methods, examine existing microstructure issues in greater detail, and identify new avenues of research.

Two prominent municipal bond studies, Harris and Piwowar [26] and Green, Hollifield, and Schurhoff [22], develop and use very different methods to examine various economic aspects of trading in the municipal bond market. These two studies provide independent sets of similar and robust results that support two important conclusions related to retail investors. The first is that municipal bonds are expensive for retail investors to trade. Harris and Piwowar [26] and Green, Hollifield, and Schurhoff [22] both find that, unlike in equity markets, municipal bond trading costs decrease with trade size.

The second is that "complexity" is costly for retail investors. Harris and Piwowar [26] find that "instrument complexity" makes municipal bonds more expensive to trade. Instrument complexity is measured in terms of attached features, such as calls, puts, sinking funds, credit enhancement, nonstandard interest payment frequencies, and nonstandard interest accrual methods. Green, Hollifield, and Schurhoff [22] find that "deal complexity" also increases trading costs. Bond dealers charge higher markups on more difficult trades.

Harris and Piwowar (2006)

Harris and Piwowar [26] estimate municipal bond trading costs using an econometric model. They denote the unobserved "true value" of the bond at the time t asV_t and assume that the price of a trade, P_t, is equal to V_t plus or minus a price concession that depends on whether the trade is buyer-initiated or seller-initiated. The absolute customer transaction cost, $c(S_t)$, is estimated as the effective half-spread, measured as a percentage of the price.

I^{D}_t is an indicator variable that takes a value of 1 if the trade was an interdealer trade or 0 if the trade was a customer trade. Q_t is an indicator variable that takes a value of 1 if the customer was a buyer, −1 if the customer was a seller, or 0 if it was an interdealer trade. This results in:

$$\begin{aligned} P_t &= V_t + Q_t P_t c(S_t) + I^{\mathrm{D}}_t P_t \delta_t \\ &= V_t \left(1 + \frac{Q_t P_t c(S_t) + I^{\mathrm{D}}_t P_t \delta_t}{V_t}\right) . \end{aligned}$$

The continuously compounded bond price and "true value" returns between trades t and s, r^{P}_{ts} and r^{V}_{ts} respectively, are found by taking logs of both sides, making two small approximations, and subtracting the same expression for trade s:

$$r^{\mathrm{P}}_{ts} = r^{\mathrm{V}}_{ts} + Q_t c(S_t) - Q_s c\,(S_s) + I^{\mathrm{D}}_t \delta_t - I^{\mathrm{D}}_s \delta_s \,.$$

The "true value" return r^{V}_{ts} is represented with a factor model by decomposing it into the linear sum of a time drift, a short-term municipal bond factor return, a long-term municipal bond factor return, and a bond-specific valuation factor, ε_{ts}:

$$\begin{aligned} r^{\mathrm{V}}_{ts} &= \mathit{Days}_{ts}\,(5\% - \mathit{CouponRate}) \\ &\qquad + \beta_{\mathrm{Avg}} \mathit{SLAvg}^{+}_{ts} \beta_{\mathrm{Dif}} \mathit{SLDif}^{+}_{ts}\, \varepsilon_{ts} \,, \end{aligned}$$

where Days_{ts} counts the number of calendar days between trades t and s, *CouponRate* is the bond coupon rate. SLAvg_{ts} and SLDif_{ts} are the average and difference, respectively, of continuously compounded short- and long-duration factor returns between trades t and s. The first term models the continuously compounded bond price return that traders expect when interest rates are constant and the bond's coupon interest rate differs from a notional five percent bond, the median coupon rate in their sample. The two index returns model municipal bond value changes due to changes in interest rates and tax-exempt yield spreads. Harris and Piwowar [26] use repeat sales methods to estimate these indices. They assume that the bond-specific valuation factor ε_{ts} has mean zero and variance given by

$$\sigma^2_{\varepsilon_{ts}} = N^{\mathrm{Sessions}}_{ts} \sigma^2_{\mathrm{Sessions}}$$

where $N^{\mathrm{Sessions}}_{ts}$ is the total number of full and partial trading sessions between trades t and s.

To model customer transaction costs, Harris and Piwowar [26] consider several alternative functional forms that are flexible enough to model very high average trading costs for small trade sizes and very low average trading costs for large trade sizes. Harris and Piwowar [26] choose following parsimonious expression:

$$c(S_t) = c_0 + c_1 \frac{1}{S_t} + c_2 \log S_t + \kappa_t \,,$$

where the first three terms specify the cost function that represents average trade costs and κ_t represents the unexplained variation in the observed customer trading costs. The constant term allows total transaction costs to grow in proportion to size. The second term captures fixed costs per trade and the third term allows the costs per bond to vary by size.

The Harris and Piwowar [26] time-series estimation model is obtained by combining the last four equations:

$$r^{\mathrm{P}}_{ts} - Days_{ts}\left(5\% - CouponRate\right) = c_0\left(Q_t - Q_s\right) + c_1\left(Q_t\frac{1}{S_t} - Q_s\frac{1}{S_s}\right) + c_2\left(Q_t\log S_t - Q_s\log S_s\right) + \beta_{\mathrm{SLAvg}}SLAvg^{+}_{ts}\beta_{\mathrm{SLDif}}SLDif^{+}_{ts}\eta_{ts}\,,$$

where the expression for the regression term, η_{ts}, is given by:

$$\eta_{ts} = \varepsilon_{ts} + Q_t\kappa_t - Q_s\kappa_s + I^{\mathrm{D}}_t\delta_t - I^{\mathrm{D}}_s\delta_s\,.$$

The mean of the error term is zero and its variance is:

$$\sigma^2_{ts} = N^{\mathrm{Sessions}}_{ts}\sigma^2_{\mathrm{Sessions}} + D_{ts}\sigma^2_{\delta} + (2 - D_{ts})\,\sigma^2_{\kappa}\,,$$

where D_{ts} represents the number (0, 1, or 2) of interdealer trades involved in trades t and s. For each bond, Harris and Piwowar [26] separately estimate their time-series transaction cost estimation model using an iterated least squares method, with the weight given by the inverse of the estimates of σ^2_{ts}. For a wide range of trade sizes, they calculate weighted cross-sectional mean cost estimates across all municipal bonds. Each bond's weight is given by the inverse of its estimation error variance at that trade size.

Harris and Piwowar [26] find that retail-size municipal bond trades are substantially more expensive than similar-sized equity trades. Average effective spreads in municipal bonds are almost 2% for representative retail-size trades ($20,000). They point out that this is the equivalent of almost 4 months of total annual return for a bond with a 6% yield-to-maturity.

Harris and Piwowar [26] also find that retail-size municipal bond trades are more expensive than institutional-size trades. Unlike in equities, municipal bond transaction costs decrease with trade size. Harris and Piwowar [26] also find that, unlike in equities, municipal bond transaction costs do not depend on trade frequency. They attribute these results to the lack of price transparency in the municipal bond market during their sample period.

To investigate how estimated transaction costs vary across municipal bonds, Harris and Piwowar [26] conduct cross-sectional weighted least squares regressions for various trade sizes. The dependent variable is the estimated average transaction costs in a given municipal bond at a given trade size. The weight for each bond observation is given by the inverse of the estimation error variance of its cost estimate. The independent variables include measures of credit quality, age, and instrument complexity.

Harris and Piwowar [26] show that bond trading costs increase with credit risk, time to maturity, and time since issuance. They also find that trading costs increase with instrument complexity, and that retail investors are more adversely affected by instrument complexity than institutional investors. They conjecture that investors and issuers might benefit if simpler bonds were issued.

Green, Hollifield, and Schurhoff (2007a)

Green, Hollifield, and Schurhoff [22] focus on trades that can reasonably be assumed to represent two sides of a single intermediated transaction, and employ a structural model to decompose the cost faced by a customer into a portion that represents the cost the dealer incurs and a portion attributable to the dealer's market power. They formulate and estimate a simple structural bargaining model that allows them to estimate measures of dealer bargaining power and relate it to characteristics of the trades.

Green, Hollifield, and Schurhoff [22] use a theoretical model to seek evidence that the high costs of trading are due to dealer market power and to find out how the exercise of market power depends on the characteristics of the trade. They develop a simple theoretical model of the interaction between dealers and their customers in which the expected profits to the dealer reflect both the dealer's costs and his bargaining power relative to the customer. Both of these, in turn, can be parametrized as functions of observable variables, and estimated as a Stochastic Frontier Model. The dealer's cost is the stochastic frontier, which represents the expected mark-up the customer would obtain if dealers were always driven by their reservation values, as they would be if the provision of dealer services were perfectly competitive. The observed markup, expressed in excess returns over a municipal bond index, can be written as:

$$\frac{p_i - p^*_i}{p^*_i} - R_{\mathrm{index},i} = \left[\frac{c\left(X_i,\theta\right)}{p^*_i} - E\left(R_{\mathrm{index},i}\middle|\,X_i\right)\right] + \varepsilon_i + \xi_i\,,$$

where p_i is the dealer's selling price, p^*_i is the dealer's purchase price, and $R_{\mathrm{index},i}$ is the municipal bond market index return.

The first term on the right-hand side of the equation represents the dealer's costs in excess of the expected municipal bond index return, where X_i is a set of conditioning variables observable to the buyer and seller and θ is a set of parameters to be estimated. They refer to this term as the cost of intermediation.

The second and third terms capture how the observed markup can differ from the dealer's cost of intermediation.

The second term, ε_i, is a symmetric, normally-distributed error term:

$$\varepsilon_i \equiv \frac{e_i}{p_i^*} - \eta_i \,,$$

reflecting a zero-mean forecast error:

$$\eta_i = R_{\text{index},i} - E\left(R_{\text{index},i} \middle| X_i\right) \,.$$

The third term, ξ_i, is a one-sided, exponentially-distributed error term:

$$\xi \equiv \frac{\rho_i \left[E\left(p_i \middle| X_i\right) - c\left(X_i, \theta\right) - \nu_i\right]}{p_i^*} \,,$$

reflecting the distribution of sellers' reservation values (ν_i) and dealer bargaining power.

Green, Hollifield, and Schurhoff [22] estimate restricted and unrestricted versions of the following regression model via maximum likelihood:

$$\frac{p_i - p_i^*}{p_i^*} - R_{\text{index},i} = \theta_0 + \sum_{l=1}^{L} \theta_l X_{il} + \varepsilon_i + \xi_i \,,$$

with $l = 1, \ldots, L$ conditioning variables. The residual ε_i is normally distributed with standard deviation $b_0 \Pi_{k=1}^{K} \mathrm{e}^{b_{ik} Z_k}$, with Z_{ik} for $k = 1, \ldots, K$ conditioning variables. The residual ξ_i is exponentially distributed with mean and standard deviation $a_0 \Pi_{k=1}^{K} \mathrm{e}^{a_{ik} Z_k}$. In the "market power" version of their model, all of the parameters are unrestricted. In the restricted ("no market power") model, all of the parameters on the one-sided error are constrained to zero: $a_0 = a_1 = \ldots = a_k = 0$.

The data used by Green, Hollifield, and Schurhoff [22] includes both customer trades and interdealer trades. But, because their data does not identify the specific broker-dealer associated with a given trade, they must infer their trades and profits indirectly by studying pairs of trades that appear to be direct exchanges of bonds through a single dealer. They assume that a customer buy transaction of a given size of a given bond that occurs within a very short time of customer sell transaction of the same size in the same bond are most likely related. The reasonableness of this assumption is confirmed by Harris and Piwowar [26], whose data contains dealer identities.

Green, Hollifield, and Schurhoff [22] find that municipal bond dealers earn lower average markups on larger trades, even though larger trades lead the dealers to bear more risk of losses. Their results suggest that municipal bond dealers exercise substantial market power, particularly in retail-sized transactions. Their measures of market power decrease in trade size and increase in variables that indicate the complexity of the trade for the dealer.

Transaction Reporting and Compliance Engine (TRACE) Research

TRACE not only brought unprecedented transparency to corporate bond market investors, it also provided an unprecedented opportunity for market microstructure researchers to examine new issues. Chief among them was the "natural experiment" of adding price transparency to an opaque market. Three prominent studies (collectively, "the TRACE studies") that examined the introduction of price transparency to the corporate bond market were Edwards et al. [17], Bessembinder, Maxwell, and Venkataraman [7], and Goldstein, Hotchkiss, and Sirri [20].

These TRACE studies were very complementary in terms of their contributions to the market microstructure literature. To understand the full impact of this collective research, it is important to remember that they were written at a time when many market participants and some regulators were concerned that public dissemination of bond pricing data might have an adverse impact on liquidity. Using different experimental designs and empirical methods, the TRACE studies produced similar results, conclusions, and implications for regulatory policymakers. Overall, the results in all three TRACE studies show that public investors benefit significantly from the introduction of price transparency.

Edwards et al. [17] estimate transaction costs for all corporate bonds that trade at least nine times between January 2003 and January 2005. Their TRACE data set includes all reported OTC trades in corporate bonds, whether transparent or not. Consistent with the results of Harris and Piwowar [26] for the municipal bond market, Edwards et al. [17] find that corporate bonds are expensive for retail investors to trade and that corporate bond transaction costs decrease significantly with trade size. They find that effective spreads in corporate bonds average 1.24% of the price of representative retail-sized trades ($20,000). They point out that this is the equivalent of over 2 months of the total annual return for a bond with a 6% yield to maturity, or 52 cents per share for a $40 stock. In cross-sectional tests, Edwards et al. [17] find that transaction costs are lower for highly rated bonds, recently issued bonds, and bonds close to maturity.

Edwards et al. [17] find that costs are lower for bonds with transparent trade prices, and they drop when the TRACE system starts to publicly disseminate their prices. Their results suggest that introduction of price transparency results in a drop in customer trading costs of at least 5 basis points (bps). In 2003, public investors traded approximately $2 trillion in bonds for which prices were not disseminated. If the prices for these bonds had been

TRACE-transparent, a quick back-of the-envelope calculation shows investors could have saved a minimum of $1 billion that year. Edwards et al. [17] point out that the $1 billion figure represents a lower bound for two reasons. First, because many unsophisticated investors were unaware that prices became available, and because learning how to use the price data takes, time, the long-run benefits are undoubtedly much greater. Second, they do not capture the initial reduction in trading costs at the initiation of TRACE. Bessembinder, Maxwell, and Venkataraman [7] find that sophisticated institutional investors benefited from an immediate reduction in trading costs of about $1 billion.

Bessembinder, Maxwell, and Venkataraman [7] estimate their trade execution costs for a sample of institutional (insurance company) trades in corporate bonds before and after the initiation of public transaction reporting for some bonds through the TRACE system in July 2002. They find that the average reduction in one-way trading costs or bonds eligible for TRACE transaction reporting is about 5 to 8 bps. This translates to a reduction in trade execution costs of about 50%. Moreover, they find a 20% reduction for bonds not eligible for TRACE reporting. Bessembinder, Maxwell, and Venkataraman [7] interpret their results as suggesting that better pricing information regarding some bonds also improves valuation and execution cost monitoring for related bonds. They find no evidence that market quality deteriorated in other dimensions.

Bessembinder, Maxwell, and Venkataraman [7] also find that larger trading cost reductions for less liquid and lower-rated bonds, and for larger trades. They estimate that their results equate to annual trading cost reductions of roughly $1 billion per year for the entire corporate bond market, reinforcing that market design can have first-order effects, even for relatively sophisticated institutional customers.

Goldstein, Hotchkiss, and Sirri [20] design and construct a controlled experiment to examine the impact of introducing price transparency on liquidity for BBB-rated corporate bonds. They selected the 120 BBB-rated bonds for which the NASD began disseminating trade data on April 14, 2003. They simultaneously selected a control sample of non-disseminated bonds.

Goldstein, Hotchkiss, and Sirri [20] find that DRT spreads decrease for most BBB-rated corporate bonds whose prices become transparent, and that this effect is strongest for intermediate trade sizes. The only caveat to this result is that they do not find any significant transparency effect for the most thinly-traded bonds. Overall, Goldstein, Hotchkiss, and Sirri [20] conclude that their finds indicate that the introduction of post-trade price transparency has a neutral or positive effect on market liquidity.

The similar results and conclusions in the three complementary TRACE studies collectively generate important policy implications. Foremost, policymakers should take comfort in the fact that there are few, if any, instances in the combined results that show any harm to investors from introducing price transparency to securities markets. To the contrary, the results show that both retail and institutional investors benefit from price transparency. The empirical results from the TRACE studies support the well-founded economic theoretical arguments that transparency should lower transaction costs, especially for smaller trades.

Speeches and testimony by US bond market regulators, such as those listed in the bibliography, show that these studies critically informed the debate over adding price transparency to the US bond markets. Moreover, they continue to provide important lessons for policy makers in bond markets outside of the United States. The bibliography also contains a partial listing of international reports, discussion papers, and conference proceedings that prominently cite the TRACE studies.

Edwards, Harris, and Piwowar (2007)

Edwards et al. [17] apply the Harris and Piwowar [26] econometric approach to corporate bonds. They also extend the approach by allowing liquidity to be time varying. This extension allows them to examine how the introduction of price transparency affects corporate bond transaction costs.

They model the unobserved value return r^{V}_{ts} by decomposing it into the linear sum of a time drift, an average bond index return, differences between index returns for long and short term bonds and for high and low quality bonds, and a bond-specific valuation factor, ε_{ts}.

$$\begin{aligned} r^{V}_{ts} = {} & Days_{ts}\,(DriftRate) + \beta_1 AveIndexRet_{ts} \\ & + \beta_2 DurationDif_{ts} + \beta_3 CreditDif_{ts} + \varepsilon_{ts}\,, \end{aligned}$$

where $Days_{ts}$ counts the number of calendar days between trades t and s, $DriftRate$ is the bond coupon rate subtracted from five percent, $AveIndexRet_{ts}$ is the index return for the average bond between trades t and s and $DurationDif_{ts}$ and $CreditDif_{ts}$ are the corresponding differences between index returns for long and short term bonds and high and low credit risk bonds. The first term accounts for the continuously compounded bond price return that traders expect when interest rates are constant and the bond's coupon interest rate differs from five percent. The three factor returns account for bond value changes due to shifts in interest rates and credit spreads. Edwards et al. [17] estimate the bond indices using repeat sale regression methods with terms that account for bond transaction costs. Finally, the bond-specific valuation factor ε_{ts} has mean zero and variance given by

$$\sigma^2_{\varepsilon_{ts}} = N^{\text{Sessions}}_{ts} \sigma^2_{\text{Sessions}} \,,$$

where N^{Sessions}_{ts} is the number of trading sessions and fractions of trading sessions between trades t and s.

Edwards et al. [17] model customer transaction costs using the following additive expression:

$$c(S_t) = c_0 + c_1 \frac{1}{S_t} + c_2 \log S_t + c_3 S_t + c_4 S_t^2 + \kappa_t \,,$$

where κ_t represents variation in the actual customer transaction cost that is unexplained by the average transaction cost function. This variation may be random or due to an inability of the average transaction cost function to represent average trade costs for all trade sizes. They assume κ_t has zero mean and variance given by σ^2_κ.

The first three terms of the cost function are the same as in Harris and Piwowar [26], where the constant term allows total transaction costs to grow in proportion to size, the second term characterizes any fixed costs per trade, and the third term allows for costs per bond to vary by trade size. The two additional terms allow more flexibility in the costs to vary by size. Because corporate bonds trade more frequently than municipal bonds, Edwards et al. [17] did not need to be as concerned about degrees of freedom as Harris and Piwowar [26].

Combining the last three equations produces the Edwards et al. [17] version of the Harris and Piwowar [26] transaction cost estimation model:

$$\begin{aligned} r^{\text{P}}_{ts} - \mathit{Days}_{ts}\left(\mathit{DriftRate}\right) &= c_0 \left(Q_t - Q_s\right) \\ &+ c_1 \left(Q_t \frac{1}{S_t} - Q_s \frac{1}{S_s}\right) + c_2 \left(Q_t \log S_t - Q_s \log S_s\right) \\ &+ c_3 \left(Q_t S_t - Q_s S_s\right) + c_4 \left(Q_t S_t^2 - Q_s S_s^2\right) \\ &+ \beta_1 \mathit{AveIndexRet}_{ts} + \beta_2 \mathit{DurationDif}_{ts} + \beta_3 \mathit{CreditDif}_{ts} \\ &+ \eta_{ts} \,, \end{aligned}$$

where the left hand side is simply the continuously compounded bond return expressed as the equivalent rate on a notional five percent coupon bond. Edwards et al. [17] estimate their time-series model in the same way as Harris and Piwowar [26].

Edwards et al. [17] extend Harris and Piwowar [26] by introducing a pooled time-series regression model that they use to estimate average transaction costs for each day for a class of bonds. With this model, they are able to estimate the daily average transaction costs for bonds that became transparent in 2003, and compare these estimates to those for comparable bonds that were either TRACE-transparent throughout 2003 or never TRACE-transparent in 2003.

The pooled time-series regression model that Edwards et al. [17] use to estimate daily transaction costs differs in two respects from the time-series regression model that they use to estimate average transaction costs for a given bond. First, they specify separate average transaction cost functions, $c_T(S_t)$, for each day T in the sample. Second, to minimize the total number of parameters to be estimated, they use the three-parameter average cost function:

$$c_T(S_t) = c_{0T} + c_{1T} \frac{1}{S_t} + c_{2T} \log S_t + \kappa_t \,.$$

For a given bond, the change in value between bond trades is modeled as:

$$\log V_t - \log V_s = f_s r_S + \sum_{J=S+1}^{T-1} r_J + f_t r_T + e_{st} \,,$$

where S is the day on which trade s took place and T is the day on which a subsequent trade t took place, r_J is the common index return (to be estimated) for day J and f_s and f_t, respectively, are the fractions of the S and T trading days overlapped by the period spanned by transactions s and t. This portion of the specification is the same as appears in many paired trade regression index estimation procedures. With these changes, the regression model is

$$\begin{aligned} r^{\text{P}}_{ts} - \mathit{Days}_{ts}\left(5\% - \mathit{CouponRate}\right) &= c_{0T} Q_t - c_{0S} Q_s \\ + c_{1T} Q_t \frac{1}{S_t} - c_{1S} Q_s \frac{1}{S_s} &+ c_{2T} Q_t \log S_t - c_{2S} Q_s \log S_s \\ &+ f_s r_S + \sum_{J=S+1}^{T-1} r_J + f_t r_T + \eta_{ts} \,. \end{aligned}$$

They use iterated weighted least squares methods, where the weights are equal to the predicted values of the regression of the squared residuals on the independent variables appearing in the residual variation expression. Edwards et al. [17] estimate the model using a three-month wide sliding window that moves forward one month at a time. The time series of coefficient estimates are assembled from the center months of each of the sliding regressions. They compute transaction costs for various transaction sizes by evaluating the estimated transaction cost functions at the given transaction sizes. Using the estimated variance-covariance matrix of the estimators, they also compute daily standard errors of the various daily transaction cost estimates.

Bessembinder, Maxwell, and Venkataraman (2006)

Bessembinder, Maxwell, and Venkataraman [7] develop and estimate an indicator variable regression model:

$$\Delta P = a + wX_t + \gamma S Q_t^* + \alpha S \Delta Q + \omega_t \,,$$

where ΔP is the change in the price of the bond from time $t-1$ to time t, a is the regression intercept, w is the fraction of public information that is observable in the data with realizations X_t, γS is the informational component of the spread, αS is the non-informational component of the spread (where $\alpha = (1-\gamma)$), Q_t^* is the market maker's estimate of bond value due to surprises in order flow, ΔQ is the change in indicator variable Q (which takes a value of 1 if the trade is a customer buy and -1 if it is a customer sell) from time $t-1$ to time t, and ω_t is the regression error term.

Bessembinder, Maxwell, and Venkataraman [7] develop this regression model in the following way. $E_t(V)$ is the market-maker's estimate of the bond's unobserved true value (V) at time t conditional on whether the observed trade is a customer buy or a customer sell. Transaction prices are given by:

$$P_t = E_t(V) + \alpha S Q_t \,.$$

The market maker's estimate of bond value at time t, $E_t(V)$, is her estimate from the prior period, $E_{t-1}(V)$, updated to reflect surprises in order flow, $Q_t - E_{t-1}(Q_t)$, and public information revealed since the prior period, η_τ Substitution yields:

$$E_t(V) = E_{t-1}(V) + \gamma S Q_t^* + \eta_t \,,$$

where $Q_t^* = Q_t - E_{t-1}(Q_t)$. To allow for the possibility that bond market order flow is positively autocorrelated, Bessembinder, Maxwell, and Venkataraman [7] assume that it follows a simple AR1 process, so that $E_{t-1}(Q_t) = \rho(Q_{t-1})$. The change in the price of the bond from time $t-1$ to time t is:

$$P_t - P_{t-1} = \gamma S Q_t^* + \alpha S Q_t - \alpha S Q_{t-1} + \eta_t \,.$$

Substituting ΔP for P_t – P_{t-1} and ΔQ for Q_t – Q_{t-1}, this expression can be rewritten as:

$$\Delta P = \gamma S Q_t^* + \alpha S \Delta Q + \eta_t \,.$$

To incorporate observable public information that affects bond value, they assume that a fraction w of public information becomes observable in the data with realizations X_t, while the remaining portion $(1-w)$ is due to unobservable innovations U_t that represent statistical noise. Substitution yields their regression model:

$$\Delta P = wX_t + \gamma S Q_t^* + \alpha S \Delta Q + \omega_t \,,$$

where $\omega = (1-w)\,U_t$. Bessembinder, Maxwell, and Venkataraman [7] show that their model is equivalent to the Madhavan et al. [39] model. Moreover, in the special case of no autocorrelation in order flow ($\rho = 0$), their model is equivalent to Huang and Stoll [33], Schultz [42] and Warga [44].

Goldstein, Hotchkiss, and Sirri (2007)

Goldstein, Hotchkiss, and Sirri [20] use two different methods to estimate transaction costs for a sample of BBB-rated bonds. Their first method involves identifying “dealer round-trip” (DRT) transaction chains. These transaction chains involve a dealer purchasing a bond from a customer and then selling that same bond to another customer within a specified period of time. DRT spreads are calculated as the difference between the customer buy price at the end of the transaction chain and the customer sell price at the beginning of the chain. Their DRT method is similar to the methods used in the municipal bond studies of Green et al. [22] and Biais and Green [9], except their data contains individual dealer identifiers. Goldstein, Hotchkiss, and Sirri [20] estimate DRT spreads for transaction chains that occur with one-day, five-day, and unlimited time intervals. They estimate DRT spreads for various trade size groups.

Their second method is a regression method similar to Warga [44] and Schultz [42]. For each trade size group, Goldstein, Hotchkiss, and Sirri [20] estimate spreads by regressing the difference between the transaction price for a customer (T) and an estimated bid price (B) on a dummy variable that equals one for customer buys and zero for customer sells:

$$[T - B]_i = \alpha_0 + \alpha_1 D_i^{\text{Buy}} + \varepsilon_i \,,$$

where estimated bid prices are obtained from Reuters dealer bid price estimates from the end of the day prior to the transaction. Reuters estimates are based on daily quotes obtained directly from individual dealers.

Goldstein, Hotchkiss, and Sirri [20] estimate a second regression to consider the effect of dissemination while controlling for other bond characteristics impacting the spread:

$$
\begin{aligned}
[T-B]_i &= \alpha_0 + \alpha_1 D_i^{\text{Buy}} + \alpha_2 D_i^{\text{DisseminatedBond}} \\
&+ \alpha_3 D_i^{\text{Post-disseminationPeriod}} \\
&+ \alpha_4 D_i^{\text{DisseminationBond}^{*}\,\text{Post-disseminationPeriod}} \\
&\qquad + \alpha_5 X_5 + \cdots + \alpha_{10} X_{10} + \varepsilon_i \ ,
\end{aligned}
$$

where additional dummies are included for disseminated bonds, transactions that occur in the post-dissemination period, and the interaction of these two dummies for transaction in disseminated bonds that occur in the post-dissemination period. As in Schultz [42] the additional dummies are expressed a $+1$ for buys and -1 for sells. Variables $X_5, \ldots, X_{10}$ are six bond characteristics related to spreads: trade size, time-to-maturity, age, issue amount, average daily volume over the prior 30 days, and days since last trade.

The Links Between Bond Market Microstructure Research and Other Finance and Economics Research

The discussion of bond market research has thus far been presented solely within the framework of the market microstructure literature. However, some of the most interesting bond market research is connected to other areas of finance and economics. The instrument complexity results of Harris and Piwowar [26], for example, provide evidence to support Carlin's [11] formal model of strategic price complexity in security design for retail markets. Additionally, Chen, Lesmond, and Wei [13] provide an example of how bond market microstructure research is linked to asset pricing models in finance. Green, Hollifield, and Schurhoff [23] develop a theoretical model that is analogous to the costly consumer search models in the broader economics literature.

Chen, Lesmond, and Wei (2007)

Beginning with Amihud and Mendelson [3], market microstructure research has consistently shown that a liquidity premium exists in equity markets. Recently, bond market microstructure researchers have begun investigating whether a liquidity premium also exists in bond markets. One such paper is Chen, Lesmond, and Wei [13]. Their investigation of the link between bond liquidity and corporate yield spreads provides important implications for the default risk literature.

Chen, Lesmond, and Wei [13] investigate whether liquidity is priced in corporate yield spreads. They use several approaches, including a regression approach that is an extension to the Lesmond, Ogden, and Trzcinka [36] (LOT) approach developed for equities. The LOT approach assumes that a zero return day (or a non-trading day) is observed when the true price changes by less than the transaction costs. Because marginal informed investors will only trade on information if the trade yields expected profits net of transaction costs, an individual bond's trading costs represent a threshold that must be exceeded before its return will reflect new information. The premise of this approach is that if the value of the information is insufficient to exceed the costs of trading, then the marginal investor will either reduce trading or not trade, causing a zero return.

Chen, Lesmond, and Wei [13] extend the LOT approach to corporate bonds by applying a two-factor return-generating model to estimate bond trading costs:

$$
\begin{aligned}
R^{*}_{j,t} &= \beta_{j1} \mathit{Duration}^{*}_{j,t} \Delta R_{ft} \\
&\qquad + \beta_{j2} \mathit{Duration}^{*}_{j,t} \Delta \mathit{S\&P\ Index}_t + \varepsilon_{j,t} \ ,
\end{aligned}
$$

where $R^{*}_{j,t}$ is the unobserved "true" return for bond j on day t that investors would bid given zero trading costs. The daily change in the 10-year risk-free interest rate, ΔR_{ft}, is the factor that is more important for investment grade bonds, while the second factor, $\Delta \mathit{S\&P\ Index}_t$, the daily return on the Standard & Poor's 500 equity index, is more important for high-yield bonds. Both factors are scaled by $\mathit{Duration}_{j,t}$, the bond's duration.

Chen, Lesmond, and Wei [13] then apply the Amihud and Mendelson [3] liquidity premium to bonds. In Amihud and Mendelson [3], observed asset prices differ from true values because of a liquidity premium that compensates investors for liquidity costs. Chen, Lesmond, and Wei [13] state the liquidity effects on bond returns as:

$$
R_{j,t} = R^{*}_{j,t} - \alpha_{i,j} \ ,
$$

where $R_{j,t}$ is the measured return, $\alpha_{2,j}$ is the effective buy-side cost, and $\alpha_{1,j}$ is the effective sell-side cost for bond j. The resulting liquidity constraint is:

$$
\begin{array}{lll}
R_{j,t} = R^{*}_{j,t} - \alpha_{1j} & \text{if } R^{*}_{j,t} < \alpha_{1j} & \text{and } \alpha_{1j} < 0 \\
R_{j,t} = 0 & \text{if } \alpha_{1j} \le R^{*}_{j,t} \le \alpha_{2j} & \\
R_{j,t} = R^{*}_{j,t} - \alpha_{2j} & \text{if } R^{*}_{j,t} > \alpha_{2j} & \text{and } \alpha_{2j} > 0 \, .
\end{array}
$$

Combining the liquidity constraint with the return generating model, Chen, Lesmond, and Wei [13] us a maximum likelihood method outlined in LOT to estimate transaction costs. They specify the log-likelihood function as:

$$\begin{aligned}\mathrm{Ln}L = {} & \sum_{1} \mathrm{Ln}\frac{1}{\left(2\pi\sigma_j^2\right)^{1/2}} \\ & - \sum_{1} \frac{1}{2\sigma_j^2}\left(R_j + \alpha_{1,j} - \beta_{j1}\mathit{Duration}_{j,t} * \Delta R_{ft}\right. \\ & \qquad \left. - \beta_{j2}\mathit{Duration}_{j,t} * \Delta \mathit{S\&P\ Index}\right)^2 \\ & + \sum_{2} \mathrm{Ln}\frac{1}{\left(2\pi\sigma_j^2\right)^{1/2}} \\ & + \sum_{2} \frac{1}{2\sigma_j^2}\left(R_j + \alpha_{2,j} - \beta_{j1}\mathit{Duration}_{j,t} * \Delta R_{ft}\right. \\ & \qquad \left. - \beta_{j2}\mathit{Duration}_{j,t} * \Delta \mathit{S\&P\ Index}\right)^2 \\ & + \sum_{0} \mathrm{Ln}\left(\Phi_{2,j} - \Phi_{1,j}\right) ,\end{aligned}$$

where $\Phi_{i,j}$ represents the cumulative distribution function for each bond-year evaluated at:

$$\frac{\left(\alpha_{1,j} - \beta_{j1}\mathit{Duration}_{j,t} * \Delta R_{ft}\right)}{\sigma_j} - \frac{\left(\beta_{j2}\mathit{Duration}_{j,t} * \Delta \mathit{S\&P\ Index}_t\right)}{\sigma_j} .$$

Σ_1 (region 1) represents the negative nonzero measured returns, Σ_2 (region 2) represents the positive nonzero measured returns, and Σ_0 (region 0) represents the zero measured returns. The difference in the buy-side and sell-side cost estimates, $\alpha_{2,j} - \alpha_{1,j}$, represents round-trip trading costs.

The model's implicit assumption that information motivates bond trades and that information is efficiently impounded into bond prices is supported by the results of Hotchkiss and Ronen [31]. The error term captures noise trading and trades due to unanticipated public information.

In addition to LOT estimates, Chen, Lesmond, and Wei [13] use bid-ask spreads and zero-returns as liquidity cost measures. The bid-ask spreads the use are bond-year proportional bid-ask spreads, calculated as the average of quarterly proportional spreads. Quarterly proportional spreads are calculated from quarterly bid-ask spreads obtained from Bloomberg consensus quotes among market participants, divided by the average bid and ask price. Zero-returns are simply the percentage of days with returns equal to zero.

They find that liquidity costs are related to credit rating. Liquidity costs are much higher for high-yield bonds than for investment grade bonds. They also find that liquidity costs are related to maturity. Liquidity costs for long-maturity bonds are higher than for short-maturity bonds.

They also find that yield spreads generally increase with maturity for investment grade bonds. But, they find that yield spreads generally decrease with maturity for high-yield bonds. They point out the endogeneity issue stemming from the Helwege and Turner [28] finding that relatively safer firms within the same high-yield credit rating category tend to issue longer-term bonds. This endogeneity issue causes the average yield spread to decline with maturity for high-yield bonds.

To investigate whether liquidity is priced in corporate yield spreads, Chen, Lesmond, and Wei [13] first run the following regression specification for investment grade bonds and high-yield bonds separately:

$$\begin{aligned}\mathit{Yield\ Spread}_{it} = {} & \eta_0 + \eta_1\mathit{Liquidity}_{it} + \eta_2\mathit{Maturity}_{it} \\ & + \eta_3\mathit{Amount\ Outstanding}_{it} + \eta_4\mathit{Coupon}_{it} \\ & + \eta_5\mathit{Treasury\ Rate}_{it} + \eta_6 10\mathit{Yr} - 2\mathit{Yr\ Treasury\ Rate}_{it} \\ & + \eta_7\mathit{EuroDollar}_{it} + \eta_8\mathit{Volatility}_{it} + \eta_9\mathit{Bond\ Rating}_{it} \\ & + \eta_{10}\mathit{PreTax\ Coverage\ Dummy}_{it} \\ & + \eta_{11}\mathit{Operating\ Income/Sales}_{it} + \eta_{12}\mathit{Debt/Assets}_{it} \\ & + \eta_{13}\mathit{Debt/Capitalization}_{it} + \varepsilon_{it} ,\end{aligned}$$

where the subscript *it* refers to bond *i* in year *t*. *Liquidity* refers to the three liquidity cost measures – bid-ask spread, zero-returns, or the LOT estimate. Additional variables control for bond-specific, firm-specific, and macroeconomic factors. *Maturity* is the number of years until the bond matures relative to the year being analyzed, and *Amount Outstanding* is natural logarithm of the dollar amount outstanding, *Coupon* is the bond coupon rate. *Treasury Rate* is the 1-year Treasury Note rate, *10Yr-2Yr Treasury Rate* is the difference between the 10-year and 2-year Treasury rates, and *Eurodollar* is the 30-day Eurodollar rate minus the 3-month T-Bill rate. *Volatility* is the equity volatility for each issuer and *Bond Rating* is a credit rating scale that ranges from 1 (AAA rating) to 10 (BBB- rating) for investment grade bonds and from 1(BB+ rating) to 12 (D rating) for high-yield bonds. *Pre-Tax Coverage Dummy* represents four dummy variables corresponding to groupings of pre-tax income, *Operating Income/Sales*, *Debt/Assets*, and *Debt/Capitalization* are each firm's respective accounting ratios.

They find that all three liquidity measures are positively related to the yield spread in both the investment grade and high-yield samples. The liquidity coefficients are statistically significant at the 1% level in every scenario. This provides strong evidence that liquidity is priced in corporate yield spreads. This finding is robust to controlling for issuer influences with issuer fixed-effects regressions. The only caveat is that they achieve slightly weaker results for the zero-return liquidity cost measure than for bid-ask spreads and LOT estimates. This finding is also robust to controlling for potential endogeneity problems arising from the contemporaneous measurement of the yield spread, liquidity costs, and credit rating. They perform this robustness check by employing a simultaneous equations model using three equations that correspond to each of the potentially endogenous variables:

$$\begin{aligned}&\mathit{Yield\ Spread}_{it} = \eta_0 + \eta_1 \mathit{Liquidity}_{it} + \eta_2 \mathit{Maturity}_{it}\\ &+ \eta_3 \mathit{Coupon}_{it} + \eta_4 \mathit{Treasury\ Rate}_{it}\\ &+ \eta_5 10\mathit{Yr} - 2\mathit{Yr\ Treasury\ Rate}_{it} + \eta_6 \mathit{EuroDollar}_{it}\\ &+ \eta_7 \mathit{Volatility}_{it} + \eta_8 \mathit{Bond\ Rating}_{it}\\ &+ \eta_9 \mathit{PreTax\ Coverage\ Dummy}_{it}\\ &+ \eta_{10} \mathit{Operating\ Income/Sales}_{it} + \eta_{11} \mathit{Debt/Assets}_{it}\\ &\qquad\qquad + \eta_{12} \mathit{Debt/Capitalization}_{it} + \varepsilon_{it}\ ,\end{aligned}$$

$$\begin{aligned}&\mathit{Liquidity}_{it} = \eta_0 + \eta_1 \mathit{Maturity}_{it} + \eta_2 \mathit{Age}_{it}\\ &+ \eta_3 \mathit{Amount\ Outstanding}_{it} + \eta_4 \mathit{Bond\ Rating}_{it}\\ &\quad + \eta_5 \mathit{Bond\ Volatility}_{it} + \eta_6 \mathit{Yield\ Spread}_{it} + \varepsilon_{it}\ ,\end{aligned}$$

$$\begin{aligned}&\mathit{Credit\ Rating}_{it} = \eta_0 + \eta_1 \mathit{Treasury\ Rate}_{it}\\ &+ \eta_2 10\mathit{Yr} - 2\mathit{Yr\ Treasury\ Rate}_{it}\\ &+ \eta_3 \mathit{PreTax\ Coverage\ Dummy}_{it}\\ &+ \eta_4 \mathit{Operating\ Income/Sales}_{it}\\ &+ \eta_5 \mathit{Debt/Assets}_{it} + \eta_6 \mathit{Debt/Capitalization}_{it}\\ &\qquad\qquad + \eta_7 \mathit{Yield\ Sprad}_{it} + \varepsilon\ .\end{aligned}$$

The model is estimated using twostage least squares. The simultaneous equation model estimation results show that the potential endogeneity does not affect the relation between liquidity and yield spreads for either the investment grade or the high-yield bonds.

Thus, Chen, Lesmond, and Wei [13] find extremely consistent and robust evidence that liquidity is a key determinant in corporate yield spreads. This finding provides at least a partial explanation for the findings of Collin-Dufresne, Goldstein, and Martin [15] and others who show that default risk does not completely explain corporate yield spreads.

Green, Hollifield, and Schurhoff (2007b)

Green, Hollifield, and Schurhoff [23] examine secondary market trading in newly issued municipal bonds for the first 60 trading days of their lives. They begin by descriptively documenting the price behavior of newly issued municipal bonds. They show that municipal bonds are underpriced when issued. But, unlike equities, the average price rises slowly over a period of several days. Green, Hollifield, and Schurhoff [23] also find that the observed price patterns are complex. High levels of price dispersion are observed for small trade sizes in the aftermarket for new municipal bond issues. While some small traders purchase bonds on attractive terms, others do not. In contrast, there is very little price dispersion for large trade sizes. Virtually all of the large traders purchase bonds on attractive terms.

They argue that the price level and dispersion patterns are the result of bond dealers discriminating between informed and uninformed customers. Accordingly, Green, Hollifield, and Schurhoff [23] develop and estimate a mixed distribution model for the markups that uninformed and informed investors pay when they purchase newly issued bonds. Their model incorporates investor search costs, i. e., the costs in terms of time and effort needed for investors to become informed about new bond issues.

The mixed distribution model of Green, Hollifield, and Schurhoff [23] is analogous to economic models of costly consumer search, such as the gametheoretic model of Shilony [43] that focuses on advertising and price competition among retail stores in homogeneous product markets. Shilony [43] assumes that all stores are required to advertise, but the advertising is segmented (e. g., signs are posted on store windows). Consumers have a preference for the particular store that that offers them free access to the advertising (e. g., the store right outside their house or the one that they regularly visit) and they will pay more for a product at this store even if it does not offer the lowest price.

The institutional mechanisms of the primary market and the structure of the secondary market for municipal bonds fits particularly well with the informational interpretation of Shilony's [43] model. Every investor has free information about the price that will be charged by his broker. Also, because all firms must disseminate their last sale information on a real-time basis, the investor can choose to look on www.investinginbonds.com or some other free website to find the range of prices charged by all brokers. But, this last sale information does not identify which broker charged the lowest price. To find this out, the investor must incur some cost.

Green, Hollifield, and Schurhoff [23] begin with the assumption that there are both observable and unobservable sources of heterogeneity in the costs investors face in gathering and using information about prices of new municipal issues. They assume that for investor i, the difference between the benefit and the cost of learning about a new issue is z_i^* with:

$$z_i^* = w_i\delta + \mu_i \ ,$$

where w_i is a vector of conditioning variables, δ is a parameter vector, and μ_ι is an error term. The error term is observed by the investor, but not by the econometrician. Investor i becomes informed about the price of a new issue if and only if $z_i^* \geq 0$. They do not observe z_i^*, but they do observe w_i and the price the investor pays for the bond.

An investor who is uninformed about the reoffering price for a new bond is willing to pay the percentage markup y_U of:

$$y_{Ui} = x_i\beta + \varepsilon_{Ui} \ ,$$

where x_i is a vector of conditioning variables, β is a parameter vector, and ε_{Ui} is an error term. Similarly, an investor who is informed about the underwriter's pricing of a new bond is willing to pay the percentage markup y_I of:

$$y_{Ii} = x_i\gamma + \varepsilon_{Ii} \ ,$$

where x_i is a vector of conditioning variables, γ is a parameter vector, and ε_{Ii} is an error term. The uncertainty about the percentage markup is expected to be lower when the investor is informed than when the investor is uninformed:

$$\sigma_I < \sigma_U \ .$$

They use this condition to empirically identify the informed versus uninformed distributions from which the observed markups, y_i, are drawn:

$$y_i = \begin{cases} y_{Ui} & \text{if} \quad z_i^* < 0 \ , \\ y_{Ii} & \text{if} \quad z_i^* \geq 0 \ . \end{cases}$$

Green, Hollifield, and Schurhoff [23] use iterated expectations to show that investors take the markup into account when deciding whether to become informed about an upcoming bond issue or not:

$$\begin{aligned} E\left(y_i\,|w_i, x_i\right) = {} & E\left(y_i\,|\text{Informed}_i, w_i, x_i\right) \\ & \Pr\left(\text{Informed}_i\,|w_i\right) \\ & + E\left(y_i\,|\text{Uninformed}_i, w_i, x_i\right) \Pr\left(\text{Uninformed}_i\,|w_i\right) . \end{aligned}$$

They estimate their model under the assumption that the error terms are drawn independently and identically from a multivariate normal distribution:

$$\begin{pmatrix} u_i \\ \varepsilon_{Ui} \\ \varepsilon_{Ii} \end{pmatrix} \sim N\left(\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}, \begin{bmatrix} 1 & \rho_U\sigma_U & \rho_I\sigma_I \\ \rho_U\sigma_U & \sigma_U^2 & 0 \\ \rho_I\sigma_I & 0 & \sigma_I^2 \end{bmatrix} \right),$$

where ρ_U is the correlation between u_i and ε_{Ui} and ρ_I is the correlation between u_i and ε_{Ii}. Denoting the cumulative standard normal distribution as Φ and the standard normal density as φ, Green, Hollifield, and Schurhoff [23] show that the condition that investor i becomes informed if and only if $z_i^* \geq 0$ implies that:

$$\begin{aligned} \Pr\left(\text{Informed}_i\,|w_i\right) &= \Pr\left(z_i^* \geq 0\,|w_i\right) \\ &= \Pr\left(u_i \geq -w_i\delta\,|w_i\right) \\ &= \Phi\left(w_i\delta\right) \ , \end{aligned}$$

and

$$\Pr\left(\text{Uninformed}_i\,|w_i\right) = 1 - \Phi\left(w_i\delta\right) \ .$$

By combining equations and using the distributional assumptions of the error terms, Green, Hollifield, and Schurhoff [23] show that

$$E\left(y_i\,|\text{Informed}_i, w_i, x_i\right) = x_i\gamma + \rho_I\sigma_I\frac{\phi\left(w_i\delta\right)}{\Phi\left(w_i\delta\right)} \ ,$$

and

$$E\left(y_i\,|\text{Uninformed}_i, w_i, x_i\right) = x_i\beta + \rho_U\sigma_U\frac{-\phi\left(w_i\delta\right)}{1-\Phi\left(w_i\delta\right)} .$$

Therefore, the expected markup is:

$$\begin{aligned} E\left(y_i\,|w_i, x_i\right) = {} & \left(x_i\gamma + \rho_I\sigma_I\frac{\phi\left(w_i\delta\right)}{\Phi\left(w_i\delta\right)}\right)\Phi\left(w_i\delta\right) \\ & + \left(x_i\beta + \rho_U\sigma_U\frac{-\phi\left(w_i\delta\right)}{1-\Phi\left(w_i\delta\right)}\right)1 - \Phi\left(w_i\delta\right) \ . \end{aligned}$$

Green, Hollifield, and Schurhoff [23] estimate this equation as a switching regression. Their results are consistent with two pricing regimes for newly issued municipal bonds. Uninformed investors pay higher average prices than informed investors and there is very little variation in prices paid by informed investors. They also find that the upward trend in prices after issuance is related to the change in the mix if informed and uninformed investors. Informed investors buy soon after issuance, while uninformed investors buy later on.

With respect to the decision about whether to become informed about a new municipal bond issue, they find that large buyers are more likely to become informed than small buyers. To examine how much money is left on the table by uninformed investors who pay large markups to dealers, Green, Hollifield, and Schurhoff [23] classify each transaction into either the Informed or Uninformed regime. The classification is based on whether the expected benefit from becoming informed about a new bond issue is greater than the cost of doing so:

$$\begin{aligned}\text{Informed}_i = 1 &\Leftrightarrow E\left(z_i^* \,|y_i, w_i, x_i\right) \geq 0\,,\\ \text{Uninformed}_i = 1 &\Leftrightarrow E\left(z_i^* \,|y_i, w_i, x_i\right) < 0\,.\end{aligned}$$

The difference in the expected markup between an informed investor and an uninformed investor is:

$$\begin{aligned}E\left(y_{Ui}y_{Ii}\,|\text{Uninformed}_i, w_i, x_i\right) &= x_i\left(\beta - \gamma\right)\\ &\quad + \left(\rho_U\sigma_U - \rho_I\sigma_I\right)\frac{-\phi\left(w_i\delta\right)}{1-\Phi\left(w_i\delta\right)}\,.\end{aligned}$$

They define the money left on the table in each transaction with an uninformed investor as

$$\Delta_i = \begin{cases}\max\left\{E\left(y_{Ui}y_{Ii}\,|\text{Uninformed}_i, w_i, x_i\right), 0\right\}, & \\ & \text{if Uninformed}_i = 1\,,\\ 0\,, & \text{else}\,.\end{cases}$$

They denote the estimates of Δ_i as $\widehat{\Delta}_i$ and obtain a cumulative measure across all sales transactions i in a given bond issue j, and then across all issues in a bond deal:

$$\widehat{\text{Money Left on the Table}} = \sum_{\text{Issues}\,j}\,\sum_{i\in j}\widehat{\Delta}_i\,.$$

Green, Hollifield, and Schurhoff [23] find that money left on the table by uninformed investors represents a significant fraction of the overall expected profits to the underwriters and dealers.

Correlated Equilibria and Communication in Games

FRANÇOISE FORGES
Ceremade, Université Paris-Dauphine, Paris, France

Article Outline

Glossary

Bayesian game An interactive decision problem consisting of a set of n players, a set of types for every player, a probability distribution which accounts for the players' beliefs over each others' types, a set of actions for every player and a *von Neumann–Morgenstern utility function* defined over n-tuples of types and actions for every player.

Nash equilibrium In an n-person strategic form game, a strategy n-tuple from which unilateral deviations are not profitable.

von Neumann–Morgenstern utility function A *utility function* which reflects the individual's preferences over lotteries. Such a utility function is defined over outcomes and can be extended to any lottery λ by taking expectation with respect to λ.

Pure strategy (or simply strategy) A mapping which, in an interactive decision problem, associates an action with the information of a player whenever this player can make a choice.

Sequential equilibrium A refinement of the *Nash equilibrium* for n-person multistage interactive decision problems, which can be loosely defined as a strategy n-tuple together with beliefs over past information for every player, such that every player maximizes his expected utility given his beliefs and the others' strategies, with the additional condition that the beliefs satisfy (possibly sophisticated) Bayes updating given the strategies.

Strategic (or normal) form game An interactive decision problem consisting of a set of n players, a set of strategies for every player and a (typically, *von Neumann–Morgenstern) utility function* defined over n-tuples of strategies for every player.

Utility function A real valued mapping over a set of outcomes which reflects the preferences of an individual by associating a utility level (a "payoff") with every outcome.

Definition of the Subject

The correlated equilibrium is a game theoretic solution concept. It was proposed by Aumann [1,2] in order to capture the strategic correlation opportunities that the players face when they take into account the extraneous environment in which they interact. The notion is illustrated in Sect. "Introduction". A formal definition is given in Sect. "Correlated Equilibrium: Definition and Basic Properties". The correlated equilibrium also appears as the appropriate solution concept if preplay communication is allowed between the players. As shown in Sect. "Correlated Equilibrium and Communication", this property can be given several precise statements according to the constraints imposed on the players' communication, which can go from plain conversation to exchange of messages through noisy channels. Originally designed for static games with complete information, the correlated equilibrium applies to any strategic form game. It is geometrically and computationally more tractable than the better known Nash equilibrium. The solution concept has been extended to dynamic games, possibly with incomplete information. As an illustration, we define in details the communication equilibrium for Bayesian games in Sect. "Correlated Equilibrium in Bayesian Games".

Introduction

Example

Consider the two-person game known as "chicken", in which each player i can take a "pacific" action (denoted as p^i) or an "aggressive" action (denoted as a^i):

$$\begin{array}{ccc} & p^2 & a^2 \\ p^1 & (8,8) & (3,10) \\ a^1 & (10,3) & (0,0) \end{array}$$

The interpretation is that player 1 and player 2 simultaneously choose an action and then get a payoff, which is determined by the pair of chosen actions according to the previous matrix. If both players are pacific, they both get 8. If both are aggressive, they both get 0. If one player is aggressive and the other is pacific, the aggressive player gets 10 and the pacific one gets 3. This game has two pure Nash equilibria (p^1, a^2), (a^1, p^2) and one mixed Nash equilibrium in which both players choose the pacific action with probability 3/5, resulting in the expected payoff 6 for both players. A possible justification for the latter solution is that the players make their choices as a function of independent extraneous random signals. The assumption of independence is strong. Indeed, there may be no way to prevent the players' signals from being correlated.

Consider a random signal which has no effect on the players' payoffs and takes three possible values: low, medium or high, occurring each with probability 1/3. Assume that, before the beginning of the game, player 1 distinguishes whether the signal is high or not, while player 2 distinguishes whether the signal is low or not. The relevant interactive decision problem is then the extended game in which the players can base their action on the private information they get on the random signal, while the payoffs only depend on the players' actions. In this game, suppose that player 1 chooses the aggressive action when the signal is high and the pacific action otherwise. Similarly, suppose that player 2 chooses the aggressive action when the signal is low and the pacific action otherwise. We show that these strategies form an equilibrium in the extended game. Given player 2's strategy, assume that player 1 observes a high signal. Player 1 deduces that the signal cannot be low so that player 2 chooses the pacific action; hence player 1's best response is to play aggressively. Assume now that player 1 is informed that the signal is not high; he deduces that with probability 1/2, the signal is medium (i. e., not low) so that player 2 plays pacific and with probability 1/2, the signal is low so that player 2 plays aggressive. The expected payoff of player 1 is 5.5 if he plays pacific and 5 if he plays aggressive; hence, the pacific action is a best response. The equilibrium conditions for player 2 are symmetric. To sum up, the strategies based on the players' private information form a Nash equilibrium in the extended game in which an extraneous signal is first selected. We shall say that these strategies form a "correlated equilibrium". The corresponding probability distribution over the players' actions is

$$\begin{array}{ccc} & p^2 & a^2 \\ p^1 & \frac{1}{3} & \frac{1}{3} \\ a^1 & \frac{1}{3} & 0 \end{array} \tag{1}$$

and the expected payoff of every player is 7. This probability distribution can be used directly to make private recommendations to the players before the beginning of the game (see the canonical representation below).

Correlated Equilibrium: Definition and Basic Properties

Definition

A game in strategic form $G = (N, (\Sigma^i)_{i \in N}, (u^i)_{i \in N})$ consists of a set of players N together with, for every player $i \in N$, a set of strategies (for instance, a set of actions) Σ^i and a (von Neumann–Morgenstern) utility function $u^i : \Sigma \to \mathbb{R}$, where $\Sigma = \prod_{j \in N} \Sigma^j$ is the set of all strategy profiles. We assume that the sets N and Σ^i, $i \in N$, are finite.

A correlation device $d = (\Omega, \boldsymbol{q}, (\mathcal{P}^i)_{i \in N})$ is described by a finite set of signals Ω, a probability distribution $\boldsymbol{q}$ over

Ω and a partition $\mathcal{P}^i$ of Ω for every player $i \in N$. Since Ω is finite, the probability distribution $\boldsymbol{q}$ is just a real vector $\boldsymbol{q} = (\boldsymbol{q}(\omega))_{\omega\in\Omega}$ such that $\boldsymbol{q}(\omega) \geq 0$ and $\sum_{\omega\in\Omega} \boldsymbol{q}(\omega) = 1$.

From G and d, we define the extended game G_d as follows:

- ω is chosen in Ω according to $\boldsymbol{q}$
- every player i is informed of the element $P^i(\omega)$ of $\mathcal{P}^i$ which contains ω
- G is played: every player i chooses a strategy σ^i in Σ^i and gets the utility $u^i(\sigma)$, $\sigma = (\sigma^j)_{j\in N}$.

A (pure) strategy for player i in G_d is a mapping $\alpha^i \colon \Omega \to \Sigma^i$ which is $\mathcal{P}^i$-measurable, namely, such that $\alpha^i(\omega') = \alpha^i(\omega)$ if $\omega' \in P^i(\omega)$. The interpretation is that, in G_d, every player i chooses his strategy σ^i as a function of his private information on the random signal ω which is selected before the beginning of G.

According to Aumann [1], a *correlated equilibrium* of G is a pair (d, α), which consists of a correlation device $d = (\Omega, \boldsymbol{q}, (\mathcal{P}^i)_{i\in N})$ and a Nash equilibrium $\alpha = (\alpha^i)_{i\in N}$ of G_d. The equilibrium conditions of every player i, conditionally on his private information, can be written as:

$$\begin{aligned}&\sum_{\omega'\in P^i(\omega)} q(\omega'|P^i(\omega))u^i(\alpha(\omega'))\\ &\quad\geq \sum_{\omega'\in P^i(\omega)} q(\omega'|P^i(\omega))u^i(\tau^i, \alpha^{-i}(\omega'))\,,\\ &\qquad\qquad \forall i \in N,\ \forall \tau^i \in \Sigma^i,\ \forall \omega \in \Omega\colon q(\omega) > 0\,, \end{aligned} \tag{2}$$

where $\alpha^{-i} = (\alpha^j)_{j\neq i}$.

A mixed Nash equilibrium $\rho = (\rho^i)_{i\in N}$ of G can be viewed as a correlated equilibrium of G. By definition, every ρ^i is a probability distribution over Σ^i, the finite set of pure strategies of player i. Let us consider the correlation device $d = (\Omega, \boldsymbol{q}, (\mathcal{P}^i)_{i\in N})$ in which $\Omega = \Sigma = \prod_{j\in N} \Sigma^j$, $\boldsymbol{q}$ is the product probability distribution induced by the mixed strategies (i. e., $\boldsymbol{q}((\sigma^j)_{j\in N}) = \prod_{j\in N} \rho^j(\sigma^j)$) and for each i, $\mathcal{P}^i$ is the partition of Ω generated by Σ^i (i. e., for $\omega, \nu \in \Omega$, $\nu \in P^i(\omega) \Leftrightarrow \nu^i = \omega^i$). Let $\alpha^i \colon \Sigma \to \Sigma^i$ be the projection over Σ^i (i. e., $\alpha^i(\sigma) = \sigma^i$). The correlation device d and the strategies α^i defined in this way form a correlated equilibrium. As we shall see below, this correlated equilibrium is "canonical" .

Canonical Representation

A *canonical* correlated equilibrium of G is a correlated equilibrium in which $\Omega = \Sigma = \prod_{j\in N} \Sigma^j$ while for every player i, the partition $\mathcal{P}^i$ of Σ is generated by Σ^i and $\alpha^i \colon \Sigma \to \Sigma^i$ is the projection over Σ^i. A canonical correlated equilibrium is thus fully specified by a probability distribution $\boldsymbol{q}$ over Σ. A natural interpretation is that a mediator selects $\sigma = (\sigma^j)_{j\in N}$ according to $\boldsymbol{q}$ and privately recommends σ^i to player i, for every $i \in N$. The players are not forced to obey the mediator, but σ is selected in such a way that player i cannot benefit from deviating unilaterally from the recommendation σ^i, i. e., $\tau^i = \sigma^i$ maximizes the conditional expectation of player i's payoff $u^i(\tau^i, \sigma^{-i})$ given the recommendation σ^i. A probability distribution $\boldsymbol{q}$ over Σ thus defines a canonical correlated equilibrium if and only if it satisfies the following linear inequalities:

$$\begin{aligned}&\sum_{\sigma^{-i}\in\Sigma^{-i}} \boldsymbol{q}(\sigma^{-i}|\sigma^i)u^i(\sigma^i, \sigma^{-i})\\ &\quad\geq \sum_{\sigma^{-i}\in\Sigma^{-i}} \boldsymbol{q}(\sigma^{-i}|\sigma^i)u^i(\tau^i, \sigma^{-i})\,,\\ &\qquad\qquad \forall i \in N,\ \forall \sigma^i \in \Sigma^i\colon \boldsymbol{q}(\sigma^i) > 0,\ \forall \tau^i \in \Sigma^i\end{aligned}$$

or, equivalently,

$$\begin{aligned}&\sum_{\sigma^{-i}\in\Sigma^{-i}} \boldsymbol{q}(\sigma^i, \sigma^{-i})u^i(\sigma^i, \sigma^{-i})\\ &\quad\geq \sum_{\sigma^{-i}\in\Sigma^{-i}} \boldsymbol{q}(\sigma^i, \sigma^{-i})u^i(\tau^i, \sigma^{-i})\,,\\ &\qquad\qquad \forall i \in N,\ \forall \sigma^i,\ \tau^i \in \Sigma^i\end{aligned} \tag{3}$$

The equilibrium conditions can also be formulated *ex ante*:

$$\begin{aligned}&\sum_{\sigma\in\Sigma} \boldsymbol{q}(\sigma)u^i(\sigma) \geq \sum_{\sigma\in\Sigma} \boldsymbol{q}(\sigma)u^i(\alpha^i(\sigma^i), \sigma^{-i})\,,\\ &\qquad\qquad \forall i \in N,\ \forall \alpha^i\colon \Sigma^i \to \Sigma^i\end{aligned}$$

The following result is an analog of the "revelation principle" in mechanism design (see, e. g., Myerson [41]): *let (α, d) be a correlated equilibrium associated with an arbitrary correlation device $d = (\Omega, \boldsymbol{q}, (\mathcal{P}^i)_{i\in N})$. The corresponding "correlated equilibrium distribution", namely, the probability distribution induced over Σ by $\boldsymbol{q}$ and α, defines a canonical correlated equilibrium*. For instance, in the introduction, (1) describes a canonical correlated equilibrium.

Duality and Existence

From the linearity of (3), duality theory can be used to study the properties of correlated equilibria, in particular to prove their existence without relying on Nash's [45] theorem and its fixed point argument (recall that every mixed Nash equilibrium is a correlated equilibrium). Hart and Schmeidler [30] establish the existence of a correlated equilibrium by constructing an auxiliary two person zero-sum game and applying the minimax theorem. Nau and McCardle [47] derive another elementary proof of existence from an extension of the "no arbitrage opportunities" axiom that underlies subjective probability theory. They introduce jointly coherent strategy profiles, which do not expose the players as a group to arbitrage from an outside observer. They show that a strategy profile is jointly coherent if and only if it occurs with positive probability in some correlated equilibrium. From a technical point of view, both proofs turn out to be similar. Myerson [44] makes further use of the linear structure of correlated equilibria by introducing dual reduction, a technique to replace a finite game with a game with fewer strategies, in such a way that any correlated equilibrium of the reduced game induces a correlated equilibrium of the original game.

Geometric Properties

As (3) is a system of linear inequalities, the set of all correlated equilibrium distributions is a convex polytope. Nau et al. [49] show that if it has "full" dimension (namely, dimension $|\Sigma| - 1$), then all Nash equilibria lie on its relative boundary. Viossat [60] characterizes in addition the class of games whose correlated equilibrium polytope contains a Nash equilibrium in its relative interior. Interestingly, this class of games includes two person zero-sum games but is not defined by "strict competition" properties. In two person games, all extreme Nash equilibria are also extreme correlated equilibria [13,25]; this result does not hold with more than two players. Finally, Viossat [59] proves that having a unique correlated equilibrium is a robust property, in the sense that the set of n person games with a unique correlated equilibrium is open. The same is not true for Nash equilibrium (unless $n = 2$).

Complexity

From (3), correlated equilibria can be computed by linear programming methods. Gilboa and Zemel [24] show more precisely that the complexity of standard computational problems is "NP-hard" for the Nash equilibrium and *polynomial* for the correlated equilibrium. Examples of such problems are: "Does the game G have a Nash (resp., correlated) equilibrium which yields a payoff greater than r to every player (for some given number r)?" and "Does the game G have a unique Nash (resp., correlated) equilibrium?". Papadimitriou [50] develops a polynomial-time algorithm for finding correlated equilibria, which is based on a variant of the existence proof of Hart and Schmeidler [30].

Foundations

By re-interpreting the previous canonical representation, Aumann [2] proposes a decision theoretic foundation for the correlated equilibrium in games with complete information, in which Σ^i for $i \in N$, stands merely for a set of *actions* of player i. Let Ω be the space of all states of the world; an element ω of Ω thus specifies all the parameters which may be relevant to the players' choices. In particular, the action profile in the underlying game G is part of the state of the world. A partition $\mathcal{P}^i$ describes player i's information on Ω. In addition, every player i has a prior belief, i. e., a probability distribution, $\boldsymbol{q}^i$ over Ω. Formally, the framework is similar as above except that the players possibly hold different beliefs over Ω. Let $\alpha^i(\omega)$ denote player i's action at ω; a natural assumption is that player i knows the action he chooses, namely that α^i is $\mathcal{P}^i$-measurable. According to Aumann [2], player i is *Bayes-rational* at ω if his action $\alpha^i(\omega)$ maximizes his expected payoff (with respect to $\boldsymbol{q}^i$) given his information $P^i(\omega)$. Note that this is a separate rationality condition for every player, not an equilibrium condition. Aumann [2] proves the following result: *Under the common prior assumption (namely, $\boldsymbol{q}^i = \boldsymbol{q}$, $i \in N$), if every player is Bayes-rational at every state of the world, the distribution of the corresponding action profile α is a correlated equilibrium distribution*. The key to this decision theoretic foundation of the correlated equilibrium is that, under the common prior assumption, Bayesian rationality amounts to (2).

If the common prior assumption is relaxed, the previous result still holds, with *subjective* prior probability distributions, for the *subjective* correlated equilibrium which was also introduced by Aumann [1]. The latter solution concept is defined in the same way as above, by considering a device $(\Omega, (\boldsymbol{q}^i)_{i \in N}, (\mathcal{P}^i)_{i \in N})$, with a probability distribution $\boldsymbol{q}^i$ for every player i, and by writing (2) in terms of $\boldsymbol{q}^i$ instead of $\boldsymbol{q}$. Brandenburger and Dekel [10] show that (a refinement of) the subjective correlated equilibrium is equivalent to (correlated) rationalizability, another well-established solution concept which captures players' minimal rationality. Rationalizable strategies reflect that the players commonly know that each of them makes an optimal choice given some belief. Nau and McCardle [48] reconcile objective and subjective correlated equilibrium by proposing the no arbitrage principle as a unified approach to individual and interactive decision problems. They argue that the objective correlated equilibrium concept applies to a game that is revealed by the players' choices, while the subjective correlated equilibrium concept applies to the “true game”; both lead to the same set of jointly coherent outcomes.

Correlated Equilibrium and Communication

As seen in the previous section, correlated equilibria can be achieved in practice with the help of a mediator and emerge in a Bayesian framework embedding the game in a full description of the world. Both approaches require to extend the game by taking into account information which is not generated by the players themselves. Can the players reach a correlated equilibrium without relying on any extraneous correlation device, by just communicating with each other before the beginning of the game?

Consider the game of “chicken” presented in the introduction. The probability distribution

$$\begin{array}{ccc} & p^2 & a^2 \\ p^1 & 0 & \frac{1}{2} \\ a^1 & \frac{1}{2} & 0 \end{array} \tag{4}$$

describes a correlated equilibrium, which amounts to choosing one of the two pure Nash equilibria, with equal probability. Both players get an expected payoff of 6.5. Can they safely achieve this probability distribution if no mediator tosses a fair coin for them? The answer is positive, as shown by Aumann et al. [3]. Assume that before playing “chicken”, the players independently toss a coin and simultaneously reveal to each other whether heads or tails obtains. Player 1 tells player 2 “h^1” or “t^1” and, at the same time, player 2 tells player 1 “h^2” or “t^2”. If both players use a fair coin, reveal correctly the result of the toss and play (p^1, a^2) if both coins fell on the same side (i. e., if (h^1, h^2) or (t^1, t^2) is announced) and (a^1, p^2) otherwise (i. e., if (h^1, t^2) or (t^1, h^2) is announced), they get the same effect as a mediator using (4). Furthermore, none of them can gain by unilaterally deviating from the described strategies, even at the randomizing stage: the two relevant outcomes, $[(h^1, h^2)$ or $(t^1, t^2)]$ and $[(h^1, t^2)$ or $(t^1, h^2)]$, happen with probability 1/2 provided that one of the players reveals the toss of a fair coin. This procedure is known as a “jointly controlled lottery” . An important feature of the previous example is that, in the correlated equilibrium described by (4), the players know each other's recommendation. Hence, they can easily reproduce (4) by exchanging messages that they have selected independently. In the correlated equilibrium described by the probability distribution (1), the private character of recommendations is crucial to guarantee that (p^1, p^2) be played with positive probability. Hence one cannot hope that a simple procedure of direct preplay communication be sufficient to generate (1). However, the fact that direct communication is necessarily public is typical of two-person games.

Given the game $G = (N, (\Sigma^i)_{i \in N}, (u^i)_{i \in N})$, let us define a (bounded) “cheap talk” extension ext(G) of G as a game in which T stages of costless, unmediated preplay communication are allowed before G is played. More precisely, let M_t^i be a finite set of messages for player i, $i \in N$, at stage t, $t = 1, 2, \ldots T$; at every stage t of ext(G), every player i selects a message in M_t^i; these choices are made simultaneously before being revealed to a subset of players at the end of stage t. The rules of $ext(G)$ thus determine a set of “senders” for every stage t (those players i for whom M_t^i contains more than one message) and a set of “receivers” for every stage t. The players perfectly recall their past messages. After the communication phase, they choose their strategies (e. g., their actions) as in G; they are also rewarded as in G, independently of the preplay phase, which is thus “cheap” . Communication has an indirect effect on the final outcome in G, since the players make their decisions as a function of the messages that they have exchanged. Specific additional assumptions are often made on ext(G), as we will see below.

Let us fix a cheap talk extension ext(G) of G and a Nash equilibrium of $ext(G)$. As a consequence of the previous definitions, the distribution induced by this Nash equilibrium over Σ defines a correlated equilibrium of G (this can be proved in the same way as the canonical representation of correlated equilibria stated in Sect. “Correlated Equilibrium: Definition and Basic Properties”). The question raised in this section is whether the reverse holds.

If the number of players is two, the Nash equilibrium distributions of cheap talk extensions of G form a subset of the correlated equilibrium distributions: the convex hull of Nash equilibrium distributions. Indeed, the players have both the same information after any direct exchange of messages. Conversely, by performing repeated jointly controlled lotteries like in the example above, the players can achieve any convex combination (with rational weights) of Nash equilibria of G as a Nash equilibrium of a cheap talk extension of G. The restriction on probability distributions whose components are rational numbers is only needed as far as we focus on *bounded* cheap talk extensions.

Bárány [4] establishes that, if the number of players of G is at least four, every (rational) correlated equilibrium distribution of G can be realized as a Nash equilibrium of a cheap talk extension ext(G), provided that ext(G) allows the players to publicly check the record of communication under some circumstances. The equilibria of ext(G) constructed by Bárány involve that a receiver gets the same message from two different senders; the message is nevertheless not public thanks to the assumption on the number of players. At every stage of ext(G), every player can ask for the revelation of all past messages, which are assumed to be recorded. Typically, a receiver can claim that the two senders' messages differ. In this case, the record of communication surely reveals that either one of the senders or the receiver himself has cheated; the deviator can be punished (at his minmax level in G) by the other players.

The punishments in Bárány's [4] Nash equilibria of ext(G) need not be credible threats. Instead of using double senders in the communication protocols, Ben-Porath [5,6] proposes a procedure of random monitoring, which prescribes a given behavior to every player in such a way that unilateral deviations can be detected with probability arbitrarily close to 1. This procedure applies if there are at least three players, which yields an analog of Bárány's result already in this case. If the number of players is exactly three, Ben-Porath [6] needs to assumes, as Bárány [4], that public verification of the record of communication is possible in ext(G) (see Ben-Porath [7]). However, Ben-Porath concentrates on (rational) correlated equilibrium distributions which allow for strict punishment on a Nash equilibrium of G; he constructs *sequential* equilibria which generate these distributions in ext(G), thus dispensing with incredible threats. At the price of raising the number of players to five or more, Gerardi [22] proves that every (rational) correlated equilibrium distribution of G can be realized as a sequential equilibrium of a cheap talk extension of G which does not require any message recording. For this, he builds protocols of communication in which the players base their decisions on majority rule, so that no punishment is necessary.

We have concentrated on two extreme forms of communication: mediated communication, in which a mediator performs lotteries and sends private messages to the players and cheap talk, in which the players just exchange messages. Many intermediate schemes of communication are obviously conceivable. For instance, Lehrer [36] introduces (possibly multistage) "mediated talk": the players send private messages to a mediator, but the latter can only make deterministic public announcements. Mediated talk captures real-life communication procedures, like elections, especially if it lasts only for a few stages. Lehrer and Sorin [37] establish that whatever the number of players of G, every (rational) correlated equilibrium distribution of G can be realized as a Nash equilibrium of a single stage mediated talk extension of G. Ben-Porath [5] proposes a variant of cheap talk in which the players do not only exchange verbal messages but also "hard" devices such as urns containing balls. This extension is particularly useful in two-person games to circumvent the equivalence between the equilibria achieved by cheap talk and the convex hull of Nash equilibria. More precisely, the result of Ben-Porath [5] stated above holds for two-person games if the players first check together the content of different urns, and then each player draws a ball from an urn that was chosen by the other player, so as to guarantee that one player only knows the outcome of a lottery while the other one only knows the probabilities of this lottery.

The various extensions of the basic game G considered up to now, with or without a mediator, implicitly assume that the players are fully rational. In particular, they have unlimited computational abilities. By relaxing that assumption, Urbano and Vila [55] and Dodis et al. [12] build on earlier results from cryptography so as to implement any (rational) correlated equilibrium distribution through unmediated communication, including in two-person games.

As the previous paragraphs illustrate, the players can modify their intitial distribution of information by means of many different communication protocols. Gossner [26] proposes a general criterion to classify them: a protocol is "secure" if under all circumstances, the players cannot mislead each other nor spy on each other. For instance, given a cheap talk extension ext(G), a protocol P describes, for every player, a strategy in ext(G) and a way to interpret his information after the communication phase of ext(G). P induces a correlation device $d(P)$ (in the sense of Sect. "Correlated Equilibrium: Definition and Basic Properties"). P is secure if, *for every game* G and every Nash equilibrium α of $G_{d(P)}$, the following procedure is a Nash equilibrium of ext(G): communicate according to the strategies described by P in order to generate $d(P)$ and make the final choice, in G, according to α. Gossner [26] gives a tractable characterization of secure protocols.

Correlated Equilibrium in Bayesian Games

A Bayesian game $\Gamma = (N, (T^i)_{i \in N}, p, (A^i)_{i \in N}, (v^i)_{i \in N})$ consists of: a set of players N; for every player $i \in N$, a set of types T^i, a probability distribution p^i over $T = \prod_{j \in N} T^j$, a set of actions A^i and a (von Neumann–Morgenstern) utility function $v^i : T \times A \to \mathbb{R}$, where $A = \prod_{j \in N} A^j$. For simplicity, we make the common prior assumption: $p^i = p$ for every $i \in N$. All sets are assumed finite. The interpretation is that a virtual move of nature chooses $t = (t^j)_{j \in N}$ according to p; player i is only informed of his own type t^i; the players then choose simultaneously an action. We will focus on two possible extensions of Aumann's [1] solution concept to Bayesian games: the strategic form correlated equilibrium and the communication equilibrium. Without loss of generality, the definitions below are given in "canonical form" (see Sect. "Correlated Equilibrium: Definition and Basic Properties").

Strategic Form Correlated Equilibrium

A (pure) strategy of player i in Γ is a mapping $\sigma^i : T^i \to A^i$, $i \in N$. The strategic form of Γ is a game $G(\Gamma)$, like the game G considered in Sect. "Correlated Equilibrium: Definition and Basic Properties", with sets of pure strategies $\Sigma_i = A_i^{T_i}$ and utility functions u^i over $\Sigma = \prod_{j \in N} \Sigma^j$ computed as expectations with respect to p: $u^i(\sigma) = E[v^i(t, \sigma(t))]$, with $\sigma(t) = (\sigma^i(t^i))_{i \in N}$. A strategic form correlated equilibrium, or simply, a correlated equilibrium, of a Bayesian game Γ is a correlated equilibrium, in the sense of Sect. "Correlated Equilibrium: Definition and Basic Properties", of $G(\Gamma)$. A canonical correlated equilibrium of Γ is thus described by a probability distribution Q over Σ, which selects an N-tuple of pure strategies $(\sigma^i)_{i \in N}$. This lottery can be thought of as being performed by a mediator who privately recommends σ^i to player i, $i \in N$, before the beginning of Γ, i. e., before (or in any case, independently of) the chance move choosing the N -tuple of types. The equilibrium conditions express that, once he knows his type t^i, player i cannot gain in unilaterally deviating from $\sigma^i(t^i)$.

Communication Equilibrium

Myerson [41] transforms the Bayesian game Γ into a mechanism design problem by allowing the mediator to collect information from the players before making them recommendations. Following Forges [15] and Myerson [42], a canonical communication device for Γ consists of a system $\boldsymbol{q}$ of probability distributions $\boldsymbol{q} = (\boldsymbol{q}(.|t))_{t \in T}$ over A. The interpretation is that a mediator invites every player i, $i \in N$, to report his type t^i, then selects an N-tuple of actions a according to $\boldsymbol{q}(.|t)$ and privately recommends a^i to player i. The system $\boldsymbol{q}$ defines a communication equilibrium if none of the players can gain by unilaterally lying on his type or by deviating from the recommended action, namely if

$$\begin{aligned}&\sum_{t^{-i} \in T^{-i}} p(t^{-i}|t^i) \sum_{a \in A} q(a|t) v^i(t, a)\\ &\geq \sum_{t^{-i} \in T^{-i}} p(t^{-i}|t^i) \sum_{a \in A} q(a|s^i, t^{-i}) v^i(t, \alpha^i(a^i), a^{-i}) \,,\\ &\qquad \forall i \in N,\ \forall t^i,\ s^i \in T^i,\ \forall \alpha^i : A^i \to A^i\end{aligned}$$

Correlated Equilibrium, Communication Equilibrium and Cheap Talk

Every correlated equilibrium of the Bayesian game Γ induces a communication equilibrium of Γ, but the converse is not true, as the following example shows.

Consider the two-person Bayesian game in which $T^1 = \{s^1, t^1\}$, $T^2 = \{t^2\}$, $A^1 = \{a^1, b^1\}$, $A^2 = \{a^2, b^2\}$, $p(s^1) = p(t^1) = \frac{1}{2}$ and payoffs are described by

		a^2	b^2
s^1	a^1	$(1, 1)$	$(-1, -1)$
	b^1	$(0, 0)$	$(0, 0)$

		a^2	b^2
t^1	a^1	$(0, 0)$	$(0, 0)$
	b^1	$(-1, -1)$	$(1, 1)$

In this game, the communication equilibrium $\boldsymbol{q}(a^1, a^2|s^1) = \boldsymbol{q}(b^1, b^2|t^1) = 1$ yields the expected payoff of 1 to both players. However the maximal expected payoff of every player in a correlated equilibrium is 1/2. In order to see this, one can derive the strategic form of the game (in which player 1 has four strategies and player 2 has two strategies). Let us turn to the game in which player 1 can cheaply talk to player 2 just after having learned his type. In this new game, the following strategies form a Nash equilibrium: player 1 truthfully reveals his type to player 2 and plays a^1 if s^1, b^1 if t^1; player 2 chooses a^2 if s^1, b^2 if t^1 . These strategies achieve the same expected payoffs as the communication equilibrium.

As in Sect. "Correlated Equilibrium and Communication", one can define cheap talk extensions ext(Γ) of Γ. A wide definition of ext(Γ) involves an *ex ante* preplay phase, before the players learn their types, and an *interim* preplay phase, after the players learn their types but before they choose their actions. Every Nash equilibrium of ext(Γ) induces a communication equilibrium of Γ. In order to investigate the converse, namely whether cheap talk can simulate mediated communication in a Bayesian game, two approaches have been developed. The first one (Forges [17], Gerardi [21,22], Vida [58]) proceeds in two steps, by reducing communication equilibria to correlated equilibria before applying the results obtained for strategic form games (see Sect. "Correlated Equilibrium and Communication"). The second approach (Ben-Porath [6], Krishna [33]) directly addresses the question in a Bayesian game.

By developing a construction introduced for particular two person games (Forges [14]), Forges [17] shows that every communication equilibrium outcome of a Bayesian game Γ with at least four players can be achieved as a correlated equilibrium outcome of a two stage *interim* cheap talk extension $\mathrm{ext}_{\mathrm{int}}(\Gamma)$ of Γ. No punishment is necessary in $\mathrm{ext}_{\mathrm{int}}(\Gamma)$: at the second stage, every player gets a message from three senders and uses majority rule if the messages are not identical. Thanks to the underlying correlation device, each receiver is able to privately decode his message. Vida [58] extends Forges [17] to Bayesian games with three or even two players. In the proof, he constructs a correlated equilibrium of a long, but almost surely finite, *interim* cheap talk extension of Γ, whose length depends both on the signals selected by the correlation device and the messages exchanged by the players. No recording of messages is necessary to detect and punish a cheating player. If there are at least four players in Γ, once a communication equilibrium of Γ has been converted into a correlated equilibrium of $\mathrm{ext}_{\mathrm{int}}(\Gamma)$, one can apply Bárány's [4] result to $\mathrm{ext}_{\mathrm{int}}(\Gamma)$ in order to transform the correlated equilibrium into a Nash equilibrium of a further, *ex ante*, cheap talk preplay extension of Γ. Gerardi [21] modifies this ex ante preplay phase so as to postpone it at the *interim* stage. This result is especially useful if the initial move of nature in Γ is just a modelling convenience. Gerardi [22] also extends his result for at least five person games with complete information (see Sect. "Correlated Equilibrium and Communication") to any Bayesian game with full support (i. e., in which all type profiles have positive probability: $p(t) > 0$ for every $t \in T$) by proving that every (rational) communication equilibrium of Γ can be achieved as a *sequential* equilibrium of a cheap talk extension of Γ.

Ben-Porath [6] establishes that if Γ is a three (or more) person game with full support, every (rational) communication equilibrium of Γ which strictly dominates a Nash equilibrium of Γ for every type t^i of every player i, $i \in N$, can be implemented as a Nash equilibrium of an *interim* cheap talk extension of Γ in which public verification of past record is possible (see also Ben-Porath [7]). Krishna [33] extends Ben-Porath's [5] result on two person games (see Sect. "Correlated Equilibrium and Communication") to the incomplete information framework. The other results mentioned at the end of Sect. "Correlated Equilibrium and Communication" have also been generalized to Bayesian games (see [26,37,56]).

Related Topics and Future Directions

In this brief article, we concentrated on two solution concepts: the strategic form correlated equilibrium, which is applicable to any game, and the communication equilibrium, which we defined for Bayesian games. Other extensions of Aumann's [1]solution concept have been proposed for Bayesian games, as the agent normal form correlated equilibrium and the (possibly belief invariant) Bayesian solution (see Forges [18,19] for definitions and references). The Bayesian solution is intended to capture the players' rationality in games with incomplete information in the spirit of Aumann [2] (see Nau [46] and Forges [18]). Lehrer et al. [38] open a new perspective in the understanding of the Bayesian solution and other equilibrium concepts for Bayesian games by characterizing the classes of equivalent information structures with respect to each of them. Comparison of information structures, which goes back to Blackwell [8,9] for individual decision problems, was introduced by Gossner [27] in the context of games, both with complete and incomplete information. In the latter model, information structures basically describe how extraneous signals are selected as a function of the players' types; two information structures are equivalent with respect to an equilibrium concept if, in every game, they generate the same equilibrium distributions over outcomes.

Correlated equilibria, communication equilibria and related solution concepts have been studied in many other classes of games, like multistage games (see, e. g., [15,42]), repeated games with incomplete information (see, e. g., [14,16]) and stochastic games (see, e. g., [53,54]). The study of correlated equilibrium in repeated games with imperfect monitoring, initiated by Lehrer [34,35], proved to be particularly useful and is still undergoing. Lehrer [34] showed that if players are either fully informed of past actions or get no information (" standard-trivial" information structure), correlated equilibria are equivalent to Nash equilibria. In other words, all correlations can be generated internally, namely by the past histories, on which players have differential information. The schemes of internal correlation introduced to establish this result are widely applicable and inspired those of Lehrer [36] (see Sect. "Correlated Equilibrium and Communication"). In general repeated games with imperfect monitoring, Renault and Tomala [52] characterize communication equilibria but the amount of correlation that the players can achieve in a Nash equilibrium is still an open problem (see, e. g., [28,57] for recent advances).

Throughout this article, we defined a correlated equilibrium as a *Nash* equilibrium of an extension of the game under consideration. The solution concept can be strengthened by imposing some refinement, i. e., further rationality conditions, to the Nash equilibrium in this definition (see, e. g., [11,43]). Refinements of communication equilibria have also been proposed (see, e. g., [22,23,42]). Some authors (see, e. g., [39,40,51]) have also developed notions of *coalition proof* correlated equilibria, which resist not only to unilateral deviations, as in this article, but even to multilateral ones. A recurrent difficulty is that, for many of these stronger solution concepts, a useful canonical representation (as derived in Sect. "Correlated Equilibrium: Definition and Basic Properties") is not available.

Except for two or three references, we deliberately concentrated on the results published in the game theory and mathematical economics literature, while substantial achievements in computer science would fit in this survey. Both streams of research pursue similar goals but rely on different formalisms and techniques. For instance, computer scientists often make use of cryptographic tools which are not familiar in game theory. Halpern [29] gives an idea of recent developments at the interface of computer science and game theory (see in particular the section "implementing mediators") and contains a number of references.

Finally, the assumption of full rationality of the players can also be relaxed. Evolutionary game theory has developed models of learning in order to study the long term behavior of players with bounded rationality. Many possible dynamics are conceivable to represent more or less myopic attitudes with respect to optimization. Under appropriate learning procedures, which express for instance that agents want to minimize the regret of their strategic choices, the empirical distribution of actions converge to correlated equilibrium distributions (see, e. g., [20,31,32] for a survey). However, standard procedures, as the "replicator dynamics", may even eliminate all the strategies which have positive probability in a correlated equilibrium (see [61]).

Article Outline

Definition of the Subject

Cluster concepts have been extremely useful in elucidating many problems in physics. Percolation theory provides a generic framework to study the behavior of the cluster distribution. In most cases the theory predicts a geometrical transition at the percolation threshold, characterized in the percolative phase by the presence of a spanning cluster, which becomes infinite in the thermodynamic limit. Standard percolation usually deals with the problem when the constitutive elements of the clusters are randomly distributed. However correlations cannot always be neglected. In this case correlated percolation is the appropriate theory to study such systems. The origin of correlated percolation could be dated back to 1937 when Mayer [76] proposed a theory to describe the condensation from a gas to a liquid in terms of mathematical clusters (for a review of cluster theory in simple fluids see [88]). The location for the divergence of the size of these clusters was interpreted as the condensation transition from a gas to a liquid. One of the major drawbacks of the theory was that the cluster number for some values of thermodynamical parameters could become negative. As a consequence the clusters did not have any physical interpretation [50]. This theory was followed by Frenkel's phenomenological model [54], in which the fluid was considered as made of non interacting physical clusters with a given free energy. This model was later improved by Fisher [50], who proposed a different free energy for the clusters, now called droplets, and consequently a different scaling form for the droplet size distribution. This distribution, which depends on two geometrical parameters, σ and τ, has the nice feature that the mean droplet size exhibits a divergence at the liquid-gas critical point. Interestingly the critical exponents of the liquid gas critical point can be expressed in terms of the two parameters, σ and τ, and are found to satisfy the standard scaling relations proposed at that time in the theory of critical phenomena.

Introduction

Fisher's droplet model was very successful, to describe the behavior of a fluid or of a ferromagnet near the critical point, in terms of geometrical clusters. However the microscopic definition of such a cluster in a fluid or ferromagnet was still a challenge. While the exact definition in a continuum fluid model is still an open problem, a proper definition in the Ising model or lattice gas model has been provided. A first attempt to define a cluster in the Ising model which had the same properties of Fisher's droplet model was to consider a cluster as set of parallel spins. In two dimensions, in fact, these clusters seemed to have the properties of Fisher's droplets, i. e. the mean cluster size of these clusters were found to diverge at the Ising critical point on the basis of numerical analysis [8]. This result was later proved rigorously [36,37]. However the critical exponents for the mean cluster size in $2d$ was found to be larger than the corresponding critical exponent of the susceptibility [100], contrary to the requirement of Fisher's droplet model. Moreover numerical simulations in $3d$ and analytical results on the Bethe lattice showed that the critical point and the percolation point of such clusters were different. It was clear then that the clusters made of nearest neighbors parallel spins were too big to describe correlated regions. A different definition of clusters was then proposed [30] obtained by breaking the clusters of parallel spins by introducing fictitious bonds with a probability p_b between parallel spins. The new clusters are defined as a maximal set of parallel spins connected by bonds. For a particular choice of $p_\mathrm{b} \equiv p = 1 - \mathrm{e}^{-2J/k_\mathrm{B}T}$ it was shown that these clusters (Coniglio–Klein droplets) have the same properties of Fisher's droplets, namely their size diverges at the Ising critical point with Ising exponents. Note that the bonds are only fictitious and do not change the energy of the spins. They only have the role of breaking the clusters made of parallel spins. Some years earlier Kasteleyn and Fortuin defined a random cluster model, obtained starting from an Ising model and by changing the spin interaction J in $J = \infty$, with probability p, and J into $J = 0$, with probability $1 - p$. They showed that the partition function of this modified model, called the random cluster model, coincides with the partition function of the original Ising model. In the random cluster model the clusters are defined as a maximal set of spins connected by infinite interactions. Although these clusters have the same properties of the droplet model, they were defined in the random cluster model, and for this reason these clusters were not associated with the droplets of the Ising model. It was only after Swendsen and Wang [99] introduced a cluster dynamics based on the Kasteleyn and Fortuin formalism, that it was formally shown [40] that the distribution of the Coniglio–Klein (CK) droplets are the same as the distribution of Kasteleyn–Fortuin (KF) clusters in the random cluster model. For this reason often the CK droplets and the KF clusters are identified, however the different meanings should be kept in mind.

A further development was obtained when the fractal structure of the droplets was studied not only for the

Ising model but for the full hierarchy of the q-state Potts model, which in the limit $q = 1$ gives the random percolation problem. It was shown that the critical droplets of the Potts model have the same structure, made of links and blobs, as found for the clusters in the random percolation problem. One of the consequences of this study was a better understanding of scaling and universality in terms of geometrical cluster and fractal dimension [74].

The cluster approach to the phase transitions leads also to a deeper understanding of why critical exponents do not depend on dimensionality above the upper critical dimension, and coincide with mean field exponents. It was in fact suggested [26] that, at least for random percolation, the mean field behavior is due to the presence of an infinite multiplicity of critical clusters at the percolation point. This suggests that similar results may be also extended to thermal problems.

Although the original interest in the field of correlated percolation was the study of critical phenomena in terms of geometrical concepts, later it was suggested that correlated percolation could be applied to the sol-gel transition, in particular when correlation was too large to be neglected. In many cases in fact the sol-gel transition, which is based on long range connectivity and percolation transition, interferes with large density fluctuation or critical point. The interplay between percolation points and critical points gives rise to interesting phenomena which are well understood within the concepts of correlated percolation. Correlated percolation has been studied also in systems with different types of long range correlation [108], and has been applied to many other fields such as nuclear physics [69], Gauge Theory [52] and O(n) models [7], fragmentation [15], urban growth [70], random resistor network [6], interacting colloids [12], biological models [1].

In Sect. "Random Percolation" we introduce random percolation concepts. In Sect. "Percolation in the Ising Model" in the context of the Ising model it is shown how clusters have to be defined in order to describe correlated regions corresponding to spin fluctuations. In Subsects. "Ising Clusters" and "Ising Droplets" the Ising clusters and droplets are respectively introduced, and in Subsect. "Ising Droplets Above $d = 4$" it is shown how the mapping between thermal properties and connectivity breaks down below T_c above $d = 4$. In Subsect. "Generalization to the q-State Potts Model" the results found for the Ising model are extended to the q-state Potts model, and in Subsect. "Fractal Structure in the Potts Model: Links and Blobs" the fractal structure is studied in terms of links and blobs. In Subsect. "Fortuin–Kasteleyn–Random Cluster Model" Fortuin–Kasteleyn–Random Cluster Model is presented, and the connection with the Coniglio–Klein droplets is further developed in Appendix A. In Sect. "Hill's Clusters" the possibility to extend the definition of droplets to simple fluids is discussed. In Sect. "Clusters in Weak and Strong Gels" the mechanism, leading to the formation of bound states in gelling systems, is considered, and in Sect. "Scaling Behavior of the Viscosity" the effect that finite bond lifetime has on the behavior of viscosity in weak or colloidal gels. Finally future directions and open problems are discussed in Sect. "Future Directions".

Random Percolation

In this section we define some connectivity quantities and present some results in the context of random percolation, which we will use in the following sections, where the correlated percolation will be presented.

Consider a d-dimensional hypercubic lattice of linear dimension L. Suppose that each edge has a probability p of being occupied by a bond. For small values of p, small clusters made of sites connected by nearest-neighbor bonds are formed. Each cluster is characterized by its size or mass s, the number of sites in the cluster. For large values of p in addition to small clusters we expect a macroscopic cluster that connects the opposite boundaries. This spanning cluster becomes infinite as the system size becomes infinite. For an infinite system there exists a percolation threshold p_c below which only finite clusters are present.

In order to describe the percolation transition [13,58,95], one defines: an order parameter, $P_\infty(p)$, as the density of sites in the infinite cluster, the mean cluster size, $S(p)$, of the finite clusters, and the average number of clusters, $K(p)$.

These quantities can be related to the average number of clusters of s sites per site, $n(s, p)$, and near the percolation threshold the critical behavior is characterized by critical exponents:

$$K(p)|_{\text{sing}} = \sum n(s,p)|_{\text{sing}} \sim |p - p_c|^{2-\alpha_p} , \tag{1}$$

$$P_\infty(p) = 1 - \sum sn(s,p) \sim \begin{cases} 0 & \text{if } p < p_c \\ (p-p_c)^{\beta_p} & \text{if } p > p_c , \end{cases} \tag{2}$$

$$S(p) = \sum s^2 n(s,p) \sim |p - p_c|^{-\gamma_p} , \tag{3}$$

where the sum is over all finite clusters, and in Eq. (1) only the singular part has been considered. Finally one can define the pair connectedness function p^f_{ij} as the probability that *i* and *j* are in the same finite cluster through

$$\xi^2(p) = \frac{\sum r_{ij}^2 p_{ij}^f}{\sum p_{ij}^f} \,. \tag{4}$$

The connectedness length, $\xi(p)$, which is the critical radius of the finite clusters, diverges as

$$\xi \sim |p - p_c|^{-\nu_p} \,. \tag{5}$$

The critical exponents defined in Eqs. (1)–(4) are not all independent. Scaling relations can be derived among them as for ordinary second phase transitions. These scaling laws are intimately related to the property of the incipient infinite cluster of being a self similar fractal [74] to all length scales. The mass, s^*, of a typical cluster of linear dimension, ξ, scales as $s^* \sim \xi^{D_p}$, where D_p is the fractal dimension of the cluster.

Scaling and Hyperscaling

To obtain scaling laws, following Kadanoff's original idea, we perform [26] the following three steps: (i) divide the system into cells of linear dimension *b*, (ii) coarse grain by some suitable rule, (iii) rescale the lengths by a factor *b*. The result is a renormalized system where the size of the large clusters *s* has been reduced by factor b^{D_p} and all lengths by a factor *b*:

$$L' = \frac{L}{b} \,, \quad \xi = \frac{\xi'}{b} \,, \quad s' = \frac{s}{b^{D_p}} \,. \tag{6}$$

Assuming that the large clusters do not interpenetrate, the sum over the large clusters in an interval between $(s, s + \Delta s)$ must be the same before and after rescaling, i. e.

$$N(s,\xi)\Delta s \sim N(s',\xi')\Delta s' \tag{7}$$

where $N(s,\xi)/L^d = \overline{n}(s,\xi)$ is the number of clusters of *s* sites per unit volume. Dividing by the volume L^d, from (6) we obtain

$$\overline{n}(s,\xi) = b^{-d-D_p}\overline{n}(sb^{-D_p} \,,\ \xi b^{-1}) \,. \tag{8}$$

Choosing $b = s^{1/D_p}$ from (8) we obtain

$$n(s,p) = s^{-\tau_p} f((p - p_c)s^{\sigma_p}) \tag{9}$$

where $n(s,p) = \overline{n}(s,\xi)$ and

$$\tau_p = \frac{\mathrm{d}}{D_p} + 1, \quad \sigma_p = \frac{1}{\nu_p D_p} \,. \tag{10}$$

Equation (9) exhibits the scaling form postulated by Stauffer [13,58,95]. From (1), (2) and (10) we have:

$$2-\alpha_p = \frac{\tau_p - 1}{\sigma_p} \,, \quad \beta_p = \frac{\tau_p - 2}{\sigma_p} \,, \quad -\gamma_p = \frac{\tau_p - 3}{\sigma_p} \tag{11}$$

and

$$\tau_p = 2 + \frac{\beta_p}{\beta_p + \gamma_p} \,, \quad \sigma_p = \frac{1}{\beta_p + \gamma_p} \,, \tag{12}$$

from which the following scaling relations are obtained:

$$\alpha_p + 2\beta_p + \gamma_p = 2 \,, \tag{13}$$

$$\frac{1}{\nu_p}(\beta_p + \gamma_p) = D_p \,. \tag{14}$$

From (10), (11) one can also find relations which contain the Euclidean dimensionality *d* called hyperscaling relation:

$$2 - \alpha_p = \nu_p d \,, \tag{15}$$

$$d - \frac{\beta_p}{\nu_p} = D_p \,. \tag{16}$$

Equation (16) was originally suggested in [68]. In 2*d* exact results give $\tau_p = 187/91$ and $\sigma_p = 36/91$, and in 3*d* the best estimates $\tau_p \simeq 2.18$, $\sigma_p \simeq 0.45$. From mean field theory [57] we know that for any *d* above the upper critical dimension $d_c = 6$, the critical exponents coincide with the mean field ones, namely $-\alpha_p = \beta_p = \gamma_p = 1$, $\nu_p = \sigma_p = 1/2$ and $\tau_p = 5/2$. These exponents satisfy the scaling relation (13), but fail to satisfy the hyperscaling relation (15) except for $d = 6$.

Moreover, while Eq. (14), for any $d > 16$, shows that the fractal dimension is stacked at the value $D_p = 4$, the hyperscaling relation (16) breaks down for $d > 6$.

Breakdown of Hyperscaling

By following a less conventional scaling approach, here we want to propose a geometrical interpretation of hyperscaling, why it breaks down above d_c, and why the hyperscaling breakdown occurs when the mean field becomes valid [26].

Let us assume that the singular behavior comes only from the critical clusters. Say N_ξ is the number of such clusters in a volume of the order ξ^d. The singular part of the cluster number is given by

$$\frac{N_\xi}{\xi^d} \sim \xi^{\frac{\alpha_p - 2}{\nu_p}} \,. \tag{17}$$

At the same time, the density of sites in the infinite cluster $P_\infty \sim |p-p_c|^{\beta_p}$ scales as the total mass of the spanning clusters $N_\xi s^*$ in a volume of linear dimension ξ divided by the volume ξ^d, namely

$$\frac{N_\xi \xi^{D_p}}{\xi^d} \sim \xi^{\frac{-\beta_p}{\nu_p}} , \tag{18}$$

where we have used $s^* \sim \xi^{D_p}$. Similarly the mean cluster size:

$$\frac{N_\xi \xi^{2D_p}}{\xi^d} \sim \xi^{\frac{\gamma_p}{\nu_p}} . \tag{19}$$

These equations lead to the scaling relations, Eqs. (13) and (14). Now if N_ξ is of the order of unity, we recover the hyperscaling relations [48], Eqs. (15) and (16), while if N_ξ diverges hyperscaling breaks down. We know that for dimension d above $d_c = 6$, $n(s,p) \sim s^{-5/2} e^{-(p-p_c)^2 s}$ for large s. Therefore $N_\xi = \xi^d \sum n(s,p) \sim \xi^{d-6}$, where $\xi \sim |p-p_c|^{-1/2}$. This calculation shows that, above d_c, N_ξ diverges and hyperscaling breaks down, and from Eqs. (17) and (18) the hyperscaling relations are replaced by $2-\alpha_p = 6\nu_p$ and $D_p = 6 - \beta_p/\nu_p$, which in fact are satisfied for mean field exponents.

The more standard scaling approach of the previous section must be modified taking into account that for $d > 6$ the large number of clusters will be reduced by a factor b^{6-d}, then Eq. (7) will be modified as $N(s,\xi)\Delta s = b^{6-d} N(s', \xi')\Delta s'$ which still leads to all the Eqs. (7)–(14), except that d is replaced everywhere by 6. In particular, both Eqs. (14) and (16) give a fractal dimension $D_p = 4$.

The multiplicity of infinite clusters above d_c was numerically shown in [42,53]. The average (finite) number N_ξ of distinct clusters below d_c have been estimated theoretically and calculated numerically [3,63,94].

Consider now a critical cluster for $d > d_c$ just below p_c and its center of mass, 0. Say ξ_1 is the distance from 0, below which the cluster has not been penetrated by the other critical clusters. This length can be obtained by equating the mass density inside the region of radius ξ_1 to the mass density inside the region of radius ξ, $N_\xi \xi^{4-d} = \xi_1^{4-d}$, which gives $\xi_1 \sim \xi^{2/(d-4)}$.

If $\rho(r)$ is the density profile defined as the mass density of all the critical clusters at a distance r from 0, we expect that the density profile behaves as a power law r^{d-4} for $r < \xi_1$, as it should be for an object with fractal dimension $D_p = 4$ and as a constant for $r > \xi_1$ due to the penetration of the other critical clusters. Consequently we can make the following scaling Ansatz [2]:

$$\rho(r) = \frac{1}{r^{d-4}} f\left(\frac{r}{\xi_1}\right) , \tag{20}$$

where $f(x) \sim$ const for $x < 1$ and $\sim x^{d-4}$ for $x > 1$.

In conclusion, while for $d < 6$ the density of the order parameter fluctuates over a distance of the order ξ, for $d > 6$, where the mean field holds, the fluctuations are damped by the presence of infinitely many interpenetrating clusters, and the density of the order parameter crosses over from a power law (fractal) regime to a homogeneous regime at a distance $\xi_1 \ll \xi$.

The mean field solution is therefore a consequence of the presence of infinitely many interpenetrating clusters which suppress the spatial fluctuation of the order parameter. The condition for the validity of mean field theory is then given by $N_\xi \gg 1$. Using Eqs. (18) and (14) this condition implies

$$N_\xi^{-1} \sim \frac{\xi^{\frac{\gamma_p}{\nu_p}}}{\xi^d \xi^{\frac{-\beta_p}{\nu_p}}} \sim \frac{\langle \Delta M^2 \rangle}{\xi^d M^2} \ll 1 , \tag{21}$$

where M and $\langle \Delta M^2 \rangle$ are the order parameter and the fluctuations of the order parameter (here we used that the mean cluster size $S(p)$ has the same critical behavior as the fluctuations of the order parameter [18,34]). Interestingly enough Eq. (21) coincides with Ginzburg criterion for the validity of mean field theory.

Cluster Structure

Nodes and Links In the previous sections we have shown that the Incipient Infinite Cluster (IIC) is a fractal. Here we want to show in more details the internal structure of the IIC. A very useful nodes and links picture for the infinite cluster just above p_c was introduced by Skal and Shklowskii [89] and de Gennes [44]. In this picture the infinite cluster consists of a superlattice made of nodes, separated by a distance of the order of ξ, connected by macrobonds. Just below p_c the structure of the very large cluster, the IIC, was expected to have the same structure as the macrobonds.

Later on, in 1977, Stanley [90] made the important observation that in general for each configuration of bonds at p_c the IIC can be partitioned into three categories. By associating an electric unit resistance to each bond, and applying a voltage between the ends of the cluster, one distinguishes the dangling bonds which do not carry current (yellow bonds). The remaining bonds are the backbone bonds. The backbone can be partitioned in singly connected bonds (red bonds) and all the others, the multiply connected bonds, which lump together in "blobs" (blue bonds). The red bonds, which carry the whole current, have also the property that if one is cut the cluster breaks into two parts. This partition in three types of bonds is very general and can be done for any cluster or aggregate.

The next major problem was to determine whether the blobs are or not relevant. In the nodes and links picture the assumption is that the blobs are irrelevant and only links are relevant. A further elaboration [90] assumed that the backbone close to p_c would reduce to a self-avoiding walk chain, which implies that the blobs are not relevant. This self-avoiding walk Ansatz received a large amount of attention, since it predicted a value for the crossover exponent of the dilute Heisenberg ferromagnetic model near the percolation threshold in $2d$, in good agreement with the experimental data, although the prediction for the dilute Ising crossover exponent did not agree as well with the data [9].

Syerpinsky Gasket: A Model Without Links In 1981 a completely alternative model was proposed by Gefen et al. [55]. Based on the observation that in a computer simulation the red bonds were hardly seen, they proposed an alternative model, the Syerpinsky gasket, that represents the opposite extreme of the nodes and links picture. It has a self-similar structure but only multiply connected bonds are present. A great advantage of this model is that it can be solved exactly. It also gives good prediction for the fractal dimension of the backbone, but it fails to predict the correct value for the dilute Ising crossover exponent [9].

Nodes, Links and Blobs Motivated by all these conflicting models, some rigorous results were presented which led unambiguously to the nodes, links and blobs picture of the infinite cluster [23,24], in which both links and blobs are relevant below $d = 6$, while only links are relevant above $d = 6$ or in the mean field. In particular the following relation was proven for any p and for any lattice in any dimension:

$$p \frac{\mathrm{d} p_{ij}}{\mathrm{d} p} = \lambda_{ij} \qquad (22)$$

where p_{ij} is the probability that i and j are connected, λ_{ij} is the average number of red bonds between i and j, such that if one is cut, i and j would have been disconnected. From Eq. (22) it is possible to calculate the average number L_{ij} of red bonds between i and j under the condition that i and j are in the same cluster:

$$L_{ij} = \frac{\lambda_{ij}}{p_{ij}} . \qquad (23)$$

From the scaling form of $p_{ij} = r_{ij}^{-d+2-\eta_p} f(r_{ij}/\xi)$ it follows

$$L_{ij} = r_{ij}^{\frac{1}{\nu_p}} f_1\left(\frac{r_{ij}}{\xi}\right) , \qquad (24)$$

where $f_1(x)$ is related via Eqs. (22) and (23) to $f(x)$ and goes to a constant for $x \ll 1$. In particular, by putting $r_{ij} = \xi$ in Eq. (24) we obtain

$$L_{\mathrm{R}} \sim \xi^{\frac{1}{\nu_p}} , \qquad (25)$$

where $L_{\mathrm{R}} \equiv L(r_{ij} = \xi)$ is the average number of red bonds between two points separated by a distance of the order of ξ. From Eq. (25) it follows that the fractal dimension of the red bonds is $D_{\mathrm{R}} = 1/\nu_p$. An immediate consequence is that not only the red bonds are relevant but also the number of bonds L_{B} in the blobs diverge. For more details, see [23,24]. Later Eq. (25) was confirmed numerically by Pike and Stanley [83] in $d = 2$. Although the links are much less in number than the backbone bonds, they can be detected experimentally, in fact it can be shown [23,25] that only the links determine the critical behavior of the dilute Ising model at p_c leading to a crossover exponent 1 in any d. While for a dilute Heisenberg system the crossover exponent is related to the resistivity exponent, in agreement with the experimental data of [9].

In conclusion we can write the following relations

$$y_{\mathrm{H}} = D_p , \quad y_{\mathrm{T}} = D_{\mathrm{R}} \qquad (26)$$

where $y_{\mathrm{H}} = d - \beta_p/\nu_p$ is the so-called magnetic field scaling exponent and $y_{\mathrm{T}} = 1/\nu_p$ is the thermal scaling exponent in the renormalization group language. This result is quite interesting as it shows that the scaling exponents can be expressed in terms of geometric quantities: The fractal dimension D_p of the entire incipient infinite cluster, and the fractal dimension D_{R} of the subset made of red bonds.

Surfaces and Interfaces

The study of the structure of the surfaces and interfaces of the large clusters below p_c has not received as much attention as the study of the internal structure of the IIC. This problem is relevant to the study of the dielectric constant of random composite materials, the viscosity of a gel, the conductivity of a random superconducting network, and the relative termite diffusion model.

For simplicity, let us consider a random superconducting network in which superconducting bonds are present with probability p and normal bonds carrying a unit resistance with probability $1 - p$. For small values of p we have finite superconducting clusters in a background of normal resistor. As $p \to p_c$, the superconductivity Σ diverges. For a finite cell of linear dimension L just below p_c, the typical configurations are characterized by two very large clusters almost touching, each one attached to one of two opposite faces. Inside these clusters there are islands of normal resistors. If a unit voltage is applied between the opposite face of the hypercube, there is no current flowing through the bonds in the island. We call these "dead" bonds, analogous to the dead ends of the percolating cluster. The remaining normal bonds connect one superconducting cluster to the other. These bonds are made of "bridges", also called "antired" bonds, which have the property that if one is replaced by a superconducting bond, a percolating superconducting cluster is formed, and the remaining multiple "connecting" bonds. Similar to the red bonds, it can be proved [26] that the fractal dimensionality of the antired bonds is $1/\nu_p$. The proof is based on the following relation which can be proved for any lattice in any dimension

$$(1-p)\frac{\mathrm{d}p_{ij}}{\mathrm{d}p} = \mu_{ij} , \tag{27}$$

where p_{ij} is the pair connectedness function (the probability that sites i and j belong to the same cluster) and μ_{ij} is the average number of antired bonds between i and j. These are defined as non-active bonds, such that if one is made active, i and j become connected.

The above considerations suggest that just below p_c the system can be imagined as a superlattice made of large critical clusters whose centers are separated by a distance of the order ξ. The surfaces of these clusters almost touch, and are connected by bridges made of single bonds and other paths made of more than one bond [33].

Finally we mention the following result which relates the size of the critical cluster s^* and the size of the entire perimeter t^* [13,58,95]

$$t^* = \frac{1-p}{p}s^* - As^{*\sigma_p} , \tag{28}$$

where $\sigma_p = 1/(\nu_p D_p)$ is the critical exponent which appears in the cluster number Eq. (9) and A is a constant. The last term $s^{*\sigma_p}$ which appears also in Fisher's droplet model [50] is usually interpreted as the surface of the droplet. However, if it was a surface, σ_p should satisfy the following boundary $(d-1)/d \le \sigma_p \le 1$. The upper bound corresponds to the fully rarefied droplets and the lower bound to compact droplets. Surprisingly enough for the percolation problem σ_p is strictly smaller than $(d-1)/d$. This paradox can be solved by using a result [25], which shows that $As^{*\sigma_p}$ is equal to a number of antired bonds between critical clusters separated by a distance of order ξ. Since the subset of antired bonds is only a subset of the entire perimeter, it explains why $\sigma_p < (d-1)/d$. This result gives the best geometrical interpretation of the thermal scaling exponent y_{T}. It in fact shows that $y_{\mathrm{T}} = D_{\mathrm{AR}}$, where D_{AR} is the fractal dimension of the antired bonds namely that part of the surface which contributes to the surface tension.

Percolation in the Ising Model

In this section we want to extend the percolation problem to the case in which the particles are correlated. The simplest model to consider is the lattice gas or Ising model. In the following we will use the Ising terminology. We know that the Ising model exhibits a thermodynamic transition for zero external field, $H = 0$, at a critical temperature T_c. The question that we ask is how the percolation properties are modified due to the presence of correlation. We first consider the case when the clusters are made of nearest-neighbor down spins (Subsect. "Scaling and Hyperscaling"). Later in Subsect."Breakdown of Hyperscaling" we will modify the cluster definition in such a way that these new clusters describe the thermal fluctuations namely we require that the clusters satisfy the same properties as the droplets in Fisher's droplet model [50]. Namely, i) the size of the clusters must diverge at the Ising critical points, ii) the linear dimension of the clusters must diverge with the same exponent as the correlation length, and iii) the mean cluster size must diverge with the same exponent as the susceptibility.

These conditions are satisfied if the cluster size distribution for zero external field has the following form

$$n(s,T) = s^{-\tau} f((T-T_c)s^{\sigma}) . \tag{29}$$

The parameters σ and τ are related to critical exponents α, β and γ through Eqs. (10) and (11), where now α, β and γ are the Ising critical exponents. In particular for $d = 2$, $\sigma = 8/15 \simeq 0.53$ and $\tau = 31/15 \simeq 2.07$, and for $d = 3$, $\sigma \simeq 0.64$ and $\tau \simeq 2.21$.

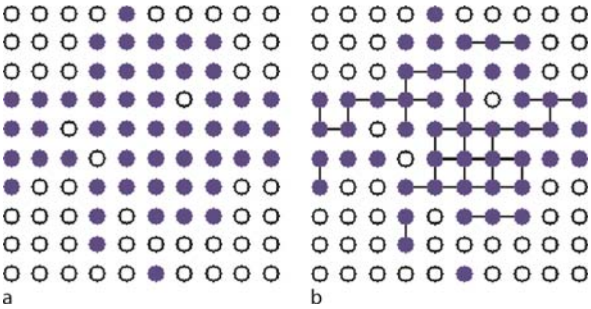
Ising Clusters

The Hamiltonian of the Ising model is given by:

$$\mathcal{H} = -J\sum_{\langle ij\rangle} S_i S_j - H\sum_i S_i \tag{30}$$

where $S_i = \pm 1$ are the spin variables, J is the interaction between two nearest-neighbor (nn) spins and H is the magnetic field.

From the thermodynamic point of view the only quantities of interest are those which can be obtained from the free energy and those were the only quantities that Onsager was concerned with in his famous solution of the 2d Ising model. However one can look at the Ising model from a different perspective by studying the connectivity properties using concepts such as clusters which have been



Correlated Percolation, Figure 1

a Ising configuration at T_c: "down" spins are represented by *filled circles*. **b** Correct clusters are obtained from the configuration given in (**a**) by putting bonds between occupied sites with probability $p = 1 - e^{-2\beta J}$

systematically elaborated in percolation theory [92]. There are two reasons for approaching the problem also from the connectivity point of view. One reason is that it gives a better understanding of the mechanism of the phase transition [50]. In fact, concepts like universality and scaling have been better understood in terms of geometrical clusters and fractal dimensions [27]. A second reason is that there are physical quantities amenable to experimental observations, which are associated to the connectivity properties and cannot be obtained from the free energy. It is very important to note however that the definition of connectivity, and therefore the definition of the cluster, is not always the same, but may depend on the particular observable associated with it.

In the Ising model, for a given configuration of spins it is rather natural to define a cluster as a maximal set of *nn* down parallel spins[1] (Fig. 1). For some time these clusters were believed to be responsible for the correlations present in the Ising model. This idea was also based on numerical results which showed evidence that in two dimensions the mean cluster size diverges at the thermal critical point [8]. However the idea that the clusters could describe thermal correlations was definitively abandoned when it was shown, by numerical simulations in the three-dimensional Ising model [78] and by exact solution on the Bethe lattice [22], that the percolation point appeared in the low density phase of down spins on the coexistence curve at a temperature T_p before the critical point T_c is reached ($T_p < T_c$).

Later it was suggested by topological arguments [21] that only in two dimensions does the critical point coincide with the percolation point, but not necessarily in higher dimensions. The arguments followed two steps: in the first step it was argued that an infinite cluster of up spins is a necessary condition for having a spontaneous magnetization. This implies a percolation transition of down spins on the coexistence curve $T_p \leq T_c$, in the second step it was argued that due to topological reasons in two dimensions it is not possible to have an infinite cluster of up spins coexisting with an infinite cluster of down spins, which implies $T_p \geq T_c$. Combining with the previous inequalities one obtains in two dimensions $T_p = T_c$.

Later these results were proven rigorously [36,37] along with many other results relating connectivity and thermodynamic quantities. For more details we refer to the original papers.

It is clear that the Ising clusters, defined as a group of *nn* parallel spins, do not have the property of describing correlated regions corresponding to spin fluctuations as originally expected. In fact even in two dimensions, where the thermal critical point coincides with the percolation point, the Ising clusters were not suitable for such description. Series expansion showed that the mean cluster size diverges with an exponent, $\gamma^* = 1.91 \pm 0.001$, rather different from the susceptibility exponent, $\gamma = 1.75$ [100]. Later it has been shown exactly that $\gamma^* = 91/48$ [97].

Ising Droplets

From the properties mentioned in Subsect. "Ising Clusters", it appears that the Ising clusters are too big to describe the proper droplets. The reason is that there are two contributions to the Ising clusters. One is due to correlations but there is another contribution purely geometrical due to the fact that two *nn* spins even in the absence of correlation have a finite probability of being parallel. The last contribution becomes evident in the limit of infinite temperature and zero external field. In this case, in fact, although there is no correlation and the susceptibility is zero, the cluster size is different from zero. In fact in 3*d* at infinite temperature there is even an infinite cluster of "up" and "down" spins.

Binder [8] proposed to cut the infinite cluster in order to have $T_p = T_c$ in $d = 3$, but he did not give the microscopic prescription to do it. Later Coniglio and Klein [30] proposed to reduce the cluster size by introducing fictitious bonds between *nn* parallel spins with probability p_b (Fig. 1). These new clusters are made of *nn* parallel spins connected by bonds. The original Ising cluster will either reduce its size or will break into smaller clusters. If $p_b = 1$, we obtain the Ising clusters again. This case is known as the site correlated percolation problem because one looks

[1] The Ising Hamiltonian, Eq. (30), is equivalent to the lattice gas Hamiltonian $\mathcal{H}_{LG} = -J' \sum_{\langle ij \rangle} n_i n_j - \mu \sum_i n_i$, with $n_i = (1 - S_i)/2$, $J' = 4J$ and $\mu = 2H - 4J$. In the lattice gas terminology an Ising cluster is a maximal set of *nn* occupied sites.

at the properties of the Ising clusters just as in the random percolation problem. The main difference is that in random percolation the occupied sites are randomly distributed, while in this case the down (or up) spins are correlated according to the Ising Hamiltonian. In the infinite temperature limit one recovers random percolation. The case $p_b \neq 1$ is called site-bond correlated percolation [39].

A Hamiltonian formalism was proposed to study site correlated percolation [79]. This formalism was generalized in [30] to study site-bond correlated percolation. In this case for the zero external field the Hamiltonian is given by the following dilute Ising s-state Potts Model (DIPM)[2]:

$$-\mathcal{H}_{\mathrm{DP}} = J_b \sum_{\langle ij \rangle} (\delta_{\sigma_i \sigma_j} - 1)(S_i S_j + 1) + J \sum_{\langle ij \rangle} S_i S_j , \quad (31)$$

where $\sigma_i = 1, \ldots, s$ are Potts variables and the sum is over all nearest neighbor sites. In the same way as the s-state Potts model in the limit $s = 1$ [110] describes the random bond percolation model, the DIPM describes percolation in the Ising model where the clusters are made of parallel spins connected by bonds with probability, $p_b = 1 - \mathrm{e}^{-2\beta J_b}$.

In particular the average number of clusters G, that plays the role of the free energy in the percolation problem is given by $G = \mathrm{d}F/\mathrm{d}s|_{s=1}$, where

$$-\beta F = \lim_{N \to \infty} \frac{1}{N} \ln \left(\sum_{\{\sigma_i S_i\}} \mathrm{e}^{-\beta \mathcal{H}_{\mathrm{DP}}} \right) . \quad (32)$$

At that time the DIPM was investigated in a different context by Berker et al. [81]. The model exhibits the interesting properties that by choosing $J_b = J$ it coincides with a pure $s+1$-state Potts model. Therefore in the limit $s = 1$ the DIPM coincides with the $s = 2$ Potts model namely with the Ising model. Consequently F becomes the Ising model free energy and G has a singularity at the Ising critical point. This argument immediately suggested that the site-bond correlated percolation for $J_b = J$ namely with the bond probability given by

$$p_b \equiv p = 1 - \mathrm{e}^{-2\beta J} , \quad (33)$$

should reproduce the same critical behavior of the Ising model. Namely the percolation quantities become critical at the Ising critical point in the same way as the corresponding thermal quantities.

In fact using real space renormalization group arguments, it was possible to show that the size of the clusters of parallel spins connected by bonds with probability, p_b, given by Eq. (33), diverges at the Ising critical point with Ising exponents, exhibiting thus the same properties as the droplets in Fisher's model. These clusters were called droplets to distinguish them from the Ising clusters.

Droplets in Two and Three Dimensions

This site-bond correlated percolation problem has been studied by real space renormalization groups in two dimensions [30,35], by ϵ expansion, near six dimensions [31] and by Monte Carlo in two and three dimensions [64,82,85,92].

The renormalization group analysis shows that in $2d$ the Ising critical point is a percolation point for down or up spins connected by bonds for all values of bond probability such that $1 \leq p_b < 1 - \mathrm{e}^{-2\beta J}$. The fractal dimension $D^* = (\gamma^*/\nu + 2)/2 = 187/96$ [97] being higher than the fractal dimension $D = (\gamma/\nu + 2)/2 = 15/8$ for the value of $p_b \equiv p = 1 - \mathrm{e}^{-2\beta J}$.

In the renormalization group language this means that there are two fixed points, one corresponding to the universality class of the Ising cluster, the other one corresponding to the droplets. In the first one, the variable J_b is irrelevant, namely the scaling exponent associated with it, $y_b < 0$. In the second fixed point associated with the droplets instead $y_b > 0$. The result is that the Ising critical point is a percolation point for a range of values of p_b, at the first sight seems counter-intuitive. In fact if the Ising critical point corresponds to the onset of percolation for Ising clusters ($p_b = 1$), one would expect that for $p_b < 1$ the clusters would not percolate anymore. The puzzle can be clarified by studying the fractal structure of the Ising clusters and the droplets at T_c [27]. In fact it can be shown that y_b is the scaling exponent of the red bonds, namely $L_R \sim l^{y_b}$ where L_R is the number of red bonds between two connected sites separated by a distance of the order l, consequently the droplets, characterized by $y_b > 0$, are made of links and blobs, like in random percolation. Due to the presence of links the cluster breaks apart and does not percolate anymore as the bond probability decreases. On the contrary the Ising clusters ($p_b = 1$), characterized by $y_b < 0$, are made only of blobs and no links, therefore by decreasing the bond probability the infinite cluster does not break and still percolates, until $p_b = p$.

In $3d$ at the Ising critical point, T_c, there is an analogous line of anomalous percolation points for clusters of down spins connected by bonds, for all values of bond probability such that $1 \leq p_b < 1 - \mathrm{e}^{-2\beta J}$, although the

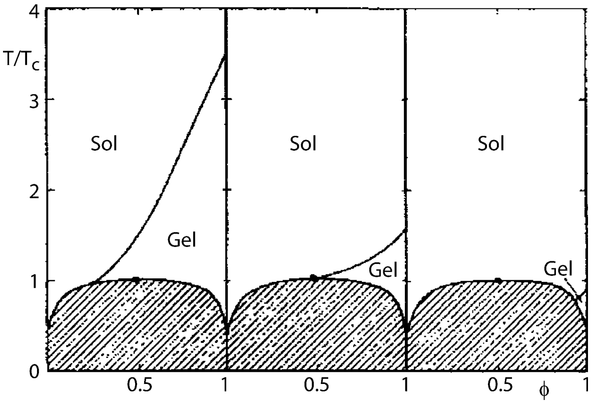
[2] Originally in [30] the Hamiltonian of the DIPM, $\mathcal{H}_{\mathrm{DP}}$, was expressed in terms of the lattice gas variables n_i, and the Ising droplets were defined as nn occupied sites connected by bonds, corresponding to nn down spins.

probability P_∞ for a down spin to be in the infinite cluster is different from zero. More precisely the quantity $p_{ij} - P_\infty^2$ decays as a power law, where p_{ij} is the probability that i and j are connected. For more details see [29]. As p_b decreases towards $p = 1 - e^{-2\beta J}$ there is a crossover towards a different power law characterized by the Ising exponent, while P_∞ goes to 0.

Droplets in an External Field

By keeping the same definition of droplets given above, in the case of an Ising model in an external field $H > 0$ one finds a phase diagram in the H, T plane or in the M, T plane, with a percolation line of "down" spins ending at the Ising critical point (see Fig. 2). Along the percolation line one finds critical exponents in the universality class of random percolation with a cross-over to Ising critical exponents as the Ising critical point is approached. The Ising critical point being a higher order critical point for the percolation transition. This percolation line, also known as the Kertesz line, has received some attention [66,93,95,105] (see for more details the review by Sator [88]). Although the Ising free energy has no singularity along this line some physical interpretation is given to the Kertesz line [17].

On the other hand this line disappears if the droplet definition is modified in the presence of an external field [40,104], according to Kasteleyn and Fortuin formalism [65] and the Swendsen and Wang approach [99]. In this approach the field is treated as a new interaction between each spin and a ghost site. Consequently for positive H (negative H) an "up" ("down") spin can be connected to the ghost spin with a probability $p_H = 1 - e^{-2\beta|H|}$. Droplets now are defined as a maximal set of spins connected by bonds where as before the bonds between nearest-neighbor parallel spins have probability p_b given by Eq. (33) and p_H between spins and the ghost spin. Note that two far away spins can be easily connected through the ghost spin. In this way the presence of a positive (negative) magnetic field implies always the presence of an infinite cluster of "up" ("down") spins.



Correlated Percolation, Figure 2
Monte Carlo simulations of the 3*d* lattice gas model for three values of the bond probability $p_b = 1 - e^{-2c\beta J}$ with the constant $c = 2.25, 1, 0.564$ from *left* to *right*. Φ is the density of down spins. The Gel and the Sol indicates the percolation and non percolation phase. From [59]

Exact Relations Between Connectivity and Thermal Properties

Interestingly it was also shown [40] that the droplets so defined have the same statistics as the clusters in the random cluster model introduced by Kasteleyn and Fortuin (KF) [65] (see Subsect. "Fortuin–Kasteleyn–Random Cluster Model"), although the CK droplets and the KF clusters have a different meaning. Using the relations between the connectivity properties of the random cluster model and the thermal properties of the Ising model, it was finally possible to prove that in any dimension and for any temperature T and external field $H > 0$, provided that the extension of the droplet definition in the external field is considered, the following relations between connectivity and thermal properties hold [40]:

$$\begin{cases} \rho_\infty = m \\ p_{ij} = g_{ij} \end{cases} \tag{34}$$

where ρ_∞ is the density of up spins in the percolating droplet, m is the magnetization per site, p_{ij} is the probability that i and j are connected (through both finite or infinite droplet) and $g_{ij} = \langle S_i S_j \rangle$.

In particular, for $T > T_c$ and zero external field $H \to 0$, we have that the magnetization $m = 0$ and g_{ij} coincides with the spin-spin pair correlation function. Consequently $\rho_\infty = 0$, namely the probability for a spin to be in an infinite droplet is zero, and therefore p_{ij} coincides with the probability that two spins i and j are in the same finite droplet. For $T < T_c$ instead we have $\rho_\infty = m > 0$, and $p_{ij} = p_{ij}^f + p_{ij}^\infty$, where p_{ij}^f (p_{ij}^∞) is the probability that spins in i and j are in a finite (infinite) droplet. From Eq. (34) it follows for $T < T_c$:

$$p_{ij}^f + p_{ij}^\infty - \rho_\infty^2 = \langle S_i S_j \rangle - m^2 \,. \tag{35}$$

By summing over i and j we have

$$S + (\Delta\rho_\infty)^2 = \chi \,, \tag{36}$$

where S is the mean cluster size of the finite clusters, $(\Delta\rho_\infty)^2$ is the fluctuation of the density of the infinite cluster and χ is the susceptibility. These exact results show that above T_c mean cluster size and susceptibility coincide, while below T_c there are two contributions to the susceptibility, one due to the mean cluster size and the second related to the fluctuation of the density of the infinity cluster. Monte Carlo calculations [85] show that both terms have the same critical behavior as also occurs in random percolation [18,34], so the mean cluster size S diverges like the susceptibility. We expect that this is the case for dimensions up to $d = 4$, the upper critical dimensionality of the Ising model. In the mean field, as we will see, the mean cluster size below T_c diverges with an exponent different from the susceptibility.

One very interesting application based on the KF approach was produced by Swendsen and Wang [99,106], who elaborated a cluster dynamics which drastically reduced the slowing down near the critical point of the Ising and Potts model (see also [109] for further developments).

The droplet definition can be extended to the *nn* antiferromagnetic Ising model [4] and to the Ising model with any ferromagnetic interaction J_{ij} between sites i and j [64]. In this case the CK clusters are defined as set of parallel spins connected by bonds present between i and j with probability $p_{ij} = 1 - \exp[-2\beta J_{ij}]$. It can be shown that also in this case the relations (34) between connectivity and thermal quantities hold.

Ising Droplets Above $d = 4$

In Subsect. "Ising Droplets" we have reported the relations Eqs. (34) and (35), which are exact and are valid in any dimension including the mean field. As a matter of fact in the mean field the percolation order parameter and the magnetization are identical and go to zero with the exponent $\beta = 1/2$, while the mean cluster size above T_c coincides with the susceptibility and diverges with the exponent $\gamma = 1$. The same is true for the connectedness length above T_c, which coincides with the correlation length, and diverges with an exponent $\nu = 1/2$. However below T_c the mean cluster size diverges with an exponent $\gamma' = 1/2$ and the correlation length with an exponent $\nu' = 1/4$. The result is a consequence that the two terms in Eq. (35), the probability that two sites are in the same finite droplet, p^f_{ij}, and the correlation of the infinite droplet density at site i and j, $p^\infty_{ij} - \rho^2_\infty$, do not scale in the same way, giving rise to two lengths, diverging respectively with exponents ν' and ν.

These somehow anomalous results are probably a consequence that the Ising model has an upper critical dimension $d_c = 4$ while the DIPM which describes the droplet problem has an upper critical dimension $d_c = 6$ [31]. In fact there are arguments that for $4 \le d \le 6$ below T_c the critical exponents are $\nu' = 1/(d-2)$, $\gamma' = 2/(d-2)$, $\beta = 1/2$, $\eta = 0$ and fractal dimension $D_p = 1/2(d+2)$, with an upper critical dimension $d_c = 6$. Of course for $T > T_c$ the exponents are $\gamma = 1$, $\nu = 1/2$ and $\eta = 0$.

Due to the breakdown of the mapping between thermal fluctuations and mean cluster size below T_c above $d = 4$, it is not possible to extend easily the geometrical picture, employed in random percolation, to explain the breakdown of hyperscaling in the Ising model. For a study of droplets inside the metastable region see [5].

Generalization to the q-State Potts Model

All the results found for the Ising case have been extended [32] to the q-state Potts model. This model is defined by the following Hamiltonian:

$$-\mathcal{H}_q = qJ \sum_{\langle ij \rangle} \delta_{\sigma_i \sigma_j} , \qquad (37)$$

where the spin variables σ_i can assume q values, $\sigma_i = 1, \ldots, q$. This model coincides with the Ising model for $q = 2$, reproduces the random percolation problem in the limit $q = 1$ and the tree percolation model in the limit $q = 0$ [110]. The geometrical approach developed in the previous sections for the Ising model, can be extended to the q-state Potts model. In particular one can define the site-bond Potts correlated percolation, where clusters are made of *nn* spins in the same state, connected by bonds with bond probability p_b. By choosing $p_b = p = 1 - e^{-q\beta J}$, it is possible to show that these clusters percolate at the Potts critical temperature $T_c(q)$, with percolation exponents identical to the thermal exponents and therefore behave as the critical droplets.

The formalism is based on the following diluted Potts model [32,102]:

$$-\mathcal{H}^q_{\mathrm{DP}} = J_b \sum_{\langle ij \rangle} (\delta_{\tau_i \tau_j} - 1)\delta_{\sigma_i \sigma_j} + qJ \sum_{\langle ij \rangle} \delta_{\sigma_i \sigma_j} , \quad (38)$$

where the second term, which controls the distribution of spin variables, is the q-state Potts Hamiltonian, whereas the first term contains auxiliary Potts variables $\tau_i = 1, 2, \ldots, s$ and controls the bonds distribution.

As in the Ising case, Hamiltonian (37) in the limit $s \to 1$ describes the site-bond Potts correlated percolation problem with p_b given by $p_b = 1 - e^{-q\beta J_b}$. The droplets are obtained in the particular case $J_b = qJ$. For this value in fact Hamiltonian (37) for $s \to 1$ coincides with the q-state Potts model.

Correlated Percolation, Table 1

Fractal dimensions, for $d = 2$, of the whole cluster (D), of the Hull (D_H), and of the red bonds (D_R) for the Potts droplets. It is also reported the thermal power exponent y_T

q	D	y_T	D_H	D_R
0	2	0	2	5/4
1	91/48	3/4	7/4	3/4
2	15/8	1	5/3	13/24
3	28/15	6/5	8/5	7/20
4	15/8	3/2	3/2	0

Once the Ising and Potts model has been mapped onto a percolation problem, we can extend some of the results of random percolation to thermal problems.

Fractal Structure in the Potts Model: Links and Blobs

Like in random percolation, also in the q-state Potts model it can be shown that at $T_\mathrm{c}(q)$ the critical droplets have a fractal structure made of links and blobs, with a fractal dimension $D(q) = d - \beta(q)/\nu(q)$, where $\beta(q)$ and $\nu(q)$ are respectively the order parameter and correlation length exponent. Therefore $D(q)$ coincides with the magnetic scaling exponent $y_\mathrm{H}(q)$. However the fractal dimension of the red bonds $D_\mathrm{R}(q)$ does not coincide with the thermal scaling exponent $y_\mathrm{T}(q)$, associated with the thermal variable J, like in random percolation. Instead $D_\mathrm{R}(q)$ is found to coincide with the bond probability scaling exponent y_b associated with the variable J_b in Hamiltonian (37) [27].

Like for random percolation the fractal dimension of the red bonds coincides with the fractal dimension of the antired bonds. Using the mapping from the Potts model to the Coulomb gas [87], it is possible to obtain the exact value of the fractal dimension of the red bonds and of the external perimeter or hull [27]. For further exact results see also [10,97].

From Table 1 it appears that the exact value of $D(q)$ does not vary substantially with q, for $d = 2$. This observation can be understood by noting that, using this geometrical approach, the driving mechanism of the critical behavior can be viewed as coalescence of clusters just like in random percolation. Then one would expect for any q that the fractal dimension should be close to the fractal dimension of the critical clusters in the percolation problem. This also explains the observation of Suzuky [98], known as strong universality, that for a large class of models the ratio γ/ν or β/ν do not vary appreciably. Since these ratios of critical exponents for fixed d depend only on the magnetic scaling exponent, which is identical to the fractal dimension, the strong universality is a consequence of the quasi-universal feature of the fractal dimension as discussed above. Unlikely the fractal dimension of the whole cluster, $D_\mathrm{R}(q)$ and $D_\mathrm{H}(q)$ do change substantially and characterize the different models as function of q. Particularly sensitive to q is the fractal dimension of the red bonds, which has its largest value at $q = 0$ (tree percolation), where the backbone is made only of links. As q approaches q_c the cluster becomes less ramified until the red bonds vanish ($D_\mathrm{R}(4) = 0$). This results in a drastic structural change from a links and blobs picture to a blobs picture only, anticipating a first order transition. Interestingly, the fractal dimension of the red bonds for $q = 0$, $D_\mathrm{R} = 5/4$, has been related to the abelian sandpile model [47]. The reason why $D_\mathrm{R}(q)$ is so model-dependent is due to the fact that the fractal set of the red bonds is only a small subset of the entire droplet, and therefore this "detail" is strongly model dependent. Also the thermal exponent $y_\mathrm{T}(q)$ is strongly model-dependent, however so far the geometrical characterization in terms of a fractal dimension for such exponent has not been found except $q = 1$ (random percolation).

Fortuin–Kasteleyn–Random Cluster Model

We will present here the random cluster model introduced by Kasteleyn and Fortuin. Let us consider the q-state Potts model on a d-dimensional hypercubic lattice. By freezing and deleting each interaction of the Hamiltonian (see "Appendix: Random Cluster Model and Ising Droplets"), they managed to write the partition function of the Potts model, $Z = \sum_{\{\sigma_i\}} \mathrm{e}^{-\beta \mathcal{H}_q}$, in the following way

$$Z = \sum_C p^{|C|}(1-p)^{|A|} q^{N_C} , \qquad (39)$$

where C is a configuration of bonds defined in the same hypercubic lattice, just like a bond configuration in the standard percolation model, $|C|$ and $|A|$ are respectively the number of bonds present and absent in the configuration C, and N_C is the number of clusters in the configuration C.

In conclusion, in the KF formalism the partition function of the Potts model is identical to the partition function (39) of a correlated bond percolation model [62,65] where the weight of each bond configuration C is given by

$$W(C) = p^{|C|}(1-p)^{|A|} q^{N_C} \qquad (40)$$

which coincides with the weight of the random percolation except for the extra factor q^{N_C}. They called this particular correlated bond percolation model the random cluster model. Clearly for $q = 1$ the cluster model coincides with the random percolation model.

Kasteleyn and Fortuin have related the percolation quantities associated with the random cluster model to the corresponding thermal quantities in the q-state Potts model [65]. In particular for the Ising case, $q = 2$,

$$|\langle S_i \rangle| = \langle \gamma_i^{\infty} \rangle_W \tag{41}$$

and

$$\langle S_i S_j \rangle = \langle \gamma_{ij} \rangle_W \, , \tag{42}$$

where $\langle \ldots \rangle$ is the Boltzmann average and $\langle \ldots \rangle_W$ is the average over bond configurations in the bond correlated percolation with weights given by (40). Here $\gamma_i^{\infty}(C)$ is equal to 1 if the spin at i belongs to the infinite cluster, 0 otherwise; $\gamma_{ij}(C)$ is equal to 1 if the spins at sites i and j belong to the same cluster, 0 otherwise.

Interestingly the connectivity properties in the KF random cluster model can be related to the CK droplets:

$$\rho_{\infty} = \langle \gamma_i^{\infty} \rangle_W \, , \tag{43}$$

$$p_{ij} = \langle \gamma_{ij} \rangle_W \, , \tag{44}$$

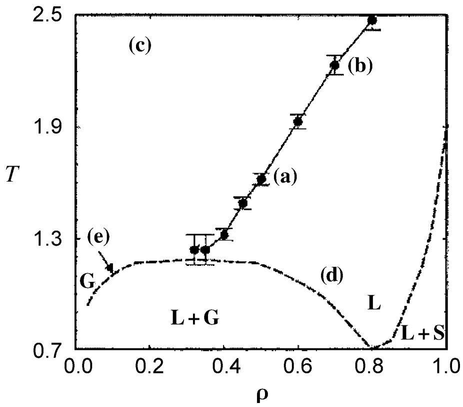
where ρ_{∞} and p_{ij} are defined in Subsect. "Ising Droplets Above $d = 4$". From Eqs. (41)–(44) it follows Eqs. (34).

Hill's Clusters

In this section we discuss the possibility to extend the definition of droplets to simple fluids. In 1955 Hill [60] introduced the concept of physical clusters in a fluid in an attempt to explain the phenomenon of condensation from a gas to a liquid. In a fluid made of particles interacting via a pair potential $u(r)$ physical clusters are defined as a group of particles pairwise bounded. A pair of particles is bounded if in the reference frame of their center of mass their total energy is less than zero. Namely their relative kinetic energy plus the potential energy is less than zero. The probability that two particles at distance r are bounded can be calculated [60] and is given by

$$p_{\mathrm{H}}(r) = \frac{4}{\pi} \int_0^{\sqrt{-\beta u(r)}} x^2 \mathrm{e}^{-x^2} \mathrm{d}x \, . \tag{45}$$

More recently it was noted [16] that the bond probability Eq. (45) calculated for the interaction of the three-dimensional nn lattice gas model is almost coincident with the bond probability p of Eq. (33). This implies that Hill's physical clusters for the $3d$ lattice gas almost coincide with the droplets defined by Coniglio and Klein, and in fact Hill's clusters percolate along a line almost indistinguishable from the droplets percolation line (see Fig. 2).



Correlated Percolation, Figure 3
Phase diagram of the Lennard–Jones fluid using molecular dynamics. The full line corresponds to percolation of cluster following Hill's definition. From [17]

In order to calculate percolation quantities in a fluid, in [38] the authors developed a theory based on Mayer's expansion. In particular, using this theory they calculated analytically for a potential made of a hard core plus an attractive interaction, the percolation line of Hill's physical clusters in a crude mean field approximation and compared with the liquid gas coexistence curve. They found that the percolation line ended just below the critical point in the low density phase but not exactly at the critical point. For further developments of the theory see [56].

Very recently, Campi et al. [17], using molecular dynamics have calculated the percolation line of Hill's physical clusters for a Lennard–Jones potential. The results showed a percolation line ending close or at the critical point (Fig. 3) suggesting that Hill's clusters are good candidates to describe the density fluctuations like the droplets in the lattice gas model, although there is no proof of relations analogous to those valid for the droplets in the lattice gas such as Eq. (34), which would prove that their size would diverge exactly at the critical point with thermal exponents.

Although Hill's clusters may represent the critical fluctuation near the critical point, we may wonder whether they have a physical meaning away from the critical point. In particular we may wonder whether we can detect experimentally the percolation line in the phase diagram. In a Lennard–Jones fluid, molecular dynamics shows that quantities such as viscosity or the diffusion coefficient do not seem to exhibit any anomalous behavior through the percolation line [17]. In some colloids instead the percolation line is detected through a steep increase of the viscosity. What would be the difference in the two cases? The difference may rely on their lifetime. The possibility to detect the percolation line of these clusters is expected to depend on the lifetime of the clusters which in turn depends on the bond lifetime. The larger the cluster lifetime, the larger the increase of the viscosity, and the better the percolation line can be detected. In Sect. "Scaling Behavior of the Viscosity" we will discuss the behavior of the viscosity as function of the lifetime of the clusters.

Clusters in Weak and Strong Gels

In the previous section we have shown the case in which the probability of having a bond between two particles coincides with the probability that the two particles form a bound state defined according to Hill's criterion. Now we want to show another mechanism leading to the formation of bound states, which is more appropriate to gels. The importance of connectivity in gels was first emphasized by Flory [51]. The application of percolation theory to gels was later suggested by de Gennes [43] and Stauffer [91,96]. Here we consider a system made of monomers in a solvent. Following [39] we shall assume that the monomers can interact with each other in two ways. One is the usual van der Waals interaction, and the other is a directional interaction that leads to a chemical bond. A simple model for such a system is a lattice gas model where an occupied site represents a monomer and an empty site a solvent. For simplicity we can put the monomer-solvent interaction and the solvent-solvent interaction equal to zero, and include such interactions in an effective monomer-monomer interaction. The monomer-monomer interaction ε_{ij} can reasonably be approximated by a nearest neighbor interaction

$$\varepsilon_{ij} = \begin{cases} -W \\ -E \end{cases} \tag{46}$$

where $-W$ is the van der Waals type of attraction and $-E$ is the bonding energy. Of course, this second interaction, which is the chemical interaction, occurs only when the monomers are in particular configurations. For simplicity we can suppose that there is one configuration which corresponds to the interaction of strength E, and Ω configurations which correspond to the interaction of strength W. We expect $E \gg W$ and $\Omega \gg 1$. It can be easily calculated [39] that such a system is equivalent to a lattice gas model with an effective *nn* interaction $-\varepsilon$ given by

$$e^{\beta\varepsilon} = e^{\beta E} + \Omega e^{\beta W} . \tag{47}$$

Therefore from the static point of view the system exhibits a coexistence curve and a critical temperature which characterizes the thermodynamics of the system. However the system microscopically behaves rather different from a standard lattice gas. In fact in a configuration in which two monomers are *nn*, in a standard lattice gas they feel one interaction, while in the system considered here with some probability p_b they feel a strong chemical interaction $-E$ and with probability $1 - p_b$ they feel a much smaller interaction $-W$. The probability p_b can be easily calculated and is given by

$$p_b = \frac{e^{\beta E}}{e^{\beta E} + \Omega e^{\beta W}} . \tag{48}$$

In conclusion, the system from the static point of view is equivalent to a lattice gas with interaction ε given by (47). However we can also study the percolation line of the clusters made by monomers connected by chemical bonds. This can be done by introducing bonds between *nn* particles in the lattice gas with *nn* interactions, the bonds being present with probability p_b given by Eq. (48). By changing the solvent the effective interaction W changes and one can realize three cases topologically similar to those of Fig. 2, where the percolation line ends at the critical point or below the critical point in the low density or high density phase (for more details see [39]).

The lifetimes of the bonds are of the order of $e^{\beta E}$. Since E is very large the lifetime could be very large. For an infinite bond lifetime the bonded clusters are permanent and the viscosity diverges due to the divergence of the mean cluster size (see for example [96]), and the percolation line can be easily detected. We consider three particular physical systems which could be rather emblematic of a general situation where the percolation line has been detected:

a) Microemulsions of water in oil [20]
b) Triblock copolymers in unicellular systems [71,72]
c) Gelatin water methanol systems [101].

In Figs. 4, 5 and 6 we show respectively the phase diagram of the systems a), b), c), where the coexistence curve in the temperature-concentration diagram is shown together with "percolation lines".

In particular, in a) the system consists of three components AOT/water/decane. For the temperature and the concentration of interest, the system can be considered as made of small droplets of oil surrounded by water in a solvent. The droplets interact via a hard core potential plus short range attractive interaction. Because of the entropic nature of the attractive interaction, the coexistence curve is "upside-down" with the critical point being the minimum instead of the maximum (Fig. 4). The broken line is characterized by a steep increase of conductivity.

In b) the system is made of triblock copolymers unicellular in water solution, c is the volume fraction of the uni-

cells (Fig. 5). The line is characterized by a steep increase in the viscosity.

In c) the system is made of gelatin dissolved in water + methanol; ϕ is the gelatin concentration. The broken lines are characterized by the divergence of the viscosity and correspond to the sol-gel transition. Each line represents a different value of the methanol concentration, which has been chosen in such a way that the line ends at the consolute point or, below it, in the low or high density phase (Fig. 6).

In all these experiments the consolute point is characterized by a thermodynamical singularity, where the correlation length and compressibility diverge. The other lines are usually ascribed to a "percolation" transition. However it is important to precisely identify which are the relevant clusters in the three different systems. Also we would like to understand why, in system c), the viscosity diverges at the percolation transition, while in b) it reaches a plateau, and why in a) and b) the "percolation" lines end on the coexistence curve close to the critical point in the low density region. It is also important to realize that for each phenomenon is very important to define the proper cluster, which is responsible for the physical phenomenon. In the conductivity experiments in microemulsion the proper clusters are made of "touching" spheres similar to nearest neighbor particles in a lattice gas model. The viscoelastic properties of microemulsions may be more suitably described by clusters made of spheres pairwise bonded.

From the cluster properties of the lattice gas model we expect the infinite cluster is a necessary condition for a critical point therefore the percolation line ends just below the critical point in the low density region, as observed in the experiments described above and more recently in numerical simulations of models of interacting colloids [84].

In weak reversible gelatin the clusters are made of monomers (or polymers) bonded by a strong interaction which leads to chemical bond. In this case the bond probability can be changed by changing the solvent and therefore the percolation line, by properly choosing the solvent, can end on the coexistence curve at or below the critical point.

The reason why the viscosity in the gel experiments diverges at the percolation point, while it reaches a plateau in colloids, is due to the lifetime of the bonds which is much longer in the first system than in the second [46,73,86]. In low density colloids the proper cluster to describe coloidal gelation also appear to be related to strong bonds with large bond lifetime [14,41,86]. When the relaxation time is much smaller than the bond lifetime the dynamics is dominated by the clusters, otherwise a crossover is expected towards a regime due to the crowding of the particles [41]. Percolation line of clusters pairwise bonded can also be defined in fluids, but due to the negligible lifetime cannot be detected.

Scaling Behavior of the Viscosity

If the lifetime of the chemical bonds is infinite, the viscosity exhibits a divergence at the percolation threshold as recently shown in different models [11,45,103]

$$\eta \sim \xi^{\tilde{k}} \,, \tag{49}$$

where ξ is the linear dimension of the critical cluster which diverges at the percolation threshold with the exponent ν.

The relation between the diffusion coefficient $D(R)$ of a cluster of radius R and the viscosity η would be given by the Stokes–Einstein relation for a cluster radius much larger than ξ

$$D(R) \sim \frac{1}{R\eta} \,. \tag{50}$$

For cluster radius R smaller than ξ it has been proposed [75] that the viscosity will depend also on R in such a way as to satisfy a generalized Stokes–Einstein relation Eq. (50) with $\eta = \eta(R)$. When $R = \xi$ the viscosity $\eta(\xi) = \eta$, and from Eq. (50) one obtains the following scaling behavior for R:

$$D(R) \sim R^{-(1+\tilde{k})} \tag{51}$$

therefore the relaxation time $\tau(R)$ for a cluster of radius R is

$$\tau(R) \sim R^{1+\tilde{k}} \,. \tag{52}$$

If τ is the lifetime of a typical cluster, then a cluster of radius R will contribute to the viscosity if $\tau(R) < \tau$, and therefore:

$$\eta \sim \xi^{\tilde{k}} f\left(\frac{\tau}{\xi^{1+\tilde{k}}}\right) \sim \begin{cases} \xi^{\tilde{k}} & \tau > \xi^{1+\tilde{k}} \\ \tau^{\frac{\tilde{k}}{1+\tilde{k}}} & \tau < \xi^{1+\tilde{k}} \end{cases} \tag{53}$$

which implies that the viscosity will exhibit a steep increase followed by a plateau. The higher τ is, the higher the plateau.

The viscosity data on microemulsion (Fig. 5) shows in fact such a plateau, suggesting that the mechanism for the appearance of the plateau is linked to the bond lifetime which in turn is related to the cluster relaxation time.

Future Directions

In conclusion, we have discussed the interplay between the percolation line and critical point in systems where thermal correlations play an important role. The problem of defining the droplets in spin models is satisfactorily solved. However there are still some open problems. Above $d = 4$ in the Ising model the definition of droplets presents some difficulties, probably related to the upper critical dimension for the percolation problem. That critical dimension is six. This type of difficulty does not allow for a trivial extension of the arguments used in the random percolation problem, to explain the hyperscaling breakdown. Another open problem is the characterization of the thermal scaling exponent $1/\nu$, in terms of the fractal dimension of some subset of the critical droplet, as occurs in the random percolation problem.

In the last decade the KF, CK approach has been extended to frustrated systems. Interestingly this approach has led to a new frustrated percolation model, with unusual properties relevant to spin glasses and other glassy systems [77,80]. However the precise definition of clusters, which are able to characterize the critical droplets for spin glasses, is still missing.

Although some advances have been obtained towards a droplet definition in Lennard Jones systems [17], a general definition for continuum models of fluids still needs to be formulated.

Appendix: Random Cluster Model and Ising Droplets

In 1969 Kasteleyn and Fortuin (KF) [65] introduced a correlated bond percolation model, called the random cluster model, and showed that the partition function of this percolation model was identical to the partition function of the q-state Potts model. They also showed that the thermal quantities in the Potts model could be expressed in terms of connectivity properties of the random cluster model. Much later in 1980 Coniglio and Klein [30] independently have used a different approach with the aim to define the proper droplets in the Ising model. It was only later that it was realized that the two approaches were related, although the meaning of the clusters in the two approaches is different. We will discuss these two approaches here, and show that their statistical properties are the same.

Random Cluster Model

Let us consider an Ising system of spins $S_i = \pm 1$ on a lattice with nearest-neighbor interactions and, when needed, let us assume periodic boundary conditions in both directions. All interactions have strength J and the Hamiltonian is

$$\mathcal{H}(\{S_i\}) = -\sum_{\langle i,j\rangle} J(S_i S_j - 1) , \tag{54}$$

where $\{S_i\}$ represents a spin configuration and the sum is over *nn* spins. The main point in the KF approach is to replace the original Ising Hamiltonian with an annealed diluted Hamiltonian

$$\mathcal{H}'(\{S_i\}) = -\sum_{\langle i,j\rangle} J'_{ij}(S_i S_j - 1) , \tag{55}$$

where

$$J'_{ij} = \begin{cases} J' & \text{with probability } p \\ 0 & \text{with probability } (1-p) . \end{cases} \tag{56}$$

The parameter p is chosen such that the Boltzmann factor associated with an Ising configuration of the original model coincides with the weight associated with a spin configuration of the diluted Ising model

$$\begin{aligned} \mathrm{e}^{-\beta\mathcal{H}(\{S_i\})} &\equiv \prod_{\langle i,j\rangle} \mathrm{e}^{\beta J(S_i S_j - 1)} \\ &= \prod_{\langle i,j\rangle} \left(p\mathrm{e}^{\beta J'(S_i S_j - 1)} + (1-p) \right) , \end{aligned} \tag{57}$$

where $\beta = 1/k_{\mathrm{B}}T$, k_{B} is the Boltzmann constant and T is the temperature. In order to satisfy (57) we must have

$$\mathrm{e}^{\beta J(S_i S_j - 1)} = p\mathrm{e}^{\beta J'(S_i S_j - 1)} + (1-p) . \tag{58}$$

We take now the limit $J' \mapsto \infty$. In such a case $\mathrm{e}^{\beta J'(S_i S_j - 1)}$ equals the Kronecker delta $\delta_{S_i S_j}$ and from (58) p is given by

$$p = 1 - \mathrm{e}^{-2\beta J} . \tag{59}$$

From (57), by performing the products we can write

$$\mathrm{e}^{-\beta\mathcal{H}(\{S_i\})} = \sum_C W_{\mathrm{KF}}(\{S_i\}, C) , \tag{60}$$

where

$$W_{\mathrm{KF}}(\{S_i\}, C) = p^{|C|}(1-p)^{|A|} \prod_{\langle i,j\rangle \in C} \delta_{S_i S_j} . \tag{61}$$

Here C is a configuration of interactions where $|C|$ is the number of interactions of strength $J' = \infty$ and $|A|$ the number of interactions of strength 0. $|C| + |A| = |E|$, where $|E|$ is the total number of edges in the lattice.

$W_{\mathrm{KF}}(\{S_i\}, C)$ is the statistical weight associated a) with a spin configuration $\{S_i\}$ and b) with a set of interactions in the diluted model where $|C|$ edges have ∞ strength interactions, while all the other edges have 0 strength interactions. The Kronecker delta indicates that two spins connected by an ∞ strength interaction must be in the same state. Therefore the configuration C can be decomposed in clusters of parallel spins connected by infinite strength interactions.

Finally the partition function of the Ising model Z is obtained by summing the Boltzmann factor (60) over all the spin configurations. Since each cluster in the configuration C gives a contribution of 2, we obtain:

$$Z = \sum_C p^{|C|}(1-p)^{|A|} 2^{N_C} , \tag{62}$$

where N_C is the number of clusters in the configuration C.

In conclusion, in the KF formalism the partition function (62) is equivalent to the partition function of a correlated bond percolation model [62,65] where the weight of each bond configuration C is given by

$$W(C) = \sum_{\{S_i\}} W_{\mathrm{KF}}(\{S_i\}, C) = p^{|C|}(1-p)^{|A|} 2^{N_C} \tag{63}$$

which coincides with the weight of the random percolation except for the extra factor 2^{N_C}. Clearly all percolation quantities in this correlated bond model are weighted according to Eq. (63) coincide with the corresponding percolation quantities of the KF clusters made of parallel spins connected by an ∞ strength interaction, whose statistical weight is given by (61). Moreover using (61) and (60) Kasteleyn and Fortuin have proved that [65]

$$|\langle S_i \rangle| = \langle \gamma_i^\infty \rangle_W \tag{64}$$

and

$$\langle S_i S_j \rangle = \langle \gamma_{ij} \rangle_W , \tag{65}$$

where $\langle \dots \rangle$ is the Boltzmann average and $\langle \dots \rangle_W$ is the average over bond configurations in the bond correlated percolation with weights given by (63). Here $\gamma_i^\infty(C)$ is equal to 1 if the spin at site i belongs to the spanning cluster, 0 otherwise; $\gamma_{ij}(C)$ is equal to 1 if the spins at sites i and j belong to the same cluster, 0 otherwise.

Connection Between the Ising Droplets and the Random Cluster Model

In the approach followed by Coniglio and Klein [30], given a configuration of spins, one introduces at random connecting bonds between *nn* parallel spins with probability p_b, antiparallel spins are not connected with probability 1. Clusters are defined as maximal sets of parallel spins connected by bonds. The bonds here are fictitious, they are introduced only to define the clusters and do not modify the interaction energy as in the FK approach. For a given realization of bonds we distinguish the subsets C and B of *nn* parallel spins respectively connected and not connected by bonds and the subset D of *nn* antiparallel spins. The union of C, B and D coincides with the total set of *nn* pair of spins E. The statistical weight of a configuration of spins and bonds is [28,40]

$$W_\mathrm{CK}(\{S_i\}, C) = p_\mathrm{b}^{|C|}(1-p_\mathrm{b})^{|B|}\mathrm{e}^{-\beta\mathcal{H}(\{S_i\})}\,, \tag{66}$$

where $|C|$ and $|B|$ are the number of *nn* pairs of parallel spins respectively in the subset C and B not connected by bonds.

For a given spin configuration, using the Newton binomial rule, we have the following sum rule

$$\sum_C p_\mathrm{b}^{|C|}(1-p_\mathrm{b})^{|B|} = 1\,. \tag{67}$$

From Eq. (67) follows that the Ising partition function, Z, may be obtained by summing (66) over all bond configurations and then over all spin configurations.

$$Z = \sum_{\{S_i\}}\sum_C W_\mathrm{CK}(\{S_i\}, C) = \sum_{\{S_i\}} \mathrm{e}^{-\beta\mathcal{H}(\{S_i\})}\,. \tag{68}$$

The partition function of course does not depend on the value of p_b which controls the bond density. By tuning p_b instead it is possible to tune the size of the clusters. For example by taking $p_\mathrm{b} = 1$ the clusters would coincide with nearest-neighbor parallel spins, while for $p_\mathrm{b} = 0$ the clusters are reduced to single spins. By choosing the droplet bond probability $p_\mathrm{b} = 1 - \mathrm{e}^{-2\beta J} \equiv p$ and observing that $\mathrm{e}^{-\beta\mathcal{H}(\{S_i\})} = \mathrm{e}^{-2\beta J|D|}$, where $|D|$ is the number of antiparallel pairs of spins, the weight (66) simplifies and becomes:

$$W_\mathrm{CK}(\{S_i\}, C) = p^{|C|}(1-p)^{|A|}\,, \tag{69}$$

where $|A| = |B| + |D| = |E| - |C|$.

From (69) we can calculate the weight $W(C)$ that a given configuration of connecting bonds C between *nn* parallel spins occurs. This configuration C can occur in many spin configurations. So we have to sum over all spin configurations compatible with the bond configuration C, namely

$$W(C) = \sum_{\{S_i\}} W_\mathrm{CK}(\{S_i\}, C) \prod_{\langle i,j\rangle \in C} \delta_{S_i S_j}\,, \tag{70}$$

where, due to the product of the Kronecker delta, the sum is over all spin configurations compatible with the bond configuration C. From (59) and (70) we have

$$\begin{aligned} W(C) &= \sum_{\{S_i\}} p^{|C|}(1-p)^{|A|} \prod_{\langle i,j\rangle \in C} \delta_{S_i S_j} \\ &= p^{|C|}(1-p)^{|A|}2^{N_C}\,. \end{aligned} \tag{71}$$

Consequently in (68) by taking first the sum over all spins compatible with the configuration C, the partition function Z can be written as in the KF formalism (62).

$$Z = \sum_C p^{|C|}(1-p)^{|A|}2^{N_C}\,. \tag{72}$$

In spite of the strong analogies the CK clusters and the KF clusters have a different meaning. In the CK formalism the clusters are defined directly in a given configuration of the Ising model as parallel spin connected by fictitious bonds, while in the KF formalism clusters are defined in the equivalent random cluster model. However, due to the equality of the weights (69) and (61) the statistical properties of both clusters are identical [40] and due to the relations between (61) and (63) both coincide with those of the correlated bond percolation whose weight is given by (63). More precisely, any percolation quantity $g(C)$ which depends only on the bond configuration has the same average

$$\langle g(C)\rangle_\mathrm{KF} = \langle g(C)\rangle_\mathrm{CK} = \langle g(C)\rangle_W\,, \tag{73}$$

where $\langle\ldots\rangle_\mathrm{KF}$, $\langle\ldots\rangle_\mathrm{CK}$ are the average over spin and bond configurations with weights given by (61) and (69) respectively and $\langle\ldots\rangle_W$ is the average over bond configurations in the bond correlated percolation with weights given by (63). In view of (73) it follows [40]

$$|\langle S_i\rangle| = \langle\gamma_i^\infty\rangle_\mathrm{CK} \tag{74}$$

and

$$\langle S_i S_j\rangle = \langle\gamma_{ij}\rangle_\mathrm{CK}\,. \tag{75}$$

We end this section noting that in order to generate an equilibrium CK droplet configuration in a computer simulation, it is enough to equilibrate a spin configuration of the Ising model and then introduce at random fictitious bonds between parallel spins with a probability given by (59).

Article Outline

Glossary

Correlation A correlation describes the degree of relationship between two or more variables. The correlations are viewed due to the impact of random factors and can be characterized by the methods of probability theory.

Correlation function The correlation function (abbreviated, as CF) represents the quantitative measure for the compact description of the wide classes of correlation in the complex systems (CS). The correlation function of two variables in statistical mechanics provides a measure of the mutual order existing between them. It quantifies the way random variables at different positions are correlated. For example in a spin system, it is the thermal average of the scalar product of the spins at two lattice points over all possible orderings.

Memory effects in stochastic processes through correlations Memory effects (abbreviated, as ME) appear at a more detailed level of statistical description of correlation in the hierarchical manner. ME reflect the complicated or hidden character of creation, the propagation and the decay of correlation. ME are produced by inherent interactions and statistical after-effects in CS. For the statistical systems ME are induced by contracted description of the evolution of the dynamic variables of a CS.

Memory functions Memory functions describe mutual interrelations between the rates of change of random variables on different levels of the statistical description. The role of memory has its roots in the natural sciences since 1906 when the famous Russian mathematician Markov wrote his first paper in the theory of Markov Random Processes. The theory is based on the notion of the instant loss of memory from the prehistory (memoryless property) of random processes.

Information measures of statistical memory in complex systems From the physical point of view time scales of correlation and memory cannot be treated as arbitrary. Therefore, one can introduce some statistical quantifiers for the quantitative comparison of these time scales. They are dimensionless and possess the statistical spectra on the different levels of the statistical description.

Definition of the Subject

As commonly used in probability theory and statistics, a correlation (also so called correlation coefficient), measures the strength and the direction of a linear relationship between two random variables. In a more general sense, a correlation or co-relation reflects the deviation of two (or more) variables from mutual independence, although correlation does not imply causation. In this broad sense there are some quantifiers which measures the degree of correlation, suited to the nature of data. Increasing attention has been paid recently to the study of statistical memory effects in random processes that originate from nature by means of non-equilibrium statistical physics. The role of memory has its roots in natural sciences since 1906 when the famous Russian mathematician Markov wrote his first paper on the theory of Markov Random Processes (MRP) [1]. His theory is based on the notion of an instant loss of memory from the prehistory (memoryless property) of random processes. In contrast, there are an abundance of physical phenomena and processes which can be characterized by statistical memory effects: kinetic and relaxation processes in gases [2] and plasma [3], condensed matter physics (liquids [4], solids [5], and superconductivity [6]) astrophysics [7], nuclear physics [8], quantum [9] and classical [9] physics, to name only a few. At present, we have a whole toolbox available of statistical methods which can be efficiently used for the analysis of the memory effects occurring in diverse physical systems. Typical such schemes are Zwanzig–Mori's kinetic equations [10,11], generalized master equations and corresponding statistical quantifiers [12,13,14,15,16,17,18], Lee's recurrence relation method [19,20,21,22,23], the generalized Langevin equation (GLE) [24,25,26,27,28,29], etc.

Here we shall demonstrate that the presence of statistical memory effects is of salient importance for the functioning of the diverse natural complex systems. Particularly, it can imply that the presence of large memory times scales in the stochastic dynamics of discrete time series can characterize catastrophical (or pathological for live systems) violation of salutary dynamic states of CS. As an example, we will demonstrate here that the emergence of strong memory time scales in the chaotic behavior of complex systems (CS) is accompanied by the likely initiation and the existence of catastrophes and crises (Earthquakes, financial crises, cardiac and brain attack, etc.) in many CS and especially by the existence of pathological states (diseases and illness) in living systems.

Introduction

A common definition [30] of a correlation measure $\rho(X, Y)$ between two random variables X and Y with the mean values $E(X)$ and $E(Y)$, and fluctuations $\delta X = X - E(X)$ and $\delta Y = Y - E(Y)$, dispersions $\sigma_X^2 = E(\delta X^2) = E(X^2) - E(X)^2$ and $\sigma_Y^2 = E(\delta Y^2) = E(Y^2) - E(Y)^2$ is defined by:

$$\rho(X, Y) = \frac{E(\delta X\, \delta Y)}{\sigma_X\, \sigma_Y}\,,$$

where E is the expected value of the variable. Therefore we can write

$$\rho(X, Y) = \frac{[E(XY) - E(X)\, E(Y)]}{(E(X^2) - E(X)^2)^{1/2}\, (E(Y^2) - E(Y)^2)^{1/2}}\,.$$

Here, a correlation can be defined only if both of the dispersions are finite and both of them are nonzero. Due to the Cauchy–Schwarz inequality, a correlation cannot exceed 1 in absolute value. Consequently, a correlation assumes it maximum at 1 in the case of an increasing linear relationship, or -1 in the case of a decreasing linear relationship, and some value in between in all other cases, indicating the degree of linear dependence between the variables. The closer the coefficient is either to -1 or 1, the stronger is the correlation between the variables. If the variables are independent then the correlation equals 0, but the converse is not true because the correlation coefficient detects only linear dependencies between two variables.

Since the absolute value of the sample correlation must be less than or equal to 1 the simple formula conveniently suggests a single-pass algorithm for calculating sample correlations. The square of the sample correlation coefficient, which is also known as the coefficient of determination, is the fraction of the variance in σ_x that is accounted for by a linear fit of x_i to σ_y. This is written

$$R^2_{xy} = 1 - \frac{\sigma^2_{y|x}}{\sigma^2_y}\,,$$

where $\sigma^2_{y|x}$ denotes the square of the error of a linear regression of x_i on y_i in the equation $y = a + bx$,

$$\sigma^2_{y|x} = \frac{1}{n}\sum_{i=1}^{n}(y_i - a - bx_i)^2$$

and σ^2_y denotes just the dispersion of y.

Note that since the sample correlation coefficient is symmetric in x_i and y_i, we will obtain the same value for a fit to y_i:

$$R^2_{xy} = 1 - \frac{\sigma^2_{x|y}}{\sigma^2_x}\,.$$

This equation also gives an intuitive idea of the correlation coefficient for random (vector) variables of higher dimension. Just as the above described sample correlation coefficient is the fraction of variance accounted for by the fit of a 1-dimensional linear submanifold to a set of 2-dimensional vectors (x_i, y_i), so we can define a correlation coefficient for a fit of an m-dimensional linear submanifold to a set of n-dimensional vectors. For example, if we fit a plane $z = a + bx + cy$ to a set of data (x_i, y_i, z_i) then the correlation coefficient of z to x and y is

$$R^2 = 1 - \frac{\sigma^2_{z|xy}}{\sigma^2_z}\,.$$

Correlation and Memory in Discrete Non-Markov Stochastic Processes

Here we present a non-Markov approach [31,32] for the study of long-time correlations in chaotic long-time dynamics of CS. For example, let the variable x_i be defined as the R-R interval or the time distance between nearest, so called R peaks occurring in a human electrocardiogram (ECG). The generalization will consist in taking into account non-stationarity of stochastic processes and its further applications to the analysis of the heart-rate-variability.

We should bear in mind, that one of the key moments of the spectral approach in the analysis of stochastic processes consists in the use of normalized time correlation function (TCF)

$$a_0(t) = \frac{\langle\langle \mathbf{A}(T)\, \mathbf{A}(T + t)\rangle\rangle}{\langle \mathbf{A}(T)^2\rangle}\,. \qquad (1)$$

Here the time T indicates the beginning of a time serial, $\mathbf{A}(t)$ is a state vector of a complex system as defined below in Eq. (5) at t, $|\mathbf{A}(t)|$ is the length of vector $\mathbf{A}(t)$, the double angular brackets indicate a scalar product of vectors and an ensemble averaging. The ensemble averaging is, of course needed in Eq. (1) when correlation and other characteristic functions are constructed. The average and scalar product becomes equivalent when a vector is composed of elements from a discrete-time sampling, as done later. Here a continuous formalism is discussed for convenience. However further, since Sect. "Correlation and Memory in Discrete Non-Markov Stochastic Processes" we shall consider only a case of discrete processes.

The above-stated designation is true only for stationary systems. In a non-stationary case Eq. (1) is not true and should be changed. The concept of TCF can be generalized in case of discrete non-stationary sequence of signals. For this purpose the standard definition of the correlation coefficient in probability theory for the two random signals X and Y must be taken into account

$$\rho = \frac{\langle\langle \mathbf{XY}\rangle\rangle}{\sigma_X\, \sigma_Y}\,, \quad \sigma_X = \langle|\mathbf{X}|\rangle\,, \quad \sigma_Y = \langle|\mathbf{Y}|\rangle\,. \qquad (2)$$

In Eq. (2) the multi-component vectors **X**, **Y** are determined by fluctuations of signals x and y accordingly, σ_X^2, σ_Y^2 represent the dispersions of signals **x** and **y**, and values $|\mathbf{X}|, |\mathbf{Y}|$ represent the lengths of vectors **X**, **Y**, correspondingly. Therefore, the function

$$a(T,t) = \frac{\langle\langle \mathbf{A}(T)\, \mathbf{A}(T+t)\rangle\rangle}{\langle|\mathbf{A}(T)|\rangle\, \langle|\mathbf{A}(T+t)|\rangle} \tag{3}$$

can serve as the generalization of the concept of TCF (1) for non-stationary processes $\mathbf{A}(T+t)$. The non-stationary TCF (3) obeys the conditions of the normalization and attenuation of correlation

$$a(T,0) = 1\,, \quad \lim_{t\to\infty} a(T,t) = 0\,.$$

Let us note, that in a real CS the second limit, typically, is not carried out due possible occurrence nonergodocity (meaning that a time average does not equal its ensemble average). According to the Eqs. (1) and (3) for the quantitative description of non-stationarity it is convenient to introduce a function of non-stationarity

$$\gamma(T,t) = \frac{\langle|\mathbf{A}(T+t)|\rangle}{\langle|\mathbf{A}(T)|\rangle} = \left\{\frac{\sigma^2(T+t)}{\sigma^2(T)}\right\}^{1/2}\,. \tag{4}$$

One can see that this function equals the ratio of the lengths of vectors of final and initial states. In case of stationary process the dispersion does not vary with the time (or its variation is very weak). Therefore the following relations

$$\sigma(T+t) = \sigma(T)\,, \quad \gamma(T,t) = 1 \tag{5}$$

hold true for the stationary process.

Due to the condition (5) the following function

$$\mathit{\Gamma}(T,t) = 1 - \gamma(T,t) \tag{6}$$

is suitable in providing a dynamic parameter of non-stationarity. This dynamic parameter can serve as a quantitative measure of non-stationarity of the process under investigation. According to Eqs. (4)–(6) it is reasonable to suggest the existence of three different elementary classes of non-stationarity

$$\begin{aligned} |\mathit{\Gamma}(T,t)| &= |1-\gamma(T,t)| \\ &= \left\{\begin{array}{ll} \ll 1, & \text{weak non-stationarity} \\ \sim 1, & \text{intermediate non-stationarity} \\ \gg 1, & \text{strong non-stationarity} \end{array}\right\}\,. \end{aligned} \tag{7}$$

The existence of dynamic parameter of non-stationarity makes it possible to determine, on-principle, the type of non-stationarity of the underlying process and to find its spectral characteristics from the experimental data base. We intend to use Eqs. (4), (6), (7) for the quantitative description of effects of non-stationarity in the investigated temporary series of R-R intervals of human ECG's for healthy people and patients after myocardial infarction (MI).

Statistical Theory of Non-Stationary Discrete Non-Markov Processes in Complex Systems

Here we shall extend the original results of the statistical theory of discrete non-Markov processes in complex systems, developed recently in [31], for the case of non-stationary processes. The theory [31] is developed on the basis of first principles and represents a discrete finite-difference analogy for complex systems of well known Zwanzig–Mori's kinetic equations [10,11,12,13,14,15,16,17,18] used in the statistical physics of condensed matter.

We examine a discrete stochastic process $X(T+t)$, where $t = m\tau$

$$\begin{aligned} X = \{&x(T), x(T+\tau), x(T+2\tau), \dots, x(T+k\tau), \\ &\dots, x(T+(N-1)\tau)\}\,, \end{aligned} \tag{8}$$

where T is the beginning of the time and τ is a discretization time. The normalized time correlation function (TCF)

$$a(t) = \frac{1}{(N-m)\,\sigma^2} \sum_{j=0}^{N-1-m} \delta x(T+j\tau)\,\delta x(T+(j+m)\,\tau) \tag{9}$$

yields a convenient measure to analyze the dynamic properties of complex systems. Herein, we used the variance σ^2, the fluctuation $\delta x(T+j\tau)$, which in terms of the the mean value $\langle x\rangle$ reads:

$$\begin{aligned} \delta x_j &= \delta x(T+j\tau) = x(T+j\tau) - \langle x\rangle\,, \\ \sigma^2 &= \frac{1}{(N-m)} \sum_{j=0}^{N-1-m} \{\delta x(T+j\tau)\}^2\,, \end{aligned} \tag{10}$$

$$\langle x\rangle = \frac{1}{(N-m)} \sum_{j=0}^{N-1-m} x(T+j\tau)\,. \tag{11}$$

The discrete time t is given as $t = m\tau$.

In general, the mean value, the variance and TCF in (9), (10) and (11) is dependent on the numbers m and N. All indicated values cease to depend on numbers m and N for stationary processes when $m \ll N$. The definition of TCF in Eq. (9) is true only for stationary processes.

Next, we shall try to take into account this important dependence. With this purpose we shall form two k-dimensional vectors of state by the process (8):

$$\begin{aligned}\mathbf{A}_k^0 &= (\delta x_0, \delta x_1, \delta x_2, \ldots, \delta x_{k-1})\,,\\ \mathbf{A}_{m+k}^m &= (\delta x_m, \delta x_{m+1}, \delta x_{m+2}, \ldots, \delta x_{m+k-1})\,.\end{aligned} \tag{12}$$

When a vector of a state is composed of elements from a discrete-time sampling, the average and scalar product in Eq. (1) become equivalent. In an Euclidean space of vectors of state (12) TCF $a(t)$

$$a(t) = \frac{\langle \mathbf{A}_{N-1-m}^0\, \mathbf{A}_{N-1}^m \rangle}{(N-m)\{\sigma(N-m)\}^2} = \frac{\langle \mathbf{A}_{N-1-m}^0\, \mathbf{A}_{N-1}^m \rangle}{|\mathbf{A}_{N-1-m}^0|^2} \tag{13}$$

describes the correlation of two different states of the system ($t = m\tau$). Here the brackets $\langle \ldots \rangle$ indicate the scalar product of the two vectors. The dimension dependence of the corresponding vectors is also taken into account in the variance $\sigma = \sigma(N-m)$. As a matter of fact TCF $a(t) = \cos\vartheta$, where ϑ is the angle between the two vectors from Eq. (12). Let's introduce a unit vector of dimension $(N-m)$ in the following way:

$$\mathbf{n} = \frac{\mathbf{A}_{N-1-m}^0}{\sqrt{(N-m)\sigma^2}}\,. \tag{14}$$

Then, the TCF $a(t)$ (9) is given by

$$a(t) = \langle \mathbf{n}(0)\, \mathbf{n}(t) \rangle\,. \tag{15}$$

From the above discussion it is evident that Eqs. (13)–(15) are true for the stationary processes only. In case of non-stationary processes it is necessary to redefine TCF, taking into account the non-stationarity in the variance σ^2 in a line with Eqs.(2)–(7). For this purpose we shall redefine a unit vector of the final state as following

$$\mathbf{n}(t) = \frac{\mathbf{A}_{N-1}^m(t)}{|\mathbf{A}_{N-1}^m(t)|}\,. \tag{16}$$

For non-stationary processes it is convenient to write the TCF as the scalar product of the two unit vectors of the initial and final states

$$a(t) = \langle \mathbf{n}(0)\, \mathbf{n}(t) \rangle = \frac{\langle \mathbf{A}_{N-1-m}^0(0)\, \mathbf{A}_{N-1}^m(t) \rangle}{|\mathbf{A}_{N-1-m}^0(0)|\, |\mathbf{A}_{N-1}^m(t)|}\,. \tag{17}$$

Now we shall turn to the the dynamics of a non-stationary stochastic process. The equation of motion of a the random process x_j can be written in a finite-difference form for $0 \le j \le N-1$ [31,32] in the following way

$$\frac{\mathrm{d}x_j}{\mathrm{d}t} \Rightarrow \frac{\Delta \delta x_j}{\Delta t} = \frac{\delta x_j(t+\tau) - \delta x_j(t)}{\tau}\,. \tag{18}$$

Then it is convenient to define the discrete evolution single step operator $\hat{U}$ as following:

$$x(T+(j+1)\,\tau) = \hat{U}(T+(j+1)\,\tau,\, T+j\tau)\, x(T+j\tau)\,. \tag{19}$$

In the case of stationary process we can rewrite the equation of motion (18) in a more simple form

$$\frac{\Delta \delta x_j}{\Delta t} = \tau^{-1}\big\{\hat{U}(\tau) - 1\big\}\, \delta x_j\,. \tag{20}$$

The invariance of the mean value $\langle x \rangle$ is taken into account in an Eq. (20)

$$\langle x \rangle = \hat{U}(\tau)\langle x \rangle\,, \quad \big\{\hat{U}(\tau) - 1\big\}\langle x \rangle = 0\,. \tag{21}$$

In case of a non-stationary process it is necessary to turn to the equation of motion for vector of the final state $\mathbf{A}_{m+k}^m(t)$ $(k = N-1-m)$

$$\frac{\Delta \mathbf{A}_{m+k}^m(t)}{\Delta t} = i\hat{L}(t,\tau)\, \mathbf{A}_{m+k}^m(t)\,, \tag{22}$$

where Liouville's quasioperator is

$$\hat{L}(t,\tau) = (i\tau)^{-1}\big\{\hat{U}(t+\tau, t) - 1\big\}\,. \tag{23}$$

It is well known that, in general, a stochastic trajectory does not obey a linear equation, so the general evolution operator and Liouville's quasioperator should probably be non-linear. Furthermore, in statistical physics the Liouville's operator acts upon the probability densities of dynamical variables, as well upon the variables itself like in Mori's paper [12]. The evolution of the density would be indeed linear. But Mori used the Liouville operator in the quantum equation of motion in [12]. In line with Mori [12] Eqs. (20), (22) can be considered as formal and exact equations of the motion of a complex system.

Thus, due to the Eqs. (17), (22) and (23) we may take into account the non-stationarity of the stochastic process. Towards this goal let's introduce the linear projection operator in Euclidean space of the state vectors

$$\Pi \mathbf{A}(t) = \frac{\mathbf{A}(0)\rangle \langle \mathbf{A}(0)\, \mathbf{A}(t) \rangle}{|\mathbf{A}(0)|^2}\,, \qquad \Pi = \frac{\mathbf{A}(0)\rangle \langle \mathbf{A}(0)}{\langle \mathbf{A}(0)\, \mathbf{A}(0) \rangle}\,, \tag{24}$$

where angular brackets in numerator present the boundaries of action for the scalar product.

For the analysis of the dynamics of the stochastic process $\mathbf{A}(t)$ the vector $\mathbf{A}_k^0(0)$ from (12) can be considered as a vector of the initial state $\mathbf{A}(0)$, and vector $\mathbf{A}_{m+k}^m(t)$ from (12) at value $m + k = N - 1$ can be considered as the vector of the final state $\mathbf{A}(t)$.

It is necessary to note that the projection operator (24) has the required property of idem-potency $\Pi^2 = \Pi$. The presence of operator Π allows one to introduce the mutually supplementary projection operator P:

$$P = 1 - \Pi\,, \quad P^2 = P\,, \quad \Pi P = P\Pi = 0\,. \tag{25}$$

It is necessary to remark, that both projectors Π and P are linear and can be recorded for the fulfillment of operations in the particular Euclidean space. Due to the property (17) and Eq. (4) it is easy to obtain the required TCF:

$$\begin{aligned}\Pi\,\mathbf{A}(t) &= \Pi\,\mathbf{A}^m_{m+k}(t)\\ &= \mathbf{A}^0_k(0)\langle \mathbf{n}^0_k(0)\,\mathbf{n}^m_{k+m}(t)\rangle \gamma_1(t)\\ &= \mathbf{A}^0_k(0)\,a(t)\,\gamma_1(t)\,,\\ \gamma_1(t) &= \frac{|\mathbf{A}^m_{m+k}(t)|}{|\mathbf{A}^0_m(0)|}\,.\end{aligned} \tag{26}$$

Therefore the projector Π generates a unit vector along the vector of the final state $\mathbf{A}(t)$ and makes its projection onto the initial state vector $\mathbf{A}(0)$.

The existence of a pair of two mutually supplementary projection operators Π and P allows one to carry out the splitting of Euclidean space of vectors $A(\mathbf{A}(0), \mathbf{A}(t) \in A)$ into a straight sum of two mutually supplementary subspaces in the following way

$$A = A' \overset{\bullet}{+} A''\,, \quad A' = \Pi A\,, \quad A'' = PA\,. \tag{27}$$

Substituting Eq. (27) in Eq. (23) we find Liouville's quasioperator $\hat{L}$ in a matrix form

$$\hat{L} = \hat{L}_{11} + \hat{L}_{12} + \hat{L}_{21} + \hat{L}_{22}\,, \tag{28}$$

where the matrix elements are introduced

$$\begin{aligned}\hat{L}_{11} &= \Pi\hat{L}\Pi\,, \quad \hat{L}_{12} = \Pi\hat{L}P\,,\\ \hat{L}_{21} &= P\hat{L}\Pi\,, \quad \hat{L}_{22} = P\hat{L}P\,.\end{aligned} \tag{29}$$

The Euclidean space of values of Liouville's quasioperator $W = \hat{L}A$ will be generated by the vectors $\mathbf{W}$ of dimension $k-1$

$$\begin{aligned}&(\mathbf{W}(0) \in W\,,\ \mathbf{W}(t) \in W)\\ &W = W' \overset{\bullet}{+} W''\,, \quad W' = \Pi W\,, \quad W'' = PW\,.\end{aligned} \tag{30}$$

Matrix elements $\hat{L}_{ij}$ of the contracted description

$$\hat{L} = \begin{pmatrix} \hat{L}_{11} & \hat{L}_{12}\\ \hat{L}_{21} & \hat{L}_{22}\end{pmatrix} \tag{31}$$

are acting in the following way:

$\hat{L}_{11}$ – from a subspace A' to subspace W',

$\hat{L}_{12}$ – from A'' to W',

$\hat{L}_{21}$ – from W' to W'' and

$\hat{L}_{22}$ – from A'' to W''.

The projection operators Π and P provide the contracted description of the stochastic process. Splitting the dynamic Eq. (22) into two equations in the two mutually supplementary Euclidean subspaces (see, for example [11]), we find

$$\frac{\Delta \mathbf{A}'(t)}{\Delta t} = i\hat{L}_{11}\,\mathbf{A}'(t) + i\hat{L}_{12}\,\mathbf{A}''(t)\,, \tag{32}$$

$$\frac{\Delta \mathbf{A}''(t)}{\Delta t} = i\hat{L}_{21}\,\mathbf{A}'(t) + i\hat{L}_{22}\,\mathbf{A}''(t)\,. \tag{33}$$

Following [31,32] it is necessary to eliminate first the irrelevant part $\mathbf{A}''(t)$ in order to simplify Liouville's Eq. (22) and then to write a closed equation for relevant part $\mathbf{A}'(t)$. According to [32] that can be achieved by a series of successive steps (for example, see Eqs. (32)–(36) in [32]). First a solution to Eq. (33) for the first step can be obtained in a form

$$\begin{aligned}\frac{\Delta \mathbf{A}''(t)}{\Delta t} &= \frac{\mathbf{A}''(t+\tau) - \mathbf{A}''(t)}{\tau}\\ &= i\hat{L}_{21}\,\mathbf{A}'(t) + i\hat{L}_{22}\,\mathbf{A}''(t)\,,\\ \mathbf{A}''(t+\tau) &= \mathbf{A}''(t) + i\tau\,\hat{L}_{21}\,\mathbf{A}'(t) + i\tau\,\hat{L}_{22}\,\mathbf{A}''(t)\\ &= \{1 + i\tau\,\hat{L}_{22}\}\,\mathbf{A}''(t) + i\tau\,\hat{L}_{21}\,\mathbf{A}'(t)\\ &= U_{22}(t+\tau,t)\,\mathbf{A}''(t) + i\tau\,\hat{L}_{21}(t+\tau,t)\,\mathbf{A}'(t)\,.\end{aligned} \tag{34}$$

We next can derive a finite-difference kinetic equation of a non-Markov type for TCF $a(t = m\tau)$

$$\frac{\Delta a(t)}{\Delta t} = \lambda_1 a(t) - \tau\Lambda_1 \sum_{j=0}^{m-1} M_1(t - j\tau)\,a(j\tau)\,. \tag{35}$$

Here, λ_1 is a eigenvalue, Λ_1 is a relaxation parameter of Liouville's quasioperator $\hat{L}$

$$\begin{aligned}\lambda_1 &= i\,\frac{\langle \mathbf{A}^0_k(0)\,\hat{L}\,\mathbf{A}^0_k(0)\rangle}{|\mathbf{A}^0_k(0)|^2}\,,\\ \Lambda_1 &= \frac{\langle \mathbf{A}^0_k(0)\,\hat{L}_{12}\,\hat{L}_{21}\,\mathbf{A}^0_k(0)\rangle}{|\mathbf{A}^0_k(0)|^2} = \frac{\langle \mathbf{A}^0_k(0)\,\hat{L}^2\,\mathbf{A}^0_k(0)\rangle}{|\mathbf{A}^0_k(0)|^2}\,,\end{aligned} \tag{36}$$

The angular brackets indicate here a scalar product of new state vectors. Function $M_1(t - j\tau)$ on the right side of Eq. (35) represents a modified memory function (MF) of the first order

$$M_1(t - j\tau) = \frac{\gamma_1(t - j\tau)}{\gamma_1(t)}\,m_1(t - j\tau)\,. \tag{37}$$

For stationary processes the function $\gamma_1(t)$ approaches unity. Then the memory functions $M_1(t)$ and $m_1(t)$ coincide with each other. The latter equation is the first kinetic finite-difference equation for TCF. It is remarkable, that the non-Markovity, discretization and non-stationarity of stochastic process can be considered explicitly. Due to the presence of non-stationarity both in TCF and in the first memory function this equation generalizes our results recently obtained in [31].

Following the projection technique described above, we arrive at a chain of connected kinetic finite-difference equations of a non-Markov type for the normalized short memory functions $m_n(t)$ in Euclidean space of state vectors of dimension $(k-n)$ $(t = m\tau, n \geq 1)$

$$\begin{aligned} \frac{\Delta m_n(t)}{\Delta t} &= \lambda_{n+1}\, m_n(t) - \tau \Lambda_{n+1} \\ &\quad \times \sum_{j=0}^{m-1} m_{n+1}(j\tau)\, m_n(t-j\tau) \\ &\quad \times \left\{ \frac{\gamma_{n+1}(j\tau)\gamma_{n+1}(t-j\tau)}{\gamma_n(t)} \right\} , \end{aligned} \tag{38}$$

$$\begin{aligned} m_{n+1}(t) &= \frac{\langle \mathbf{W}_{n+1}(0)\, \mathbf{W}_{n+1}(t)\rangle}{|\mathbf{W}_{n+1}(0)||\mathbf{W}_{n+1}(t)|} , \\ \gamma_n(j\tau) &= \left\{ \frac{|\mathbf{W}_n(j\tau)|}{|\mathbf{W}_n(0)|} \right\} . \end{aligned} \tag{39}$$

Here, $\gamma_n(j\tau)$ is the nth order of the non-stationarity function.

The set of all memory functions $m_1(t), m_2(t), m_3(t), \ldots$ allows one to describe non-Markov processes and statistical memory effects in the considered non-stationary system. For the particular case we obtain a more simple form for the set of equations for the first three short memory functions, namely $(t = m\tau)$:

$$\begin{aligned} \frac{\Delta a(t)}{\Delta t} &= -\tau \Lambda_1 \sum_{j=0}^{m-1} m_1(j\tau) \left\{ \frac{\gamma_1(j\tau)\gamma_1(t-j\tau)}{\gamma_1(t)} \right\} \\ &\quad \times a(t-j\tau) + \lambda_1 a(t) , \\ \frac{\Delta m_1(t)}{\Delta t} &= -\tau \Lambda_2 \sum_{j=0}^{m-1} m_2(j\tau) \left\{ \frac{\gamma_2(j\tau)\gamma_2(t-j\tau)}{\gamma_2(t)} \right\} \\ &\quad \times m_1(t-j\tau) + \lambda_2 m_1(t) , \\ \frac{\Delta m_2(t)}{\Delta t} &= -\tau \Lambda_3 \sum_{j=0}^{m-1} m_3(j\tau) \left\{ \frac{\gamma_3(j\tau)\gamma_3(t-j\tau)}{\gamma_3(t)} \right\} \\ &\quad \times m_2(t-j\tau) + \lambda_3 m_2(t) . \end{aligned} \tag{40}$$

Here the relaxation parameters Λ_1, Λ_2 and Λ_3 have already been determined and the non-stationarity functions $\gamma_n(t)$ have been introduced earlier. By analogy with Eq. (6) we can introduce a set of dynamic parameters of non-stationarity (PNS) for the arbitrary nth relaxation level

$$\Gamma_n(T,t) = 1 - \gamma_n(t) = 1 - \gamma_n(T,t) . \tag{41}$$

The whole set of values of dynamic PNS $\gamma_n(t)$ determines the broad spectrum of non-stationarity effects of the considered process.

The obtained equations are similar to the well known Zwanzig–Mori's kinetic equations [10,11,12,13,14, 15,16,17,18] used in non-equilibrium statistical physics of condensed matters. Let us point out three essential distinctions of our Eqs. (40) from the results in [10,11,12]. In Zwanzig–Mori's theory the key moment in the analysis of considered physical systems is the presence of a Hamiltonian and an operation of a statistical averaging carried out with the help of quantum density operator or classic Gibbs distribution function [33]. In our examined case, both the Hamiltonian and the distribution function are absent. There are exact classic or quantum equations of motion in physics; so Liouville's equation and Liouville's operator are useful in many applications. The motion of individual particles and whole statistic system is described by variables varying in continuous time. Therefore, for physical systems it is possible to use effectively the methods of integro-differential calculus, based on the mathematically accustomed (but from the physical point of view difficult for understanding) representation of infinitesimal variations of values of coordinates and time. By nature, the monitored time evolution of most complex systems is discrete. As well known, discretization is inherent in a wide variety both of classical and quantum complex systems. This forces us to abandon the concept of an infinite small values and continuity and instead turn to discrete-difference schemes. And, at last, the third feature is connected with incorporating the issue of non-stationary processes into our theory. The Zwanzig–Mori theory is typically applied only for stationary processes. Due to the introduction of normalized vectors of states and the use of the appropriate projection technique [13] our theory allows to take into account non-stationary processes as well. The latter ones can be described by the non-Markov kinetic equations together with the introduction of the set of non-stationarity functions.

The non-stationary theory [32] put forward here differs from the stationary case [31]. The external structure of the kinetic equations remains invariant; they represent the kinetic equations with memory. However, the functions and the parameters, which are included in these equations, appreciably differ from each other. As we already remarked above, non-stationarity effects enter both, in the functions $\gamma_n(t)$ and in spectral and kinetic parameters.

Correlation and Memory in Discrete Non-Markov Stochastic Processes Generated by Random Events

Here we shall find a chain of the kinetic interconnected finite-difference equations for a discrete correlation function $a(n)$ and memory functions $M_s(n)$ in the linear scale of events $E = \{\xi_1, \xi_2, \xi_3, \dots, \xi_N\}$.

The Basic Assumptions and Concepts of the Theory of Discrete Non-Markov Stochastic Processes of the Events Correlations

As an example we shall consider the time variations of the total X-ray flux of an astrophysical object at a succession of events:

$$E = \{\xi_1, \xi_2, \xi_3, \dots, \xi_k, \dots, \xi_N\} , \tag{42}$$

where ξ_i is an event, which occurs at time instant t_i, where $i = 1, \dots, N$ counts the event number.

The average value $\langle E \rangle$, fluctuations $\delta\xi$ and dispersion σ^2 for the set of N events are obtained as:

$$\begin{aligned} \langle E \rangle &= \frac{1}{N} \sum_{i=1}^{N} \xi_i , \delta\xi_i = \xi_i - \langle E \rangle , \\ \sigma^2 &= \frac{1}{N} \sum_{i=1}^{N} \delta\xi_i^2 = \frac{1}{N} \sum_{i=1}^{N} \{\xi_i - \langle E \rangle\}^2 . \end{aligned} \tag{43}$$

According to [35,36,37,38], for the description of the dynamical properties of the studied system we introduce the correlation dependence of the discrete set of events (see Eq. (42)) using the CF:

$$a(n) = \frac{1}{(N-m)\,\sigma^2} \sum_{i=1}^{N-m} \delta\xi_i\, \delta\xi_{i+m} . \tag{44}$$

Here $n = m\Delta n$, $\Delta n = 1$ is the discretization step. The function $a(n)$, which emerges in this way, is the "event" correlation function (ECF). The normalized ECF must obey the conditions of normalization and of the attenuation of correlation, i. e.: $\lim_{n\to 1} a(n) = 1$, $\lim_{n\to\infty} a(n) = 0$. We remark, however, that the second condition for the case the physical complex systems is typically not observed (at $N \gg 0$). It is necessary to note that in [18] the correlation function for the aftershock events has been introduced:

$$C(n + n_W, n_W) = \frac{[\langle t_{n+n_W}\, t_{n_W} \rangle - \langle t_{n+n_W} \rangle \langle t_{n_W} \rangle]}{\left(\sigma^2_{n+n_W} \sigma^2_{n_W}\right)^{1/2}} ,$$

where the averages and the variance are given by

$$\begin{aligned} \langle t_m \rangle &= \frac{1}{N} \sum_{k=o}^{N-1} t_{m+k} , \\ \langle t_m\, t'_m \rangle &= \frac{1}{N} \sum_{k=o}^{N-1} t_{m+k}\, t'_{m+k} , \quad \text{and} \\ \sigma_m^2 &= \langle t_m^2 \rangle - \langle t_m \rangle^2 , \end{aligned}$$

respectively.

By the direct analogy of [31,32,35] we use the finite-difference Liouville's equation of motion in the event scale for describing the evolution of discrete set of events Eq. (11), (13):

$$\frac{\Delta\xi_i(n)}{\Delta n} = i\,\widehat{L}(n, 1)\,\xi_i(n) . \tag{45}$$

Here $\xi_i(n+1) = U(n+1, n)\,\xi_i(n)$, $U(n+1, n)$ is the "event" evolution operator. It determines the shift in linear event scale to one step Δn. The evolution operator $U(n+1, n)$ and Liouville's quasioperator $\widehat{L}(n, 1)$ can be made explicit by writing: $\widehat{L}(n, 1) = (i\Delta n)^{-1}\,(U(n$ $+1, n) - 1)$.

Let's represent the set of values of the dynamical variable $\delta\xi_j = \delta\xi(j\Delta n)$, $j = 1, \dots, N$ as the k-component vector of system state in linear Euclidean space:

a) the vector of initial state of studied complex system:

$$\mathbf{A}_k^1 = \{\delta\xi_1, \delta\xi_2, \delta\xi_3, \dots, \delta\xi_k\} , \tag{46}$$

b) the vector of final system's state, which is shifted on the m events along the event scale:

$$\mathbf{A}_{m+k}^m = \{\delta\xi_{m+1}, \delta\xi_{m+2}, \delta\xi_{m+3}, \dots, \delta\xi_{m+k}\} , \tag{47}$$

where $1 \le k \le N$. The vectors of initial and final states, which are submitted in a similar way, are very convenient for analyzing the dynamics of the observed discrete stochastic processes with the help of discrete non-Markov processes.

To represent the ECF in a more compact form, we use the expression for the scalar product of vectors $\langle \mathbf{A}_k^1 \cdot \mathbf{A}_{m+k}^m \rangle = \sum_{j=1}^{k} A_j^1\, A_{m+j}^m$, and the Eqs. (44), (46) and (47):

$$a(n) = \frac{\langle \mathbf{A}_k^1(1)\, \mathbf{A}_{k+m}^m(n) \rangle}{\langle |\mathbf{A}_k^1(1)|^2 \rangle} . \tag{48}$$

Construction of Chain of Finite-Difference Non-Markov Kinetic Equations for the Events Correlation

Let us consider the finite-difference Liouville's equation (Eq. (44)) for the vector of final system states:

$$\frac{\Delta \mathbf{A}^{m}_{m+k}(n)}{\Delta n} = i\,\widehat{L}(n,1)\,\mathbf{A}^{m}_{m+k}(n)\,. \tag{49}$$

We introduce the projection operator Π, which projects the final vector $\mathbf{A}^{m}_{m+k}(n)$ on the direction of initial vector, and also the orthogonal operator P. The operators Π and P possess the following properties: $\Pi = |\mathbf{A}^1_k(1)\rangle\langle \mathbf{A}^1_k(1)|/\langle|\mathbf{A}^1_k(1)|^2\rangle$, $\Pi^2 = \Pi$, $\mathrm{P} = 1 - \Pi$, $\mathrm{P}^2 = \mathrm{P}$, $\Pi\mathrm{P} = \mathrm{P}\Pi = 0$. They are idempotent and mutually complementary.

The initial ECF $a(n)$ (Eq. (48)) can be derived by means of projecting the vector of final states $\mathbf{A}^{m}_{m+k}(n)$ on the vector of initial state $\mathbf{A}^1_k(1)$:

$$\Pi\,\mathbf{A}^{m}_{m+k}(n) = \frac{\mathbf{A}^1_k(1)\langle \mathbf{A}^1_k(1)\,\mathbf{A}^{m}_{m+k}(n)\rangle}{\langle|\mathbf{A}^0_k|^2\rangle} = \mathbf{A}^1_k(1)\,a(n)\,. \tag{50}$$

The operators Π and P split Euclidean vector space $A(k)$ into two mutually orthogonal subspaces:

$$\begin{aligned} &A(k) = A'(k) + A''(k)\,, \quad A'(k) = \Pi A(k)\,, \\ &A''(k) = \mathrm{P}A(k)\,, \quad \mathbf{A}^{m}_{m+k} \in A(k)\,. \end{aligned} \tag{51}$$

As a result the finite-difference Liouville's Eq. (47) can be represented as a system of 2 equations into mutually orthogonal linear subspaces:

$$\frac{\Delta \mathbf{A}'(n)}{\Delta n} = i\,\widehat{L}_{11}\,\mathbf{A}'(n) + i\,\widehat{L}_{12}\,\mathbf{A}''(n)\,, \tag{52}$$

$$\frac{\Delta \mathbf{A}''(n)}{\Delta n} = i\,\widehat{L}_{21}\,\mathbf{A}'(n) + i\,\widehat{L}_{22}\,\mathbf{A}''(n)\,. \tag{53}$$

Here $\widehat{L}_{ij} = \Pi_i\,\widehat{L}\,\Pi_j$ are the matrix elements of Liouville's quasioperator:

$$\begin{aligned} &\widehat{L} = \widehat{L}_{11} + \widehat{L}_{12} + \widehat{L}_{21} + \widehat{L}_{22}\,, \\ &\widehat{L}_{11} = \Pi\widehat{L}\Pi\,, \quad \widehat{L}_{12} = \Pi\widehat{L}\mathrm{P}\,, \\ &\widehat{L}_{21} = \mathrm{P}\widehat{L}\Pi\,, \quad \widehat{L}_{22} = \mathrm{P}\widehat{L}\mathrm{P}\,. \end{aligned} \tag{54}$$

To solve the system of Eqs. (52), (53) we eliminate the non-reducible part, which contains $\mathbf{A}''(n)$ and derive the self-contained equation for the reducible part $\mathbf{A}'(n)$. In doing so we solve the Eq. (52) step-by-step and shall substitute the obtained solution into the Eq. (53). As a result we arrive at the closed kinetic equation:

$$\begin{aligned} \frac{\Delta \mathbf{A}'(n+m\Delta n)}{\Delta n} &= i\,\widehat{L}_{11}\,\mathbf{A}'(n+m\Delta n) \\ &\quad + i\,\widehat{L}_{12}\{1 + i\Delta n\,\widehat{L}_{22}\}^m\,\mathbf{A}''(n) \\ &\quad - \widehat{L}_{12}\sum_{j=1}^{m}\{1 + i\Delta n\,\widehat{L}_{22}\}^j\,\Delta n \\ &\quad \times \widehat{L}_{21}\,\mathbf{A}'(n+[m-j]\Delta n)\,. \end{aligned} \tag{55}$$

By use of projection operators Π and P we found the closed finite-difference kinetic equation of non-Markov type for the initial ECF:

$$\frac{\Delta a(n)}{\Delta n} = i\lambda_1\,a(n) - \Delta n\,\Lambda_1\sum_{j=1}^{m} M_1(j\Delta n)\,a(n-j\Delta n)\,. \tag{56}$$

As $\Delta n = 1$, solution of the last equation must be following:

$$a(n+1) = \{i\lambda_1 + 1\}\,a(n) - \Lambda_1\sum_{j=1}^{m} M_1(j)\,a(n-j)\,. \tag{57}$$

Here λ_1 is the proper value of Liouville's quasioperator $\widehat{L}$, Λ_1 is the relaxation parameter, which dimension is square of frequency, $M_1(j\Delta n)$ is the normalized memory function of the first order:

$$\begin{aligned} \lambda_1 &= \frac{\langle A^1_k(1)\,\widehat{L}\,A^1_k(1)\rangle}{\langle|A^1_k(1)|^2\rangle}\,, \\ \Lambda_1 &= \frac{\langle A^1_k\,\widehat{L}_{12}\,\widehat{L}_{21}\,A^1_k(1)\rangle}{|A^1_k(1)|^2\rangle}\,, \\ M_1(j\Delta n) &= \frac{\langle A^1_k(1)\,\widehat{L}_{12}(1 + i\Delta n\,\widehat{L}_{22})^j\,\widehat{L}_{21}\,A^1_k(1)\rangle}{\langle A^1_k(1)\,\widehat{L}_{12}\,\widehat{L}_{21}\,A^1_k(1)\rangle}\,. \end{aligned}$$

To obtain the finite-difference kinetic equation for the normalized event memory function of first order and, further, for the higher $(s-1)$th orders as well, we have to repeat the foregoing procedure step-by-step. However, we shall make use of the Gram–Schmidt orthogonalization procedure [16]:

$$\langle \mathbf{W}_s\mathbf{W}_p\rangle = \delta_{sp}\,\langle|\mathbf{W}_s|^2\rangle\,. \tag{58}$$

Where δ_{sp} is a Kronecker's symbol. Now we shall derive the recurrence formula $\mathbf{W}_s = \mathbf{W}_s(n)$ for defining the set of the orthogonal dynamic variables:

$$\begin{aligned} &\mathbf{W}_0 = \mathbf{A}^1_k\,, \\ &\mathbf{W}_1 = \{i\widehat{L} - \lambda_1\}\mathbf{W}_0\,, \\ &\mathbf{W}_2 = \{i\widehat{L} - \lambda_2\}\mathbf{W}_1 - \Lambda_1\mathbf{W}_0, \ldots \end{aligned} \tag{59}$$

According to the foregoing formulas we can introduce the succession of projection operators $\Pi_s = \Pi_1^{(s)}$ and the set of mutually complementary projectors $\mathrm{P}_s = 1 - \Pi_s$, which possess the following properties:

$$\Pi_s = \frac{|\mathbf{W}_s\rangle\langle\mathbf{W}_s|}{\langle|\mathbf{W}_s|^2\rangle}\,, \qquad \Pi_s^2 = \Pi_s\,,$$
$$\mathrm{P}_s^2 = \mathrm{P}_s\,, \qquad \Pi_s\,\mathrm{P}_s = \mathrm{P}_s\,\Pi_s = 0\,,$$
$$\Pi_s\,\Pi_p = \delta_{sp}\,\Pi_s\,, \qquad \mathrm{P}_s\,\mathrm{P}_p = \delta_{sp}\,\mathrm{P}_s\,.$$

Each of these operators pairs Π_s, P_s splits the corresponding Euclidean vector space $\mathbf{W}_s$ into the two mutual complementary subspaces: $W_s = W_s' + W_s'$, $W_s' = \Pi_s W_s$, $W_s'' = P_s W_s$. Using the projection operator technique for the next orthogonal variables $\mathbf{W}_s$, we shall obtain the chain of interconnected kinetic finite-difference equations of the non-Markov type for the normalized correlation functions of the $(s-1)$th order:

$$\frac{\Delta M_1(n)}{\Delta n} = i\,\lambda_2\,M_1(n) - \Lambda_2 \sum_{j=1}^{m} M_2(j)\,M_1(n-j)\,,$$
$$\dots\,,$$
$$\frac{\Delta M_{s-1}(n)}{\Delta n} = i\,\lambda_s\,M_{s-1}(n) - \Lambda_s \sum_{j=1}^{m} M_{s-1}(j)\,M_s(n-j)\,. \tag{60}$$

In these equations the normalized events memory function of the first order: $M_1(n) = \langle \mathbf{W}_1(1+i\Delta n\widehat{L})^m \mathbf{W}_1\rangle / \langle|\mathbf{W}_1|^2\rangle$, memory function of the $(s-1)$th order: $M_{s-1}(n) = \langle \mathbf{W}_{s-1}(1+i\Delta n\widehat{L})^m \mathbf{W}_{s-1}\rangle / \langle|\mathbf{W}_{s-1}|^2\rangle$, the proper value of the Liouville's quasioperator $\widehat{L}$: $\lambda_s = \langle \mathbf{W}_s \widehat{L} \mathbf{W}_s\rangle / \langle|\mathbf{W}_s|^2\rangle$ and the relaxation parameter $\Lambda_s = \langle|\mathbf{W}_s|^2\rangle / \langle|\mathbf{W}_{s-1}|^2\rangle$ are introduced.

The foregoing finite-difference kinetic Eqs. (60) present the generalization of the statistical theory [31,32,35] for the case of event correlations in discrete stochastic evolution of non-Hamilton complex systems.

Information Measures of Memory in Complex Systems

As an information measures of memory it is useful to apply different dimensionless quantifiers. As a first measure we use the frequency dependence of non-Markovity parameter. This measure was introduced in [31] and it is defined as:

$$\varepsilon_i(\nu) = \left\{\frac{\mu_{i-1}(\nu)}{\mu_i(\nu)}\right\}^{1/2}\,. \tag{61}$$

Here, $\mu_i(\nu)$ denotes the frequency power spectrum of memory function of the ist order $M_i(n)$: $\mu_i(\nu) = |\Delta n \sum_{n=1}^{N} M_i(n)\cos(2\pi n\nu)|^2$. The non-Markovity parameter $\varepsilon_i(\nu)$ along with the memory functions enables us to characterize quantitatively the statistical memory effects in discrete complex systems of various nature. Because the functions $\mu_i(\nu)$ exist for each of the ith levels of relaxation, we obtain the statistical spectrum of parameters: $\varepsilon_i(\nu)$, $i = 1, 2, 3, \dots$.

Alternatively, a study of 'memory' in physiological time series for electroencephalographic (EEG) and magnetoencephalographic (MEG) signals, both of healthy subjects and patients (including epilepsy patients) has been based on the detrended-fluctuation analysis (DFA) [39,40].

The characterization of memory *per se* is based on a set of dimensionless statistical quantifiers which are capable for measuring the memory strength which is inherent to the complex dynamics.

According to [41] a second set an information memory measure can be constructed as follows:

$$\delta_i(\nu) = \left|\frac{\tilde{M}_i'(\nu)}{\tilde{M}_{i+1}'(\nu)}\right|\,.$$

Here, $\mu_i(\nu) = |\tilde{M}_i(\nu)|^2$ denotes the power spectrum of the corresponding memory function $M_i(t)$, $\tilde{M}_i'(\nu) = \mathrm{d}\tilde{M}_i(\nu)/\mathrm{d}\nu$ and $\tilde{M}_i(\nu)$ is the Fourier transform of the memory function $M_i(t)$. The measures $\varepsilon_i(\nu)$ are suitable for the quantification of the memory effects on a relative scale whereas the second set $\delta_i(\nu)$ proves to be useful for quantifying the amplification of relative memory effects occurring on different complexity levels. Both measures provide statistical criteria for comparison between the relaxation time scales and memory time scales of the process under consideration. For values obeying $\{\varepsilon, \delta\} \gg 1$ one can observe a complex dynamics characterized by the short-ranged temporal memory scales. In the memoryless limit these processes assume a δ-like memory with parameters $\varepsilon, \delta \to \infty$. When $\{\varepsilon, \delta\} > 1$ one deals with a situation with moderate memory strength, and the case where both $\varepsilon, \delta \sim 1$ typically constitutes a more regular and robust random process exhibiting strong memory features.

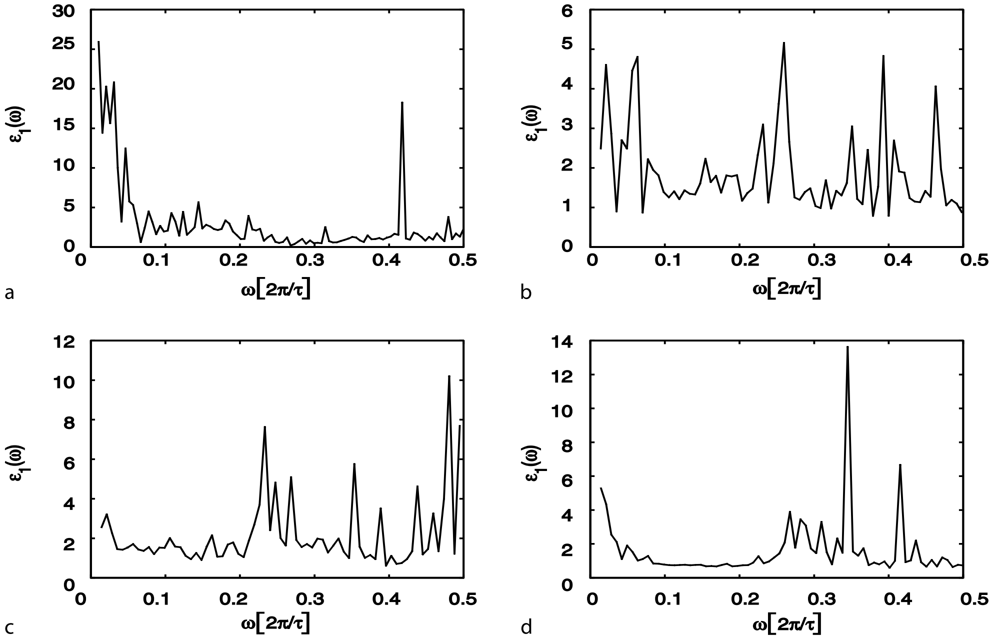
Manifestation of Strong Memory in Complex Systems

A fundamental role of the strong and weak memory in the functioning of the human organism and seismic phenomena can be illustrated by the example of some situations examined next. We will consider some examples of the time series for both living and for seismic systems. It is necessary to note that a comprehensive analysis of the experimental data includes the calculation and the presentation of corresponding phase portraits in some planes of the dynamic orthogonal variables, the autocorrelation time functions, the memory time functions and their frequency power spectra, etc. However, we start out by calculating two statistical quantifiers, characterizing two informational measures of memory: the parameters $\epsilon_1(\omega)$ and $\delta_1(\omega)$.

Figures 1 and 3 present the results of experimental data of pathological states of human cardiovascular systems (CVS). Figure 2 depicts the analysis for the seismic observation. Figures 4 and 5 indicate the memory effects for the patients with Parkinson disease (PD), and the last two Figs. 6, 7 demonstrate the key role of the strength of memory in the case of time series of patients suffering from photosensitive epilepsy which are contrasted with signals taken from healthy subjects. All these cases convincingly display the crucial role of the statistical memory in the functioning of complex (living and seismic) systems.

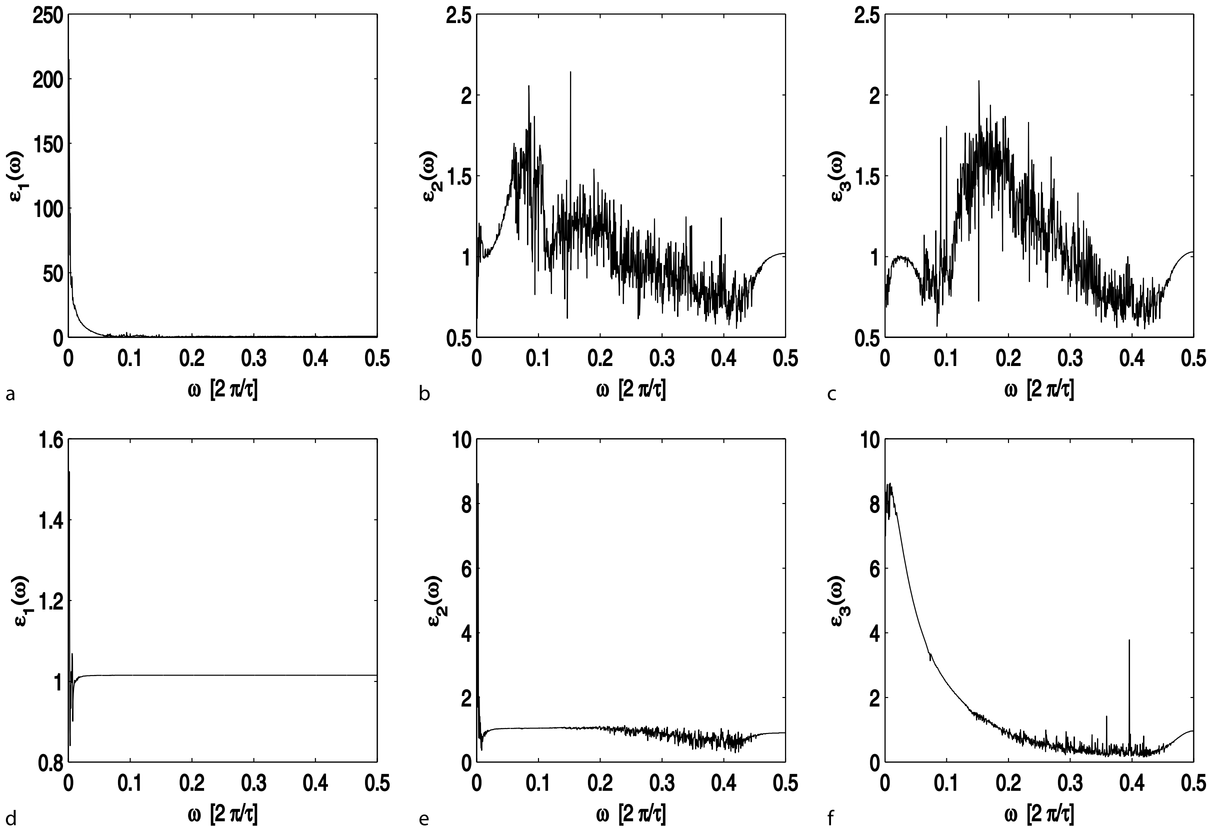
A characteristic role of the statistical memory can be detected from Fig. 1 for the typical representatives taken from patients from four different CVS-groups: (a) for healthy subject, (b) for a patient with rhythm driver migration, (c) for a patient after myocardial infarction (MI), (d) for a patient after MI with subsequent sudden cardiac death (SSCD). All these data were obtained from the short time series of the dynamics of RR-intervals from the electric signals of the human ECG's. It can be seen here that significant memory effects typically lead to the long-time correlations in the complex systems. For healthy we observe weak memory effects while and large values of the measure memory $\epsilon_1(\omega = 0) \approx 25$. The strong memory and the long memory time (approximately, 10 times more) are being observed with the help of 3 patient groups: with RDM (rhythm driver migration) (b), after MI (c) and after MI with SSCD (d).

Figure 2 depicts the strong memory effects presented in seismic phenomena. By a transition from the steady state of Earth ((a), (b) and (c)) to the state of strong earthquake (EQ) ((d), (e), and (f)) a remarkable amplification



Correlations in Complex Systems, Figure 1

Frequency spectrum of the first information measure of memory (first point in the statistical spectrum on non-Markovity parameter) $\varepsilon_1(\omega)$ for the fourth cardiac patient groups from the short time series of RR-intervals: healthy subject (a), patient with rhythm driver migration (RDM) (b), patient after myocardial infarction (MI) (c), and patient after MI with subsequent sudden cardiac death (SCD) (d). The frequency is marked in terms of units of τ^{-1}. All spectra reveal the miscellaneous faces of statistical memory's strength. For the healthy subject one can see Markov effects and weak memory. For other three cases of cardiac diseases we note the diverse displays of strong memory. The strong memory has been accompanied by the spikes of the weak memory: for RDM on the all frequency regions, for patient with MI for the middle and high frequencies and for patient after MI with SSCD only for high frequencies. From Fig. 7 in [104]



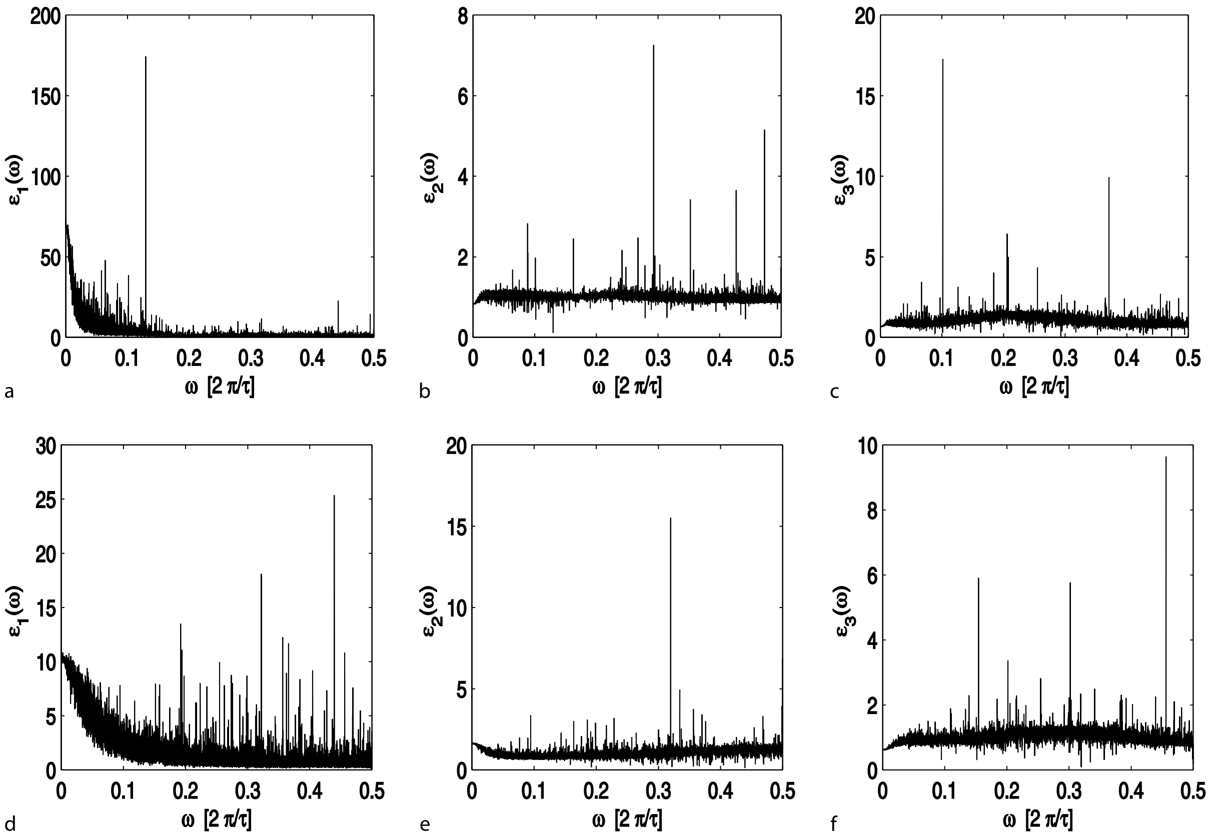
Correlations in Complex Systems, Figure 2

Frequency spectra of the first three points of the first measure of memory (non-Markovity parameters) $\varepsilon_1(\omega)$, $\varepsilon_2(\omega)$, and $\varepsilon_3(\omega)$ for the seismic phenomena: a, b, c long before the strong Earthquake (EQ) for the steady state of Earth and d, e, f during the strong EQ. Markov and quasi-Markov behavior of seismic signals with manifestation of the weak memory is observed only for ε_1 in state before the strong EQ. All remaining cases b, c, d and e relate to non-Markov processes. Strong non-Markovity and strong memory is typical for case d (state during the strong EQ). In behavior of $\varepsilon_2(\omega)$ and $\varepsilon_3(\omega)$ one can see a transition from quasi-Markovity (at low frequencies) to strong non-Markovity (at high frequencies). From Fig. 6 in [105]

of memory effects is highly visible. The term amplification refers to the appearance of strong memory and the prolongation of the memory correlation time in the seismic system. Recent study show that discrete non-Markov stochastic processes and long-range memory effects play a crucial role in the behavior of seismic systems. An approach, permitting us to obtain an algorithm of strong EQ forecasting and to differentiate technogenic explosions from weak EQs, can be developed thereupon.

Figure 3 demonstrates an intensification of memory effects of one order at the transition from healthy people ((a), (b) and (c)) to patient suffering from myocardial infarction. The figures were calculated from the long time series of the RR-intervals dynamics from the human ECG's. The zero frequency values $\epsilon_1(\omega = 0)$ at $\omega = 0$ sharply reduced, approximately of the size of one order for patient as compared to healthy subjects.

Figures 4 and 5 illustrate the behavior for patients with Parkinson's disease. Figure 4 shows time recording of the pathological tremor velocity in the left index finger of a patient with Parkinson's disease (PD) for eight diverse pathological cases (with or without medication, with or without deep brain stimulation (DBS), for various DBS, medication and time conditions). Figure 5, arranged in accordance with these conditions, displays a wide variety of the memory effects in the treatment of PD's patients. Due to the large impact of memory effects this observation permits us to develop an algorithm of exact diagnosis of Parkinson's disease and a calculation of the quantitative parameter of the quality of treatment. A physical role of the strong and long memory correlation time enables us to extract a vital information about the states of various patient on basis of notions of correlation and memory times.



Correlations in Complex Systems, Figure 3

The frequency dependence of the first three points of non-Markovity parameter (NMP) for the healthy person (a), (b), (c) and patient after myocardial infarction (MI) (d), (e), (f) from the time dynamics of RR-intervals of human ECG's for the case of the long time series. In the spectrum of the first point of NMP $\varepsilon_1(\omega)$ there is an appreciable low-frequency (long time) component, which concerns the quasi-Markov processes. Spectra NMP $\varepsilon_2(\omega)$ and NMP $\varepsilon_3(\omega)$ fully comply with non-Markov processes within the whole range of frequencies. From Fig. 6 in [106]

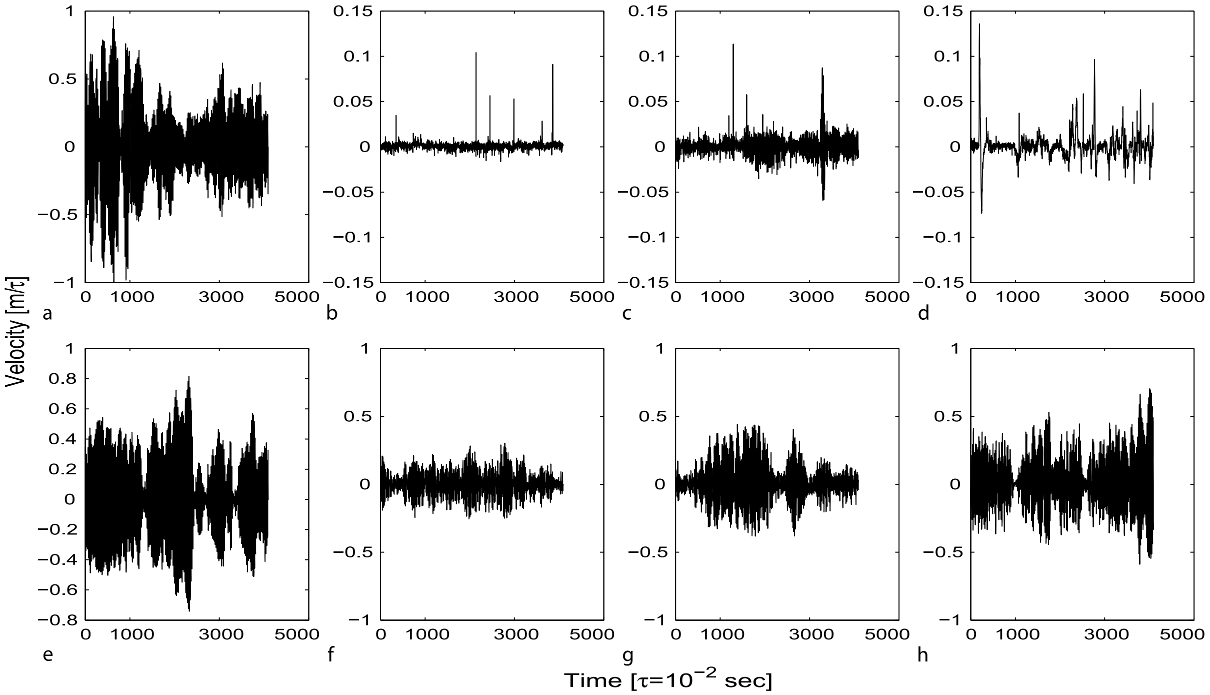
According to Figs. 6 and 7 specific information about the physiological mechanism of photosensitive epilepsy (PSE) was obtained from the analysis of the strong memory effects via the registration the neuromagnetic responses in recording of magnetoencephalogram (MEG) of the human brain core. Figure 6 presents the topographic dependence of the first level of the second memory measure $\delta_1(\omega = 0; n)$ for the healthy subjects in the whole group (upper line) vs. patients (lower line) for red/blue combination of the light stimulus. This topographic dependence of $\varepsilon_1(\omega = 0; n)$ depicted in Fig. 6 clearly demonstrates the existence of long-range time correlation. It is accompanied by a sharp increase of the role of the statistical memory effects in the all MEG's sensors with sensor numbers $n = 1, 2, \ldots, 61$ of the patient with PSE in comparison with healthy peoples. A sizable difference between the healthy subject and a subject with PSE occurs.

To emphasize the role of strong memory one can continue studying the topographic dependence in terms of the novel informational measure, the index of memory, defined as:

$$\nu(n) = \frac{\delta_1^{\text{healthy}}(0; n)}{\delta_1^{\text{patient}}(0; n)}\,, \tag{62}$$

see in Fig. 7.

This measure quantifies the detailed memory effects in the individual MEG sensors of the patient with PSE versus the healthy group. A sharp increase of the role of the memory effects in the stochastic behavior of the magnetic signals is clearly detected in sensor numbers $n = 10, 46, 51, 53$ and 59. The observed points of MEG sensors locate the regions of a protective mechanism against PSE in a human organism: frontal (sensor 10),



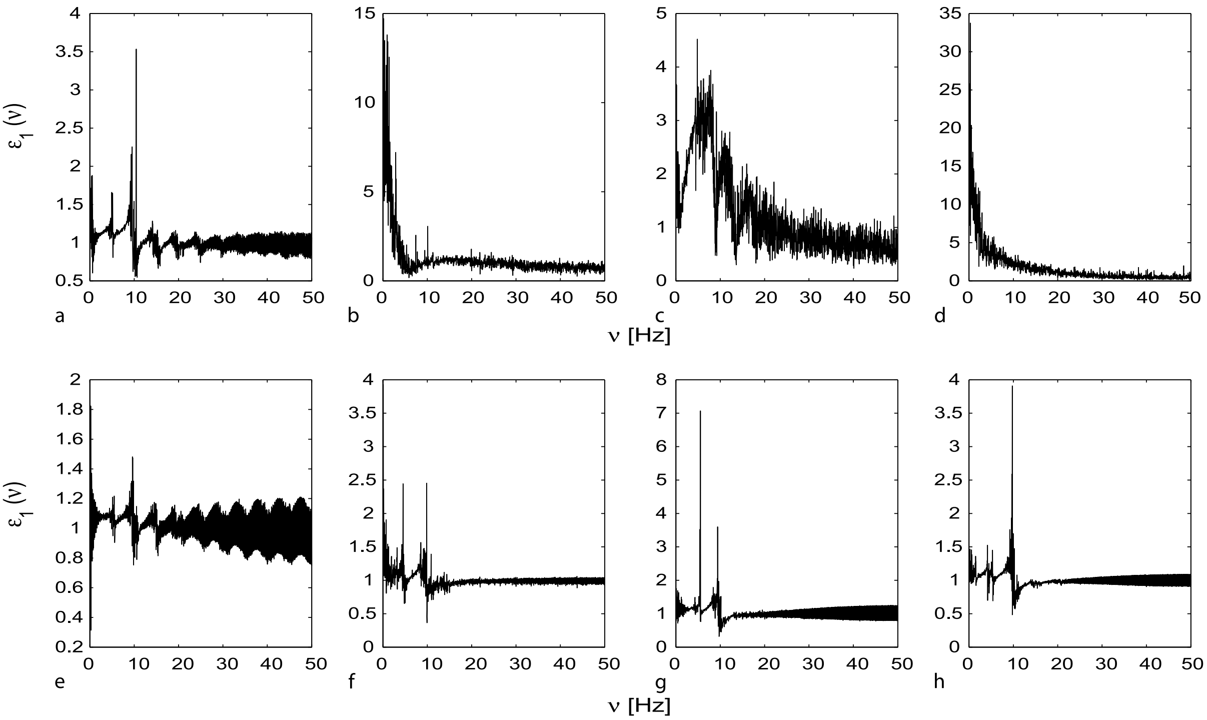
Correlations in Complex Systems, Figure 4

Pathological tremor velocity in the left index finger of the sixth patient with Parkinson's disease (PD). The registration of Parkinsonian tremor velocity is carried out for the following conditions: a "OFF-OFF" condition (no any treatment), b "ON-ON" condition (using deep brain stimulation (DBS) by electromagnetic stimulator and medicaments), c "ON-OFF" condition (DBS only), d "OFF-ON" condition (medicaments (L-Dopa) only), e–h the "15 OFF", "30 OFF", "45 OFF", "60 OFF" conditions – the patient's states 15 (30, 45, 60) minutes after the DBS is switched off, no treatment. Let's note the scale of the pathological tremor amplitude (see the vertical scale). Such representation of the time series allows us to note the increase or the decrease of pathological tremor. From Fig. 1 in [107]

occipital (sensors 46, 51 and 53) and right parietal (sensor 59) regions. The early activity in these sensors may reflect a protective mechanism suppressing the cortical hyperactivity due to the chromatic flickering.

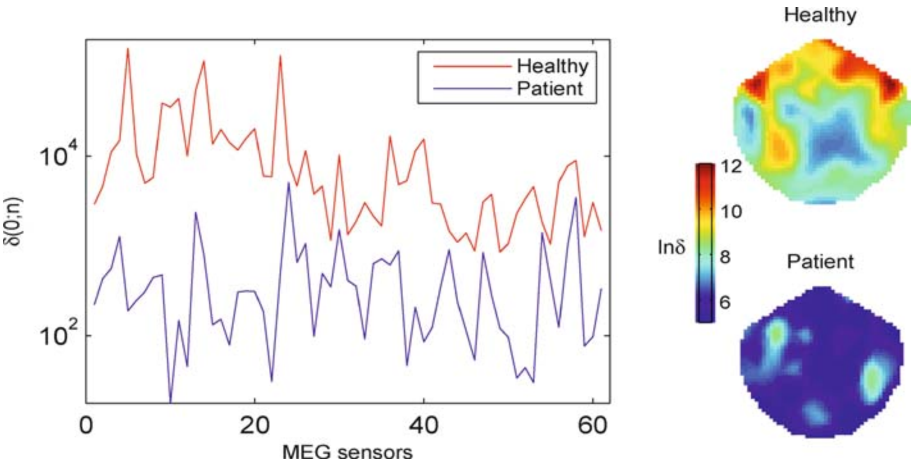
We remark that some early steps towards understanding the normal and various catastrophical states of complex systems have already been taken in many fields of science such as cardiology, physiology, medicine, neurology, clinical neurophysiology, neuroscience, seismology and so forth. With the underlying systems showing fractal and complicated spatial structures numerous studies applying the linear and nonlinear time series analysis to various complex systems have been discussed by many authors. Specifically the results obtained shows evidence of the significant nonlinear structure evident in the registered signals in the control subjects, whereas nonlinearity for the patients and catastrophical states were not detected. Moreover the couplings between distant parts and regions were found to be stronger for the control subjects. These prior findings are leading to the hypothesis that the real normal complex systems are mostly equipped with significantly nonlinear subsystems reflecting an inherent mechanism which stems against a synchronous excitation vs. outside impact or inside disturbances. Such nonlinear mechanisms are likely absent in the occurrence of catastrophical or pathological states of the complex systems.

From the physical point of view our results can be used as a toolbox for testing and identifying the presence or absence of various memory effects as they occur in complex systems. The set of our memory quantifiers is uniquely associated with the appearance of memory features in the chaotic behavior of the observed signals. The registration of the behavior belonging to these indicators, as elucidated here, is of beneficial use for detecting the catastrophical or pathological states in the complex systems. There exist alternative quantifiers of different nature as well, such as the Lyapunov's exponent, Kolmogorov–Sinai entropy, correlation dimension, etc., which are widely used in nonlinear dynamics and relevant applications. In the present context, we have found out that the employed memory measures are not only convenient for the analysis but are



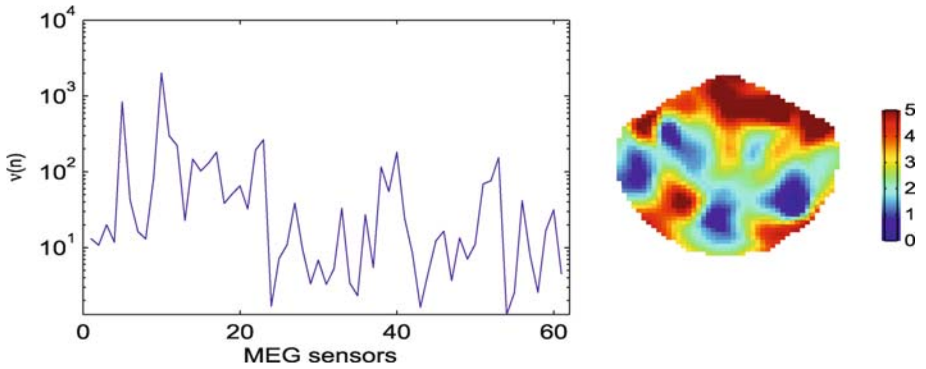
Correlations in Complex Systems, Figure 5

The frequency dependence of the first point of the non-Markovity parameter $\varepsilon_1(\nu)$ for pathological tremor velocity in the patient. As an example, the sixth patient with Parkinson's disease is chosen. The figures are submitted according to the arrangement of the initial time series. The characteristic low-frequency oscillations are observed in frequency dependence (a, e–h), which get suppressed under medical influence (b–d). The non-Markovity parameter reflects the Markov and non-Markov components of the initial time signal. The value of the parameter on zero frequency $\varepsilon_1(0)$ reflects the total dynamics of the initial time signal. The maximal values of parameter $\varepsilon_1(0)$ correspond to small amplitudes of pathological tremor velocity. The minimal values of this parameter are characteristic of significant pathological tremor velocities. The comparative analysis of frequency dependence $\varepsilon_1(\nu)$ allows us to estimate the efficiency of each method of treatment. From Fig. 5 in [107]



Correlations in Complex Systems, Figure 6

The topographic dependence of the first point of the second measure of memory $\delta_1(\omega = 0; n)$ for the healthy on average in the whole group (*upper line*) vs. patient (*lower line*) for R/B combination of the light stimulus. One can note the singular weak memory effects for the healthy on average in sensors with No. 5, 23, 14, 11 and 9



Correlations in Complex Systems, Figure 7
The topographic dependence of the memory index $\nu(n) = \nu_1(n; 0)$ for the the whole group of healthy on average vs. patient for an R/B combination of the light stimulus. Strong memory in patient vs. healthy appears clearly in sensors with No. 10, 5, 23, 40 and 53

also ideally suitable for the identification of anomalous behavior occurring in complex systems. The search for other quantifiers, and foremost, the ways of optimization of such measures when applied to the complex discrete time dynamics presents a real challenge. Especially this objective is met when attempts are made towards the identification and quantification of functioning in complex systems. This work presents initial steps towards the understanding of basic foundation of anomalous processes in complex systems on the basis of a study of the underlying memory effects and connected with this, the occurrence of long lasting correlations.

Some Perspectives on the Studies of Memory in Complex Systems

Here we present a few outlooks on the fundamental role of statistical memory in complex systems. This involves the issue of studying cross-correlations. The statistical theory of stochastic dynamics of cross-correlation can be created on the basis of the mentioned formalism of projection operators technique in the linear space of random variables. As a result we obtain the cross-correlation memory functions (MF's) revealing the statistical memory effects in complex systems. Some memory quantifiers will appear simultaneously which will reflect cross-correlation between different parts of CS. Cross-correlation MF's can be very useful for the analysis of the weak and strong interactions, signifying interrelations between the different groups of random variables in CS. Besides that the cross-correlation can be important for the problem of phase synchronization, which can find a unique way of studying of synchronization phenomena in CS that has a special importance when studying aspects of brain and living systems dynamics.

Some additional information about the strong and weak memory effects can be extracted from the observation of correlation in CS in the random event's scales. Similar effects are playing a crucial role in the differentiation between stochastic phenomena within astrophysical systems, for example, in galaxies, pulsars, quasars, microquasars, lacertides, black holes, etc. One of the most important area of application of developed approach is a bispectral and polyspectral analysis for the diverse CS. From the mathematical point of view a correct definition of the spectral properties in the functional space of random functions is quite important. A variety of MF's arises in the quantitative analysis of the fine details of memory effects in a nonlinear manner. The quantitative control of the treatment quality in the diverse areas of medicine and physiology may be one of the important biomedical application of the manifestation of the strong memory effects.

These and other features of memory effects in CS call for an advanced development of brain studies on the basis of EEG's and MEG's data, cardiovascular, locomotor and respiratory human systems, in the development of the control system of information flows in living systems. An example is the prediction of strong EQ's and the clear differentiation between the occurrence of weak EQ's and the technogenic explosions, etc.

In conclusion, we hope that the interested reader becomes invigorated by this presentation of correlation and memory analysis of the inherent nonlinear system dynamics of varying complexity. He can find further details how significant memory effects typically cause long time correlations in complex systems by inspecting more closely some of the published items in [42–103].

There are the relationships between standard fractional and polyfractal processes and long-time correlation in complex systems, which were explained in [39,40,44,45,46,49,53,54,60,62,64,76,79,83,84,94] in detail.

Example of using the Hurst exponent over time for testing the assertion that emerging markets are becoming more efficient can be found in [51].

While over 30 measures of complexity have been proposed in the research literature one can distinguish [42,55,66,81,89,99] with the specific designation of long-time correlation and memory effects.

The papers [48,57] are focused on long range correlation processes that are nonlocal in time and whence show memory effects.

The statistical characterization of the nonstationarities in real-world time series is an important topic in many fields of research and some numerous methods of characterizing nonstationary time series were offered in [59,65,84].

Long-range correlated time series have been widely used in [52,61,63,68,74] for the theoretical description of diverse phenomena.

Example of the study an anatomy of extreme events in a complex adaptive system can be found in [67].

Approaches for modeling long-time and long-range correlation in complex systems from time series are investigated and applied to different examples in [50,56,69,70,73,75,80,82,86,100,101,102].

Detecting scale invariance and its fundamental relationships with statistical structures is one of the most relevant problems among those addressed correlation analysis [47,71,72,91].

Specific long-range correlation in complex systems are the object of active research due to its implications in the technology of materials and in several fields of scientific knowledge with the use of quantified histograms [78], decrease of chaos in heart failure [85], scaling properties of ECG's signals fluctuations [87], transport properties in correlated systems [88] etc.

It is demonstrated in [43,92,93] how ubiquity of the long-range correlations is apparent in typical and exotic complex statistical systems with application to biology, medicine, economics and to time clustering properties [95,98].

The scale-dependent wavelet and spectral measures for assessing cardiac dysfunction have been used in [97].

In recent years the study of an increasing number of natural phenomena that appear to deviate from standard statistical distributions has kindled interest in alternative formulations of statistical mechanics [58,101].

At last, papers [77,90] present the samples of the deep and multiple interplay between discrete and continuous long-time correlation and memory in complex systems and the corresponding modeling the discrete time series on the basis of physical Zwanzig–Mori's kinetic equation for the Hamilton statistical systems.

Glossary

Cosmic microwave background Quasi-isotropic thermal, background of electromagnetic radiation of cosmological (i. e. not astrophysical origin). The observed spectrum of this radiation is consistent with a black body with temperature $T = 2.725\,\mathrm{K}$ and represents the best experimental confirmation of the Planck spectrum. According to the standard cosmological model, the dynamics of the primordial universe is determined, via the Einstein gravitational equations, by a hot relativistic plasma of electrons, photons and baryons. The photons interact with the plasma through Thomson scattering. As the universe expanded, the plasma cools until it becomes favorable for electrons to combine with protons and form hydrogen atoms. This occurs at a temperature of about 3×10^3 K (corresponding to an average energy of about 0.3 eV). At this point, the photons scatter off the now neutral atoms and start to travel freely through space. This process is called recombination or decoupling (referring to electrons combining with nuclei and to the decoupling of matter and radiation, respectively). Since the universe is expanding the photon temperature keeps decreasing reaching the current value of $T = 2.725\,\mathrm{K}$. Accordingly, the photons observed today (i. e. the CMB photons) come from a spherical surface, called the **surface of last scattering**, corresponding to the time of decoupling.

Friedmann–Robertson–Walker model Model based upon an isotropic and homogeneous metric describing an expanding universe corresponding to a solution of the Einstein gravitational equation with a perfect fluid source (described in terms of its energy density ρ and its pressure p). The line element depends on the three-dimensional constant curvature k and the scale factor $a(t)$ describing the expansion: $\mathrm{d}s^2 = \mathrm{d}t^2 - a^2(t)(\mathrm{d}r^2/(1 - kr^2) + r^2(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2))$. The expansion rate is given by $H = \dot{a}/a$. Given the equation of state $p = p(\rho)$, the solution for the scale factor is obtained from the **Friedmann equation** $H^2 = 8\pi G\rho/3$.

Inflation Primordial epoch in the evolution of the Universe characterized by an accelerating expansion ($\ddot{a} > 0$). In particular, to achieve acceleration, a nonstandard source is needed (i. e. a perfect fluid with an effective equation of state such that $\rho + 3p < 0$). The existence of such a phase is postulated in order to explain the observed quasi-isotropy and homogeneity of the Universe on large scales, as well as to provide a mechanism to generate primordial seeds for structure formation.

Definition of the Subject

As first predicted by Albert Einstein [1], propagation effects at finite speed in the dynamical gravitational equations yield to the existence of wave-like solutions of the gravitational field linearized around the flat-vacuum configuration. Such solutions correspond to the so-called gravitational waves (GWs). At the theoretical level, the work of Bondi [2] (who considered self-gravitating systems like binaries of compact objects) showed that GWs carry energy, while observationally the discovery of the 1916 + 13 binary pulsar system by Hulse and Taylor [3] (in particular, the speed-up of the binary pulsar period), provided an indirect evidence for the existence of GWs.

On the experimental side, after the pioneering work of Weber in the 1960s and the subsequent development of meter-scale, resonant bar detectors (ALLEGRO, AURIGA EXPLORER, NAUTILUS and NIOBE), in more recent years a number of new detectors have been designed and built to search for GWs. Kilometer-scale interferometers (GEO [4], LIGO [5], TAMA [6] and VIRGO [7]), sensitive to GWs in the frequency range between 10 Hz and 1 kHz, are already producing scientific runs at the design sensitivity (or close to it, as for VIRGO). The Laser Interferometric Space Antenna (LISA) [8], a space-based, three-arms interferometer will be aimed at detecting GWs in the frequency range between 0.1 mHz and 10 mHz, while a next generation of space-detectors especially designed to detect primordial GWs has already being planned [9,10].

Gravitational waves can be produced by violent dynamical phenomena involving compact astrophysical objects (like neutron stars and/or black holes), as well as by various mechanisms related to the dynamics of the primordial universe. Those primordial GWs produce a background of gravitational radiation that can be considered as a sort of "cosmological noise", i. e. the gravitational counterpart of the cosmic microwave background radiation (CMB). The detection of such primordial gravitational radiation can be exploited to investigate physical processes occurring during the early stages of the evolution of the universe, when the typical energy scales are not accessible experimentally in any other way. The reason why primordial GWs are characterized by this unique feature is the well-known fact that in an expanding universe particles decoupled from the primordial plasma at a temperature T_D carry information about the state of the Universe at T_D. In particular, for gravitons it is possible to estimate the decoupling temperature assuming that the gravitons are kept in thermal equilibrium through two-body scattering processes (see e. g. [11]). In this case, the interaction rate is[1]. $\Gamma_{\mathrm{G}} \sim T^5/M_{\mathrm{pl}}^4$, where M_{pl} is the Planck mass ($\sim 10^{19}$ GeV). Since the energy density for relativistic particles scales with the fourth power of the temperature, assuming an adiabatic expansion the expansion rate H scales as $H \sim \dot{T}/T$. Hence, thermal equilibrium is maintained provided that the typical time-scale for graviton interaction is smaller than the expansion time-scale, i. e. $\Gamma_{\mathrm{G}} > H$. Using the Friedmann equation, $H \propto T^2/M_{\mathrm{pl}}$ this yields

$$\left(\frac{\Gamma_{\mathrm{G}}}{H}\right) \sim \left(\frac{T}{M_{\mathrm{pl}}}\right)^3 . \tag{1}$$

Gravitons are therefore decoupled just below the Planck scale. This implies that any relic GWs retain in their spectrum (i. e., amplitude and frequency) unique information about the state of the primordial universe and the corresponding physical process occurring at extremely high energy scales.

The first papers addressing possible mechanisms for the production of a cosmological background of gravitational radiation date back to the 1970s. Grishchuck [12] and Starobinsky [13] showed that metric tensor perturbations in an expanding, homogeneous and isotropic universe can be parametrically amplified provided there is a stage in the evolution of the universe when the characteristic time scale during which the metric changes is much smaller than the intrinsic wave period of the perturbations. This phenomenon, known as parametric amplification of vacuum fluctuations, is characteristic of inflationary models and its phenomenological consequences have been widely investigated (see e. g. [14]). Furthermore, as Witten [15] and Hogan [16] first pointed out, cosmological first-order phase transitions (e. g. expected to occur at the QCD scale ($T \sim 100$ MeV) and/or at the electro-weak scale ($T \sim 100$ GeV)) may be associated to the production of gravitational radiation. In particular, Hogan and Witten showed that in a cosmological, first-order phase transition, both the collision of detonation waves triggered by the nucleation of the low-temperature phase and the generation of acoustic noise in the relativistic plasma could produce a relic background of gravitational waves. Since those pioneering works, detailed computations of various types of gravitational wave signals have been performed, and data analysis techniques for extracting this kind of signal have been developed.

Introduction

Without loss of generality, a cosmological gravitational background is expected to be Gaussian, isotropic, stationary and unpolarized (for a detailed discussion see e. g. [17]). All the physical properties are then encoded into the so-called *spectrum*, given by the following, dimensionless quantity

$$\Omega_{\mathrm{gw}}(f) = \frac{1}{\rho_{\mathrm{c}}} f\, \tilde{\rho}_{\mathrm{gw}}(f) , \tag{2}$$

where f is the frequency, $\tilde{\rho}_{\mathrm{gw}}(f)$ is the gravitational wave energy density per unit frequency, i. e.

$$\rho_{\mathrm{gw}} = \int_0^\infty \mathrm{d}f\, \tilde{\rho}_{\mathrm{gw}}(f) , \tag{3}$$

and $\rho_{\mathrm{c}} = 3H_0^2/(8\pi G)$ is the critical energy density ($H_0 = h_0 \times 100\,\mathrm{km/(s\,Mpc)}$ being the current value of the Hubble constant, with h_0 parameterizing the current experimental uncertainty). Hence, to characterize any stochastic background of gravitational radiation, the combination $h_0^2\, \Omega_{\mathrm{gw}}$ is adopted.

As a signal to be detected, a stochastic background of gravitational waves is described in terms of a random process that cannot be disentangled from the detector noise. Most of the theoretical predictions yield values for the GWs spectrum much lower than the noise level

[1] In the following, we will adopt units for which temperatures, masses and energies are all measured in electron-volts (eV) or multiples of it and distances are expressed as inverse of energies

of any current or planned earth-based detector; on the other hand, the instrumental noise features of GW detectors are not sufficiently well understood to search for excess noise. For these reasons, an optimal detection strategy has been developed [18] based upon the cross-correlation between two or more widely separated detectors (so as to minimize the common noise sources). In particular, the cross-correlation improves the sensitivity (in terms of the spectrum) by a factor $(\Delta f\, T_{\text{obs}})^{1/2}$, where Δf is the effective detector bandwidth and T_{obs} is the total observation time. Using the design LIGO sensitivity, assuming four months of observation time and a constant spectrum a stochastic background of GWs could be detected at 90% confidence level provided that $h_0^2\, \Omega_{\text{gw}} > 5 \times 10^{-6}$ [19] (the recent analysis of LIGO data [20] sets a 95% confidence level upper limit $h_0^2\, \Omega_{\text{gw}} < 6.5 \times 10^{-5}$), while the advanced-LIGO design sensitivity sets a lower detection limit $\Omega_{\text{gw}} \sim 8 \times 10^{-9}$ [19]. As for the planned, three-arm space-based interferometer LISA, a possible strategy for detecting a stochastic background of gravitational radiation exploits some combinations of the signals from the three spacecraft that are insensitive to any GW signal (the so-called Sagnac combination) [21]. Such combinations therefore provide a calibration channel to measure the instrumental noise power spectrum. However, beside primordial GWs, in the frequency range 0.1–10 mHz an astrophysical background is also expected due to the incoherent superposition of GWs emitted by large populations (both galactic and extra-galactic) of binary systems of compact objects. Such an astrophysical background provides an additional noise contribution for the detection of any primordial gravitational radiation in the LISA frequency band.

In general the intensity and the spectral content of a generic cosmological background of gravitational radiation depends upon the producing mechanism and the underlying theoretical model. However, it is possible to characterize primordial gravitational radiation in terms of both some observational constraints and some model-independent features.

Observational Bounds

There are three main observational bounds that a cosmological background of gravitational radiation must satisfy: the nucleosynthesis bound, the COBE/CMB bound and the pulsar-timing bound.

The *nucleosynthesis bound* [22] is related to the highly-accurate predictions of the standard cosmological model pertaining to the primordial abundances of light elements. Such abundances depend upon the ratio between the number density of neutrons n_{n} and the number density of protons n_{p}. In conditions of thermal equilibrium $n_{\text{n}}/n_{\text{p}} \sim \mathrm{e}^{-\Delta m/T}$, where $\Delta m = m_{\text{n}} - m_{\text{p}} \sim 1.3\,\text{MeV}$. In particular, the process responsible for maintaining thermal equilibrium is $p + e^- \rightleftarrows n + \nu_e$, as long as the corresponding rate Γ is greater than the expansion rate H. When this condition is no longer fulfilled, the ratio $n_{\text{n}}/n_{\text{p}}$ freezes out at a value $\mathrm{e}^{-\Delta m/T_{\text{f}}}$, and this determines the number of neutrons yielding the formation of light elements (mainly He^4). Since the Hubble constant is given by the Friedmann equation $H^2 = 8\pi\, G\, \rho/3$, where the energy density ρ incorporates all the possible contributions at the nucleosynthesis epoch, its value at the freeze-out depends also upon a possible contribution due to a gravitational radiation component of cosmological origin. Hence, a constraint on the value of the freeze-out temperature yields an upper-limit for the energy density associated to any extra-contribution other than standard model particles. Assuming that the only extra contribution is due to cosmological gravitons, the corresponding spectrum must satisfy the following bound [23]

$$\int_0^\infty \mathrm{d}f\, h_0^2 \Omega_{\text{gw}}(f) \lesssim 5 \times 10^{-6} \qquad (4)$$

COBE/CMB bound. On large scales, the spectrum amplitude of a stochastic background of cosmological origin must be compatible with the measurements of the CMB temperature fluctuations. Indeed, at large wavelengths, a stochastic background of gravitational radiation produces a dynamical red-shift on the frequencies of the CMB photons, thus generating fluctuations in their temperature (according to the so-called Sachs–Wolfe effect [24]). Those fluctuations have been measured firstly by the COBE experiment [25] and more recently by WMAP [26]. Since on large scales also density perturbations (inhomogeneities in the matter distribution) generate fluctuations in the CMB temperature, any gravitational wave spectrum must satisfy the following bound [27]

$$h_0^2\, \Omega_{\text{gw}}(f) \lesssim \left(\frac{H_0}{f}\right)^2 \left\langle\frac{\delta T}{T}\right\rangle^2 , \qquad (5)$$

where $\langle \delta T/T \rangle \sim 5 \times 10^{-6}$ is the CMB temperature rms fluctuation (taking only the quadrupole contribution). The frequency range over which the constraint (5) holds corresponds to modes that are currently inside the causal horizon today ($f > 3 \times 10^{-8}\,\text{Hz}$) and were associated to super-horizon scales at the surface of last-scattering ($f < 10^{-16}\,\text{Hz}$). At the maximum frequency ($10^{-16}\,\text{Hz}$) the bound therefore yields an upperlimit for any primordial GW spectrum $h_0^2\, \Omega_{\text{gw}} \lesssim 10^{-14}$. This upperlimit is particularly relevant for gravitational backgrounds produced by the amplification of vacuum fluctuations occurring during a primordial, inflationary era: the corresponding spectra are indeed characterized by a wide frequency window ranging from $f \sim H_0 \sim 3 \times 10^{-18}$ Hz up to GHz values.

Recently, it has been pointed out [28] that since any cosmological background of gravitational radiation behaves as a gas of free-streaming particles, in addition to its effect on the expansion rate at the nucleosynthesis epoch, also the growth of density perturbations is affected. In particular, if the primordial metric perturbations yielding to a background of gravitational radiation are not adiabatic (as occurs for the parametrically amplified perturbations during inflation), then the effects on the CMB photons are different from those associated to adiabatic massless neutrinos. Using the recent WMAP data, this feature allows us to put a constraint on the spectrum of primordial gravitational radiation down to frequencies corresponding to the comoving horizon at decoupling ($f \sim 10^{-15}$ Hz). At those frequencies, the analysis carried out in [28] establishes a current 95% confidence-level upper limit $h_0^2\, \Omega_{\mathrm{gw}} \lesssim 8.4 \times 10^{-6}$, while future CMB experiments (like Planck) could reach sensitivities such that $h_0^2\, \Omega_{\mathrm{gw}} \lesssim 1.4 \times 10^{-6}$ [28].

Pulsar timing bound. A consistent fraction of known pulsars with a period in the range [1.5–30] ms (the so-called millisecond pulsars) are characterized by an extremely stable integrated pulse profile and therefore may be considered as natural clocks. Those astrophysical systems are natural detectors of gravitational radiation: a GW traveling between a detector and a pulsar produces a fluctuation in the arrival time of the pulse proportional to the wave amplitude. For a total observation time T_{obs} and an uncertainty $\Delta\tau_{\mathrm{arr}}$ in the arrival time such detectors would be sensitive to GWs whose amplitude is $h \sim \Delta\tau_{\mathrm{arr}}/T_{\mathrm{obs}}$ at frequencies $f \sim T_{\mathrm{obs}}^{-1}$. The highest sensitivity is reached for continuous signals (like a stochastic background) with observation times of one or two years (corresponding to frequencies $10^{-9} - 10^{-8}$ Hz). The most stringent constraint on a stochastic background of gravitational radiation comes from the analysis of the data concerning PSR B1855+09 [29] which gives the following 95% confidence-level bound at $\bar{f} = 4.4 \times 10^{-9}$ Hz

$$h_0^2\, \Omega_{\mathrm{gw}}(\bar{f}) < 1.0 \times 10^{-8}\,. \tag{6}$$

Characteristic Frequency and Amplitude

Beside the observational constraints discussed above, predictions concerning relic GWs are poorly constrained both because of our lack of knowledge about physics beyond the standard model and because of large uncertainties in the understanding of the various production mechanisms concerning primordial GWs. Nevertheless, it is possible to outline some general features describing the typical frequency and amplitude spectrum of cosmological gravitational radiation (see e. g. [11]).

The typical frequency at which a gravitational signal could be detected can be estimated [11] disentangling the dynamical effects associated with the production mechanism from the kinematical contribution depending on the red-shift associated to the cosmic time at which the signal is produced. Assuming that a graviton is produced at a certain temperature T_{P} with a frequency f_{P} during the epoch where the Universe was either radiation or matter dominated, the frequency at which it could be currently detected is $f_0 = f_{\mathrm{P}}/(1 + z_{\mathrm{P}})$. To compute the red-shift z_{P} one exploits the adiabatic expansion of the universe, i. e. the fact that the entropy per comoving volume $S \propto g_{\mathrm{S}}(T)\, a^3(t)\, T^3$ is conserved (here $a(t)$ is the time-dependent scale factor of the Universe and $g_{\mathrm{S}}(T)$ accounts for the effective number of degrees of freedom at temperature T). The result is ([11,30])

$$f_0 \sim 8 \times 10^{-14}\, f_{\mathrm{P}} \left(\frac{100}{g_{\mathrm{S}}(T_{\mathrm{P}})}\right)^{1/3} \left(\frac{1\,\mathrm{GeV}}{T_{\mathrm{P}}}\right) \tag{7}$$

The dynamics of the production mechanism enters into the estimate of the frequency f_{P}. It is natural to express the wavelength λ_{P} corresponding to such frequency in terms of the horizon scale H_{P}^{-1} at the time of production, i. e. $\lambda_{\mathrm{P}} = \xi H_{\mathrm{P}}^{-1}$, with $\xi \leqslant 1$. Assuming that the gravitational radiation is produced during the era where the energy density is dominated by relativistic radiation, $H_{\mathrm{P}}^2 \propto g(T_{\mathrm{P}})\, T_{\mathrm{P}}^4/M_{\mathrm{pl}}^2$, $g(T_{\mathrm{P}}) \sim g_{\mathrm{S}}(T_{\mathrm{P}})$ (here $g(T_{\mathrm{P}})$ is the number of degrees of freedom at temperature T_{P}). This yields [11]

$$f_0 \sim 1.6 \times 10^{-7}\, \frac{1}{\xi} \left(\frac{100}{g(T_{\mathrm{P}})}\right)^{-1/6} \left(\frac{T_{\mathrm{P}}}{1 GeV}\right) Hz\,. \tag{8}$$

Hence, the physics at TeV scale could be probed by space-borne interferometers like LISA, while earth-based interferometers could investigate phenomena whose typical energy scale is in the range 10^8–10^{10} GeV.

As for the characteristic intensity of primordial gravitational radiation, despite a strong dependence upon the production mechanism, it is still possible to draw some general considerations [11]. When primordial gravitational waves are produced at the Planck scale by collisions and decay together with other relativistic particles that are currently observed (i. e. CMB photons), it is reasonable to assume $\rho_{\text{gw}}(t_{\text{P}}) \sim \rho_{\gamma}(t_{\text{P}})$. In this case, taking into account the different red-shift characterizing photons and gravitons (the latter decoupling just below the Planck scale), the present value for the GW spectrum is estimated to be [30]

$$h_0^2\,\Omega_{\text{gw}} \sim 1.7 \times 10^{-5} \left(\frac{100}{g(T_{\text{P}})}\right)^{1/3} \Omega_{\text{gw}}(t_{\text{P}})\,, \tag{9}$$

where $\Omega_{\text{gw}}(t_{\text{P}})$ is the fraction of energy density produced in GWs. Another possible scenario incorporates all possible mechanisms of primordial production of GWs different from the ones giving rise to CMB photons. Also in this case it is possible to relate the GW spectrum to the CMB spectrum. For instance, one may consider the spectrum of gravitational radiation produced by the amplification of vacuum fluctuations during an inflationary epoch; in particular, it is possible to estimate the spectrum amplitude for a frequency corresponding to the highest curvature scale H_{max} reached during the inflationary phase (see e. g. [11]). The result is

$$h_0^2\,\Omega_{\text{gw}} \sim \left(\frac{H_{\text{max}}}{M_{\text{pl}}}\right)^2 h_0^2\,\Omega_{\gamma}\,, \tag{10}$$

where $h_0^2\,\Omega_{\gamma} \sim 10^{-5}$ is the current fraction (in terms of the critical density) of radiation energy density. Slow-roll inflationary models are characterized by a typical Hubble scale during the acceleration era that cannot exceed a value of about $8 \times 10^{-6}\,M_{\text{pl}}$ (to be consistent with the CMB anisotropy measurements) [31], yielding to an almost constant spectrum in the frequency window $[10^{-16}, 10^{9}]$ Hz $h_0^2\,\Omega_{\text{gw}} \sim 10^{-15}$ [32]. While this is too low to be detected both by earth-based interferometers (even in their advanced configurations) and by LISA (because of the presence of a strong astrophysical background) [33], a space detector sensitive in the frequency band $[0.1, 1]$ Hz (which is almost free from astrophysical backgrounds) could reach the desired sensitivity [34]. Pre-big-bang models [35], string-theory-based cosmological models, are characterized by an inflationary phase where the curvature grows reaching a maximum threshold value $H_{\text{max}} \sim 10^{-1}\,M_{\text{pl}}$. Such a feature in particular produces a stochastic background characterized by a steep-blue spectrum [36] ($\Omega_{\text{gw}} \sim f^3$); the COBE bound is easily satisfied, and, for a certain range of the free parameters of the model, the spectrum can reach a maximum value $h_0^2\,\Omega_{\text{gw}} \sim 10^{-7}$ [37] (compatible with the nucleosynthesis bound) in the frequency range $[10^{-4}, 10^{3}]$ Hz. This signal could be in principle detected by Advanced LIGO.

Production Mechanisms of Relic GWs

The main mechanisms that can produce a primordial stochastic background of gravitational radiation can be divided into two broad classes:

- Parametric amplification of metric tensor perturbations occurring during an early epoch of inflationary expansion;
- Causal process (mainly phase transitions) occurring during the primordial stages of the evolution of the Universe.

Parametric Amplification of Vacuum Fluctuations

In a cosmological model characterized by different dynamical epochs, in each of them any quantum field has different normal modes corresponding to different sets of creation and annihilation operators. Those sets are connected by the so-called Bogoliubov transformations [38] that mix positive frequency modes (i. e. annihilation operators) with negative frequency modes (i. e. creation operators). As a consequence, in an expanding universe, an initial vacuum state (with respect to a certain set of annihilation/creation operators), due to the dynamical evolution of the metric, in a different epoch corresponds to a multi-particle state. The physical idea underlying quantum production of particles in an expanding universe can be qualitatively explained as follows [11]. For the sake of simplicity, let's consider a cosmological model with two different phases (A and B), where the transition between them occurs over a time scale $\Delta\tau \sim H^{-1}(\tau)$. For a mode whose physical frequency at the time of transition is f_τ there exist two alternative regimes: abrupt/sudden transition ($2\pi f_\tau \Delta\tau \ll 1$) or smooth, adiabatic transition ($2\pi f_\tau \Delta\tau \gg 1$). For modes characterized by a sudden transition, while the physical state associated to the field in the phase A has not significantly changed, the corresponding particle number must be evaluated with respect to the set of annihilation and creation operators relative to the phase B. Furthermore, due to the mixing between positive frequency and negative frequency modes, the vacuum state relative to the phase A corresponds to a multi-particle state relative to the phase B. On the other hand, for modes for which the transition is adiabatic, no particle production takes place. Applying this analysis to a cosmological scenario with a primordial phase of accelerated expansion driven by a scalar field, vacuum metric fluctuations are amplified thus producing, in the final decelerating radiation/matter dominated phase a final, multi-graviton phase that gives rise to a stochastic background of gravitational radiation. The corresponding spectrum is given by [11]

$$\Omega_{\mathrm{gw}} = \frac{16\pi^4}{\rho_{\mathrm{c}}} n_{\mathrm{f}} f^4 , \tag{11}$$

where n_{f} is the number of gravitons per cell of phase space. As mentioned before the frequency spectrum of such backgrounds extends over a huge range of frequencies, from $f_{\mathrm{min}} \sim 3 \times 10^{-18}$ Hz (corresponding to a wavelength compatible with the size of our observable universe) up to a maximum frequency in the GHz range (this ultraviolet cut-off is fixed by the maximum curvature attained during the inflationary phase). As for the strength of the spectrum, the predictions are sensitive to the mechanism that produces the inflationary stage (see previous section).

Causal Mechanisms: Phase Transitions

During the cosmological evolution of the Universe, phase transitions corresponding to symmetry breaking of particle physics fundamental interactions are expected to take place. As for the generation of relic GWs, the presence and type of topological defects and the order of the transition are of particular relevance.

Cosmic Strings Cosmic strings are topological defects forming as a consequence of the spontaneous breaking of a global $U(1)$ gauge symmetry [39,40]. They are characterized by a large mass-per-unit-length μ (related to the scale at which the symmetry is broken), a closed shape and a typical length-scale that can be larger or smaller than the Hubble radius $r_{\mathrm{H}} = 1/H$. Since their tension is equal to their mass per unit length, they have relativistic oscillations, therefore shrinking in size and emitting gravitational radiation. Assuming that a multi-scale network of such strings has been formed, loops whose radius is smaller than r_{H} oscillate, radiate away GWs, shrink and eventually disappear, replaced by loops broken off from loops whose radius is larger than r_{H}. The typical scale for the GW spectrum is determined by the loop radius: since in the network loops with different sizes are present, the corresponding (almost Gaussian) spectrum is nearly flat over a frequency range $[10^{-8}, 10^{10}]$ Hz. A simple dimensional analysis shows that the spectrum can be estimated as $\Omega_{\mathrm{gw}} \sim \gamma\mu/M_{\mathrm{pl}}^2$, where γ is a dimensionless parameter encoding the radiation efficiency. Numerical simulations of cosmic strings predict $h_0^2\, \Omega_{\mathrm{gw}} \sim 10^{-9} \div 10^{-8}$ for $\mu/M_{\mathrm{pl}}^2 < 10^{-6}$ [41]. Cosmic strings may also produce intense bursts of gravitational radiation [42]: in particular, the strongest bursts are produced at sections of strings characterized by large Lorentz boosts. Though the analysis of [42] suggests that such bursts could be detected even with the current LIGO design sensitivity, a more recent analysis [43] points out that large-scale earth-based interferometers at current sensitivity (such as LIGO) are unlikely to detect such GW radiation when the string network is characterized by a classical distribution of loop sizes. On the other hand, if the size of the string loops is much smaller than its classical value ($l_{\mathrm{classical}} \sim \gamma\mu t/M_{\mathrm{pl}}^2$) and it is determined by gravitational back-reaction, the burst amplitude is enhanced and those signals could be detectable with the Advanced LIGO design sensitivity [43].

Cosmic strings can also be produced in some classes of inflationary models based upon string theory [44]. Those strings, dubbed cosmic superstrings, have two key features distinguishing them from the usual field-theoretic strings: (a) Due to their probabilistic interaction and to the higher dimensionality of the underlying theory, their reconnection probability p is less than 1 ($10^{-3} < p < 1$ [45], while for field theoretic strings $p = 1$); (b) different kinds of strings can be formed. As well as strong bursts of gravitational radiation, cosmic superstrings can also generate a stochastic background of GWs, as a result of the incoherent superposition of cusp bursts from a strings network. Taking into account various effects, Siemens and collaborators [46] have investigated the detectability of such a background considering a wide range of experiments. In particular, they have found that interferometric GW detectors are sensitive to portions of the parameter space $[p, \mu/M_{\mathrm{pl}}]$, complementary to ones constrained by the various experimental bounds.

First-Order Phase Transitions In a first-order phase transition, the universe is locally trapped into a meta-stable, high-temperature unbroken symmetry phase. Such a meta-stable configuration is separated from the stable vacuum phase by a barrier in the (temperature-dependent) potential describing the order parameter of the transition. At the quantum level, a transition from the meta-stable to the stable vacuum state takes place through tunneling. As a consequence, random nucleation of bubbles occurs, where the configuration inside a generic bubble corresponds to the true vacuum, while outside it is represented by the meta-stable phase. When the temperature drops below a critical threshold, bubbles have enough volume to expand (the latent heat released during the transition is converted into kinetic energy for the bubbles); they approach a velocity close to the speed of light, collide and eventually yield to a universe in the unbroken-symmetry phase. The occurrence of such collisions breaks the bubbles spherical symmetry and GWs (as well as other kinds of radiation) are produced ([15,16,47]). The corresponding GW spectrum is described by two parameters, the bubble nucleation rate per unit volume β and the ratio α between the false vacuum energy density and the radiation energy density released at the critical, transition temperature T_{tr}. Since the gravitational radiation is produced by collision of bubbles, the spectrum is strongly peaked at the frequency characteristic of the collision rate ($2\pi f_{\mathrm{P}} \sim \beta$). A detailed calculation yields [47]

$$f_{\mathrm{P}} \sim 5 \times 10^{-8} \left(\frac{\beta}{H_{\mathrm{tr}}}\right) \left(\frac{T_{\mathrm{tr}}}{1\,\mathrm{GeV}}\right) \left(\frac{g_{\mathrm{tr}}}{100}\right)^{1/6} \mathrm{Hz} \qquad (12)$$

where H_{tr} and g_{tr} are the Hubble parameter and the number of degrees of freedom at the transition temperature T_{tr}. For the electroweak phase transition (EWPT) $\beta/H_{\mathrm{tr}} \sim 10^2 \div 10^3$, $T_{\mathrm{tr}} \sim 100\,\mathrm{GeV}$ and the peak frequency is therefore in the range $10^{-4} \div 5 \times 10^{-3}$ Hz. A calculation of the peak of the spectrum gives [47]

$$h_0^2\, \Omega_{\mathrm{gw}}(f_{\mathrm{P}}) \sim 10^{-6} \xi^2 \frac{\alpha^2}{1+\alpha^2} \frac{v_b^3}{0.24+v_b^3} \left(\frac{H_{\mathrm{tr}}}{\beta}\right)^2 \left(\frac{100}{g_{\mathrm{tr}}}\right)^{1/3} \qquad (13)$$

where ξ is the fraction of latent heat converted into bubble-wall kinetic energy and v_b is the Hubble expansion velocity. If the Higgs mass is larger than the W-masses (as required by current phenomenological constraints), nonperturbative analysis based upon lattice simulations establishes that within the Standard Model the EWPT cannot be first-order. In the class of the minimal supersymmetric extensions of the standard model, provided that the Higgs mass lies in the range 110–115 GeV and the right-handed stop (i. e. the supersymmetric partner of the top quark) has a mass between 105 and 165 GeV, a first-order EWPT can take place. In this case the GWs spectrum is too weak. Within the larger class of non-minimal supersymmetric extensions of the standard model the strength of the transition can be enhanced: in particular, considering a class of models where an additional gauge singlet in the Higgs sector (thus also obtaining a model explaining the observed baryon asymmetry), for the GW spectrum peak values of $h_0^2\, \Omega_{\mathrm{gw}}(f_{\mathrm{p}}) \sim 10^{-15} \div 10^{-10}$ can be reached [48], corresponding to peak frequencies $f_{\mathrm{p}} \sim 10\,\mathrm{mHz}$.

During a first-order phase transition, the onset of turbulent anisotropic eddies induced in the background fluid by the rapid expansion and collision of bubbles may also produce a GW background ([47,48,49,50]). Again within the non-minimal supersymmetric extensions of the standard model there are regions of the parameter space [48] where the GW spectrum can reach peak values $h_0^2\, \Omega_{\mathrm{gw}} \sim 10^{-10}$ for frequencies $f_{\mathrm{P}} \sim 10^{-3}$ Hz. Cosmic turbulence with additional magnetic fields (affecting the turbulent energy spectrum) can also generate a GW background at the end of a first-order phase transition. In [51] a scenario is analyzed where a first-order phase transition occurs before neutrino decoupling (i. e. much later than EWPT); the corresponding GW spectrum presents a peak in the frequency window relevant for the LISA experiment.

Finally, phenomenologically interesting GW spectra can be produced in non-minimal inflationary models (the so-called extended inflation models) where the accelerating phase ends with bubble collision [52]: the peak frequency of the spectrum lies in the frequency range of ground-based detectors. A detailed analysis [53] has shown that in two-field models where one field performs the first-order phase transition and the other drives the accelerating phase by slowly rolling towards the minimum of the potential, if the phase transition takes place well before the end of inflation, the spectrum has a peak in the frequency range $[10, 10^3]$ Hz and can be detectable by large-scale, earth-based interferometers.

Future Directions

The search for primordial gravitational waves is rather challenging both experimentally and theoretically. While so little is known about the earliest evolution of the Universe (thus rendering the predictions for a cosmological background of gravitational waves as mere indications), the experimental effort to detect such a signal is rather challenging. Nevertheless, the development of space-based detectors, combined with the possibility that future CMB experiments could detect the tensor contributions of primordial metric perturbations hopefully will provide some concrete chances to detect primordial gravitational waves.

Article Outline

Glossary

Branes, D-branes Brane – after membrane – is the name given generically to the "solitons" (the non-perturbative states) of Superstring theory. The most important class is that of Dirichlet- or D-branes, which are dynamical hypersurfaces in which the fundamental strings can end. The number of spatial dimensions of the brane is sometimes indicated explicitly (e. g. D3-branes, D7-branes). A D1-brane is also known as a D-string.

Cosmic strings Cosmic strings are non-dissipative linear concentrations of energy that form at phase transitions in the early universe at which axial symmetries are broken. They are extremely long and thin, their length could be many times the size of the observable universe while their thickness is usually subatomic.

Cusps Closed loops of string undergo periodic oscillations, with a period related to the size of the loop. The dynamical equations predict that during each oscillation there may be a few points at which the string instantaneously doubles back on itself, dubbed cusps. In the neighborhood of the cusp, the string velocity approaches the speed of light. Such an event generates an intense pulse of gravitational and other forms of radiation, strongly beamed in the direction of motion of the cusp (like the sound produced by the cracking of a whip).

Deficit angle The spacetime metric around a straight static cosmic string looks like Minkowski space in cylindrical coordinates, except that the azimuthal coordinate has a range smaller than the usual 2π. This means that the spacetime is actually conical with a global deficit angle $\alpha = 8\pi G\mu/c^2$ if μ is the mass per unit length of the string. Pictorially, an angular wedge of width α is removed from the plane orthogonal to the string and the remaining edges identified.

Horizon, cosmological Roughly speaking, the size of the observable universe at any given time. It is the maximum distance light could have traveled since the Big Bang, and therefore the maximum distance over which physical phenomena can be causally correlated, since information cannot travel faster than light.

Goto–Nambu action An Action principle – in the sense of Lagrange – that describes the relativistic motion of an idealized, infinitely thin (Goto–Nambu) cosmic string with no internal structure and whose energy per unit length equals its tension. It is a generalization of the Action for a relativistic point particle, being proportional to the invariant area of the surface swept out in spacetime by the string motion. It provides a very good approximation to the dynamics of a relativistic magnetic flux line whenever the effects of the string core and of massive excitations transverse to the string can be ignored.

Inflation, cosmological A near-exponential expansion of the (extremely smooth) early universe in which quantum fluctuations would have been frozen and blown up to cosmological size, providing the initial inhomogeneities that would later grow, under the effect of gravity, into large scale structures such as galaxies and clusters visible in the universe today.

Kibble mechanism The inevitable formation of cosmic strings, if they are stable, in rapid phase transitions. After a symmetry-breaking phase transition the choice of a minimum depends on random fluctuations, and will be different in different regions. Neighboring regions in different ground states will have defects separating them. Below a critical temperature the field fluctuations are not enough to change between ground states and the domains effectively freeze. In a cosmological context, the typical scale of defects at formation must be smaller than the causal horizon.

Scaling The notion that a single lengthscale characterizes the evolution of a string network, so that it always looks the same (in a statistical sense) when relevant quantities are re-scaled by that lengthscale. A particular case relevant for cosmology is linear scaling, where this scale is the horizon size. A structureless (Goto–Nambu) cosmic string network usually evolves in such a scale-invariant manner, with about 40 strings crossing any horizon volume throughout the history of the universe. The long string network is diluted by the creation of small closed loops which oscillate and decay into a stochastic background of radiation, cosmic rays and gravitational waves.

Superstrings, cosmic Superstring theory is a candidate model for a quantum theory of gravity unified with all other interactions. It is based on the idea that the fundamental constituents of nature are one-dimensional "strings" whose vibrational modes produce all known particles and interactions (the prefix "super" refers to a symmetry between bosonic and fermionic excitations, known as supersymmetry). These fundamental superstrings are not to be confused with cosmic strings, but superstrings can also be cosmic in some particular models, in which case they are known as cosmic superstrings.

VOS model Shorthand for Velocity-dependent One-Scale model, a quantitative and physically simple analytic model for the evolution of Goto–Nambu string networks. Comparison with numerical simulations shows that the model provides an accurate description of the large-scale features of the network through two averaged (macroscopic) quantities, a characteristic length scale (or correlation length) and the root-mean square string velocity.

Worldsheet A point particle's position as a function of time traces a line in spacetime known as a worldline. A one-dimensional object such as a string traces a two-dimensional worldsheet.

Definition of the Subject

Cosmic strings are linear concentrations of energy that form whenever phase transitions in the early universe break axial symmetries, as originally shown by Kibble [31]. They are the result of frustrated order in the quantum fields responsible for elementary particles and their interactions. For about two decades, motivation for their study was provided by the possibility that they could be behind the density inhomogeneities that led to the observed large-scale structures in the universe. Precision observations, particularly of the cosmic microwave background radiation, have limited strings to a sub-dominant role in structure formation. Instead, the inhomogeneities appear to be consistent with a period of cosmological inflation, but it turns out that particle-physics models of the early universe that predict a period of inflation very often also predict the generation of cosmic strings at the end of it [27,28].

More recently, interest has been revived with the realization that there may be strong links between field theory cosmic strings and fundamental strings. The latter are the supposed ultimate building blocks of matter, and in their original context of superstring theory were thought to be microscopic. However, in its modern version – sometimes referred to as M-theory – it is possible and perhaps even mandatory to have macroscopic (cosmological-sized) fundamental strings [37,53]. Their behavior is expected to be quite similar to that of field theory cosmic strings, although there are some important differences so they may in principle be observationally distinguishable. Being relics of the phase transitions that produced them, cosmic strings provide us with a unique window into the early universe. If they are stable and survive for a significant amount of time (possibly even up to the present day), they may leave an imprint in many astrophysical and cosmological observables, and provide us with information on fundamental physics and the very early universe that would otherwise be inaccessible to us. On the other hand, gaining a quantitative understanding of their properties, interactions, evolution and consequences represents a significant challenge because of their intrinsic complexity. Their non-linearity is particularly noteworthy, with highly non-trivial feedback mechanisms between large (cosmological) and small (microscopic) scales affecting the network dynamics. Considerable reliance, therefore, must be placed on numerical simulations, which are technically difficult and computationally costly. A complementary approach is the use of analytic or semi-analytic models, usually to describe the large-scale features of the networks.

The basic picture of the cosmological evolution of string networks that has emerged for the simplest, Goto–Nambu, networks is of a scaling solution with about 40 long strings always stretching across each horizon volume plus a population of loops (other string types can lead to a different behavior). It is then possible to estimate their cosmological implications quantitatively. For example, these strings continuously source gravitational perturbations on sub-horizon scales. The one parameter in these models is the energy scale of the phase transition at which the strings are created. The astrophysical consequences of strings stem from the non-trivial gravitational field around a string [58]. Particles in the vicinity of a static straight string feel no gravitational acceleration, because in general relativity tension is a negative source of gravity and, since tension equals energy per unit length, their effects cancel. The space-time around the string is locally, but not globally, flat. In fact the space is conical, with a deficit angle

$$\alpha = 8\pi \frac{G\mu}{c^2} \,, \tag{1}$$

where μ is the mass per unit length; the simple way to picture this is to imagine a plane in which an angular wedge α has been removed and the edges glued together. For cosmologically interesting strings the deficit angle ranges from a few seconds of arc to a few millionths of a second of arc.

Introduction

To understand the cosmological evolution and effects of cosmic strings we start in this section with a quick summary of basic cosmology concepts that will be needed later and a description of the simplest type of cosmic strings in which the main features are already apparent. But, first, a warning about units: from now on we will set the speed of light to unity, $c = 1$, so we measure distances in light-travel time, and masses in units of Energy (and viceversa, using $E = mc^2$). Boltzmann's constant is set to unity, so temperature is measured in units of mass/energy (using $E = K_B T$). Finally, we set Planck's constant to unity, $\hbar = 1$, and measure all lengths and masses in units of Planck's length and mass/energy: $l_P = 1.62 \times 10^{-35}$ m,

$M_\mathrm{P} = 2.18 \times 10^{-8}\,\mathrm{kg} = 1.22 \times 10^{19}\ \mathrm{GeV/c^2}$. In these units, Newton's constant is given by $G = M_\mathrm{P}^{-2}$.

The early universe is very smooth. To a very good approximation it is a homogeneous and isotropic spacetime described by a single variable: the rate of expansion of its three-dimensional spatial sections. In Einstein's general relativity this spacetime is described by the flat Friedmann–Robertson–Walker (FRW) metric

$$ds^2 = dt^2 - a^2(t)[d\vec{x} \cdot d\vec{x}]\,, \tag{2}$$

where $\vec{x}$ are fixed (comoving) spatial coordinates and $a(t)$ is the scale factor that determines the fractional or *Hubble expansion rate*

$$H(t) = \frac{1}{a(t)} \frac{da}{dt}\,. \tag{3}$$

The time coordinate t is known as cosmological time; to analyze cosmic string evolution we will also need a different time parametrization known as conformal time, τ. They are related by $d\tau = dt/a(t)$, leading to the metric

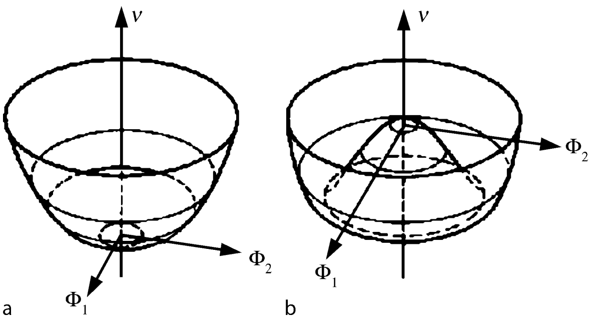
$$ds^2 = a^2(\tau)[d\tau^2 - d\vec{x} \cdot d\vec{x}]\,. \tag{4}$$

The age of the universe is currently estimated to be about 13.7 billion years [55]. The universe starts very hot and dense and is cooled by the expansion, with the temperature decreasing as $T(t) \sim a(t)^{-1}$. The Hubble expansion rate is determined by the energy contents of the universe. In a universe dominated by radiation or very relativistic matter (the hottest, earliest stages), the scale factor evolves as $a(t) \sim t^{1/2}$ and the energy density in radiation as $\rho_\mathrm{radiation} \sim a(t)^{-4} \sim t^{-2}$. The energy density of non-relativistic matter is inversely proportional to volume $\rho_\mathrm{matter} \sim a(t)^{-3}$ and eventually takes over (after about 4000 years), leading to a period of matter domination, during which $a(t) = t^{2/3}$ and therefore $\rho_\mathrm{matter} \sim t^{-2}$. More recently – about five billion years ago – we have entered an epoch of accelerated expansion due possibly to a cosmological constant or some unknown form of *dark energy* whose energy density is constant in time $\rho_\mathrm{dark\ energy} \sim$ const. Dark energy should not be confused with dark matter, an unknown form of matter whose presence we can detect through its gravitational effects but that does not interact with electromagnetic fields and so in particular does not emit light – hence the adjective "dark"–. In the currently accepted cosmological model the energy density in the universe today would be dominated by dark energy (about 74%), followed by about 22% dark matter and only about 4% of regular (baryonic) matter [55]. Dark matter is widely believed to be a particle still to be discovered.

The universe today is far from smooth, but the structure we observe on the scale of clusters of galaxies is consistent with the gravitational collapse of tiny primordial density inhomogeneities $\delta\rho/\rho \sim 10^{-5}$ at the time the cosmic microwave background (CMB) radiation was emitted. The CMB is the oldest radiation we observe, dating back to the time when the universe was only about 380 000 years old. At this epoch the primordial plasma cooled enough to allow the formation of the first atoms (a process known as recombination), and it became transparent to photons (which is referred to as decoupling). Before that moment, the photons behave like a fluid that is strongly coupled to the protons and electrons. An overdense region in the baryon fluid would like to contract but the photon pressure pushes it back, causing both fluids to oscillate. These oscillations are imprinted in the cosmic microwave background and can be detected today in the form of Doppler peaks in its power spectrum.

The spectrum of density inhomogeneities has been accurately measured in the CMB and found to be near scale-invariant and of the right magnitude to produce the structure we observe. The perturbations to the FRW metric can be classified as *scalar* (overall changes to the Newtonian gravitational potential), *vector* (associated with velocity and/or rotational effects) and *tensor* (transverse traceless perturbations to the spatial metric, such as gravitational waves). Each of these affects the CMB in different ways, so their relative contributions can in principle be observationally distinguished. Finally, Thomson scattering of the anisotropic distribution of the CMB photons is particularly important during decoupling and recombination, and induces a partial linear polarization of the scattered radiation, at a level that is around ten percent of the anisotropy. Detection of this polarization signal is at the borderline of the sensitivity of ongoing experiments at the time of writing, but is expected to become standard with forthcoming experiments.

The energy density of a network of cosmic strings in the linear scaling regime is $\rho_\mathrm{strings} \sim t^{-2}$ and therefore it remains a constant fraction of the dominant form of energy during matter or radiation domination. Numerical estimates for the simplest, Goto–Nambu, networks suggest the fraction is around $100G\mu$. Provided the string mass is not close to the Planck scale, this is small enough not to disturb the cosmological evolution; at the same time, for a broad range of values of $G\mu$ this is large enough to be detectable in precision experiments today. Other string types (see Sect. "Field Theory Strings with More Degrees of Freedom") may have larger or smaller fractions or qualitatively different signatures. In particular, networks that do not reach linear scaling may come to dominate



Cosmic Strings, Figure 1
The effective potential energy *V* for a simple string-forming field theory model. The a and b plots correspond to the high and low temperature configurations, respectively. For simplicity the complex field $\mathbf{\Phi}$ has been split into two real scalar fields, $\mathbf{\Phi}_1$ and $\mathbf{\Phi}_2$

the energy density (which rules them out) or to disappear completely.

The simplest field theory model that produces cosmic strings has a single complex scalar field $\mathbf{\Phi}$ (this is shorthand for a function $\mathbf{\Phi}(t,\vec{x})$ with complex values that do not change under coordinate transformations). Let us assume that the Hamiltonian determining the field dynamics is invariant under an axial symmetry such as a phase rotation, $\mathbf{\Phi} \to \mathbf{\Phi}\mathrm{e}^{i\theta}$. For example, take the potential energy

$$\int \mathrm{d}^3x\, V = \int \mathrm{d}^3x \frac{\lambda}{2}\left(|\mathbf{\Phi}|^2 - \eta^2\right)^2 \tag{5}$$

where λ is a dimensionless coupling constant and η is an energy scale related to the temperature of the symmetry-breaking transition. This has a set of degenerate ground states: the minimum of the potential in field space is the circle $|\mathbf{\Phi}| = \eta$, known as the *vacuum manifold*. Any configuration $\mathbf{\Phi}(t,\vec{x}) = \text{const.} = \eta\mathrm{e}^{i\chi}$ with χ real and constant is a possible ground state or *vacuum*, irrespective of the value of the phase χ.

Figure 1 illustrates what happens. At high temperature the field fluctuations are large enough to make the central peak around $|\mathbf{\Phi}| = 0$ irrelevant, and the effective potential is symmetric and has a minimum there. As the temperature falls the energy will eventually be too low to permit fluctuations over the peak, at which point the field will tend to settle towards one of the ground states. The random choice of minimum in this condensation process then breaks the original axial symmetry. This is the case, for instance, in superfluid ^{4}He.

When a large system goes through a phase transition like this, each part of it has to make this random choice, which need not be the same everywhere. The minimization of gradient terms in the energy of the system tends to make it evolve towards increasingly more uniform configurations, but causality (the principle that no information can travel faster than light) imposes that this evolution can only happen at a limited rate. As a result one expects many domains, each with an uncorrelated choice of ground state. Where these domains meet there is some probability of forming linear defects – cosmic strings – around which the phase angle varies by 2π (or possibly multiples thereof). This is the Kibble mechanism. Notice that the field vanishes at the string's core, so there is trapped potential energy (as well as gradient energy). These strings are known as *global* strings because the axial symmetry that is broken below the phase transition is "global", that is, the transformation $\mathbf{\Phi} \to \mathbf{\Phi}\mathrm{e}^{i\theta}$ is independent of position.

The next step is to consider charged scalar fields interacting with an electromagnetic field. The best known example of a symmetry–breaking transition of this kind is the condensation of Cooper pairs in a superconductor, that has the effect of making photons massive below the critical temperature (in this case the axial symmetry is of the "local" of "gauge" type). The cosmic strings that result are magnetic flux tubes that do not dissipate because the magnetic field is massive outside the string core.

This type of vortex was first discussed by Abrikosov [1] in the context of type II superconductors. Nielsen and Olesen [45] generalized these ideas to the relativistic quantum field theory models used in particle physics, in particular the Abelian Higgs model which is a relativistic version of the Landau–Ginzburg model of superconductivity, governed by the action

$$S = \int \mathrm{d}^4x \left[|\partial_\mu \mathbf{\Phi} - iqA_\mu \mathbf{\Phi}|^2 - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} \right. \\ \left. - \frac{\lambda}{2}(|\mathbf{\Phi}|^2 - \eta^2)^2 \right] . \tag{6}$$

A_μ is the gauge field and $\mathbf{\Phi}$ is a complex scalar of charge $q\,(q = 2e$ in superconductors, where $\mathbf{\Phi}$ is the Cooper pair wavefunction). The second term is the usual Maxwell action for the electromagnetic field, $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$. The energy per unit length of a straight, static string lying on the z-axis is

$$E = \int \mathrm{d}^2x \left[|\partial_x \mathbf{\Phi} - iqA_x \mathbf{\Phi}|^2 + |\partial_y \mathbf{\Phi} - iqA_y \mathbf{\Phi}|^2 \right. \\ \left. + \frac{1}{2}B^2 + \frac{\lambda}{2}(|\mathbf{\Phi}|^2 - \eta^2)^2 \right] \tag{7}$$

where $B = \partial_x A_y - \partial_y A_x$ is the z-component of the magnetic field. Finite energy configurations must have $|\mathbf{\Phi}| = \eta$

(the *vacuum manifold* is still a circle) but the phase of $\mathbf{\Phi}$ is undetermined provided the gradient terms and the magnetic field go to zero fast enough. This condition allows for finite energy solutions $A_t = A_r = A_z = 0$, $\mathbf{\Phi}(r,\theta) \sim \eta e^{in\theta}$, $A_\theta(r,\theta) \sim n/(qr)$, as $r \to \infty$, in which the total magnetic flux in the plane perpendicular to the string is quantized,

$$\int \mathrm{d}^2 x B = \oint \vec{A} \cdot \vec{\mathrm{d}} l = \frac{2\pi n}{q}$$

and n is the winding number of the string. If the constants λ and q are such that fluctuations in the scalar field $\mathbf{\Phi}$ and the gauge field A_μ have equal masses, it is possible to show that the string saturates an inequality of the form

$$\text{Energy per unit length} \geq \text{constant x} \mid \text{magnetic flux}|$$

known as the Bogomolnyi bound [7]. In this case, parallel strings at close range exert no force on each other and there are static multivortex solutions [56]. If the mass of the scalar excitations is lower (higher) than that of the gauge excitations, parallel strings will attract (repel).

More complicated particle physics models – in particular those describing the early universe – involve gauge symmetries that generalize the electromagnetic interaction, mediated by photons, to more complicated interactions such as the electroweak or Grand Unified (GUT) interactions. The messenger fields that play the role of the photons may be massless in the early universe and become massive following a symmetry-breaking transition, and cosmic strings carry the magnetic flux of these other massive gauge fields (not the electromagnetic field).

From a cosmological point of view, the gauge field has the important effect of making the gradient terms decay exponentially fast away from the string so the energy per unit length of these strings is finite. Abrikosov–Nielsen–Olesen strings have no long-range interactions, so their evolution is dominated by their tension and is well described in the thin string or Goto–Nambu approximation.

Field continuity implies that a string of this kind cannot simply come to an end: it must form a closed loop or extend to infinity, and it cannot break into segments. For this reason, strings, once formed, are hard to eliminate. In the absence of energy loss mechanisms, the strings would eventually dominate the energy density of the universe. On the other hand, the strings can decay into radiation, they may cross and exchange partners, and they may also cross themselves, forming a closed loop which may shrink and eventually disappear. The outcome of these competing mechanisms is that the network is expected to reach a scale-invariant (or *scaling*) regime, where the network's characteristic length scale is proportional to the size of the horizon. We will discuss string evolution in more detail in Sect. "String Evolution". If a random tangle of strings was formed in the early universe, there would always be some strings longer than the horizon, so a few would remain even today. Because cosmological phase transitions typically happen in the very early universe, cosmic strings contain a lot of trapped energy, and can therefore significantly perturb the matter distribution. To first order there is a single parameter quantifying the effects of strings, its energy per unit length. In the simple relativistic strings, the mass per unit length and the string tension are equal, because of Lorentz invariance under boosts along the direction of the string (but this need not be true for more elaborate models, see Sect. "Field Theory Strings with More Degrees of Freedom"). Cosmic strings are exceedingly thin, but very massive. Typically, for strings produced around the epoch of grand unification, the mass per unit length would be of order $\mu \sim 10^{21}$ kg m^{-1} and their thickness 10^{-24} m. The gravitational effects of strings are effectively governed by the dimensionless parameter $G\mu$, where G is Newton's constant. For GUT-scale strings, this is 10^{-6}, while for electroweak-scale strings it is 10^{-34}.

String Formation

Spontaneous symmetry breaking is a ubiquitous feature of our theories of fundamental particle interactions. Cosmic strings are formed in many symmetry-breaking phase transitions. If the symmetry is broken from a group G down to a subgroup H, the set of degenerate vacuum or ground states is the manifold $M = G/H$, and the topology of this manifold determines the types of defect that can form. In our previous examples M was a circle; in general, strings can form if M contains closed curves that cannot be contracted within M (the technical term is that M is not simply connected, or that its first homotopy group is nontrivial) [31].

The Kibble mechanism described in Sect. "Introduction" relates the initial density of strings to the size ξ of the domains over which the field is correlated,

$$\rho_{\text{string}} \sim C \frac{1}{\xi^2}$$

with C a constant of order one reflecting the probability that a string forms when three or more domains meet. The correlation length cannot grow faster than the speed of light so in the early universe an obvious upper bound on ξ is the size of the horizon at the time of the phase transition. If the dynamics of the phase transition is known, ξ can be estimated more accurately. In a first order phase transition ξ is given by the typical distance between bubble nucleation sites, which depends on the nucleation rate. In second order phase transitions ξ depends on the critical exponents and the rate of cooling through the critical temperature, T_c, as shown by Zurek [65].

Vortex lines or topological strings can therefore appear in a wide range of physical contexts, from cosmic strings in the early universe through disclinations in room-temperature nematic liquid crystals, to magnetic flux tubes in some superconductors and vortex lines in low-temperature superfluid helium. These systems provide us with a range of opportunities to test aspects of the cosmic string formation and evolution scenario experimentally.

The Kibble mechanism in first order transitions was confirmed in experiments on nematic liquid crystals [15,16]. The Kibble–Zurek scenario for second order transitions has been experimentally verified in Superfluid ^{3}He [11,50] and in Josephson Tunneling Junction arrays [41].

The ^{3}He experiments in a rotating cryostat in Helsinki also confirmed the scale invariance of the initial distribution of loops, $n(R) \sim R^{-4}$, where $n(R)\mathrm{d}R$ is the number density of loops with radii between R and $R + \mathrm{d}R$, as predicted by Vachaspati and Vilenkin [61].

More recently, the formation of a defect network following the annihilation of ^{3}He–A / ^{3}He–B boundary layers has been observed [14]. The precise type of defects is still under investigation but this system constitutes an interesting analogue to the formation of strings from the annihilation of branes in brane inflation scenarios.

There are also a few systems where the string density disagrees with the Kibble–Zurek predictions. In ^{4}He, [21] the reasons are understood: the strings are fuzzy and the network does not survive long enough to be detected [36]. In the case of superconducting films the results are somewhat inconclusive [40] and also it is not completely clear what the expected density of flux quanta should be after a temperature quench; an alternative formation mechanism with different vortex clustering properties has been proposed in [24]. In fact the formation of defects in systems with gauge fields is clearly very relevant to cosmology but is still not completely understood (see Kibble [33] for a recent discussion).

String Evolution

The motion of a cosmic string with worldsheet coordinates σ^a and background space-time coordinates x^μ in a metric $g_{\mu\nu}$ is obtainable from a variational principle applied to the Goto–Nambu action [22,43] ($a = 0, 1; \mu = 0, 1, 2, 3$)

$$S = \mu \times \text{Area} = \mu \int \mathrm{d}\tau\, \mathrm{d}\sigma |\det g_{ab}|^2$$
$$= \mu \int \mathrm{d}\tau\, \mathrm{d}\sigma \left| \det \begin{pmatrix} \dot{x}^\rho \dot{x}^\nu g_{\rho\nu} & \dot{x}^\rho x^{\nu\prime} g_{\rho\nu} \\ x^{\rho\prime} \dot{x}^\nu g_{\rho\nu} & x^{\rho\prime} x^{\nu\prime} g_{\rho\nu} \end{pmatrix} \right|^{\frac{1}{2}} \qquad (8)$$

where μ is again the string mass per unit length, and with dots and primes respectively denoting derivatives with respect to the time-like (σ^0) and space-like ($\sigma^1 = \sigma$) coordinates on the worldsheet. g_{ab} is called the induced metric. We are interested in strings in a FRW background spacetime (see Eq. (4)) and can choose worldsheet coordinates that make the induced metric diagonal

$$\sigma^0 = \tau\,, \quad \dot{\mathbf{x}} \cdot \mathbf{x}' = 0\,, \qquad (9)$$

The choice of conformal time coordinate simplifies the microscopic evolution equations, although as we shall see later on physical time is a more natural choice for the macroscopic evolution (see Sect. "Introduction" for definitions of the two time choices). It is also useful to define the coordinate energy per unit σ,

$$\epsilon^2 = \frac{\mathbf{x}'^2}{1 - \dot{\mathbf{x}}^2}\,. \qquad (10)$$

Then the usual variational techniques can be used to show that the microscopic string equations of motion are

$$\ddot{\mathbf{x}} + 2\frac{\dot{a}}{a}\dot{\mathbf{x}}(1 - \dot{\mathbf{x}}^2) = \frac{1}{\epsilon}\left(\frac{\mathbf{x}'}{\epsilon}\right)' \qquad (11)$$

and

$$\dot{\epsilon} + 2\epsilon\frac{\dot{a}}{a}\dot{\mathbf{x}}^2 = 0\,. \qquad (12)$$

For simplicity we are neglecting effects such as cusps and a frictional force due to particle scattering (which for heavy strings is only relevant during a transient period very early in the network's evolution). The first one is just a wave equation with a particular damping term (provided by the expansion of the universe). The damping also has the effect of reducing the coordinate energy per unit σ.

As was mentioned earlier the expansion of the universe stretches the strings, so in the absence of energy loss mechanisms their energy would grow with the scale factor and the string network would eventually become the dominant component of the universe's energy density – which would be in conflict with observational results. Such decay mechanisms do exist (at least for the simplest models), being ultimately due to radiation losses and to the fact that whenever strings interact they will reconnect [42,51]. In particular closed loops may be formed, and these subsequently oscillate and eventually decay. This decay is thought to be mainly into gravitational radiation, but other forms of radiation are also produced very efficiently.

Provided the decay rate is high enough, the network will not have pathological consequences, but will instead reach a linear scaling solution, where the string density is a constant fraction of the background density and on large scales the network looks the same (in a statistical sense) at all times. Scaling is in fact an attractor solution, as has been shown both using numerical simulations and analytic models. Physically, the reason for this is that if one has a high density of strings then the number of string interactions increases and therefore loop production becomes more efficient and the decay rate increases. Conversely if the density is too low then there are few interactions and the decay rate is correspondingly lower. Numerical simulations confirm this broad picture, but also reveal that string evolution is a complex non-linear process, involving non-trivial interactions between various different scales.

There have been thus far two generations of numerical simulations of Goto–Nambu cosmic string networks in expanding universes. The first (Albrecht and Turok [2], Bennett and Bouchet [9], Allen and Shellard [3]) dates from around 1990, at the peak of the interest in cosmic strings as possible seeds for the large-scale structures we observe today. In the last few years, the renewed interest in strings in the context of models with extra dimensions led to a second generation of simulations (Martins and Shellard [39], Ringeval et al. [49], Olum and Vanchurin [46]), which build upon previous knowledge and exploit the dramatic improvements in hardware and software in the intervening decade and a half to achieve a much higher resolution.

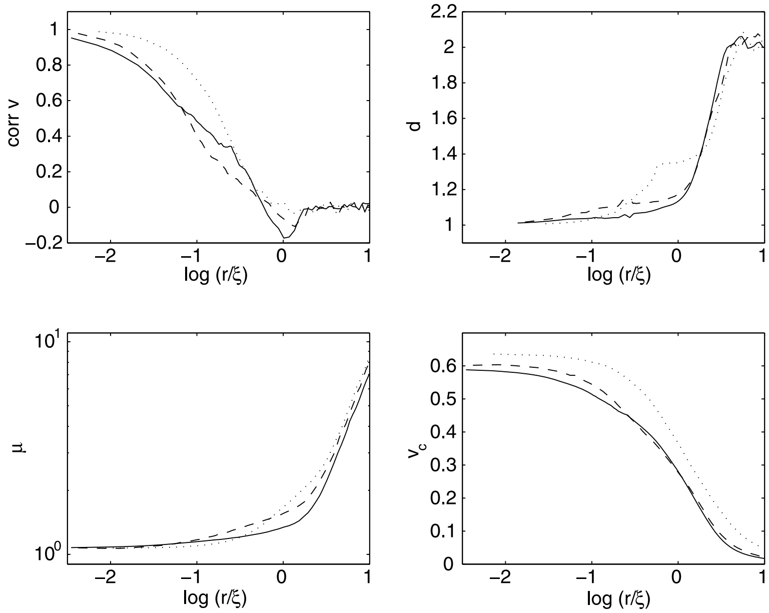
A different approach is provided by full field theory simulations [62]. These are closer to the microphysics of the defects and provide important information on the interactions of the defects and their energy loss mechanisms, but their shorter dynamic range means that they are not optimal for understanding the non-linear feedback mechanisms between widely different scales which affect the dynamics of the network. From this point of view they play a very important role as calibrators, both for Goto–Nambu simulations and for analytic models. One can also carry out Minkowski space simulations (either of Goto–Nambu or field theory type). Neglecting the expansion of the universe is numerically desirable, since such simulations are much easier to implement and evolve much faster. However, the expansion plays a non-trivial role in the network dynamics, so these results should not be naively extrapolated to realistic cosmological scenarios.

Initial conditions for the numerical simulations are usually set up using the Vachaspati–Vilenkin algorithm [61]. One often adds to it random initial velocities, since these tend to enhance the rate of relaxation. All simulations agree on the broad, large-scale features of string networks, and in particular on the fact that the linear scaling solution is an attractor for the evolution. In Goto–Nambu simulations, the initial fraction of the total energy in the form of closed loops is around 20%, but in the linear scaling regime this fraction is around 50% or even slightly more. On the other hand, in field theory simulations this fraction tends to be somewhat smaller.

The first-generation simulations suggested a dynamical picture where the long-string network lost energy to large, long-lived loops, with sizes of order the correlation length. Refinements had each loop self-intersecting into around 10 daughter loops, but loop production from the long strings was essentially monochromatic. The second-generation simulations, however, reveal a quite different picture. Large loops do self-intersect (and indeed the number of daughter loops produced by each one seems to be around 20), but there is also a direct production of large quantities of small loops from slowly moving long-strings with fractal-like substructure. In other words, the loop production is in fact bi-modal. All three second-generation simulations agree on this broad picture, though not on which of the two loop production scales is dominant.

The second-generation simulations present some tentative evidence for the scaling of small-scale features of the network. An open question is whether or not this is expected to happen, given that gravitational backreaction (which would provide a characteristic scale) is not included in any of the network simulations carried out to date. One possible explanation stems from the fact that large loops are not scaled up versions of small loops. Indeed, small loops tend to be nearly circular, whereas large loops are not only far from circular but even far from planar. In other words, the self-intersection probability for a given loop depends on its size, and this may be sufficient to dynamically select a preferred scale. Incidentally, the loop fragmentation processes in these networks highlight the fact that there is a steady flow of energy from large to small scales which is entirely analogous to a Richardson cascade in turbulence. (In this case energy enters via long strings falling inside the horizon, and leaves via radiative decays.)

Figure 2 shows some relevant quantities characterizing Goto–Nambu string networks in the linear scaling regime. These are always plotted as a function of relative scale, to the network's correlation length. The top left panel shows the correlation function for the velocity vectors. A first striking feature is that in the expanding universe cosmic string velocities are anti-correlated on scales around the



Cosmic Strings, Figure 2
Characteristic small-scale properties of cosmic string networks in the linear scaling regime, for matter (*solid lines*), radiation (*dashed*) and Minkowski spacetime (*dotted*) runs. In all plots the horizontal axis represents the logarithm of the physical lengthscale relative to the correlation length of the network. The simulations leading to these results are described in [39]. Top panels show the correlation function for the velocity vectors and the fractal dimension, *bottom panels* show coarse-grained mass per unit length and coherent velocity. The plotted quantities are described in the main text

correlation length (which is smaller than but comparable to the causal horizon), but such a feature is not present in Minkowski space. This anti-correlation is the result of a 'memory' of the network for recent reconnection events, and it is ultimately due to the damping effect of expansion. The top right panel depicts the fractal dimension of the network: this interpolates between $d = 1$ (straight segments) on small scales and $d = 2$ (Brownian network) on large scales, but it does so in a non-trivial way (which is again different depending on whether or not there is expansion) and over a wide range of scales. The fractal dimension evolves with time, decaying on any given physical scale: the strings continually become smoother on any scale, so as to minimize energy. Finally, the bottom panels show the renormalized (or 'coarse-grained') string mass per unit length on the left, and the corresponding coherent velocity on the right panel – notice that the effect of expansion is to reduce the velocities on any given scale.

The technical difficulty and computational cost of numerical simulation provide strong motivation for alternative analytic approaches, which essentially abandon the detailed statistical physics of the string network to concentrate on its thermodynamics. The best example is the velocity-dependent one-scale (VOS) model [38], which builds on previous work by Kibble and Bennett [8,32] and has demonstrated quantitative success when compared with both field theory and Goto–Nambu numerical simulations. The 'one-scale' assumption is that the network has a single characteristic lengthscale, which coincides with the string correlation length and the string curvature radius. This is an approximation which can be tested numerically.

The first assumption in this analysis is to localize the string so that we can treat it as a one-dimensional line-like object. This is clearly a good assumption for gauged strings, such as magnetic flux lines, but may seem more questionable for strings possessing long-range interactions, such as global strings or superfluid vortex lines. However, good agreement between the VOS model and simulations has been found in both cases. The second step is to average the microscopic string equations of motion to derive the key evolution equations for suitable macroscopic quantities, specifically its energy E and RMS velocity v defined by

$$E = \mu a(\tau) \int \epsilon \, d\sigma \, , \quad v^2 = \langle \dot{\mathbf{x}}^2 \rangle = \frac{\int \dot{\mathbf{x}}^2 \epsilon \, d\sigma}{\int \epsilon \, d\sigma} \, . \tag{13}$$

Notice that the energy is an 'extensive' quantity but the RMS velocity is an averaged quantity (and the averaging is weighted by the coordinate energy ϵ). In keeping with the above coordinate choices, the microscopic quantities (on the right-hand side of both equations) are defined in terms of conformal time, but it turns out that the macroscopic evolution that we are now considering is best described in terms of physical time – please refer to the cosmology review for the explicit relation between the two.

Any string network divides fairly neatly into two distinct populations, *viz.* long (or 'infinite') strings and small closed loops. In the following we will focus on the long strings. The long string network is a Brownian random walk on large scales and can be characterized by a correlation length L, which can be used to replace the energy $E = \rho V$ in long strings in our averaged description, that is,

$$\rho \equiv \frac{\mu}{L^2} \,. \tag{14}$$

A phenomenological term must then be included to account for the loss of energy from long strings by the production of loops, which are much smaller than L. A *loop chopping efficiency* parameter $\tilde{c}$ is introduced to characterize this loop production as

$$\left(\frac{\mathrm{d}\rho}{\mathrm{d}t}\right)_{\text{to loops}} = \tilde{c}v\frac{\rho}{L} \,. \tag{15}$$

In this approximation, we would expect the loop parameter $\tilde{c}$ to be a constant; comparison with numerical simulations suggests $\tilde{c} \sim 0.23$.

From the microscopic string equations of motion, one can then average to derive the evolution equation for the correlation length L,

$$2\frac{\mathrm{d}L}{\mathrm{d}t} = 2HL(1+v^2) + \tilde{c}v \,, \tag{16}$$

where H is the Hubble expansion rate defined in Eq. (3). The first term in (16) is due to the stretching of the network by the Hubble expansion which is modulated by the redshifting of the string velocity, while the second is the loop production term. One can also derive an evolution equation for the long string velocity with only a little more than Newton's second law

$$\frac{\mathrm{d}v}{\mathrm{d}t} = \left(1-v^2\right)\left(\frac{k(v)}{L} - 2Hv\right) \,. \tag{17}$$

The first term is the acceleration due to the curvature of the strings and the second is the damping term from the Hubble expansion. Note that strictly speaking it is the curvature radius R which should appear in the denominator of the first term. In the present context we are identifying $R = L$. The function $k(v)$ is the *momentum parameter*, defined by

$$k(v) \equiv \frac{\langle(1-\dot{\mathbf{x}}^2)(\dot{\mathbf{x}}\cdot\mathbf{u})\rangle}{v(1-v^2)} \,, \tag{18}$$

with $\dot{\mathbf{x}}$ the microscopic string velocity and $\mathbf{u}$ a unit vector parallel to the curvature radius vector. For most relativistic regimes relevant to cosmic strings it is sufficient to define it as follows:

$$k_{\mathrm{r}}(v) = \frac{2\sqrt{2}}{\pi}\frac{1-8v^6}{1+8v^6} \,, \tag{19}$$

while in the opposite case ($v \to 0$), we have the non-relativistic limit $k_0 = 2\sqrt{2}/\pi$.

Scale-invariant attractor solutions of the form $L \propto t$ (or $L \propto H^{-1}$) together with $v =$ const., only appear to exist when the scale factor is a power law of the form

$$a(t) \propto t^{\beta} \,, \quad 0 < \beta = \text{const.} < 1 \,. \tag{20}$$

This condition implies that

$$L \propto t \propto H^{-1} \,, \tag{21}$$

with the proportionality factors dependent on the expansion rate β. It is useful to introduce the following parameters to describe the relative correlation length and density, defining them respectively as

$$L = \gamma t \,, \quad \zeta \equiv \gamma^{-2} = \rho t^2/\mu \,. \tag{22}$$

By looking for stable fixed points in the VOS equations, we can express the actual scaling solutions in the following implicit form:

$$\gamma^2 = \frac{k(k+\tilde{c})}{4\beta(1-\beta)} \,, \quad v^2 = \frac{k(1-\beta)}{\beta(k+\tilde{c})} \,, \tag{23}$$

where k is the constant value of $k(v)$ given by solving the second (implicit) equation for the velocity. It is easy to verify numerically that this solution is well-behaved and stable for all realistic parameter values.

If the scale factor is not a power law, then simple scale-invariant solutions like (23) do not exist. Physically this happens because the network dynamics are unable to adapt rapidly enough to the changes in the background cosmology. An example of this is the transition between the radiation and matter-dominated eras. Indeed, since this relaxation to a changing expansion rate is rather slow, realistic cosmic string networks are strictly speaking *never* in scaling during the matter-dominated era. Another example is the onset of dark energy domination around the present day. In this case, the network is gradually slowed down by the accelerated expansion, and asymptotically it becomes frozen in comoving coordinates. The corresponding scaling laws for the correlation length and velocity are $L \propto a$ and $v \propto a^{-1}$.

Despite its success in describing the large-scale features of string networks, the VOS model has the shortcoming of not being able to account for the small-scale features developing on the strings as the network evolves, as clearly shown by numerical simulations. This small-scale structure is in the form of wiggles and kinks, and can be phenomenologically characterized by its fractal properties, as we have sketched above. As a first analytic simplification, the string wiggles can be characterized through a renormalized string mass per unit length that is larger than the bare (Goto–Nambu) mass. This effectively corresponds to considering a model with a non-trivial equation of state (the relation between the string tension and the mass per unit length), which turns out to be one among a larger class of models known as elastic string models. This kind of description has interesting parallels with the coarse-graining approaches that are typical of condensed matter.

A more radical approach is to explicitly abandon the one-scale assumption. This is done in the three-scale model [6], which distinguishes between the characteristic lengthscale (which is simply a measure of the total string energy in a given volume) and the persistence length (which is defined in terms of the invariant length along the string and corresponds to the correlation length or inter-string distance). Additionally there is a third lengthscale which approximately describes a typical scale of the small-scale wiggles. This kind of description is in principle highly flexible, though this can be considered a blessing and a curse. The downside is that one is forced to introduce a large number of (almost free) phenomenological parameters over which one has limited control even when comparing the model with simulations.

Having said that, the three-scale model does confirm, at least qualitatively, the expectations for the behavior of string networks. Scaling of the large scales (in this case the characteristic and persistence lengths) is found to be an attractor, just as in the VOS model. Depending on the behavior of small-scale structures, the two large length scales may reach scaling simultaneously or the former may do so before the latter – a behavior that has been seen in numerical simulations. As for the behavior of the small-scale structures, their evolution timescale is typically slower, and generically they only reach scaling due to the effects of gravitational backreaction (not included in numerical simulations). In the absence of gravitational backreaction, scaling of the small-scale characteristic length is contingent on the removal of a sufficiently large amount of small-scale structure from the long strings by radiation and loop production, which in the model is controlled by a parameter whose detailed behavior is not known.

Finally, an interesting and rather different approach starts out with the assumption that there is a range of scales where stretching due to the expansion is the dominant dynamical effect, even on scales well below the cosmological horizon. A sufficient condition for this is that one is assuming that the rate of string intercommutations is fixed in horizon units. This turns out to be sufficient to allow the construction of a statistical-type description based on two-point correlation functions [48]. Their results are to a first approximation dependent on a critical exponent which physically is related to the coherent string velocity on a given scale. Comparison with numerical simulations shows, as expected, that the best agreement is found around and just below the horizon scale.

A second assumption is that loop production at those scales is sufficiently localized to be describable as a perturbation. When loop production is thus folded into the analysis, the picture that ultimately emerges is of a complicated fragmentation cascade. In particular, this model provides supporting evidence for the two-population loop distribution picture outlined above and clearly seen in high-resolution simulations. There is a population of correlation-length sized loops, produced by direct long-string intercommutation, and a second population with sizes a few orders of magnitude below (quite possibly near the gravitational backreaction scale) and due to loop fragmentation. Whether or not the smoothing provided by gravitational radiation is necessary to yield scaling of the loop sizes is again not entirely clear at the moment, but it is in principle a question for which this formalism could provide an answer.

Astrophysical and Cosmological Consequences

As was mentioned in Sect. "Definition of the Subject", the spacetime around a straight cosmic string is flat. A string lying along the z-direction has an equation of state $p_z = -\rho$, $p_x = p_y = 0$ and therefore there is no source term in the relativistic version of the Poisson equation for the Newtonian gravitational potential

$$\nabla^2 \phi = 4\pi G(\rho + p_x + p_y + p_z) = 0 \,. \qquad (24)$$

A straight string exhibits no analogue of the Newtonian pull of gravity on any surrounding matter. However, this does not mean the string has no gravitational impact at all. On the contrary, we will see that a moving string has dramatic effects on nearby matter or propagating microwave background photons. It is not difficult to derive the spacetime metric about such a straight static string [58]. It has the simple form

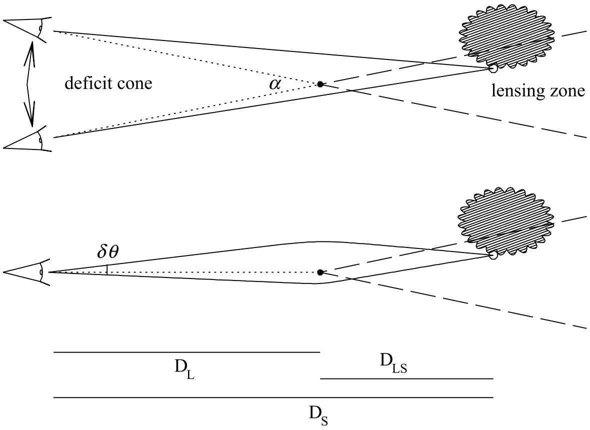
$$\mathrm{d}s^2 = \mathrm{d}t^2 - \mathrm{d}z^2 - \mathrm{d}r^2 - r^2\,\mathrm{d}\theta^2 \,, \tag{25}$$

which looks like Minkowski space in cylindrical coordinates, except for the fact that the azimuthal coordinate θ has a restricted range $0 \le \theta \le 2\pi(1 - 4G\mu)$. That is, the spacetime is actually conical with a global deficit angle

$$\alpha = 8\pi G\mu \,, \tag{26}$$

where an angular wedge of width α is removed and the remaining edges identified.

This deficit angle implies that the string acts as a cylindrical gravitational lens, creating double images of sources behind the string (such as distant galaxies), with a typical angular separation $\delta\theta$ of order α and no distortion [60]. This is illustrated in Fig. 3. A long string would yield a distinctive lensing pattern. We should expect to see an approximately linear array of lensed pairs, each separated in the transverse direction. In each lensing event the two images would be identical and have essentially the same magnitude, i. e. brightness. (Except if we happen to see only part of one of the images.) This is a very unusual signature, because most ordinary gravitational lenses produce an odd number of images of substantially different magnitudes. A number of string lensing event candidates have been discussed in the past, but no confirmed one is currently known.



Cosmic Strings, Figure 3
An illustration of the mechanism behind lensing by cosmic strings. The *thick black dot* represents a cosmic string perpendicular to the page. The spacetime metric around the string can be obtained by removing the angular wedge of width α and identifying the edges. An observer can thus see double images of objects located on a certain zone behind the string. This zone is enclosed by the *dashed lines*, while the *solid lines* depict light rays and the angular separation of the two images, $\delta\theta$, will depend on the distances of the source and the observer to the string as well as on the deficit angle. Reprinted, with permission, from [35]

However, the above simple picture is complicated in practice by the fact that cosmic strings are not generally straight or static. Whenever strings exchange partners kinks are created that straighten out only very slowly, so we expect a lot of small-scale structure on the strings. Viewed from a large scale, the effective tension and energy per unit length will no longer be equal. Since the total length of a wiggly string between two points is greater, it will have a larger effective energy per unit length, U, while the effective tension T, the average longitudinal component of the tension force, is reduced, so $T < \mu < U$. This means that there is a non-zero gravitational acceleration towards the string, proportional to $U - T$. Moreover, the strings acquire large velocities, generally a significant fraction of the speed of light, which introduces further corrections to the deficit angle.

Another effect is the formation of over-dense wakes behind a moving cosmic string [52]. When a string passes between two objects, these are accelerated towards each other to a velocity

$$u_\perp = 4\pi G\mu v \,, \tag{27}$$

where v is the string velocity. Matter therefore collides in a sheet-like structure, leaving a wake behind the moving string. This was the basic mechanism underlying the formation of large-scale structures in cosmic string models. This model has significant attractions, such as the early formation of nonlinear structures, and one can get a good match to the observed galaxy power spectrum in models with a large cosmological constant. However, as we shall discuss, it fails to reproduce the power spectrum of CMB anisotropies observed by COBE, WMAP and other experiments; cosmic strings, therefore, can only play a subdominant role in structure formation (albeit still significant, at the ten to twenty percent level). Cosmic strings create line-like discontinuities in the cosmic microwave background signal [23,34]. For the same reason that wakes form behind a cosmic string, the CMB source on the surface of last scattering is boosted towards the observer, so there is a relative CMB temperature shift across a moving string (a red-shift of the radiation ahead of it, and a blue-shift of that behind), given by

$$\frac{\delta T}{T} \sim 8\pi G\mu v_\perp \,. \tag{28}$$

where $v_\perp$ is the component of the string velocity normal to the plane containing the string and the line of sight. This is known as the Kaiser–Stebbins effect. This simple picture is again complicated in an expanding universe with a wiggly string network and relativistic matter and radiation components. The energy-momentum tensor of the string acts as a source for the metric fluctuations, which in turn create the temperature anisotropies. The problem can be recast using Green's (or transfer) functions which project forward the contributions of strings at early times to today. The actual quantitative solution of this problem entails a sophisticated formalism to solve the Boltzmann equation and then to follow photon propagation along the observer's line of sight. At the time of writing, the most recent comparisons [12] between full-sky maps of cosmic string-induced anisotropies and WMAP data yield a cosmological constraint on the models with

$$G\mu < \text{few} \times 10^{-7} \,, \tag{29}$$

with only a weak dependence on the background cosmology – in particular, on the magnitude of the cosmological constant.

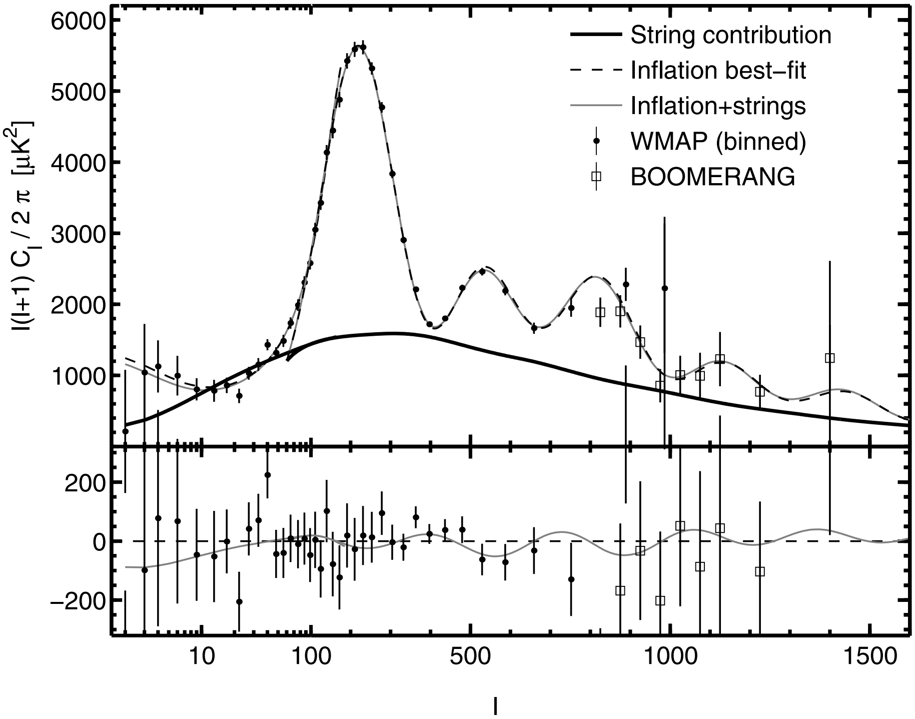
Apart from their scale-invariance (which follows from the network's attractor scaling solution discussed in the previous section), cosmic defect-induced fluctuations appear to be the antithesis of the standard inflation paradigm, because they are causal or active (they are generated inside the horizon and over an extended period), there are also large vector and tensor contributions, and they are distinctly non-Gaussian. All these characteristics leave clear signatures in the cosmic microwave background angular power spectrum, chief of which is a much broader primary Doppler peak and little evidence of secondary oscillations. Unlike inflation, active defect sources act incoherently with extra large-scale power from the vectors and tensors. Moreover, their isocurvature nature provides a partial explanation for why the broad primary peak ends up at larger multipoles (typically $\ell \sim 300$ as opposed to $\ell \sim 200$ in a flat cosmology). Isocurvature perturbations correspond to equal and opposite perturbations in the radiation and matter densities – as opposed to equal fractional perturbations in the number densities of the two components for adiabatic perturbations. On the basis of knowledge from present simulations, therefore, cosmic defects alone are extremely unlikely to have been the seeds for large-scale structure formation. However, they cannot be ruled out entirely. For example, admixtures of inflationary power spectra with significant cosmic defect contributions (at a level around 20%, see Fig. 4) do provide a satisfactory fit to present data. This is interesting among other reasons because it is the sort of level at which the non-Gaussian signatures of cosmic strings should still be discernible, although their distinct line-like discontinuities are only clearly identifiable on small angular scales around a few arc minutes.

Accelerated cosmic strings are sources of gravitational radiation [59]. Consequently, a network of long strings and closed loops produces a stochastic gravitational wave background [25] over a wide range of frequencies and with a spectrum which (at least to a first approximation) has equal power on all logarithmic frequency bins. Another distinctive signal would come from the cusps, the points at which the string instantaneously doubles back on itself, approaching the speed of light. Such an event generates an intense pulse of gravitational and other types of radiation, strongly beamed in the direction of motion of the cusp [18]. If massive cosmic strings do indeed exist, both these pulses and the stochastic background are likely to be among the most prominent signals seen by the gravitational-wave detectors now in operation or planned, in particular LIGO and LISA.

A stringent, though indirect, limit on the string energy per unit length comes from observations of the timing of millisecond pulsars. Gravitational waves between us and a pulsar would distort the intervening space-time, and so cause random fluctuations in the pulsar timing. The fact that pulsar timing is extremely regular places an upper limit on the energy density in gravitational waves, and hence on the string scale. The upper limit [29] is of order $G\mu < 10^{-7}$, though there is still considerable uncertainty because this depends on assumptions about the evolution of small-scale structure.

Although gravitational waves are thought to be the main decay byproduct of the evolution of the simplest cosmic string networks, direct decay into particle radiation is extremely efficient and there are claims that it could be the dominant energy-loss mechanism responsible for scaling [62]. In more complicated models, there are certainly other decay channels. If the strings are global (rather than local), then they will preferentially produce Goldstone bosons instead. In axion models, these Goldstone bosons acquire a small mass and become the axions (a prime dark matter candidate). One can estimate the number density of axions using analytic models of cosmic string evolution such as the VOS model. In another class of string models known as superconducting (since they have additional current-like degrees of freedom), then the decay products can include electromagnetic radiation.

Finally, we should mention the claims that cosmic strings could be responsible for a number of high energy astrophysical and cosmological enigmas, including ultra-high energy cosmic rays, gamma ray bursts, and baryo-



Cosmic Strings, Figure 4
The CMB temperature power spectrum contribution from cosmic strings, normalized to match the WMAP data at $\ell = 10$, as well as the best-fit cases from inflation only (model PL) and inflation plus strings (PL+S). These are compared to the WMAP and BOOMERANG data. The *lower plot* is a repeat but with the best-fit inflation case subtracted, highlighting the deviations between the predictions and the data. Reprinted, with permission, from [13]

genesis (the creation of the matter-antimatter asymmetry of the universe). Since cosmic defects can produce high energy particles, they could contribute to the observed cosmic ray spectrum, notably at ultra-high energies $E \geq 10^{11}$ GeV where the usual acceleration mechanisms seem inadequate [26]. Many ideas have been explored, such as particle emission from cosmic string cusps, but most have been found to produce a particle flux well below current observational limits. However, among the interesting scenarios deserving further study are those with hybrid defects (such as monopoles connected by strings) or vortons.

Field Theory Strings with More Degrees of Freedom

Kibble's original idea was to consider strings in grand unification scenarios, in which the strong and electroweak forces become unified at an energy scale of around 10^{15-16} GeV. Other studies have shown that practically any viable Supersymmetric Grand Unified Theory has a pattern of symmetry breaking transitions that leads to the possibility of cosmic string formation at some point in its history [28]. In particular, in these models the inflationary phase generically ends with a phase transition at which strings are produced. Other studies suggest that this is also a feature of brane inflation models.

So far we have discussed the field theory realization of the simplest model of cosmic string, the Abrikosov–Nielsen–Olesen string, in which the mass per unit length equals the tension and there is no internal structure apart from the magnetic field. In fact, the situation can be much more complex in the early Universe, and realistic particle physics models lead to networks with a much richer phenomenology. The added complexity makes these networks much harder to study, whether by analytic or numerical methods, and consequently they are not as well understood as the simplest case.

We can only give here a brief description of the possible complications. The list below is not complete and furthermore there are strings that fit more than one category. For a more detailed discussion we refer the reader to the reviews by Vilenkin and Shellard, Hindmarsh and Kibble, Carter, and Achúcarro and Vachaspati, where references to the original literature can also be found.

Wiggly Strings; Varying Tension String Networks; Cycloops

The name wiggly strings is sometimes used to refer to any type of string whose mass per unit length is different from its tension. We already mentioned in Sect. "Astrophysical and Cosmological Consequences" that small structure (wiggles) on the string produces a renormalized effective mass per unit length $U > \mu$ and an effective tension $T < \mu$. There are other effects that can affect the mass and tension, for instance the presence of currents along the strings.

A particular kind of small structure is found in extra dimensional models. If spacetime has more than the three spatial dimensions we observe, strings may be able to wrap around the extra dimensions in different ways leading to a renormalized four-dimensional tension and mass per unit length. The effective tension can of course vary along the strings. In extreme cases, the extra dimensional wrapping effects concentrate around certain points along the string which behave like 'beads' (see hybrid networks below) and are called cycloops.

As discussed towards the end of Sect. "String Evolution", the additional degrees of freedom (which can be thought of as a mass current) make the evolution of the networks highly non-trivial. The one-scale assumption is no longer justified: the correlation length, inter-string distance and string curvature radius become distinct lengthscales. Depending on the exact interplay between the bare strings and the mass current wiggles, these lengthscales can evolve differently, and some of them might be scaling while the others are not. The presence of extra dimensions provides a further energy flux mechanism (as energy may be lost into or gained from the extra dimensions) which will affect the string dynamics, but at the time of writing its exact effects have not been studied in detail.

Non-topological/Embedded/Electroweak/ Semilocal Strings

In the Abrikosov–Nielsen–Olesen case, the scalar field is zero at the core of the string, and the symmetry is unbroken there. The zero field is protected by the topological properties of the vacuum manifold (the non-contractible circle) and the string is called topological. In more realistic models, the criterion for topological string production is a non-simply connected vacuum manifold, however complicated. These strings are unbreakable and stable.

On the other hand there are examples in which there is no topological protection but the strings are nevertheless stable. The scalar field configuration at the core can be deformed continuously into a ground state, so these non-topological strings can break, their magnetic flux can spread out, or be converted to a different type of flux. But whether this happens is a dynamical question that depends on the detailed masses and couplings of the particles present, on the temperature, etc.

The best studied examples of non-topological strings look like Abrikosov–Nielsen–Olesen strings 'embedded' in a larger model such as the Glashow–Salam–Weinberg model of electroweak interactions [44,57]. These *electroweak* strings carry magnetic flux of the Z boson, but the strings would only be stable for unphysical values of the Z boson mass. They are closely related to *semilocal* strings, another example of embedded strings where the symmetry breaking involves both local and global symmetries intertwined in a particular way. For low scalar mass these can be remarkably stable.

In general, non-topological strings are not resilient enough for the networks to survive cosmological evolution. If the strings are unstable to spreading their magnetic flux, the network will not form. If the strings are breakable the network may form initially but it will quickly disappear (see hybrid networks below for a concrete example). A remarkable exception to this rule are semilocal strings with very low scalar mass: the network forms as a collection of segments which then grow and reconnect to form longer strings or loops. These evolve like a network of Abrikosov–Nielsen–Olesen strings plus a small population of segments and there is some evidence of scaling [5].

Dressed/Superconducting Strings/Vortons

In realistic particle physics models, a stable string will trap in its core any particles or excitations whose mass is lower inside due to the interactions with the scalar field. These *dressed* strings have a more complicated core structure. In extreme cases, the mass of these trapped particles is zero in the core and they lead to persistent currents along the strings, which are then known as *superconducting* [63]. In some cases, the decay of a loop of superconducting string can be stopped by these currents, leading to long-lived remnants called *vortons* [20] that destroy scaling; typical vortons will either dominate the energy density of the universe (contrary to observations) or contribute to the dark matter if they are sufficiently light.

Hybrid Networks

Hybrid networks contain more than one type of defect, such as for instance strings of different kinds or composite defects combining strings, monopoles and/or domain walls.

Composite Defects The production of strings may be accompanied by the production of other defects such as monopoles or domain walls, before or afterwards, that change the behavior of the network as a whole. These networks can have radically different scaling properties – in particular, linear scaling may not exist at all. Consider for instance a sequence of breakings of the form $G \to H \to K$ in which a symmetry group G first breaks down to a subgroup H which subsequently breaks to an even smaller subgroup K at a lower temperature. Two cases are particularly relevant for strings:

- The first breaking produces stable magnetic monopoles, the second confines – totally or partly – the magnetic field to flux tubes (strings) leading to a network of monopoles connected by strings. This can happen either as string segments, with monopoles at the ends, which eventually contract and disappear or as a network of strings carrying heavy "beads" (the monopoles) which can lead to a scaling solution.
- The first breaking produces stable strings, the second makes domain walls attached to the strings (e. g. in *axion* models). The network is made of pancake-like structures that contract under the wall tension and eventually disappear, although in some cases there may be long-lived remnants.

Non-Abelian/(p,q) Strings Another type of hybrid network contains different types of strings whose intercommutation leads to three-point junctions and bridges. These networks are also very different from the simplest ones but the current consensus is that they also seem to reach a scaling solution during cosmological evolution.

In the Non-abelian case, the magnetic flux carried by the string is not just a number but can have different internal "orientations". These become relevant when the strings cross, limiting the ways in which they can reconnect.

Hybrid networks containing several interacting string types are also found in superstring models (see next section). The most interesting type, usually referred to as (p,q) strings, contains two types of string each carrying different type of flux that is separately conserved: fundamental and solitonic or D-strings, roughly corresponding to electric and magnetic flux tubes. The numbers p and q refer to the units of each kind of flux carried by the strings. Since the mass per unit length depends on these fluxes, (p,q) networks are expected to have a hierarchy of different tensions, as well as junctions and bridges. In fact, junctions and bridges will also form in any model in which parallel strings have an attractive interaction, such as Abrikosov–Nielsen–Olesen strings with extremely low scalar to vector mass ratios.

The existence of string junctions and the hierarchy of string tensions make the evolution of these networks considerably more complicated than that of the simple Goto–Nambu strings. Relatively simple analyses suggest that the heavier strings will gradually decay into the lighter ones, and scaling is eventually reached for the strings at the low end of the spectrum (the heavier ones eventually disappear), although this is still under discussion. Naive expectations that the network might be slowed down to non-relativistic speeds and eventually freeze have so far not been supported by the (admittedly simplistic) numerical simulations performed so far. Further work is needed to understand the general conditions under which scaling is (or is not) an attractor.

Cosmic Superstrings

Superstring theory is to date the only candidate model for a consistent quantum theory of gravity that includes all other known interactions. In string theory, the fundamental constituents of nature are not point-like particles but one-dimensional "strings" whose vibrational modes produce all elementary particles and their interactions. Two important features of the theory are supersymmetry (a symmetry between bosonic and fermionic excitations that keeps quantum effects under control) and the presence of extra dimensions above the four spacetime dimensions that we observe.

It is not yet known how to formulate the theory in its full generality but some weak-coupling regimes are well understood. In these, the fundamental strings live in a 10-dimensional spacetime, of which 6 dimensions are "compactified", resulting in an effective 4-dimensional spacetime we live in. There is another regime, M-theory, in which the fundamental objects are two-dimensional "membranes" and the background spacetime is 11-dimensional. These regimes are related to one another by duality transformations that interchange the role of fluctuation quanta and non-perturbative, soliton-like states (branes), so the expectation is that all regimes are different limits of a unique, underlying theory usually referred to as superstring/M-theory, or just M-theory for short.

Before the discovery of D-branes, the "solitons" of superstring theory, the question of whether fundamental superstrings could ever reach cosmological sizes was analyzed and the possibility discarded [64]. There were two main problems. First, the natural mass per unit length of fundamental strings is close to the Planck scale and would correspond to deficit angles of order 2π, which would have been observed. Second, the strings were inherently unstable to either breaking or – depending on the type of string – becoming the boundary of domain walls that would quickly contract and disappear. The discovery of branes and their role in more exotic compactifications where the six compact dimensions have strong gravitational potentials (and redshifts) has changed this picture. It is now believed that networks of cosmic superstrings could be a natural outcome of brane-antibrane annihilation, especially if the branes are responsible for a period of cosmic inflation [17,30,53].

An important difference with previous scenarios is that these strings are located in regions of the compactified dimensions with very strong gravitational redshift effects ("warping") that reduce the effective mass per unit length of the strings to a level with deficit angles in the region of 10^{-12} to 10^{-7}, compatible with current observations. Another important difference is a much lower probability that the strings intercommute when they cross, estimated to be 10^{-3} to 10^{-1}, depending on the type of strings. The lower intercommutation rates lead to much denser networks. Estimates of the corresponding enhancement in the emission of gravitational radiation by cusps puts these strings in a potentially observable window by future gravitational wave detectors [19,54].

The networks are hybrid, consisting of fundamental strings and D-strings, the latter being either one-dimensional D-branes or perhaps the result of a higher dimensional D-brane where all but one dimension are wrapped around some "holes" (cycles) in the compactified space. There may also be cycloops.

As in the case of hybrid field theory strings, whether or not superstring networks eventually reach a scaling regime is an open question. Analytic studies and numerical simulations of simplified cases suggest that scaling is certainly possible, though contingent on model parameters that at the time of writing are not well understood. In this case, in addition to the presence of junctions and a non-trivial spectrum of string tensions, a third factor can affect the evolution of these networks. If the strings are actually higher-dimensional branes partially wrapped around some extra dimensions, then energy and momentum can in principle leak into or out of these extra dimensions [4]. Since the effective damping force affecting the ordinary and extra dimensions is different, one might generically expect that this will be the case. Depending on its sign and magnitude, such an energy flow can in principle prevent scaling, either by freezing the network (if too much energy leaks out) or by making the strings dominate the universe's energy density (if too much energy leaks in, though this is less likely than the opposite case). In this sense, a somewhat delicate balance may be needed to ensure scaling. At a phenomenological level, further work will be required in order to understand the precise conditions under which each of these scenarios occurs. At a more fundamental level, it is quite likely that which of the scenarios is realized will depend on the underlying compactifications and/or brane inflation models, and that may eventually be used as a discriminating test between string theory realizations.

Future Directions

One of the most exciting prospects is the discovery of magnetic-type CMB polarization (usually referred to as B-modes) as this would reveal the presence of vector and/or tensor modes. Cosmic string models may be further constrained in the near future because B-modes are predicted to have amplitudes comparable to the electric-type E-modes (at large angular scales). At high resolution, one could also hope to observe defects directly through the B-mode signal, against a relatively unperturbed background. Conversely, the detection of vector modes would provide strong evidence against inflation without cosmic defects. Polarization data will also strongly constrain a significant isocurvature contribution to the mainly adiabatic density fluctuations. Isocurvature perturbations can be a signature of more complicated physics during inflation, such as the effects of two or more scalar fields, or the formation of defects at the end of inflation.

Ongoing and future CMB experiments, especially at high resolution, will be probing the degree of Gaussianity of the primordial fluctuations. The detection of significant and unambiguous non-Gaussianity in the primary CMB signal would be inconsistent with simple (so called single field slow-roll) inflation. More general inflationary models can accommodate certain types of non-Gaussianity, and one can also envisage non-Gaussianity from excited initial states for inflation. It is interesting to note that given the existing bounds on $G\mu$, current CMB experiments do not have the sensitivity or resolution to detect cosmic string signatures directly, in particular the Kaiser–Stebbins effect in CMB maps. However, with high-resolution sensitivities becoming available in the near future, direct constraints (or detections) will be possible. This is just one example of the interesting new science that future high-resolution CMB experiments might uncover in the years ahead. In particular, ESA'a Planck Surveyor [47], scheduled for launch in late 2009, may be able to provide significant breakthroughs.

A deeper understanding of the evolution and consequences of string networks will require progress on both numerical simulations and analytic modelings. At the time of writing there is still no numerical code that includes all the relevant physics, even for the simplest (Goto–Nambu) strings. Inclusion of gravitational backreaction is particularly subtle, and may require completely new approaches. The expected improvements in the available hardware and software will allow for simulations with much longer evolution timespan and spatial resolution, which are needed in order to understand the non-linear interactions between large and small scales all the way down to the level of the constituent quantum fields. This in turn will be a valuable input for more detailed analytic modeling, that must accurately describe the non-trivial small-scale properties of the string networks as well as the detailed features of the loop populations. Better modeling is also needed to describe more general networks – three crucial mechanisms for which at present there is only a fairly simplistic description are the presence of junctions, a non-trivial spectrum of string tensions, and the flow of energy-momentum into extra dimensions.

At a more fundamental level, a better understanding of the energy loss mechanisms and their roles in the evolution of the networks is still missing [10] and it will require new developments in the theory of quantum fields out of equilibrium. Such theoretical developments are also needed to understand defect formation in systems with gauge fields, and could be tested experimentally in superconductors.

The early universe is a unique laboratory, where the fundamental building blocks of nature can be probed under the most extreme conditions, that would otherwise be beyond the reach of any human-made laboratory. Cosmic strings are particularly interesting for this endeavor: they are effectively living fossils of earlier cosmological phases, where physical conditions may have been completely different. The serendipitous discovery of cosmic defects or other exotic phenomena in forthcoming cosmological surveys would have profound implications for our understanding of cosmological evolution and of the physical processes that drove it. The search continues while, in the meantime, the absence of cosmic string signatures will remain a powerful theoretical tool to discriminate between fundamental theories. The possibility that something as fundamental as superstring theory may one day be validated in the sky, using tools as mundane as spectroscopy or photometry, is an opportunity than neither astrophysicists nor particle physicists can afford to miss.

Article Outline

Glossary

Core The *core* of a cooperative cost game $\langle N, c\rangle$ is the set of all coalitionally stable vectors of cost shares.

Cost function A *cost function* relates to each level of output of a given production technology the minimal necessary units of input to generate it. It is non-decreasing function $c\colon X \to \mathbb{R}_+$, where X is the (ordered) space of outputs.

Cost sharing problem A cost sharing problem is an ordered pair (q, c), where $q \in \mathbb{R}^N_+$ is a profile of individual demands of a fixed and finite group of agents $N = \{1, 2, \dots, n\}$ and c is a cost function.

Game theory The branch of applied mathematics and economics that studies situations where players make decisions in an attempt to maximize their returns. The essential feature is that it provides a formal modeling approach to social situations in which decision makers interact.

Cost sharing rule A *cost sharing rule* is a mapping that assigns to each cost sharing problem under consideration a vector of non-negative cost shares.

Demand game Strategic game where agents place demands for output strategically.

Demand revelation game Strategic game where agents announce their maximal contribution strategically.

Strategic game An ordered triple $G = \langle N, (A_i)_{i\in N}, (\precsim_i)_{i\in N}\rangle$, where

- $N = \{1, 2, \dots, n\}$ is the set of *players*,
- A_i is the set of available *actions* for player i,
- $\precsim_i$ is a *preference relation* over the set of possible consequences C of action.

Definition of the Subject

Throughout we will use a fixed set of agents $N = \{1, 2, \dots, n\}$, where n is a given natural number. For subsets S, T of N, we write $S \subset T$ if each element of S is contained in T; $T\backslash S$ denotes the set of agents in T except those in S. The *power set* of N is the set of all subsets of N; each coalition $S \subset N$ will be identified with the element $\mathbf{1}_S \in \{0, 1\}^N$, the vector with ith coordinate equal to 1 precisely when $i \in S$. Fix a vector $x \in \mathbb{R}^N$ and $S \subset N$. The projection of x on $\mathbb{R}^S$ is denoted by x_S, and $x_{N\backslash S}$ is sometimes more conveniently denoted by x_{-S}. For any $y \in \mathbb{R}^S$, (x_{-S}, y) stands for the vector $z \in \mathbb{R}^N$ such that $z_i = x_i$ if $i \in N\backslash S$ and $z_i = y_i$ if $i \in S$. We denote $x(S) = \sum_{i\in S} x_i$. The vector in $\mathbb{R}^S$ with all coordinates equal to zero is denoted by $\mathbf{0}_S$. Other notation will be introduced when necessary.

This article focuses on different approaches in the literature through a discussion of a couple of basic and illustrative models, each involving a single facility for the production of a finite set M of outputs, commonly shared by a fixed set $N := \{1, 2, \dots, n\}$ of agents. The feasible set of outputs for the technology is identified with a set $X \subset \mathbb{R}^M_+$. It is assumed that the users of the technology may freely dispose over any desired quantity or level of the outputs; each agent i has some demand $x_i \in X$ for output. Each profile of demands $x \in X^N$ is associated to its *cost* $c(x)$, i. e. the minimal amount of the idiosyncratic input commodity needed to fulfill the individual demands. This defines the *cost function* $c\colon X^N \to \mathbb{R}_+$ for the technology, comprising all the production externalities. A *cost sharing problem* is an ordered pair (x, c) of a demand profile x and a cost function c. The interpretation is that x is produced and the resulting cost $c(x)$ has to be shared by the collective N. Numerous practical applications fit this general description of a cost sharing problem.

In mathematical terms a cost sharing problem is equivalent to a *production sharing* problem where output is shared based on the profile of inputs. However, although many concepts are just as meaningful as they are in the cost sharing context, results are not at all easily established using this mathematical duality. In this sense consider [68] as a warning to the reader, showing that the strategic analysis of cost sharing solutions is quite different from surplus sharing solutions. This monograph will center on cost sharing problems. For further reference on production sharing see [51,67,68,91].

Introduction

In many practical situations managers or policy-makers deal with private or public enterprises with multiple users.

A production technology facilitates its users, causing externalities that have to be shared. Applications are numerous, ranging from environmental issues like pollution, fishing grounds, to sharing multipurpose reservoirs, road systems, communication networks, and the Internet. The essence in all these examples is that a manager cannot directly influence the behavior of the users, but only indirectly by addressing the externalities through some decentralization device. By choosing the right instrument the manager may help to shape and control the nature of the resulting individual and aggregate behavior. This is what is usually understood as the mechanism design or implementation paradigm. The state-of-the-art literature shows for a couple of simple but illustrative cost sharing models that one cannot push these principles too far, as there is often a trade-off between the degree of distributive justice and economic efficiency. Then this is what makes choosing 'the' right solution an ambiguous task, certainly without a profound understanding of the basic allocation principles. Now first some examples will be discussed.

Example 1 The water-resource management problem of the Tennessee Valley Authority (TVA) in the 1930s is a classic in the cost-sharing literature. It concerns the construction of a dam in a river to create a reservoir, which can be used for different purposes like flood control, hydro-electric power, irrigation, and municipal supply. Each combination of purposes requires a certain dam height and accompanying construction costs have to be shared by the purposes. Typical for the type of problem is that up to a certain critical height there are economies of scale as marginal costs of extra height are decreasing. Afterwards, marginal costs increase due to technological constraints. The problem here is to allocate the construction costs of a specific dam among the relevant purposes.

Example 2 Another illustrative cost sharing problem dating back from the early days in the cost sharing literature [69,70] deals with landing fee schedules at airports, so-called *airport problems*. These were often established to cover the costs of building and maintaining the runways. The cost of a runway essentially depends on the size of the largest type of airplane that has to be accommodated – a long runway can be used by smaller types as well. Suppose there are m types of airplanes and that c_i is the cost of constructing a landing strip suitable for type i. Moreover, index the types from small to large so that $0 = c_0 < c_1 < c_2 < \cdots < c_m$. In the above terminology the technology can be described by $X = \{0, 1, 2, \ldots, m\}$, and the cost function $c\colon X^N \to \mathbb{R}_+$ is defined by $c(x) = c_k$ where $k = \max\{x_i \mid i \in N\}$ is the maximal service level required in x. Suppose that in a given year, N_k is the set landings of type k airplanes, then the set of users of the runway is $N = \cup_k N_k$. The problem is now to apportion the full cost $c(x)$ of the runway to the users in N, where x is the demand vector given by $x_i = \ell$ if $i \in N_\ell$.

Airport problems describe a wide range of cost sharing problems, ranging from sharing the maintenance cost of a ditch system for irrigation projects [1], to sharing the dredging costs in harbors [14].

Example 3 A joint project involves a number of activities for which the estimated durations and precedence relations are known. Delay in each of these components affects the period in which the project can be realized. Then a cost sharing problem arises when the joint costs due to the accumulated delay are shared among the individuals causing the delays. See [21].

Example 4 In many applications the production technology is given by a network $G = (V, E)$ with nodes V and set of costly edges $E \subset V \times V$, and cost function $c\colon E \to \mathbb{R}_+$. The demands of the agents are now parts of the infrastructure, i. e. subsets of E. Examples include the sharing the cost of infrastructure for supply of energy and water, or transport systems.

For example, the above airport problem can be modeled as such with

$$\begin{aligned} V &= \{1, 2, \ldots, m\} \cup \{\odot\} \ , \\ E &= \{(\odot, 1), (1, 2), \ldots, (m-1, m)\} \ . \end{aligned}$$

Graphically, the situation is depicted by the line graph in Fig. 1.

Imagine that the runway starts at the special node $\odot$, and that the edges depict the different pieces of runway served to the players. An airplane of type k is situated at node k, and needs all edges towards $\odot$. The edge left to the kth node is called $e_k = (k-1, k)$, and the corresponding cost is $c(e_k) = c_k - c_{k-1}$. The demand of an airplane at node k is now described by the edges on the path from node k to $\odot$.

Example 5 In more general network design problems, a link facilitates a *flow*; for instance, in telecommunication it is data flowing through the network, in road systems it is traffic. [49] discusses a model where a network planner allocates the fixed cost of a network based on the individual

Cost Sharing, Figure 1
Graphical representation of an airport problem

demands being flows. [77,124] discuss *congested* telecommunication networks, where the cost of a link depends on the size of the corresponding flow. Then these positive network externalities lead to a concentration of flow, and thus to *hub-like* networks. Economies of scale require cooperation of the users, and the problem now is to share the cost of these so-called *hub-like* networks.

Example 6 As an insurance against the uncertainty of the future net worths of its constituents, firms are often regulated to hold an amount of riskless investments, i. e. its *risk capital*. Given that returns of normal investments are higher, the difference with the riskless investments is considered as a cost. The sum of the risk capitals of each constituent is usually larger than the risk capital of the firm as a whole, and the allocation problem is to apportion this diversification effect observed in risk measurements of financial portfolios. See Denault [28].

Solving Cost Sharing Problems: Cost Sharing Rules

A *vector of cost shares* for the cost sharing problem (x, c) is an element $y \in \mathbb{R}^N$ with the property that $\sum_{i \in N} y_i = c(x)$. This equality is also called *budget-balancing* condition. Central issue addressed in the cost sharing literature is how to determine the appropriate y. The vast majority of the cost sharing literature is devoted to a mechanistic way of sharing joint costs; given a class of cost sharing problems $\mathcal{P}$, a (simple) formula computes the vector of cost shares for each of its elements. This yields a *cost sharing rule* $\mu \colon \mathcal{P} \to \mathbb{R}^N$ where $\mu(P)$ is the vector of cost shares for each $P \in \mathcal{P}$.

At this point it should be clear to the reader that many formula's will see to a split of joint cost and heading for *the* solution to cost sharing problems is therefore an ambiguous task. The least we want from a solution is that it is consistent with some basic principles of fairness or justice and, moreover, that it creates the right incentives. Clearly, the desirability of solution varies with the context in which it is used, and so will the sense of appropriateness. Moreover, the different parties involved in the decision making process will typically hold different opinions; accountants, economists, production managers, regulators and others all are looking at the same institutional entity from different perspectives. The existing cost sharing literature is about exploring boundaries of what can be thought of desirable features of cost sharing rules. More important than the rules themselves, are the properties that each of them is consistent with. Instead of building a theory on single instances of cost sharing problems, the cost sharing literature discusses structural invariance properties over *classes* of problems. Here the main distinction is made on the basis of the topological properties of the technology, whether the cost sharing problem allows for a *discrete* or *continuous* formulation. For each type of models, divisible or indivisible goods, the state-of-the-art cost sharing literature has developed into two main directions, based on the way individual preferences over combinations of cost shares and (levels of) service are treated. On the one hand, there is a stream of research in which individual preferences are not explicitly modeled and demands are considered *inelastic*. Roughly, it accommodates the large and vast growing *axiomatic* literature (see e. g. [88,129]) and the theory on cooperative cost games [105,130,136,145]. Secondly, there is the literature on cost sharing models where individual preferences are explicitly modeled and demands are elastic. The focus is on non-cooperative *demand games* in which the agents are assumed to choose their demands strategically, see e. g. [56,91,141].

As an interested reader will soon find out, in the literature there is no shortage of plausible cost sharing techniques. Instead of presenting a kind of summary, this article focuses on the most basic and most interesting ones, and in particular their properties with respect to strategic interplay of the agents.

Outline

The article is organized as follows. Section "Cooperative Cost Games" discusses cost sharing problems from the perspective of cooperative game theory. Basic concepts like core, Shapley value, nucleolus and egalitarian solution are treated. Section "Non-cooperative Cost Games" introduces the basic concepts of non-cooperative game theory including dominance relations, preferences, and Nash-equilibrium. Demand games and demand revelation games are introduced for discrete technologies with concave cost function. This part is concluded with two theorems, the strategic characterization of the Shapley value and constrained egalitarian solution as cost sharing solution, respectively. Section "Continuous Cost Sharing Models" introduces the continuous production model and it consists of two parts. First the simple case of a production technology with homogeneous and perfectly divisible private goods is treated. Prevailing cost sharing rules like proportional, serial, and Shapley–Shubik are shortly introduced. We then give a well-known characterization of additive cost sharing rules in terms of corresponding rationing methods, discuss the related cooperative and strategic games. The second part is devoted to the heterogeneous output model and famous solutions like Aumann–Shapley, Shapley–Shubik, and serial rules. We finalize with Sect. "Future Directions" where some future directions of research are spelled out.

Cooperative Cost Games

A discussion of cost sharing solutions and incentives needs a proper framework wherein the incentives are formalized. In the seminal work of von Neumann and Morgenstern [140] the notion of a *cooperative game* was introduced as to model the interaction between actors/players who coordinate their strategies in order to maximize joint profits. Shubik [122] was one of the first to apply this theory in the cost sharing context.

Cooperative Cost Game

A cooperative cost game among players in N is a function $c\colon 2^N \to \mathbb{R}$ with the property that $c(\varnothing) = 0$; for non-empty sets $S \subset N$ the value $c(S)$ is interpreted as the cost that would arise should the individuals in S work together and serve only their own purposes. The class of all cooperative cost games for N will be denoted by CG.

Any general class $\mathcal{P}$ of cost sharing problems can be embedded in CG as follows. For the cost sharing problem $(x, c) \in \mathcal{P}$ among agents in N define the *stand-alone* cost game $c_x \in CG$ by

$$c_x(S) := \begin{cases} c(x_S, 0_{N\backslash S}) & \text{if } S \subset N, S \neq \varnothing \\ 0 & \text{if } S = \varnothing \,. \end{cases} \tag{1}$$

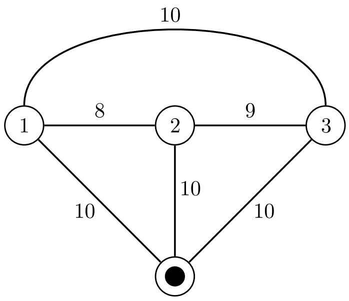
So $c_x(S)$ can be interpreted as the cost of serving only the agents in S.

Example 7 The following numerical example will be frequently referred to. An airport is visited by three airplanes in the set $N = \{1, 2, 3\}$, which can be accommodated at cost $c_1 = 12$, $c_2 = 20$, and $c_3 = 33$, respectively. The situation is depicted in Fig. 2.

The corresponding cost game c is determined by associating each coalition S of airplanes to the minimum cost of the runway needed to accommodate each of its members. Then the corresponding cost game c is given by the table below. Slightly abusing notation we denote $c(i)$ to indicate $c(\{i\})$, $c(ij)$ for $c(\{i, j\})$ and so forth.

S	$\varnothing$	1	2	3	12	13	23	123
$c(S)$	0	12	20	33	20	33	33	33

Cost Sharing, Figure 2
Airport game



Cost Sharing, Figure 3
Minimum cost spanning tree problem

Note that, since we identified coalitions of players in N with elements in 2^N, we may write c to denote the cooperative cost game. By the binary nature of the demands the cost function for the technology formally *is* a cooperative cost game. For $x = (1, 0, 1)$ the corresponding cost game c_x is specified by

S	$\varnothing$	1	2	3	12	13	23	123
$c_x(S)$	0	12	0	33	12	33	33	33

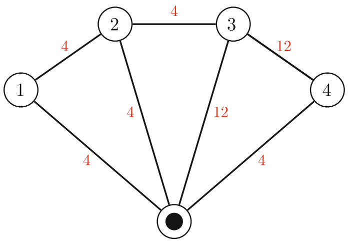
Player 2 is a *dummy player* in this game, for all $S \subset N \backslash \{2\}$ it holds $c_x(S) = c_x(S \cup \{2\})$.

Example 8 Consider the situation as depicted in the Fig. 3 below, where three players, each situated at a different node, want to be connected to the special node $\odot$ using the indicated costly links. In order to connect themselves to $\odot$ a coalition S may use only links with $\odot$ and the direct links between its members, and then only if the costs are paid for. For instance, the minimum cost of connecting player 1 in the left node to $\odot$ is 10, and the cost of connecting players 1 and 2 to $\odot$ are 18 – the cost of the direct link from 2 and the indirect link between 1 and 2. Then the associated cost game is given by

S	$\varnothing$	1	2	3	12	13	23	123
$c(S)$	0	10	10	10	18	20	19	27

Notice that in this case the network technology exhibits positive externalities. The more players want to be connected, the lower the per capita cost.

For those applications where the cost $c(S)$ can be determined irrespective of the actions taken by its complement $N \backslash S$ the interpretation of c implies *sub-additivity*, i. e. the property that for all $S, T \subset N$ with $S \cap T = \varnothing$ implies $c(S \cup T) \leq c(S) + c(T)$. This is for instance an essential feature of the technology underlying natural monopolies (see, e. g., [13,120]). Note that the cost games in Example 7 and 8 are sub-additive. This is a general property for airport games as well as minimum cost spanning tree games.



Cost Sharing, Figure 4
Non-concave MCST game

Sometimes the benefits of cooperation are even stronger. A game is called *concave* (or *sub-modular*) if for all $S, T \subset N$ we have

$$(S \cup T) + c(S \cap T) \leq c(S) + c(T) \,. \tag{2}$$

At first this seems a very abstract property, but one may show that it is equivalent with the following that

$$c(S \cup \{i\}) - c(S) \geq c(T \cup \{i\}) - c(T) \tag{3}$$

for all coalitions $S \subset T \subset N \backslash \{i\}$. This means that the marginal cost of a player i with respect to larger coalitions is non-increasing, i. e. the technology exhibits positive externalities. Concave games are also frequently found in the network literature, see [63,75,93,121].

Example 9 Although sub-additive, minimum cost spanning tree games are not always concave. Consider the following example due to [17]. The numbers next to the edges indicate the corresponding cost. We assume a complete graph and that the invisible edges cost 4. Note that in this game every three-player coalition is connected at cost 12, whereas $c(34) = 16$. Then $c(1234) - c(234) = 16 - 12 = 4$ whereas $c(134) - c(34) = -4$. So the marginal cost of player 1 is not decreasing with respect to larger coalitions.

Incentives in Cooperative Cost Games

The objective in cooperative games is to share the profits or costs savings of cooperation. Similar to the general framework, a *vector of cost shares* for a cost game $c \in CG$ is a vector $x \in \mathbb{R}^N$ such that $x(N) = c(N)$. The question is what cost share vectors make sense if (coalitions of) players have the possibility to opt out thereby destroying cooperation on a larger scale.

In order to ensure that individual players join, a proposed allocation x should at least be *individual rational* so that $x_i \leq c(i)$ for all $i \in N$. In that case no player has a justified claim to reject x as proposal, since going alone yields a higher cost. The set of all such elements is called the *imputation set*. If, in a similar fashion, $x(S) \leq c(S)$ for all $S \subset N$ then x is called *stable*; under proposal x no coalition S has a strong incentive to go alone, as it is not possible to redistribute the cost shares afterwards and make every defector better of. The *core* of a cost game c, notation core(c), consists of all stable vectors of cost shares for c. If cooperation on a voluntary basis by the grand coalition N is conceived as a desirable feature then the core and certainly the imputation set impose reasonable conditions for reaching it. Nevertheless, the core of a game can be empty.

Call a collection $\mathcal{B}$ of coalitions *balanced*, if there is a vector of positive weights $(\lambda_S)_{S \in \mathcal{B}}$ such that for all $i \in N$

$$\sum_{S \in \mathcal{B}, S \ni i} \lambda_S = 1 \,.$$

A cost game c is *balanced* if it holds for each balanced collection $\mathcal{B}$ of coalition that

$$\sum_{S \in \mathcal{B}} \lambda_S c(S) \geq c(N) \,.$$

It is the celebrated theorem below which characterizes all games with non-empty cores.

Theorem 1 (Bondareva–Shapley [20,117]**)** *The cost game c is balanced if and only if the core of c is non-empty.*

Concave cost games are balanced, see [119]. Concavity is not a necessary condition for non-emptiness of the core, since minimum cost spanning tree games are balanced as well.

Example 10 Consider the two-player game c defined by $c(12) = 10, c(1) = 3, c(2) = 8$. Then $\text{core}(c) = \{(x, 10 - x) | 2 \leq x \leq 3\}$. Note that, opposed to the general case, for two-player games sub-additivity is equivalent with non-emptiness of the core.

Cooperative Solutions

A solution on a subclass A of CG is a mapping $\mu\colon A \rightarrow \mathbb{R}^N$ that assigns to each $c \in A$ a vector of cost shares $\mu(c)$; $\mu_i(c)$ stands for the charge to player i.

The Separable Cost Remaining Benefit Solution Common practice among civil engineers to allocate costs of multipurpose reservoirs is the following solution. The *separable cost* for each player (read purpose) $i \in N$ is given by $s_i = c(N) - c(N \backslash \{i\})$, and the *remaining benefit* by $r_i = c(i) - s_i$. The separable cost remaining benefit solution charges each player i for the separable cost s_i and the non-separable costs $c(N) - \sum_{j \in N} s_j$ are then allocated in proportion to the remaining benefits r_i, leading to the formula

$$SCRB_i(c) = s_i + \frac{r_i}{\sum_{j\in N} r_j}\left[c(N) - \sum_{j\in N} s_j\right] . \qquad (4)$$

In this formula it is assumed that c is at least sub-additive to ensure that the r_i's are all positive. For the two-player game c in Example 10 the solution is given by $SCRB(c) = (2 + \frac{1}{2}(10-9), 7 + \frac{1}{2}(10-9)) = (2\frac{1}{2}, 7\frac{1}{2})$. In earlier days the solution was as well known as 'the alternate cost avoided method' or 'alternative justifiable expenditure method'. For references see [144].

Shapley Value One of the most popular and oldest solution concepts in the literature on cooperative games is due to Shapley [116], and named *Shapley-value*. Roughly it measures the average marginal impact of players. Consider an ordering of the players $\sigma\colon N \to N$ so that $\sigma(i)$ indicates the ith player in the order. Let $\sigma^*(i)$ be the set of the first i players according to σ; so $\sigma^*(1) = \{\sigma(1)\}, \sigma^*(2) = \{\sigma(1), \sigma(2)\}$, etc. The *marginal cost share vector* $m^\sigma(c) \in \mathbb{R}^N$ is defined by $m^\sigma_{\sigma(1)}(1) = c(\sigma(1))$ and for $i = 2, 3, \ldots, n$

$$m^\sigma_{\sigma(i)}(c) = c(\sigma^*(i)) - c(\sigma^*(i-1)) . \qquad (5)$$

So according to m^σ each player is charged with the increase in costs when joining the coalition of players before her. Then the *Shapley-value* for c is defined as the average of all $n!$ marginal vectors, i. e.

$$\Phi(c) = \frac{1}{n!}\sum_\sigma m^\sigma(c) . \qquad (6)$$

Example 11 Consider the airport game in Example 7. Then the marginal vectors are given by

σ	(123)	(132)	(213)	(231)	(312)	(321)
$\mu^\sigma(c)$	(12,8,13)	(12,0,21)	(0,20,13)	(0,20,13)	(0,0,33)	(0,0,33)

Hence the Shapley value of the corresponding game is $\Phi(c) = (4, 8, 21)$. Following [69,107], for airport games this allocation is easily interpreted as the allocation according to which each player pays an equal share of the cost of only those parts of the runway she uses. Then $c(e_1)$ is shared by all three players, $c(e_2)$ only by players 2 and 3, and, finally, $c(e_3)$ is paid in full by player 3. This interpretation extends to the class of standard fixed tree games, where instead of the *lattice* structure of the runway, there is a cost of a tree network to be shared, see [63].

If cost game is concave then the Shapley-value is in the core. Since then each marginal vector specifies a core-element, and in particular the Shapley-value as a convex combination of these. Reconsider the minimum cost spanning tree game c in Example 9, a non-concave game with non-empty core and $\Phi(c) = (2\frac{2}{3}, 2\frac{2}{3}, 6\frac{2}{3}, 4)$. Note that this is not a stable cost allocation since the coalition $\{2, 3\}$ would profit by defecting, $c(23) = 8 < 9\frac{1}{3} = \Phi_2(c) + \Phi_3(c)$. [50] show that in general games $\Phi(c) \in \text{core}(c)$ precisely when c is *average concave*. Although not credited as a core-selector, the classic way to defend the Shapley-value is by the following properties.

Symmetry Two players i, j are called *symmetric* in the cost game c if for all coalitions S not containing i, j it holds $c(S \cup \{i\}) = c(S \cup \{j\})$. A solution μ is *symmetric* if symmetric players in a cost game c get the same cost shares. If the cost game does not provide any evidence to distinguish between two players, symmetry is the property endorsing equal cost shares.

Dummy A player i in a cost game c is *dummy* if $c(S \cup \{i\}) = c(S)$ for all coalitions S. A solution μ satisfies *dummy* if $\mu_i(c) = 0$ for all dummy players i in c. So when a player has no impact on costs whatsoever, she can not be held responsible.

Additivity A solution is *additive* if for all cost games c_1, c_2 it holds that

$$\mu(c_1) + \mu(c_2) = \mu(c_1 + c_2) . \qquad (7)$$

For accounting reasons, in multipurpose projects it is a common procedure to subdivide the costs related to the different activities (players) into cost categories, like salaries, maintenance costs, marketing, et cetera. Each category ℓ is associated with a cost game c_ℓ where $c_\ell(S)$ is the total of category ℓ cost made for the different activities in S; then $c(S) = \sum_\ell c_\ell(S)$ is the joint cost for S. Suppose a solution is applied to each of the cost categories separately, then under an additive solution the aggregate cost share of an activity is independent from the particular cross-section in categories.

Theorem 2 (Shapley [116]) *Φ is the unique solution on CG which satisfies all three properties dummy, symmetry, additivity.*

Note that *SCRB* satisfies dummy and symmetry, but that it does not satisfy additivity. The Shapley-value is credited with other virtues, like the following due to [144].

Consider the practical situation that several division managers simultaneously take steps to increase efficiency by decreasing joint costs, but one division manager establishes a greater relative improvement in the sense that its marginal contribution to the cost associated with all possible coalitions increases. Then it is more than reasonable that this division should not be penalized. In a broader context this envisions the idea that each player in the cost game should be credited with the merits of 'uniform' technological advances.

Strong Monotonicity Solution μ is *strongly monotonic* if for any two cost games $c, \bar{c}$ it holds for all $i \in N$ that $c(S \cup \{i\}) - c(S) \geq \bar{c}(S \cup \{i\}) - \bar{c}(S)$ for all $S \subseteq N \setminus \{i\}$ implies $\mu_i(c) \geq \mu_i(\bar{c})$.

Anonymity is the classic property for solutions declaring independence of solution with respect to the name of the actors in the cost sharing problem. See e. g., [3,91,106]. Formally, the definition is as follows. For a given permutation $\pi: N \to N$ and $c \in CG$ define $\pi c \in CG$ by $\pi c(S) = c(\pi(S))$ for all $S \subseteq N$.

Anonymity Solution μ is *anonymous* if for all permutations π of N, and all $i \in N$, $\mu_{\pi(i)}(\pi c) = \mu_i(c)$ for all cost games c.

Theorem 3 (Young [144]) *The Shapley-value is the unique anonymous and strongly monotonic solution.*

[99] introduced the *balanced contributions axiom* for the model of *non-transferable utility games*, or games without side-payments, see [118]. Within the present context of *CG*, a solution μ satisfies the *balanced contributions axiom* if for any cost game c and for any non-empty subset $S \subseteq N$, $\{i, j\} \subseteq S \in N$ it holds that

$$\mu_i(S, c) - \mu_i(S \setminus \{j\}, c) = \mu_j(S, c) - \mu_j(S \setminus \{i\}, c) \,. \quad (8)$$

The underlying idea is the following. Suppose that players agree on using solution μ and that coalition S forms. Then $\mu_i(S, c) - \mu_i(S \setminus \{j\}, c)$ is the amount player i gains or loses when S is already formed and player j resigns. The balanced contributions axiom states that the gains and/or losses by other player's withdrawal from the coalition should be the same.

Theorem 4 (Myerson [99]) *There is a unique solution on CG that satisfies the balanced contributions axiom, and that is Φ.*

The balanced contribution property can be interpreted in a bargaining context as well. In the game c and with solution μ a player i can object against player j to the solution $\mu(c)$ when the cost share for j increases when i steps out of the cooperation, i. e. $\mu_j(N, c) \geq \mu_j(N \setminus \{i\})$. In turn, a *counter objection* by player j to this objection is an assertion that player i would suffer more when j ends cooperation, i. e. $\mu_j(N, c) - \mu_j(N \setminus \{i\}) \leq \mu_i(N, c) - \mu_i(N \setminus \{j\})$. The balanced contribution property is equivalent to the requirement that each objection is balanced by a counter objection. For an excellent overview of ideas developed in this spirit, see [74].

Another *marginalistic* approach is by [44]. Denote for $c \in CG$ the game restricted to the players in $S \subseteq N$ by (S, c). Given a function $P\colon CG \to \mathbb{R}$ which associates a real number $P(N, c)$ to each cost game c with player set N, the *marginal cost* of a player i is defined to be $D^i P(c) = P(N, c) - P(N \setminus \{i\}, c)$. Such a function P with $P(\varnothing, c) = 0$ is called *potential* if $\sum_{i \in N} D^i P(N, c) = c(N)$.

Theorem 5 (Hart & Mas-Colell [44]) *There exists a unique potential function P, and for every $c \in CG$ the resulting payoff vector $DP(N, c)$ coincides with $\Phi(c)$.*

Egalitarian Solution The Shapley-value is one of the first solution concepts proposed within the framework of cooperative cost games, but not the most trivial. This would be to neglect all asymmetries between the players and split total costs equally between them. But as one can expect egalitarianism in this pure form will not lead to a stable allocation. Just consider the two-player game in Example 10 where pure egalitarianism would dictate the allocation $(5, 5)$, which violates individual rationality for player 1.

In order to avoid these problems of course we can propose to look for the most egalitarian allocation *within* the core (see [7,31]). Then in this line of thinking what is needed in Example 10 is a minimal transfer of cost 2 to player 2, leading to the final allocation $(3, 7)$ – the *constrained egalitarian solution*. Although in the former example is was clear what allocation to chose, in general we need a tool to evaluate allocations for the degree of egalitarianism. The earlier mentioned papers all suggest the use of Lorenz-order (see, e. g. [8]). More precisely, consider two vectors of cost shares x and x' such that $x(N) = x'(N)$. Assume that these vectors are ordered in decreasing order so that $x_1 \geq x_2 \geq \cdots \geq x_n$ and $x'_1 \geq x'_2 \geq \cdots \geq x'_n$. Then x *Lorenz-dominates* x' – read x is more egalitarian than x' – if for all $k = 1, \ldots, n-1$ it holds that

$$\sum_{i=1}^{k} x_i \leq \sum_{i=1}^{k} x'_i \,, \quad (9)$$

with at least one strict inequality. That is, x is better for those paying the most.

Example 12 Consider the three allocations of cost 15 among three players $x = (6, 5, 4)$, $x' = (6, 6, 3)$, and $x'' = (7, 4, 4)$. Firstly, x Lorenz-dominates x'' since $x_1 =$

$6 < 7 = x''_1$, and $x_1 + x_2 = x'_1 + x'_2$. Secondly, x Lorenz-dominates x' since $x_1 = x'_1, x_1 + x_2 < x'_1 + x'_2$. Notice, however, that on the basis of only Eq. (9) we can not make any judgment what is the more egalitarian of the allocations x' and x''. Since $x'_1 = 6 < 7 = x''_1$ but $x'_1 + x'_2 = 6 + 6 > 7 + 4 = x''_1 + x''_2$. The Lorenz-order is only a partial order.

The constrained egalitarian solution is the set of Lorenz-undominated allocations in the core of a game. Due to the partial nature of the Lorenz-order there may be more than one Lorenz-undominated elements in the core. And what if the core is empty? The constrained egalitarian solution is obviously not a straight-forward solution. The original idea of constrained egalitarianism as in [30], focuses on the Lorenz-core instead of the core. It is shown that there is at most one such allocation, that may exist even when the core of the underlying game is empty.

For concave cost games c, the allocation is well defined and denoted by $\mu^{\mathrm{E}}(c)$. In particular this holds for airport games. Intriguingly, empirical studies [1,2] show there is a tradition in using the solution for this type of problems.

For concave cost games c, there exists an algorithm to compute $\mu^{\mathrm{E}}(c)$. This method, due to [30], performs the following consecutive steps. First determine the maximal set S_1 of players minimizing the per capita cost $c(S)/|S|$, where $|S|$ is the size of the coalition S. Then each of these players in S_1 pays $c(S_1)/|S_1|$. In the next step determine the maximal set S_2 of players in $N \backslash S_1$ minimizing $c_2(S)/|S|$, where c_2 is the cost game defined by $c_2(S) = c(S_1 \cup S) - c(S_1)$. The players in S_2 pay $c_2(S_2)/|S_2|$ each. Continue in this way just as long as not everybody is allocated a cost share. Then in at most n steps this procedure results in an allocation of total cost, the constrained egalitarian solution. In short the algorithm is as follows

- **Stage 0:** Initialization, put $S^*_0 = \varnothing, x^* = 0_N$, go to stage $t = 1$.
- **Stage *t*:** Determine

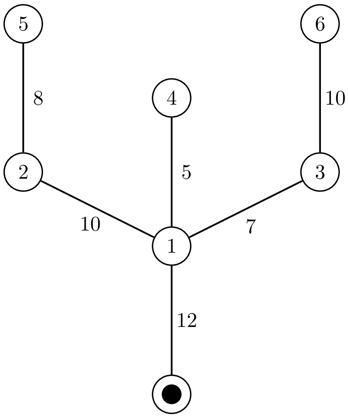
$$S_t \in \arg\max_{S \neq \varnothing} \frac{c(S \cup S^*_{t-1}) - c(S^*_{t-1})}{|S|} .$$

Put $S^*_t = S^*_{t-1} \cup S_t$ and for $i \in S_t$,

$$x^*_i := \frac{c(S^*_t) - c(S^*_{t-1})}{|S_t|} .$$

If $S^*_t = N$, we are finished, put $\mu^{\mathrm{E}}(c) = x^*$. Else repeat the stage with $t := t + 1$.

For example, this algorithm can be used to calculate the constrained egalitarian solution for the airport game in Example 7. In the first step we determine $S_1 = \{1, 2\}$, together with cost shares 10 for the players 1 and 2. Player 3 is allocated the remaining cost in the next step; hence the corresponding final allocation is $\mu^{\mathrm{E}}(c) = (10, 10, 13)$.



Cost Sharing, Figure 5
Standard fixed tree

Example 13 Consider the case where six players share the cost of the following *tree* network that connects them to ⊙. The *standard fixed tree game c* for this network associates to each coalition of players the minimum cost of connecting cost of connecting each member to ⊙, where it may use all the links of the tree. This type of games is known to be concave we can use the above algorithm to calculate $\mu^{\mathrm{E}}(c)$. In the first step we determine $S_1 = \{1, 3, 4\}$ and each herein pays 8. Then in the second step the game remains where the edges e_1, e_3, e_4 connecting S_1 have been paid for. Then it easily follows that $S_2 = \{2, 5\}$, so that players 2 and 5 pay 9 each, leaving 10 as cost share for player 6. Thus, we find $\mu^{\mathrm{E}}(c) = (8, 9, 8, 8, 9, 10)$.

Nucleolus Given a cost game $c \in CG$ the *excess* of a coalition $S \subset N$ with respect to a vector $x \in \mathbb{R}^N$ is defined as $e(S, x) = x(S) - c(S)$; it measures dissatisfaction of S under proposal x. Arrange the excesses of all coalitions $S \neq N, \varnothing$ in decreasing order and call the resulting vector $\vartheta(x) \in \mathbb{R}^{2^n-2}$. A vector of cost shares x will be preferred to a vector $\mathbf{y}$, notation $x \succ y$, whenever $\vartheta(x)$ is smaller than $\vartheta(y)$ in the lexicographic order, i. e. there exists i^* such that for $i \leq i^* - 1$ it holds $\vartheta_i(x) = \vartheta_i(y)$ and $\vartheta_{i^*}(x) < \vartheta_{i^*}(y)$. Schmeidler [115] showed that in the set of individual rational cost sharing vectors there is a unique element that is maximal with respect to $\succ$, which is called the *nucleolus*. This allocation, denoted by $\nu(c)$, is based on the idea of egalitarianism that the largest complaints of coalitions should consistently be minimized. The concept gained much popularity as a core-selector, i. e. it is a one-point solution contained in the core when it is nonempty. This contrasts with the constrained egalitarian solution which might not be well defined, and the Shapley-value which may lay outside the core.

Example 14 Consider in Example 7 the excesses of the different coalitions with respect to the constrained egalitarian solution $\mu^{\mathrm{E}}(c) = (10, 10, 13)$ and the nucleolus $\nu(c) = (6, 7, 20)$:

S	1	2	3	12	13	23
$e(S, \mu^{\mathrm{E}}(c))$	-2	10	-20	0	-10	-10
$e(S, \nu(c))$	-6	-13	-13	-7	-7	-6

Then the ordered excess vectors are

$$\vartheta(10, 10, 13) = (10, 0, -2, -10, -10, -20)\,,$$
$$\vartheta(6, 7, 20) = (-6, -6, -7, -7, -13, -13)\,.$$

Note that indeed $\vartheta(\nu(c)) \succ \vartheta(\mu^{\mathrm{E}}(c))$ since

$$\vartheta_1(6, 7, 20) = -6 < 10 = \vartheta_1(10, 10, 13)\,.$$

The nucleolus of standard fixed tree games may be calculated as a particular *home-down* allocation, as was pointed out by Maschler et al. [75].

For standard fixed tree games and minimum cost spanning tree games the special structure of the technology makes it possible to calculate the nucleolus in polynomial time, i. e. with a number of calculations bounded by a multiple of n^2 (see [39]). Sometimes one may even express the nucleolus through a nice formula; Legros [66] showed a class of cost sharing problems for which the nucleolus equals the SCRB solution. But in general calculations are hard and involve solving a linear program with a number of inequalities which is exponential in n. [124] suggests to use the nucleolus on the cost game corresponding to hub-games.

Instead of the direct comparison of excesses like above, the literature also discusses weighted excesses as to model the asymmetries of justifiable complaints within coalitions. For instance the *per capita nucleolus* minimizes maximal excesses which are divided by the number of players in the coalition (see [105]).

Cost Sharing Rules Induced by Solutions

Most of the above numerical examples deal with cost sharing problems which have a natural and intuitive representation as a cost game. Then basically on such domains of cost sharing problems there is no difference between cost sharing rules and solutions. It may seem that the cooperative solutions are restricted to this kind of situations. But recall that each cost sharing problem (x, c) is associated its stand-alone cost game $c_x \in CG$, as in Eq. (1). Now let μ be a solution on a subclass of $A \subset CG$ and B a class of cost sharing problems (x, c) for which $c_x \in A$. Then a cost sharing rule $\overline{\mu}$ is defined on B through

$$\begin{tikzcd}
(x,\, c) \arrow[r, "f"] \arrow[dr, dashed, "\overline{\mu}"'] & c_x \arrow[d, "\mu"] \\

Cost Sharing, Figure 6
Induced cost sharing rules

$$\overline{\mu}(x, c) = \mu(c_x)\,. \tag{10}$$

The general idea is illustrated in the diagram on the left. For example, since the Shapley value is defined on the class of all cost games, it defines a cost sharing rule $\overline{\Phi}$ on the class of all cost sharing problems. The cost sharing rule $\overline{\mu}^{\mathrm{E}}$ is defined on the general class of cost sharing problems with corresponding concave cost game. Cost sharing rules derived in this way, *game-theoretical rules* according to [130], will be most useful below.

Non-cooperative Cost Games

Formulating the cost sharing problem through a cooperative cost game assumes inelastic demands of the players. It might well be that for some player the private merits of service do not outweigh the cost share that is calculated by the planner. She will try to block the payment when no service at no cost is a preferred outcome. Another aspect is that the technology may operate at a sub-optimal level if benefits of delivered services are not taken into account. Below the focus is on a broader framework with elastic demands, which incorporates preferences of a player are defined over *combinations* of service levels and cost shares. The theory of non-cooperative games will provide a proper framework in which we can discuss individual aspirations and efficiency of outcomes on a larger scale.

Strategic Demand Games

At the heart of this non-cooperative theory is the notion of a *strategic game*, which models an interactive decision-making process among a group of *players* whose decisions may impact the consequences for others. Simultaneously, each player i independently chooses some available action

a_i and the so realized *action profile* $a = (a_1, a_2, \dots, a_n)$ is associated with some consequence $f(a)$. Below we will have in mind demands or offered contributions as actions, and consequences are combinations of service levels with cost shares.

Preferences Over Consequences Denote by A the set of possible action profiles and C as the set of all consequences of action. Throughout we will assume that players have preferences over the different consequences of action. Moreover, such preference relation can be expressed by a *utility function* $u_i : C \to \mathbb{R}$ such that for $z, z' \in C$ it holds $u_i(z) \le u_i(z')$ if agent i weakly prefers z' to z. Below the set of consequences for agent $i \in N$ will consist of pairs (x, y) where x is the level of service and y a cost share, so that a utilities are specified through multi-variable functions, $(x, y) \mapsto u_i(x, y)$.

Preferences Over Action Profiles In turn define for each agent i and all $a \in A$, $U_i(a) = u_i(f(a))$; then U_i assigns to each action profile the utility of its consequence. We will say that the action profile a' is weakly preferred to a by agent i if $U_i(a) \le U_i(a')$; U_i is called agent i's utility function *over action profiles*.

Strategic Game and Nash Equilibrium A strategic game is an ordered triple $G = \langle N, (A_i)_{i \in N}, (U_i)_{i \in N} \rangle$ where

- $N = \{1, 2, \dots, n\}$ is the set of *players*,
- A_i is the set of available *actions* for player i,
- U_i is player i's utility function over action profiles.

Rational players in a game will choose optimal actions in order to maximize utility. The most commonly used concept in game theory is that of *Nash-equilibrium*, a profile of strategies from where unilateral deviation by a single player does not pay. It can be seen as a *steady state* of action in which players hold correct beliefs about the actions taken by others and act rationally. An important assumption here is the level at which the players understand the game; usually it is taken as a starting point that players *know* the complete description of the game, including the action spaces and preferences of others.

Nash Equilibrium (Nash 1950) An action profile a^* in a strategic game $G = \langle N, (A_i)_{i \in N}, (u_i)_{i \in N} \rangle$ is a Nash-equilibrium if, for every player i it holds $u_i(a^*) \ge u_i(a_i, a^*_{-i})$ for every $a_i \in A_i$.

The literature discusses several refinements of this equilibrium concept. One that will play a role in the games below is that of *strong Nash equilibrium* due to Aumann [9]; it is a Nash equilibrium a^* in a strategic game G such that for all $S \subset N$ and action profile a_S there exists a player $i \in S$ such that $u_i(a_S, a^*_{N \setminus S}) \le u_i(a^*)$. This means that a strong Nash-equilibrium guarantees stability against coordinated deviations, since within the deviating coalition there is at least one agent who does not strictly improve.

Example 15 Consider the following two-player strategic game with $N = \{1, 2\}$, $A_1 = \{T, B\}$ and $A_2 = \{L, M, R\}$. Let the utilities be as in the table below

	L	***M***	***R***
T	5,4	2,1	3,2
B	4,3	5,2	2,5

Here player 1 chooses a row, and player 2 a column. The numbers in the cells summarize the individual utilities corresponding to the action profiles; the first number is the utility of player 1, the second that of player 2. In this game there is a unique Nash-equilibrium, which is the action profile (T, L).

Dominance in Strategic Games In the game $G = \langle N, (A_i)_{i \in N}, (U_i)_{i \in N} \rangle$, the action $a_i \in A_i$ is *weakly dominated* by $a'_i \in A_i$ if $U_i(a_i, a_{-i}) \le U_i(a'_i, a_{-i})$ for all $a_{-i} \in A_{-i}$, with strict inequality for some profile of actions a_{-i}. If strict inequality holds for all a_{-i} then a_i is strictly dominated by $\tilde{a}_i$. Rational players will not use strictly dominated strategies, and, as far as prediction of play is concerned, these may be eliminated from the set of possible actions. If we do this elimination step for each player, then we may reconsider whether some actions are dominated within the reduced set of action profiles. This step-by-step reduction of action sets is called the procedure of *successive elimination of (strictly) dominated strategies*. The set of all action profiles surviving this procedure is denoted by D^∞.

Example 16 In Example 15 action M of player 2 is strictly dominated by L and R. Player 1 has no dominated actions. Now eliminate M from the actions for player 2. Then the reduced game is

	L	***R***
T	5,4	3,2
B	4,3	2,5

Notice that action L for player 1 was not dominated in the original game, for the reason that B was the better of the two actions against M. But if M is never played, T is strictly better than B. Now eliminate B, yielding the reduced game

	L	***R***
T	5,4	3,2

In this game, L dominates R; hence the only action profile surviving the successive elimination of strictly dominated strategies is (T, L).

A stronger notion than dominance is the following. Call an action $a_i \in A_i$ *overwhelmed* by $a'_i \in A_i$ if

$$\max\{U_i(a_i, a_{-i}) | a_{-i} \in A_{-i}\} < \min\left\{U_i(a'_i, a_{-i}) | a_{-i} \in A_{-i}\right\} .$$

Then $\mathcal{O}^\infty$ is the set of all action profiles surviving the successive elimination of overwhelmed actions. This notion is due to [34,37]. In Example 15 the action M is overwhelmed by L, not by R. Moreover, the remaining actions in $\mathcal{O}^\infty$ are B, T, L, and R.

Demand Games

Strategic games in cost sharing problems arise when we assume that the users of the production technology choose their demands strategically and a cost sharing rule sees to an allocation of the corresponding service costs. The action profiles A_i are simply specified by the demand spaces of the agents, and utilities are specified over combinations of (level of) received service and accompanying cost shares. Hence utilities are defined over consequences of action, $u_i(q_i, x_i)$ denotes i's utility at receiving service level q_i and cost share x_i; u_i is increasing in the level of received service x_i, and decreasing in the allocated cost y_i. Now assume a cost function c and a cost sharing rule μ. Then given a demand profile $a = (a_1, a_2, \ldots, a_n)$ the cost sharing rule determines a vector of cost shares $\mu(a, c)$, and in return also the corresponding utilities over demands $U_i(a) = u_i(a_i, \mu_i(a, c))$. Observe that agents influence each others utility via the cost component. The *demand game* for this situation is then the strategic game

$$G(\mu, c) = \langle N, (A_i)_{i \in N}, (U_i)_{i \in N}\rangle \ . \tag{11}$$

Example 17 Consider the airport problem in Example 7. Each player now may request service (1) or not (0). Then the cost function is fully described by the demand of the largest player. That is, $c(x) = 33$ if 3 requires service, $c(x) = 20$ for all profiles with $x_2 = 1, x_3 = 0$ and $c(x) = 12$ if $x = (1, 0, 0)$, $c(0, 0, 0) = 0$. Define the cost sharing rule $\overline{\Phi}(x, c) = \Phi(c_x)$, that is, $\overline{\Phi}$ calculates the Shapley-value for the underlying cost game c_x as in Eq. (1). Assume that the players' preferences over ordered pairs of service level and cost shares are fully described by

$$\begin{aligned} u_1(q_1, x_1) &= 8q_1 - x_1 \ , \\ u_2(q_2, x_2) &= 6q_2 - x_2 \ , \\ u_3(q_3, x_3) &= 30q_3 - x_3 \ . \end{aligned}$$

Here q_i takes values 0 (no service) or 1 (service) and x_i stands for the allocated cost. So player 1 prefers to be served at unit cost instead of not being served at zero cost, $u_1(0, 0) = 0 < 7 = u_1(1, 1)$. The infrastructure is seen as an excludable public good, so those with demand 0 do not get access to the technology. Each player now actively chooses to be served or not, so her action set is specified by $A_i = \{0, 1\}$. Recall the definition of c_x as in Eq. (1). Then given a profile of such actions $a = (a_1, a_2, a_3)$ and cost shares $\overline{\Phi}(a, c)$, utilities of the players in terms of action profiles become $U_i(a) = u_i(a_i, \Phi_i(a, c))$, so that

$$\begin{aligned} U_1(a) &= 8a_1 - \overline{\Phi}_1(a, c) \ , \\ U_2(a) &= 6a_1 - \overline{\Phi}_2(a, c) \ , \\ U_3(a) &= 30a_3 - \overline{\Phi}_3(a, c) \ . \end{aligned}$$

Now that we provided all details of the demand game $G(\overline{\Phi}, c)$, let us look for (strong) Nash-equilibria. Suppose that the action profile $a^* = (1, 0, 1)$ is played in the game. Then in turn the complete infrastructure is realized just for players 1 and 3 and the cost allocation is given by $(6, 0, 27)$. Then the vectors of individual utilities is given by $(2, 0, 3)$. Now if we consider unilateral deviations from a^*, what happens to the individual utilities?

$$\begin{aligned} U_1(0, 0, 1) &= 0 < 2 = U_1(1, 0, 1) \ , \\ U_2(1, 1, 1) &= 6 - \overline{\Phi}_2((1, 1, 1), c) \\ &= 6 - \Phi(c) = 6 - 8 \\ &= -2 < 0 = U_2(1, 0, 1) \ , \\ U_3(1, 0, 0) &= 0 < 3 = U_3(1, 0, 1) \ . \end{aligned}$$

This means that for each player unilateral deviation does not pay, a^* is a Nash-equilibrium. The first inequality shows as well why the action profile $(0, 0, 1)$ is not. It is easy to see that the other Nash equilibrium of this game is the action profile $(0, 0, 0)$, no player can afford the completion of the infrastructure just for herself. Notice however that this zero profile is not a strong Nash equilibrium as players 1 and 3 may well do better by choosing for service at the same time, ending up in $(1, 0, 1)$. The latter profile is the unique strong Nash-equilibrium of the game.

Similar considerations in the demand game $G(\overline{\mu}^{\mathrm{E}}, c)$ induced by the constrained egalitarian solution lead to the unique strong Nash-equilibrium $(0, 0, 0)$, nobody wants service.

With cost sharing rules as decentralization tools, the literature postulates Nash-equilibria of the related demand game as the resulting behavioral mode. This is a delicate step because – as the example above shows – it is easy to find games with many equilibria, which causes a selection problem. And what can we do if there are no equilibria? This will not be the topic of this text and the interested reader is referred to any standard textbook on game theory, for instance see [103,104,109]. If there is a unique equilibrium then it is taken as the prediction of actual play.

Demand Revelation Games

For a social planner one way to retrieve the level at which to operate the production facility is via a pre-specified demand game. Another way is to ask each of the agents for the maximal amount that she is willing to contribute in order to get service, and then, contingent on the reported amounts, install an adequate level of service together with a suitable allocation of costs. Opposed to demand games ensuring the level of service, in a demand revelation game each player is able to ensure a maximum charge for service.

The approach will be discussed under the assumption of a discrete production technology with binary demands, so that the cost function c for the technology is basically the characteristic function of a cooperative game. Moreover assume that the utilities of the agents in N are quasi-linear and given by

$$u_i(q_i, x_i) = \alpha_i q_i - x_i \tag{12}$$

where $q_i \in \{0, 1\}$ denotes the service level, x_i stands for the cost share, and α_i is a non-negative real number. [93] discusses this framework and assume that c is concave, and [64,148] moreover take c as the joint cost function for the realization of several discrete public goods.

Demand Revelation Mechanisms Formally, a *revelation mechanism M* assigns to each profile η of reported maximal contributions a set $S(\eta)$ of agents receiving service and $x(\eta)$ a vector of monetary compensations. Here we will require that these monetary compensations are cost shares; given some cost sharing rule μ the vector $x(\eta)$ is given by $\mu(\mathbf{1}_{S(\eta)}, c)$ where c is the relevant cost function.

Moreover, note that by restricting ourselves to cost share vectors we implicitly assume non-positive monetary transfers. The *budget balance* condition is crucial here, otherwise mechanisms of a different nature must be considered as well, see [23,40,41]. There are other ways that a planner may use to determine a suitable service level is by demanding pre-payment from the players, and determine a suitable service level on the basis of these labeled contributions, see [64,148].

Many mechanisms come to mind, but in order to avoid too much arbitrariness from the planner's side, the more sensible ones will grant the players some control over the outcomes. We postulate the following properties:

- **Voluntary Participation (VP)** Each agent i can guarantee herself the welfare level $u_i(0, 0)$ (no service, no payment) by reporting truthfully the maximal willingness to pay, which is α_i under Eq. (12).
- **Consumer Sovereignty (CS)** For each agent i a report y_i exists so that she receives service, irrespective of the reports by others.

Now suppose that the planner receives the message $\eta = \alpha$, known to her as the profile of true player characteristics. Then for economic reasons she could choose to serve a coalition S of players that maximizes the *net benefit* at α, $\pi(S, \alpha) = \alpha(S) - c(S)$. However, problems will arise when some player i is supposed to pay more than α_i, so the planner should be more careful than that. She may want to choose a coalition S with maximal $\pi(S, \alpha)$ such that $\mu(\mathbf{1}_S, c) \le \alpha$ holds; such set S is called *efficient*. But in general the planner cannot tell whether the players reported truthfully or not, then what should she do then? One option is that she applies the above procedure thereby naively holding each reported profile η for the *true* player characteristics. In other words, she will pick a coalition that solves the following optimization problem

$$\begin{aligned} \max_{S \subset N} \quad & \pi(S, \eta) = \eta(S) - c(S) \\ \text{s.t.} \quad & \mu(\mathbf{1}_S, c) \le \eta\,. \end{aligned} \tag{13}$$

Denote such a set by $S(\mu, \eta)$. If this set is unique then the demand revelation mechanism $M(\mu)$ selects $S(\mu, \eta)$ to be served at cost shares determined by $x(\eta) = \mu(\mathbf{1}_S, c)$. This procedure will be explained through some numerical examples.

Example 18 Consider the airport problem and utilities of players over service levels and cost shares as in Example 7. Moreover assume the planner uses the Shapley cost sharing rule $\overline{\Phi}$ as in Example 17 and that she receives the true profile of preferences from the players, $\alpha = (8, 6, 30)$. Calculate for each coalition S the net benefits at α:

S	∅	1	2	3	12	13	23	N
$\pi(S,\alpha)$	0	-4	-14	-3	-6	8	3	11

Not surprisingly, the net benefits are the highest for the grand coalition. But if N were selected by the mechanism the corresponding cost shares are given by $\overline{\Phi}(\mathbf{1}_N, c) = (4, 8, 21)$, and player 2 is supposed to contribute more than she is willing to. Then the second highest net benefits are generated by serving $S = \{1, 3\}$, with cost shares $\overline{\Phi}(\mathbf{1}_S, c) = (6, 0, 27)$. Then $\{1, 3\}$ is the solution to Eq. (13).

What happens if some of the players misrepresent their preferences, for instance like in $\eta = (13, 6, 20)$? The planner determines the *conceived* net benefits

S	$\varnothing$	1	2	3	12	13	23	N
$\pi(S, \eta)$	0	1	-14	-13	-1	0	-7	6

Again, if the planner served the coalition with the highest net benefit, N, then player 2 would refuse to pay. Second highest net benefit corresponds to the singleton $S = \{1\}$, and this player will get service under $M(\overline{\Phi})$ since $\eta_3 = 13 > 12 = c(1, 0, 0)$.

Example 19 Consider the same situation but now with $\overline{\mu}^{\mathrm{E}}$ instead of $\overline{\Phi}$ as cost sharing rule. Now consider the following table, restricted to coalitions with non-negative net benefits (all other will not be selected):

S	$\varnothing$	13	23	N
$\pi(S, \alpha)$	0	8	3	11
$\overline{\mu}^{\mathrm{E}}(\mathbf{1}_S, c)$	(0,0,0)	(12,0,21)	$(0, \frac{33}{2}, \frac{33}{2})$	(10, 10, 13)

Here only the empty coalition $S = \varnothing$ satisfies the requirement $\overline{\mu}^{\mathrm{E}}(\mathbf{1}_S, c) = (0, 0, 0) \leq (8, 6, 30)$; hence according to the mechanism $M(\overline{\mu}^{\mathrm{E}})$ nobody will get service.

In general, the optimization problem Eq. (13) does not give unique solutions in case of which a planner should still further specify what she does in those cases. For concave cost functions, consider the following sequence of coalitions

$$S_1 = N, \; S_t = \{\, i \in S_{t-1} \,|\, \eta_i \geq \mu_i(\mathbf{1}_{S_t}, c) \} \; .$$

So, starting with the grand coalition N, at each consecutive step those players are removed whose maximal contributions are not consistent with the proposed cost share – until the process settles down. The set of remaining players defines a solution to Eq. (13) and taken to define $S(\mu, \eta)$.

Strategyproofness The essence of a demand revelation mechanism M is that its rules are set up in such a way that it provides enough incentives for the players not to lie about their true preferences. We will now discuss the most common non-manipulability properties of revelation mechanisms in the literature.

Fix two profiles $\alpha', \alpha \in \mathbb{R}_+^N$, where α corresponds to the true maximal willingness' to pay. Let (q', x') and (q, x) be the allocations implemented by the mechanism M on receiving the messages α' and α, respectively. The mechanism M is called *strategy-proof* if it holds for all $i \in N$ that $\alpha'_{N\backslash\{i\}} = \alpha_{N\backslash\{i\}}$ implies $u_i(q'_i, x'_i) \leq u_i(q_i, x_i)$.

So, given the situation that the other agents report truthfully, unilateral deviation by agent i from the true preference never produces better outcomes for her. Similarly, M is *group strategy-proof* if deviations of groups of agents does not pay for all deviators, i. e., for all $T \subset N$ the fact that $\alpha'_{N\backslash T} = \alpha_{N\backslash T}$ implies $u_i(q'_i, x'_i) \leq u_i(q_i, x_i)$ for all $i \in T$. So, under a (group) strategy-proof mechanism, there is no incentive to act untruthfully by misrepresenting the true preferences and this gives a benevolent planner control over the outcome.

Cross-Monotonicity Cost sharing rule μ is called *cross-monotonic* if the cost share of an agent i is not increasing if other agents demand more service, in case of a concave cost function c. Formally, if $\overline{x} \geq x$ and $\overline{x}_i = x_i$ then $\mu_i(\overline{x}, c) \leq \mu_i(x, c)$; each agent is granted a (fair) share of the positive externality due to an increase in demand by others.

Proposition 1 (Moulin & Shenker [93]) *The only group strategy-proof mechanisms $M(\mu)$ satisfying VP and CS are those related to cross-monotonic cost sharing rules μ.*

There are many different cross-monotonic cost sharing rules, and thus just as many mechanisms that are group strategy-proof. Examples include the mechanisms $M(\overline{\Phi})$ and $M(\overline{\mu}^{\mathrm{E}})$, because $\overline{\Phi}$ and $\overline{\mu}^{\mathrm{E}}$ are cross-monotonic. However, the nucleolus is not cross-monotonic and does therefore not induce a strategy-proof mechanism.

Above we discussed two instruments a social planner may invoke to implement a desirable outcome without knowing the true preferences of the agents. Basically, the demand revelation games define a so-called *direct mechanism*. The announcement of the maximal price for service pins down the complete preferences of an agent. So in fact the planner decides upon the service level based on a complete profile of preferences. In case of a cross-monotonic cost sharing rule, under the induced mechanism truth-telling is a weakly dominant strategy; announcing the true maximal willingness to pay is optimal for the agent regardless of the actions of others. This means good news for the social planner as the mechanism is self-organizing: the agents need not form any conjecture about the behavior of others in order to know what to do. In the literature [24] such a mechanism is called *straightforward*. The demand games define an *indirect mechanism*, as by reporting a demand the agents do no more than signaling their preferences to the planner.

Although in general there is a clear distinction between direct and indirect mechanisms, in the model presented in this section these are nevertheless strongly connected. Focus on a demand game $G(\mu, c)$; recall that in this game the agents simultaneously and independently decide upon requesting service or not and costs are shared using the rule μ amongst those agents receiving service. Suppose that for each profile of utility functions as in Eq. (12) the resulting game $G(\mu, c)$ has a unique (strong) Nash-equilibrium. Then this equilibrium can be taken to define a mechanism. That is, the mechanism elicits u and chooses the unique equilibrium *outcome* of the reported demand game. Then this mechanism is equivalent with the demand revelation mechanism. Observe that indeed the strong equilibrium $(1, 0, 1)$ in the game $G(\overline{\Phi}, c)$ in Example 17 corresponds to players chosen by $M(\overline{\Phi})$ under truthful reporting. And where no player is served in the strong equilibrium of $G(\overline{\mu}^{\mathrm{E}}, c)$, none of the players is selected by $M(\overline{\mu}^{\mathrm{E}})$. It is a general result in implementation theory due to [24] that a direct mechanism constructed in this way is (group) strategy-proof *provided* the underlying space of preferences is *rich*. It is easily seen that the above sets of preferences meet the requirements. To stress importance of such a structural property as richness, it is instructive to point at what is yet to come in Sect. "Uniqueness of Nash-Equilibria in $\mathcal{P}^1$-Demand Games". Here, the strategic analysis of the demand game induced by the proportional rule shows uniqueness of Nash equilibrium on the domain of preferences $\mathcal{L}^*$ if only costs are convex. However, this domain is *not* rich, and the direct mechanism defined in the same fashion as above by the Nash equilibrium selection is *not* strategyproof.

Efficiency and Strategy-Proof Cost Sharing Mechanisms

Suppose *cardinal utility* for each agent, so that inter-comparison of utility is allowed. Proceeding on the net benefit of a coalition, we may define its *value* at α by

$$v(N, \alpha) = \max_{S \subset N} \pi(S, \alpha) \,, \tag{14}$$

where $\pi(S, \alpha)$ is the net benefit of S at α. A coalition S such that $v(N, \alpha) = \pi(S, \alpha)$ is called *efficient*. It will be clear that a mechanism $M(\mu)$ that is defined through the optimization problem Eq. (13) will not implement an efficient coalition of served players, due to the extra constraint on the cost shares.

For instance, in Example 7 the value of the grand coalition at $\alpha = (8, 6, 30)$ is given by $v(N, \alpha) = \alpha(N) - c(N) = 44 - 33 = 11$. At the same profile the implemented outcome by mechanism $M(\overline{\Phi})$ gives rise to a total surplus of $38 - 30 = 8$ for the grand coalition – which is not optimal. The mechanism $M(\overline{\mu}^{\mathrm{E}})$ performs even worse as it leads to the stand alone surplus 0, none is served.

This observation holds for far more general settings, and, moreover, it is a well known result from implementation theory that – under non-constant marginal cost – any strategy-proof mechanism based on full coverage of total costs will not always implement efficient outcomes. For the constant marginal cost case see [67,71]. Then, if there is an unavoidable loss in using demand revelation mechanisms, can we still tell which mechanisms are more efficient? Is it a coincidence that in the above examples the Shapley value performs better than the egalitarian solution?

The *welfare loss* due to $M(\mu)$ at a profile of true preferences α is given by

$$L(\mu, \alpha) = v(N, \alpha) - \{\alpha(S(\mu, \alpha)) - c(S)\} \,. \tag{15}$$

For instance, with $\alpha = (8, 6, 30)$ in the above examples we calculate $L(\overline{\Phi}, \alpha) = 11 - 8 = 3$ and $L(\overline{\mu}^{\mathrm{E}}, \alpha) = 11 - 0 = 11$. An overall measure of quality of a cost sharing rule μ in terms of efficiency loss is defined by

$$\gamma(\mu) = \sup_\alpha L(\mu, \alpha) \,. \tag{16}$$

Theorem 6 (Moulin & Shenker [93]) *Among all mechanisms $M(\mu)$ derived from cross-monotonic cost sharing rules μ, the Shapley rule $\overline{\Phi}$ has the unique smallest maximal efficiency loss, or $\gamma(\overline{\Phi}) < \gamma(\mu)$ if $\mu \neq \overline{\Phi}$.*

Notice that this makes a strong case for the Shapley-value against the egalitarian solution. The story does, however, not end here.

[98] considers a model where the valuations of the agents for the good are independent random variables, drawn from a distribution function F satisfying the *monotone hazard condition*. This means that the function defined by $h(x) = f(x)/(1 - F(x))$ is non-decreasing, where F has f as density function. It is shown that the constrained egalitarian solution maximizes the probability that all members of any given coalition accept the cost shares imputed to them. Moreover, [98] characterized the solution in terms of efficiency. Suppose for the moment that the planner calculated cost share vector $\mathbf{x}$ for the coalition S, and that its members are served conditional on acceptance of the proposed cost shares. The probability that all members of S accept the shares is given by $P(x) = \prod_{i \in S}(1 - F(x_i))$, and if we assume that the support of F is $(0, m)$ then the expected surplus from such an offer can be calculated as follows

$$W(x) = P(x) \cdot \left[\sum_{i \in S} \int_{x_i}^{m} \frac{u_i}{1 - F(x_i)} \mathrm{d}F(u_i) - c(S) \right] . \tag{17}$$

The finding of [98] is that for *log-concave* f, i.e. $x \mapsto \ln(f(x))$ is concave [5], the mechanism based on the constrained egalitarian solution not only maximizes the probability that a coalition accepts the proposal, but it maximizes its expected surplus as well. Formally, the result is the following.

Theorem 7 (Mutuswami (2004)) *If the profile of valuations $(u_i)_{i \in N}$ are independently drawn form a common distribution function F with log-concave and differentiable density function f, then $W(\overline{\mu}^{\mathrm{E}}(\mathbf{1}_S, c)) \geq W(\mu(\mathbf{1}_S, c))$ for all cross monotonic solutions μ and all $S \subset N$.*

Extension of the Model: Discrete Goods

Suppose the agents consume idiosyncratic goods produced in indivisible units. Then given a profile of demands the cost associated with the joint production must be shared by the users. Then this model generalizes the binary good model discusses so far and it is a launch-pad to the continuous framework in the next section. In this discrete good setting [86] characterizes the cost sharing rules which induce strategyproof social choice functions defined by the equilibria of the corresponding demand game. As it turns out, these rules are *basically* the *sequential stand alone rules*, according to which costs are shared in an incremental fashion with respect to a fixed ordering of the agents. This means that such a rule charges the first agent for her stand alone costs, the second for the stand alone cost for the first two users minus the stand alone cost of the first, et cetera. Here the word 'basically' refers to all discrete cost sharing problems other than those with binary goods. Then here the sufficient condition for strategyproofness is that the underlying cost sharing rule be cross monotonic, which admits other rules than the sequential ones – like $\overline{\mu}^{\mathrm{E}}$ and $\overline{\Phi}$.

Continuous Cost Sharing Models

Continuous Homogeneous Output Model, $\mathcal{P}^1$

This model deals with production technologies for one single perfectly divisible output commodity. Moreover, we will restrict ourselves to private goods. Many ideas below have been studied for *public goods* as well, for further references see, e. g., [33,72,82].

The demand space of an individual is given by $X = \mathbb{R}_+$. The technology is described by a non-decreasing cost function $c\colon \mathbb{R}_+ \to \mathbb{R}$ such that $c(0) = 0$, i. e. there are no fixed costs. Given a profile of demands $x \in \mathbb{R}_+^N$ costs $c(x(N))$ have to be shared. Moreover, the space of cost functions will be restricted to those c being *absolutely continuous*. Examples include the differentiable and Lipschitz-continuous functions. Absolute continuity implies that aggregate costs for production can be calculated by the total of marginal costs

$$c(y) = \int_0^y c'(t)\,\mathrm{d}t\,.$$

Denote the set of all such cost functions by C^1 and the related cost sharing problems by $\mathcal{P}^1$. Several cost sharing rules on $\mathcal{P}^1$ have been proposed in the literature.

Average Cost Sharing Rule This is the most popular and oldest concept in the literature and advocates Aristotle's principle of proportionality.

$$\mu^{\mathrm{AV}}(x, c) = \begin{cases} \frac{x}{x(N)} \cdot c(x(N)) & \text{if } x \neq 0_N \\ 0 & \text{if } x = 0_N \end{cases} \tag{18}$$

Shapley–Shubik Rule Each cost sharing problem $(x, c) \in \mathcal{P}^1$ is related to the stand-alone cost game c_x such that $c_x(S) = c(x(S))$. Then the Shapley–Shubik rule is determined by application of the Shapley-value to this game:

$$\mu^{\mathrm{SS}}(x, c) = \Phi(c_x)\,.$$

Serial Rule This rule, due to Moulin and Shenker [91], determines cost shares by considering particular intermediate cost levels. More precisely, given $(x, c) \in \mathcal{P}^1$ it first relabels the agents by increasing demands such that $x_1 \leq x_2 \leq \cdots \leq x_n$. The intermediate production levels are

$$\begin{aligned} y^1 &= nx_1,\ y^2 = x_1 + (n-1)x_2,\ \ldots\,, \\ y^k &= \sum_{j=1}^{k-1} x_j + (n-k+1)x_k,\ \ldots\,, \\ y^n &= x(N)\,. \end{aligned}$$

These levels are chosen such that at each new level one agent more is fully served his demand: at y^1 each agent is handed out x_1, at y^2 agent 1 is given x_1 and the rest x_2, etc. The serial cost shares are now given by

$$\mu_i^{\mathrm{SR}}(x, c) = \sum_{\ell=1}^{k} \frac{c(y^\ell) - c(y^{\ell-1})}{n - \ell + 1}\,.$$

So according to μ^{SR} each agent pays a fair share of the incremental costs in each stage that she gets new units.

Example 20 Consider the cost sharing problem (x, c) with $x = (10, 20, 30)$ and $c(y) = \frac{1}{2}y^2$. Then first calculate the intermediate production levels $y^0 = 0$, $y^1 = 30$, $y^2 = 50$, and $y^3 = 60$. Then the cost shares are calculated as follows

$$\mu_1^{\mathrm{SR}}(x, c) = \frac{c(y^1) - c(y^0)}{3} = 150\,,$$

$$\begin{aligned}\mu_2^{\mathrm{SR}}(x,c) &= \mu_1^{\mathrm{SR}}(x,c) + \frac{c(y^2)-c(y^1)}{2}\\ &= 150 + \frac{1250-450}{2} = 550\,,\\ \mu_3^{\mathrm{SR}}(x,c) &= \mu_2^{\mathrm{SR}}(x,c) + c(y^3) - c(y^2) = 550 + 550\\ &= 1100\,.\end{aligned}$$

The serial rule has attracted much attention lately in the network literature, and found its way in fair queuing packet scheduling algorithms in routers [27].

Decreasing Serial Rule De Frutos [26] proposes serial cost shares where demands of agents are put in decreasing order. Resulting is the *decreasing serial rule*. Consider a demand vector $x \in \mathbb{R}_+^N$ such that $x_1 \leq x_2 \leq \cdots \leq x_n$. Define recursively the numbers y^ℓ for $\ell = 1, 2, \ldots, n$ by $y^\ell = \ell x_\ell + x_{\ell+1} + \cdots + x_n$, and put $y^{n+1} = 0$. Then the decreasing serial rule is defined by

$$\mu_i^{\mathrm{DSR}}(x,c) = \sum_{\ell=i}^{n} \frac{c(y^\ell) - c(y^{\ell+1})}{\ell}\,. \tag{19}$$

Example 21 For the cost sharing problem in Example 20 calculate $y^1 = 90$, $y^2 = 70$, $y^1 = 60$, then

$$\begin{aligned}\mu_3^{\mathrm{DSR}}(x,c) &= \frac{c(y^3)-c(y^4)}{3} = \frac{4050-0}{3} = 1350\,,\\ \mu_2^{\mathrm{DSR}}(x,c) &= \mu_3^{\mathrm{DSR}}(x,c) + \frac{c(y^2)-c(y^3)}{2}\\ &= 1350 + \frac{2450-4050}{2} = 550\,,\\ \mu_1^{\mathrm{DSR}}(x,c) &= \mu_2^{\mathrm{DSR}}(x,c) + (c(y^1)-c(y^2))\\ &= 550 + (1800-2450) = -100\,.\end{aligned}$$

Notice that here the cost share of agent 1 is negative, due to the convexity of c! This may be considered as an undesirable feature of the cost sharing rule. Not only are costs increasing in the level of demand, in case of a convex cost function each agent contributes to the negative externality. It seems fairly reasonable to demand a non-negative contribution in those cases, so that none profits for just being there. The mainstream cost sharing literature includes positivity of cost shares into the very definition of a cost sharing rule. Here we will add it as a specific property:

Positivity μ is *positive* if $\mu(x,c) \geq 0_N$ for all (x,c) in its domain. All earlier discussed cost sharing rules have this property, except for the decreasing serial rule.

The decreasing serial rule is far more intuitive in case of economies of scale, in presence of a concave cost function. The larger agents now are credited with a lower price per unit of the output good. [47,57] propose variations on the serial rule that coincide with the increasing (decreasing) serial rule in case of a convex (concave) cost function, meeting the positivity requirement.

Marginal Pricing Rule A popular way of pricing an output of a production facility is *marginal cost pricing*. The price of the output good is set to cover the cost producing one extra unit. It is frequently used in the domain of public services and utilities. However, a problem is that for concave cost functions the method leads to budget deficits. An adapted form of marginal cost pricing splits these deficits equally over the agents. The *marginal pricing rule* is defined by

$$\mu_i^{\mathrm{MP}}(x,c) = x_i c'(x(N)) + \tfrac{1}{n}\left[c(x(N)) - x(N)c'(x(N))\right]. \tag{20}$$

Note that in case of convex cost functions agents can receive negative cost shares, just like it is the case with decreasing serial cost sharing.

Additive Cost Sharing and Rationing

The above cost sharing rules for homogeneous production models share the following properties:

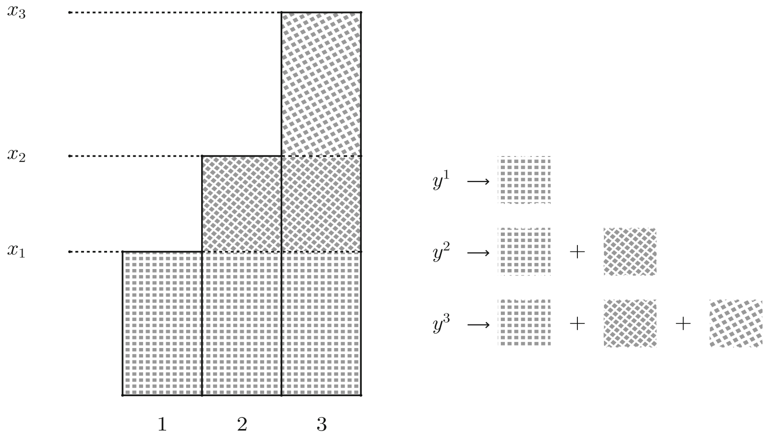
Additivity $\mu(x, c_1 + c_2) = \mu(x, c_1) + \mu(x, c_2)$ for all relevant cost sharing problems. This property carries the same flavor as the homonymous property for cost games.

Constant Returns $\mu(x,c) = \vartheta x$ for linear cost functions c such that $c(y) = \vartheta y$ for all y. So if the agents do not cause any externality, the fixed marginal cost is taken as a price for the good.

It turns out that the class of all positive cost sharing rules with these properties can be characterized by solutions to *rationing problems* – which are the most basic of all models of distributive justice. A rationing problem amongst the agents in N consists of a pair $(x,t) \in \mathbb{R}_+^N \times \mathbb{R}_+$ such that $x(N) \geq t$; t is the available amount of some (in)divisible good and x is the set of demands. The inequality sees to the interpretation of rationing as not every agent may get all she wants.

A *rationing method* r is a solution to rationing problems, such that each problem (x,t) is assigned a vector of shares $r(x,t) \in \mathbb{R}_+^N$ such that $\mathbf{0}_N \leq r(x,t) \leq x$. The latter restriction is a weak solidarity statement assuring that everybody's demand be rationed in case of shortages.

For $t \in \mathbb{R}_+$ define the special cost function Γ_t by $\Gamma_t(y) = \min\{y, t\}$. The cone generated by these base



Cost Sharing, Figure 7
Intermediate production levels

functions lays dense in the space of all *absolutely continuous* cost functions c; if we know what the values $\mu(x, \Gamma_t)$ are, then basically we know $\mu(x, c)$. Denote by $\mathcal{M}$ the class of all cost sharing rules with the properties positivity, additivity, and constant returns.

Theorem 8 (Moulin & Shenker [88,92]) *Consider the following mappings associating rationing methods with cost sharing rules and vice versa,*

$$\begin{aligned} r \mapsto \mu &: \mu(x, c) = \int_0^{x(N)} c'(t) dr(x, t) \,, \\ \mu \mapsto r &: r(x, t) = \mu(x, \Gamma_t) \,. \end{aligned}$$

These define an isomorphism between $\mathcal{M}$ and the space of all monotonic rationing methods.

So each monotonic rationing method relates to a cost sharing rule and vice versa. In this way μ^{P} is directly linked with the proportional rationing method, μ^{SR} to the *uniform gains* method, and μ^{SS} to the *random priority* method. Properties of rationing methods lead to properties of cost sharing rules and vice versa [61].

Incentives in Cooperative Production

Stable Allocations, Stand-Alone Core Suppose again, like in the framework of cooperative cost games, that (coalitions of) agents can decide to leave the cost sharing and organize their own production facility. Under the ability to replicate the technology the question arises whether cost sharing rules induce stable cost share vectors.

Theorem 9 (Moulin [85]) *For concave cost functions c, if μ is an anonymous and cross-monotonic cost sharing rule then $\mu(x, c) \in$* core(c_x).

Under increasing returns to scale, this implies that $\mu^{\mathrm{P}}, \mu^{\mathrm{SR}}$ are core-selectors but μ^{MC} is not. [137] associates to each cost sharing problem (x, c) a *pessimistic* one, (x, c^*); here $c^*(y)$ reflects the maximum of marginal cost on $[0, x(N)]$ to produce y units,

$$c^*(y) = \begin{cases} \sup\left\{\int_T c'(t)\mathrm{d}t \mid T \subset [0, x(N)], \lambda(T) = y\right\} & \\ & \text{if } y \leq x(N)\,, \\ c(y) & \text{else}\,. \end{cases} \tag{21}$$

Here λ denotes the Lebesgue measure.

Theorem 10 (Koster [60]) *For any cost sharing problem (x, c), it holds* core$(c_x^*) = \{\mu(x, c) \mid \mu \in \mathcal{M}\}$.

In particular this means that for $\mu \in \mathcal{M}$ it holds that $\mu(x, c) \in$ core(c_x) whenever c is concave, since this implies $c^* = c$. This result appeared earlier as a corollary to Theorem 8, see [88]. [47,57,61] show *non-linear* cost sharing rules yielding core elements for concave cost functions as well, so additivity is only a sufficient condition in the above statement. For average cost sharing, one can show more, $\mu^{\mathrm{P}}(x, c) \in$ core(c_x) for all x precisely when the average cost $c(y)/y$ is decreasing in y.

Strategic Manipulation Through Reallocation of Demands In the cooperative production model, there are other ways that agents may use to manipulate the final allocation. In particular, note that the serial procedure gives the larger demanders an advantage in case of positive externalities; as marginal costs decrease, the price paid by the larger agents per unit of output is lower than that of the smaller agents. In the other direction larger demanders are punished if costs are convex. Then as the examples below show, this is just why the serial ideas are vulnerable to misrepresentation of demands, since combining demands and redistribute the output afterwards can be beneficial.

Example 22 Consider the cost function c given by $c(y) = \min\{5y, 60 + 2y\}$. Such cost functions are part of daily life, whenever one has to decide upon telephone or energy supply contracts: usually customers get to choose between a contract with high fixed cost and a low variable cost, and another with low or no fixed cost and a high variable price. Now consider the two cost sharing problems (x, c) and (x', c) where $x = (10, 20, 30)$, $x' = (0, 30, 30)$. The cost sharing problem (x', c) arises from (x, c) if agent 2 places a demand on behalf of agent 1 – without letting agent 3 know. The corresponding average and serial cost shares are given by

$$\begin{aligned} \mu^{\mathrm{P}}(x,c) &= (30,60,90) \quad & \mu^{\mathrm{P}}(x',c) &= (0,90,90) \\ \mu^{\mathrm{SR}}(x,c) &= (40,60,80) \quad & \mu^{\mathrm{SR}}(x',c) &= (0,90,90)\,. \end{aligned}$$

Notice that the total of average cost shares for 1 and 2 is the same in both cost sharing problems. But if the serial rule were used, these agents can profit by *merging* their demands; if agent 2 returns agent 1's demand and requires a payment from agent 1 between €30 and €40, then both agents will have profited by such *merging* of demand.

Example 23 Consider the five-agent cost sharing problems (x, c) and $(\overline{x}, c)$ with $x = (1, 2, 3, 0, 0)$, $\overline{x} = (1, 2, 1, 1, 1)$ and convex cost function $c(y) = \frac{1}{2}y^2$. $(\overline{x}, c)$ arises out of (x, c) if agent 3 splits her demand over agents 4 and 5 as well. Then

$$\begin{aligned} \mu^{\mathrm{P}}(x,c) &= (6,12,18,0,0) \quad & \mu^{\mathrm{P}}(\overline{x},c) &= (6,12,6,6,6)\,, \\ \mu^{\mathrm{SR}}(x,c) &= (3,11,22,0,0) \quad & \mu^{\mathrm{SR}}(\overline{x},c) &= (5,16,5,5,5)\,. \end{aligned}$$

The aggregate of average cost shares for agents 3, 4, and 5 does not change. But notice that according to the serial cost shares, there is a clear advantage for the agents. Instead of paying 22 in the original case, now the total of payments equals 15. Agent 3 may consider a transfer between 0 and 7 to 3 and 4 for their collaboration and still be better of. In general, in case of a convex cost function the serial rule is vulnerable with respect to manipulation of demands through splitting.

Note that in the above cases the proportional cost sharing rule does prescribe the same cost shares. It is a non-manipulable rule: reshuffling of demands will not lead to different aggregate cost shares. The rule does not discriminate between units, when a unit is produced is irrelevant. It is actually a very special feature of the cost sharing rule that is basically not satisfied by any other cost sharing rule.

Theorem 11 *Assume that N contains at least three agents. The proportional cost sharing rule is the unique rule that charges nothing for a null demand and meets any one of the following properties:*

- *Independence of merging and splitting,*
- *No advantageous reallocation,*
- *Irrelevance of reallocation.*

The second property shows even a stronger property than merging and splitting: agents may redistribute the demands in any preferred way without changing the aggregate cost shares of the agents involved. The third property states that in such cases the cost shares of the other agents do not change. Then this makes proportional cost sharing compelling in situations where one is not capable of detecting the true demand characteristics of individuals.

Demand Games for $\mathcal{P}^1$

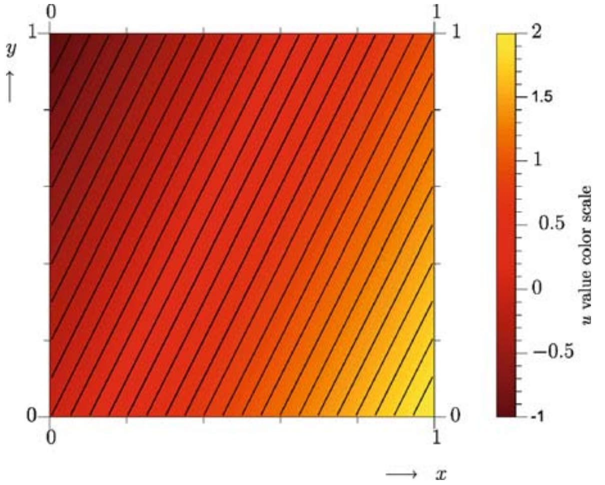
Consider demand games $G(\mu, c)$ as in Eq. (11), Sect. "Demand Games", where now μ is a cost sharing rule on $\mathcal{P}^1$. These games with uncountable strategy spaces are more complex than the demand games that we studied before.

The set of consequences for players is now given by $C = \mathbb{R}^2_+$, combinations of levels of production and costs (see Sect. "Strategic Demand Games"). Then an individual i's preference relation is *convex* if for the corresponding utility function u_i and all pairs $z, z' \in C$ it holds

$$\begin{aligned} &u_i(z) = u_i(z') \\ &\quad \Longrightarrow\; u(tz + (1-t)z) \geq u_i(z) \quad \text{for all } t \in [0,1]\,. \end{aligned} \tag{22}$$

This means that a weighted average of the consequences is weakly preferred to both consequences, if these are equivalent. Such utility functions u_i are called *quasi-concave*. An example of convex preferences are those related to *linear utility* functions of type $u_i(x, y) = \alpha x - y$. Moreover, *strictly convex* preferences are those with strict inequality in Eq. (22) for $0 < t < 1$; the corresponding utility functions are *strictly quasi-concave*. Special classes of preferences are the following.

- $\mathcal{L}$: the class of all convex and continuous preferences utility functions that are non-decreasing in the service component x, non-increasing in the cost component y, non-locally satiated and decreasing on $(x, c(x))$ for x large enough. The latter restriction is no more than assuring that agents will not place requests for unlimited amounts of the good.



Cost Sharing, Figure 8
Linear, convex preferences, $u(x, y) = 2x - y$. The contours indicate indifference curves, i.e. sets of type $\{(x, y)|u(x, y) = k\}$, the k-level curve of u

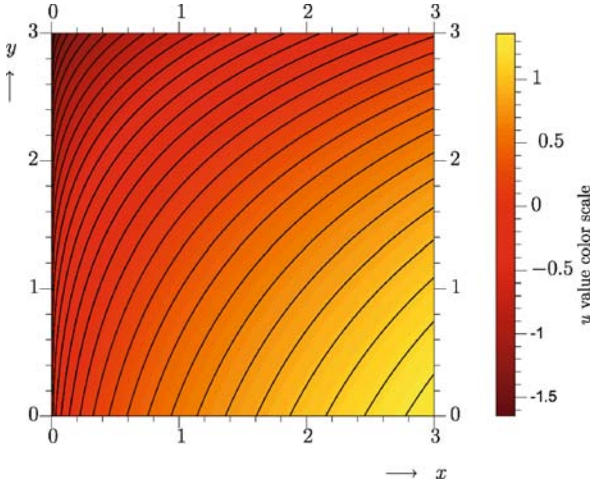
- $\mathcal{L}^*$: the class of *bi-normal* preferences in $\mathcal{L}$. Basically, if such a preference is represented by a differentiable utility function u then the slope $\mathrm{d}y/\mathrm{d}x$ of the indifference contours is non-increasing in x, non-decreasing in y. For a concise definition see [141]. Examples include Cobb–Douglas utility functions and also those of type $u_i(x, y) = \alpha(x) - \beta(y)$ where α and β are concave and convex functions, respectively. A typical plot of level curves of such utility functions is in Fig. 9. Note that the approach differs from the standard literature where agents have preferences over endowments. Here costs are 'negative' endowments. In the latter interpretation, the condition can be read as that the *marginal rate of substitution* is non-positive. At equal utility, an increase of the level of output has to be compensated by a decrease in the level of input good.

Nash-Equilibria of Demand Games in a Simple Case

Consider a production facility shared by three agents $N = \{1, 2, 3\}$ with cost function $c(y) = \frac{1}{2}y^2$. Assume that the agents have quasi-linear utilities in $\mathcal{L}$, i.e. $u_i(x_i, y_i) = \alpha_i x_i - y_i$ for all pairs $(x_i, y_i) \in \mathbb{R}^2_+$. Below the Nash-equilibrium in the serial and proportional demand game is calculated in two special cases. This numerical example is based on [91].

Proportional Demand Game Consider the corresponding proportional demand game, $G(\mu^{\mathrm{P}}, c)$, with utility over actions given by

$$U_i^{\mathrm{P}}(x) = \alpha_i x_i - \mu^{\mathrm{P}}(x, c) = \alpha_i x_i - \tfrac{1}{2} x_i x(N)\,. \qquad (23)$$



Cost Sharing, Figure 9
Strictly convex preferences, $u(x, y) = \sqrt{x} - \mathrm{e}^{0.5y}$. The straight line connecting any two points on the same contour lays in the lighter area – with higher utility. Fix the y-value, then an increase of x yields higher utility, whereas for fixed x an increase of y causes the utility to decrease

In a Nash-equilibrium x^* of $G(\mu^{\mathrm{P}}, c)$ each player i gives a best response on x^*_{-i}, the action profile of the other agents. That is, player i chooses $x^*_i \in \arg\max_t U_i^{\mathrm{P}}(t, x^*_{-i})$. Then first order conditions implies for an interior solution

$$\alpha_i - \tfrac{1}{2} x^*(N) - \tfrac{1}{2} x^*_i = 0 \qquad (24)$$

for all $i \in N$. Then $x^*(N) = \frac{1}{2}(\alpha_1 + \alpha_2 + \alpha_3)$ and $x^*_i = 2\alpha_i - \frac{1}{2}(\alpha_1 + \alpha_2 + \alpha_3)$.

Serial Demand Game Consider the same production facility and the demand game $G(\mu^{\mathrm{SR}}, c)$, corresponding to the serial rule. Then the utilities over actions are given by

$$U_i^{\mathrm{SR}}(x) = \alpha_i x_i - \mu^{\mathrm{SR}}(x, c)\,. \qquad (25)$$

Now suppose $\overline{x}$ is a Nash equilibrium of this game, and assume without loss of generality that $\overline{x}_1 \le \overline{x}_2 \le \overline{x}_3$. Then player 1 with the smallest equilibrium demand maximizes the expression

$$U_1^{\mathrm{SR}}((t, \overline{x}_2, \overline{x}_3) = \alpha_1 t - c(3t)/3 = \alpha_1 t - \tfrac{3}{2}t^2$$

at $\overline{x}_1$, from which we may conclude that $\alpha_1 = 3\overline{x}_1$. In addition, in equilibrium, player 2, maximizes

$$U_2^{\mathrm{SR}}(\overline{x}_1, t, \overline{x}_3) = \alpha_2 t - (\tfrac{1}{3}c(3\overline{x}_1) + \tfrac{1}{2}(c(\overline{x}_1 + 2t) - c(3\overline{x}_1))\,,$$

for $t \ge \overline{x}_1$, yielding $\alpha_2 = \overline{x}_1 + 2\overline{x}_2$. Finally, the equilibrium condition for player 3 implies $\alpha_3 = \overline{x}(N)$. Then it is not hard to see that actually this constitutes *the* serial equilibrium.

Comparison of Proportional and Serial Equilibria (I)

Now let's compare the serial and the proportional equilibrium in the following two cases:

$$\begin{aligned}&\text{(i)} && \alpha_1 = \alpha_2 = \alpha_3 = \alpha\\ &\text{(ii)} && \alpha_1 = \alpha_2 = 2, \alpha_3 = 4\,.\end{aligned}$$

Case (i): Then we get $x^* = (\frac{1}{2}\alpha, \frac{1}{2}\alpha, \frac{1}{2}\alpha)$ and $\overline{x}_i = (\frac{1}{3}\alpha, \frac{1}{3}\alpha, \frac{1}{3}\alpha)$ for all i. The resulting equilibrium payoff vectors are given by

$$U^{\mathrm{P}}(x^*) = (\tfrac{1}{8}\alpha^2, \tfrac{1}{8}\alpha^2, \tfrac{1}{8}\alpha^2) \text{ and}$$
$$U^{\mathrm{SR}}(\overline{x}) = (\tfrac{1}{6}\alpha^2, \tfrac{1}{6}\alpha^2, \tfrac{1}{6}\alpha^2)\,.$$

Not only the average outcome is less efficient than its serial counterpart, it is also Pareto-inferior to the latter.

Case (ii): The proportional equilibrium is a boundary solution, $x^* = (0, 0, 2)$ with utility profile $U^{\mathrm{P}}(x^*) = (0, 0, 8)$. The serial equilibrium strategies and utilities are given by

$$\overline{x} = (\tfrac{2}{3}, \tfrac{2}{3}, \tfrac{8}{3}), U^{\mathrm{SR}}(\overline{x}) = (\tfrac{2}{3}, \tfrac{2}{3}, 4)\,.$$

Notice that the serial equilibrium is now less efficient, but is not Pareto-dominated by the proportional utility distribution.

Uniqueness of Nash-Equilibria in $\mathcal{P}^1$-Demand Games

In the above demand games there is a unique Nash-equilibrium which serves as a prediction of actual play. This need not hold for any game. In the literature strategic characterizations of cost sharing rules are discussed in terms of uniqueness of equilibrium in the induced cost games, relative to specific domains of preferences and cost functions. Below we will discuss the major findings of [141]. These results concern a broader cost sharing model with the notion of a cost function as a differentiable function $\mathbb{R}_+ \to \mathbb{R}_+$. So in this paragraph such cost function can decrease, fixed cost need not be 0. This change in setup is not crucial to the overall exposition since the characterizations below are easily interpreted within the context of $\mathcal{P}^1$.

Demand Monotonicity The mapping $t \mapsto \mu_i((t, x_{-i}), c)$ is non-decreasing; μ is strictly demand monotonic if this mapping is increasing whenever c is increasing.

Smoothness The mapping $x \mapsto \mu(x, c)$ is continuously differentiable for all continuously differentiable $c \in C^1$.

Recall that $\mathcal{L}^*$ is the domain of all bi-normal preferences.

Theorem 12 (Watts [141]) *Fix a differentiable cost function c and a demand monotonic and smooth cost sharing rule μ. A cost sharing game $G(\mu, c)$ has a unique equilibrium whenever agents' preferences belong to $\mathcal{L}^*$, only if, for all $x = (x_1, \ldots, x_n)$*

- *Every principal minor of the matrix W with rows w^i is non-negative for all*

$$w^i \in \left\{ \left(\frac{\partial \mu_i}{\partial x_1}, \ldots, \frac{\partial \mu_i}{\partial x_n} \right), \left(\frac{\partial^2 \mu_i}{\partial x_1 \partial x_1}, \ldots, \frac{\partial^2 \mu_i}{\partial x_i \partial x_n} \right) \right\}. \tag{26}$$

- *The determinant of the Hessian matrix corresponding to the mapping $x \mapsto \mu(x, c)$ is strictly positive.*

A sufficient condition to have uniqueness of equilibrium is that the principle minor of the matrix W is strictly positive.

The impact of this theorem is that one can characterize the class of cost functions yielding unique equilibria if the domain of preferences is $\mathcal{L}^*$.

- $G(\mu^{\mathrm{SR}}, c), G(\mu^{\mathrm{DSR}}, c)$: Necessary condition for uniqueness of equilibrium is that c is strictly convex, i. e. $c'' > 0$. A sufficient condition is that c is increasing and strictly convex. Actually, [141] also shows that the conclusions for the serial rule do not change when $\mathcal{L}$ is used instead of $\mathcal{L}^*$. As will get more clear below, the serial games have unique strategic properties.
- $G(\mu^{\mathrm{P}}, c)$: The necessary and sufficient conditions are those for the serial demand game, including $c'(y) > c(y)/y$ for all $y \neq 0$. Notice, that the latter property does not pose additional restrictions on cost functions within the framework of $\mathcal{P}^1$.
- $G(\mu^{\mathrm{SS}}, c)$: Necessary condition is $c'' > 0$. In general it is hard to establish uniqueness if more than 2 players are involved.
- $G(\mu^{\mathrm{MP}}, c)$: even in 2 player games uniqueness is not guaranteed. For instance, uniqueness is guaranteed for cost functions $c(y) = y^{\alpha}$ only if $1 < \alpha \leq 3$. For $c(y) = y^4$ there are preference profiles in $\mathcal{L}^*$ such that multiple equilibria reside.

Decreasing Returns to Scale The above theorem basically shows that uniqueness of equilibrium in demand games related to $\mathcal{P}^1$ can be achieved for preferences in $\mathcal{L}^*$ if only costs are convex, i. e. the technology exhibits decreasing returns to scale. Starting point in the literature to characterize cost sharing rules in terms of their strategic properties is the seminal paper by Moulin and Shenker [91]. Their finding is that on $\mathcal{L}$ basically μ^{SR} is the only cost sharing rule of which the corresponding demand game passes the unique equilibrium test like in Theorem 12.

Call a smooth and strictly demand monotonic cost sharing rule μ *regular* if it is *anonymous*, so that the name of an agent does not have an impact on her cost share.

Theorem 13 (Moulin & Shenker [91]) *Let c be a strictly convex continuously differentiable cost function, and let μ be a regular cost sharing rule. The following statements are equivalent:*

- $\mu = \mu^{\mathrm{SR}}$,
- *for all profiles $(u_1, u_2, \dots, u_n)$ of utilities in $\mathcal{L}$, $G(\mu, c)$ has at most one Nash-equilibrium,*
- *for all profiles $(u_1, u_2, \dots, u_n)$ of utilities in $\mathcal{L}$ every Nash-equilibrium of $G(\mu, c)$ is also a strong equilibrium, i. e., no coalition can coordinate in order to improve the payoff for all its members.*

This theorem makes a strong case for the serial cost sharing rule, especially when one realizes that the serial equilibrium is the unique element surviving successive elimination of strictly dominated strategies. Then this equilibrium may naturally arise through evolutive or eductive behavior, it is a robust prediction of non-cooperative behavior. Recent experimental studies are in line with this theoretical support, see [22,108]. Proposition 1 in [141] shows how easy it is to construct preferences in $\mathcal{L}$ such that regular cost sharing rules other than μ^{SR} give rise to multiple equilibria in the corresponding demand game, even in two-agent cost sharing games.

Besides other fairness concepts in the distributive literature the most compelling is *envy-freeness*. An allocation passes the no envy test if no player prefers her own allocation less than that of other players. Formally, the definition is as follows.

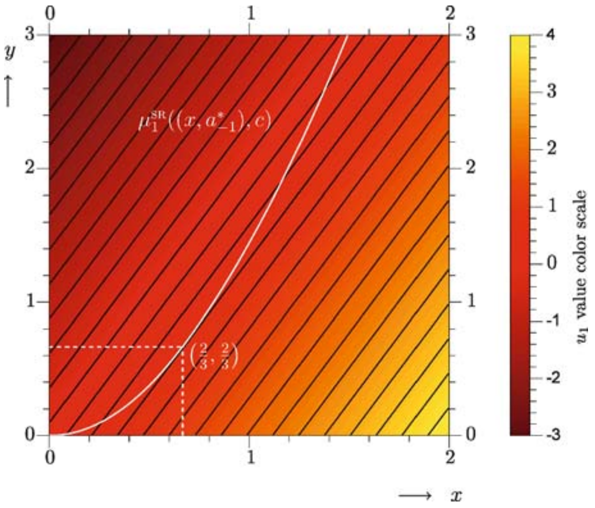
No Envy Test Let x be a demand profile and y a vector of cost shares. Then the allocation $(x_i, y_i)_{i \in N}$ is *envy-free* if for all $i, j \in N$ it holds $u_i(x_i, y_i) \geq u_i(x_j, y_j)$.

It is easily seen that the allocations associated with the serial equilibria are all envy-free.

Increasing Returns to Scale As Theorem 12 already shows, uniqueness of equilibrium in demand games for all utility profiles in $\mathcal{L}^*$ is in general inconsistent with concave cost functions.

Theorem 14 (de Frutos [26]) *Let c be a strictly concave continuously differentiable cost function, and let μ be a regular cost sharing rule. The following statements are equivalent:*

- $\mu = \mu^{\mathrm{DSR}}$ *or* $\mu = \mu^{\mathrm{SR}}$.
- *For all utility profiles $u = (u_i)_{i \in N}$ in $\mathcal{L}$ the induced demand game $G(\mu, c)$ has at most one Nash equilibrium, or*
- *For all utility profiles $u = (u_i)_{i \in N}$ in $\mathcal{L}$, every Nash equilibrium of the game $G(\mu, c)$ is a strong Nash equilibrium as well.*



Cost Sharing, Figure 10
Scenario (ii). The indifference curves of agent 1 together with the curve $\kappa : t \mapsto \mu_1^{\mathrm{SR}}((t, \bar{x}_{-1}), c)$. Best response of player 1 against $\bar{x}_{-1} = (\frac{2}{3}, \frac{8}{3})$ is the value of x where the graph of κ is tangent to an indifference curve of u_1

Moreover, if the curvature of the indifference curves is bigger than that of the curve generated by the cost sharing rule as in Fig. 10 then the second and third statement are equivalent with $\mu = \mu^{\mathrm{DSR}}$.

Theorem 15 (Moulin [85]) *Assume agents have preferences in $\mathcal{L}^*$. The serial cost sharing rule is the unique continuous, cross-monotonic and anonymous cost sharing rule for which the Nash-equilibria of the corresponding demand games all pass the no-envy test.*

Comparison of Serial and Proportional Equilibria (II)

Just as in the earlier analysis in Sect. "Efficiency and Strategy-Proof Cost Sharing Mechanisms", performance of cost sharing rules can be measured by the related surpluses in the Nash-equilibria of the corresponding demand games. Assume in this section that the preferences of the agents are quasi-linear in cost shares, and represented by functions $U_i(x_i, y_i) = u_i(x_i) - y_i$. Moreover, assume that u_i is non-decreasing and concave, $u_i(0) = 0$. Then the surplus at the demand profile x and utility profile is the number $\sum_{i \in N} u_i(x_i) - c(x(N))$. Define the *efficient surplus* or *value* of N relative to c and U by

$$v(c, U) = \sup_{x \in \mathbb{R}^N_+} \sum_{i \in N} u_i(x_i) - c(x(N)) \,. \tag{27}$$

Denote the set of Nash-equilibria in the demand game $G(\mu, c)$ with profile of preferences U by $\mathrm{NE}(\mu, c, U)$. Given c, μ the *guaranteed (relative) surplus* of the cost sharing rule μ for N is defined by

$$\gamma(c, \mu) = \inf_{U, x \in \mathrm{NE}(\mu, c, U)} \frac{\sum_{i \in N} u_i(x_i) - c(x(N))}{v(c, U)} . \quad (28)$$

Here the infimum is taken over all utility profiles discussed above. This measure is also called the *price of anarchy* of the game, see [65]. Let C^* be the set of all convex increasing cost functions with $\lim_{y \to \infty} c(y)/y = \infty$. Then [89] shows that for the serial and the proportional rule the guaranteed surplus is at least $1/n$. But sometimes the distinction is eminent. Define the number

$$\delta(y) = \frac{y c''(y)}{c'(y) - c'(0)} ,$$

which is a kind of elasticity. The below theorem shows that on certain domains of cost functions with bounded δ the serial rule prevails over the proportional rule. For large n the guaranteed surplus at μ^{SR} is of order $1/\ln(n)$, that of μ^{AV} of order $1/n$. More precise, write $K_n = 1 + \frac{1}{3} + \cdots + \frac{1}{2n-1} \approx 1 + \frac{\ln n}{2}$, then:

Theorem 16 (Moulin [89]) *For any convex increasing cost function c with* $\lim_{y \to \infty} c(y)/y = \infty$ *it holds that*

- *If c' is concave and* $\inf\{\delta(y) | y \geq 0\} = p > 0$, *then*

$$\gamma(c, \mu^{\mathrm{SR}}) \geq \frac{p}{K_n} \qquad \gamma(c, \mu^{\mathrm{AV}}) \leq \frac{4}{n+3}$$

- *If c' is convex and* $\sup\{\delta(y) | y \geq 0\} = p < \infty$ *then*

$$\gamma(c, \mu^{\mathrm{SR}}) \geq \frac{1}{2p-1} \frac{1}{K_n}$$
$$\frac{4}{n+3} \leq \gamma(c, \mu^{\mathrm{AV}}) \leq \frac{4(2p-1)}{n}$$

A Word on Strategy-Proofness in $\mathcal{P}^1$

Recall the discussion on strategyproofness in Sect. "Strategyproofness". The serial demand game has a unique strong Nash equilibrium in case costs are convex and preferences are drawn from $\mathcal{L}$. Suppose the social planner aims at designing a mechanism to implement the outcomes associated with these equilibria. [91] show an efficient way to implement this *serial choice function* by an *indirect* mechanism. It is defined through a multistage game which mimics the way the serial Nash equilibria are calculated. It is easily seen that here each agent has a unique dominant strategy, in which demands result from optimization of the true preferences. Then this gives rise to a strategyproof mechanism.

Note that the same approach can not be used for the proportional rule. The strategic properties of the proportional demand game are weaker than that of the serial demand game in several aspects. First of all, it is not hard to find preference profiles in $\mathcal{L}$ leading to multiple equilibria. Whereas uniqueness of equilibrium can be repaired by restricting $\mathcal{L}$ to $\mathcal{L}^*$, the resulting equilibria are, in general, not strong (like the serial counterparts). In the proportional equilibria there is overproduction, see e. g. the example in Sect. "Proportional Demand Game" where a small uniform reduction of demands yields higher utility for all the players. Besides, a single-valued Nash equilibrium selection corresponds to a strategyproof mechanism *provided* the underlying domain of preferences is rich, and $\mathcal{L}^*$ is not. Though richness is not a necessary condition, the proportional rule is not consistent with a strategyproof demand game.

Bayesian $\mathcal{P}^1$-Demand Games

Recall that at the basis of a strategic game there is the assumption that each player *knows* all the ingredients of the game. However, as [56] argues, production cost and output quality may vary unpredictably as a consequence of the technology and worker quality. Besides that, changes in the available resources and demands will have not foreseen influences on individual preferences. On top of that, the players may have asymmetrical information regarding the nature of uncertainty. [56] study the continuous homogeneous cost sharing problem within the context of a *Bayesian demand game* [43], where these uncertainties are taking into account. The qualifications of the serial rule in the stochastic model are roughly the same as in the deterministic framework.

Continuous Heterogeneous Output Model, $\mathcal{P}^n$

The analysis of continuous cost sharing problems for multi-service facilities are far more complex than the single-output model. The literature discusses two different models, one where each agent i demands a different good, and one where agents may require mixed bundles of goods. As the reader will notice, the modeling and analysis of solutions differs in abstraction and complexity. In order to concentrate on the main ideas, here we will stick to the first model, where goods are identified with agents. This means that a demand profile is a vector $x \in \mathbb{R}_+^N$, where x_i denotes the demand of agent i for good i. From now we deal with technologies described by continuously differentiable cost functions $c\colon \mathbb{R}^N_+ \to \mathbb{R}_+$, non-decreasing and $c(0_N) = 0$; the class of all such functions is denoted by C^n.

Extensions of Cost Sharing Rules The single-output model is connected to the multi-output model via the homogeneous cost sharing problems. Suppose that for $c \in C^n$ there is a function $c_0 \in C$ such that $c(x) = c_0(x(N))$ for all x. For instance, such functions are found if we distinguish between production of blue and red cars; the color of the car does not affect the total production costs. Essentially, a homogeneous cost sharing problem (x, c) may be solved as if it were in $\mathcal{P}^1$. If μ is the compelling solution on $\mathcal{P}^1$ then any cost sharing rule on $\mathcal{P}^n$ should determine the same solution on the class of *homogeneous* problems therein. Formally the cost sharing rule on $\mathcal{P}^n$ extends $\overline{\mu}$ on $\mathcal{P}^1$ if for all homogeneous cost sharing problems (x, c) it holds $\overline{\mu}(x, c) = \mu(x, c_0)$. In general a cost sharing rule μ on $\mathcal{P}^1$ allows for a whole class of extensions. Below we will focus on extensions of $\mu^{\text{SR}}, \mu^{\text{P}}, \mu^{\text{SS}}$.

Measurement of Scale Around the world quantities of goods are measured by several standards. Length is expressed in inches or centimeters, volume in gallons or liters, weight in ounces to kilos. Here measurement conversion involves no more than multiplication with a fixed scalar. When such linear scale conversions do not have any effect on final cost shares, a cost sharing rule is called *scale invariant*. It is an *ordinal* rule if this invariance extends to essentially all transformations of scale. Scale invariance captures the important idea that the relative cost shares should not change, whether we are dividing 1 Euro or 1,000 Euros. Ordinality may be desirable, but for many purposes too strong as a basic requirement. Formally, a *transformation of scale* is a mapping $f\colon \mathbb{R}^N_+ \to \mathbb{R}^N_+$ such that $f(x) = (f_1(x_1), f_2(x_2), \ldots, f_n(x_n))$ for all x and each of the coordinate mappings f_j is differentiable and strictly increasing.

Ordinality A cost sharing rule μ on $\mathcal{P}^n$ is *ordinal* if for all transformations of scale f and all cost sharing problems $(x, c) \in \mathcal{P}^n$, it holds that

$$\mu(x, c) = \mu(f(x), c \circ f^{-1})\,. \tag{29}$$

Scale Invariance A cost sharing rule μ on $\mathcal{P}^n$ is scale invariant if Eq. (29) holds for all linear transforms f. Under a scale invariant cost sharing rule final cost shares do not change by changing the units in which the goods are measured.

Path-Generated Cost Sharing Rules Many cost sharing rules on $\mathcal{P}^n$ calculate the cost shares for $(x, c) \in \mathcal{P}^n$ by the total of marginal costs along some *production path* from 0 toward x. Here a path for x is a non-decreasing mapping $\gamma^x\colon \mathbb{R}_+ \to \mathbb{R}^N_+$ such that $\gamma(0) = 0_N$ and there is a $T \in \mathbb{R}_+$ with $\gamma^x(T) = x$. The cost sharing rule *generated by the path collection* $\gamma = \{\gamma^x | x \in \mathbb{R}^N_+\}$ is defined by

$$\mu^\gamma_i(x, c) = \int_0^\infty \partial_i c(\gamma^x(t))(\gamma^x_i)'(t)\mathrm{d}t\,. \tag{30}$$

Special path-generated cost sharing rules are the *fixed-path cost sharing rules*; a single path $\gamma^*\colon \mathbb{R}_+ \to \mathbb{R}^N_+$ with the property that $\lim_{t\to\infty} \gamma^*_i(t) = \infty$ defines the whole underlying family of paths. More precisely, the *fixed path cost sharing rule* μ generated by γ^* is the path-generated rule for the family of paths $\{\gamma^x | x \in \mathbb{R}^N_+\}$ defined by $\gamma^x(t) = \gamma^*(t) \wedge x$, the vector with coordinates $\min\{\gamma^*_i(t), x_i\}$. So the paths are no more than the projections of $\gamma^*(t)$ on the cube $[0, x]$. Below we will see many examples of (combinations of) such fixed-path methods.

Aumann–Shapley Rule The early characterizations by [15,79] on this rule set off a vast growing literature on cost sharing models with variable demands. [16] suggested to use the Aumann–Shapley rule to determine telephone billing rates in the context of sharing the cost of a telephone system. This extension of proportional cost sharing calculates marginal costs along the path $\gamma^{\text{AS}}(t) = tx$ for $t \in [0, 1]$. Then

$$\mu^{\text{AS}}_i(x, c) = x_i \int_0^1 \partial_i c(tx)\mathrm{d}t\,. \tag{31}$$

The Aumann–Shapley rule can be interpreted as the Shapley-value of the *non-atomic* game where each unit of the good is a player, see [11]. It is the uniform average over marginal costs along all increasing paths from 0_N to x. The following is a classic result in the cost sharing literature:

Theorem 17 (Mirman & Tauman [79], Billera & Heath [15]) *There is only one additive, positive, and scale invariant cost sharing rule on $\mathcal{P}^n$ that extends the proportional rule, and this is μ^{AS}.*

Example 24 If c is positively homogeneous, i. e. $c(\alpha y) = \alpha c(y)$ for $\alpha \geq 0$ and all $y \in \mathbb{R}^N_+$, then

$$\mu^{\text{AS}}_i(x, c) = \frac{\partial_i c}{\partial x_i}(x)$$

i. e. μ^{AS} calculates the marginal costs of the ith good at the final production level x. The risk measures (cost functions) as in [28] are of this kind.

Friedman–Moulin Rule This serial extension [36] calculates marginal costs along the diagonal path, i. e. $\gamma^{\text{FM}}(t) = t\mathbf{1}_N \wedge x$

$$\mu_i^{\text{FM}}(x, c) = \int_0^{x_i} \partial_i c(\gamma^x(t))\mathrm{d}t \,. \tag{32}$$

This fixed path cost sharing rule is demand monotonic. As far as invariance with the choice of unit is concerned, the performance is bad as it is not a scale invariant cost sharing rule.

Moulin–Shenker Rule This fixed-path cost sharing rule is proposed as an ordinal serial extension by [125]. Suppose that the partial derivatives of $c \in C^n$ are bounded away from 0, i. e. there is a such that $\partial_i c(x) > a$ for all $x \in \mathbb{R}_+^N$. The Moulin–Shenker rule μ^{MS} is generated by the path γ^{MS} as solution to the system of ordinary differential equations

$$\gamma_i'(t) = \begin{cases} \frac{\sum_{j\in N}\partial_j c(\gamma(t))}{\partial_i c(\gamma(t))} & \text{if } \gamma_i(t) < x_i \,, \\ 0 & \text{else} \,. \end{cases} \tag{33}$$

The interpretation of this path is that at each moment the total expenditure for production of extra units for the different agents is equal; if good 2 is twice as expensive as good 1, then the production device γ^{MS} will produce twice as much of the good 1. The serial rule embraces the same idea – as long as an agent desires extra production, the corresponding incremental costs are equally split. This makes μ^{MS} a natural extension of the serial rule. Call t_i^* the completion time of production for agent i, i. e. $\gamma_i^{\text{MS}}(t) < x_i$ if $t < t_i^*$ and $\gamma_i^{\text{MS}}(t_i^*) = x_i$. Assume without loss of generality that these completion times are ordered such that $0 = t_0^* \le t_1^* \le t_2^* \le \dots \le t_n^*$, then the Moulin–Shenker rule is given by

$$\mu_i^{\text{MS}}(x, c) = \sum_{\ell=1}^{i} \frac{c(\gamma^{\text{MS}}(t_\ell^*)) - c(\gamma^{\text{MS}}(t_{\ell-1}^*))}{n - \ell + 1} \,. \tag{34}$$

Note that the path varies with the cost function, and that this is the reason why μ^{MS} is a non-additive solution. Such solutions – though intuitive – are in general notoriously hard to analyze. There are two axiomatic characterizations of the Moulin–Shenker rule. The first is by [125], in terms of the *serial principle* and the technical condition that a cost sharing rule be a partial differentiable functions of the demands. The other characterization by [60] is more in line with the ordinal character of this *serial extension.*

Continuity A cost sharing rule μ on $\mathcal{P}^n$ is *continuous* if $q \mapsto \mu(q, c)$ is continuous on $\mathbb{R}_+^N$ for all c.

Continuity is weaker than partial differentiability, as it requires stability of the solution with respect to small changes in the demands.

Upperbound A cost sharing rule μ satisfies *upperbound* if for all $(q, c) \in \mathcal{P}^n$, $i \in N$

$$\mu_i(q, c) \le \max_{y\in[\mathbf{0},q]} \partial_i c(y) \,.$$

An upperbound provides each agent with a conservative and rather pessimistic estimate of her cost share, based on the maximal value of the corresponding marginal cost toward the aggregate demand.

Suppose that d is a demand profile smaller than q. A reduced cost sharing problem is defined by $(q - d, c^d)$ where c^d is defined by $c^d(y) = c(y + d) - c(d)$. So c^d measures the incremental cost of production beyond the level d.

Self-consistency A cost sharing rule μ is *self-consistent* if for all cost sharing problems $(q, c) \in \mathcal{P}^n$ with $q_{N\setminus S} = \mathbf{0}_{N\setminus S}$ for some $S \subseteq N$, and $d \le q$ such that $\mu_i(d, c) = \mu_j(d, c)$ for all $\{i, j\} \subset S$, then $\mu(q, c)_S = \mu(d, c)_S + \mu(q - d, c^d)_S$.

So, self-consistency is expresses the idea that if cost shares of agents with non-zero demand differ, then this is not due to the part of the problem that they are equally charged for, but due to the asymmetries in the related reduced problem. The property is reminiscent of the *step-by-step negotiation property* in the bargaining literature, see [54].

Theorem 18 (Koster [60]) *There is only one continuous, self-consistent and scale invariant cost sharing rule satisfying upper bounds, which is the Moulin–Shenker rule.*

Shapley–Shubik Rule For each demand profile x the stand-alone cost game c_x is defined as before. Then the Shapley–Shubik rule is no more than the Shapley value of this game, i. e. $\mu^{\text{SS}}(x, c) = \Phi(c_x)$. The Shapley–Shubik rule is ordinal.

A Numerical Example Consider the cost sharing problem (x, c) with $N = \{1, 2\}, x = (5, 10)$, and $c \in C^2$ is given by $c(t_1, t_2) = \mathrm{e}^{2t_1+t_2} - 1$ on $[0, 10] \times [0, 10]$. We calculate the partial derivatives $\partial_1 c(t_1, t_2) = 2\mathrm{e}^{2t_1+t_2} = 2\partial_2 c(t_1, t_2)$ for all $(t_1, t_2) \in \mathbb{R}_+^2$. The Aumann–Shapley path is given by $\gamma(t) = (5t, 10t)$ for $t \in [0, 1]$ and

$$\mu_1^{\text{AS}}(x, c) = \int_0^1 \partial_1 c(5t, 10t) \cdot 5\mathrm{d}t$$

$$= \int_0^1 2\mathrm{e}^{20t}\cdot 5\mathrm{d}t = \tfrac{1}{2}\left(\mathrm{e}^{20}-1\right)$$

$$\mu_2^{\mathrm{AS}}(x,c) = \int_0^1 \partial_2 c(5t,10t)\cdot 10\mathrm{d}t$$

$$= \int_0^1 \mathrm{e}^{20t}\cdot 10\mathrm{d}t = \tfrac{1}{2}\left(\mathrm{e}^{20}-1\right) .$$

The Friedman–Moulin rule uses the path

$$\gamma^{\mathrm{FM}}(t) = t\mathbf{1}_N \wedge q = \begin{cases} (t,t) & \text{if } 0 \le t < 5\,, \\ (5, 5+t) & \text{if } 5 \le t\,, \end{cases}$$

and the corresponding cost shares are calculated as follows:

$$\mu_1^{\mathrm{FM}}(x,c) = \int_0^5 \partial_1 c(t,t)\mathrm{d}t$$

$$= \int_0^5 2\mathrm{e}^{3t}\mathrm{d}t = \tfrac{2}{3}\left(\mathrm{e}^{15}-1\right) ,$$

$$\mu_2^{\mathrm{FM}}(x,c) = \int_0^5 \partial_2 c(t,t)\mathrm{d}t + \int_5^{10} \partial_2 c(5,5+t)\mathrm{d}t$$

$$= \tfrac{1}{3}\left(\mathrm{e}^{15}-1\right) + \mathrm{e}^{20} - \mathrm{e}^{15} .$$

Note that both discussed cost sharing rules use one and the same path for all cost sharing problems with demand profile x. This is characteristic for *additive* cost sharing rules (see e. g. [35,42]).

Now turn to the Moulin–Shenker rule. Since $\partial_1 c = 2\partial_2 c$ everywhere on $[0,10]\times[0,10]$, according the solution γ^{MS} of Eq. (33), until one of the demands is reached, for each produced unit of good 1 two units of good 2 are produced. In particular there is a parametrization $\overline{\gamma}$ of γ^{MS} such that $\overline{\gamma}(t) = (t, 2t)$ for $0 \le t \le 5$. The corresponding cost shares are equal since $\overline{\gamma}$ reaches both coordinates of x at the same time, so $\mu_1^{\mathrm{MS}}(x,c) = \mu_2^{\mathrm{MS}}(x,c) = \frac{1}{2}c(\overline{\gamma}(5)) = \frac{1}{2}c(5,10) = \frac{1}{2}(\mathrm{e}^{20}-1)$. Now suppose that the demands are summarized by $x^* = (10,10)$. In order to calculate $\mu^{\mathrm{MS}}(x^*,c)$, notice that there is a parametrization of γ^* of the corresponding path γ^{MS} such that

$$\gamma^*(t) = \begin{cases} (t,2t) & \text{if } t \le 5\,, \\ (t,10) & \text{for } 5 < t \le 10\,, \end{cases}$$

Notice that this path extends $\overline{\gamma}$ just to complete service for agent 1, so that – like before – agent 2 only contributes while $t < 5$. Then the cost shares are given by

$$\mu_2^{\mathrm{MS}}(x^*,c) = \tfrac{1}{2}c(\gamma^*(5)) = \tfrac{1}{2}c(5,10) = \tfrac{1}{2}(\mathrm{e}^{20}-1)\,,$$

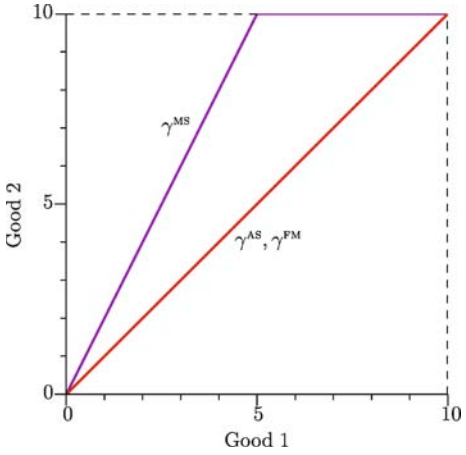
$$\mu_1^{\mathrm{MS}}(x^*,c) = \mu_2^{\mathrm{MS}}(x^*,c) + c(\gamma^*(10)) - c(\gamma^*(5))$$

$$= \mathrm{e}^{30} - \tfrac{1}{2}(\mathrm{e}^{20}+1)\,.$$

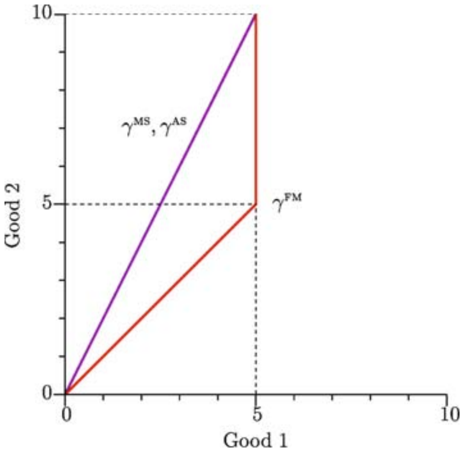
For x^* the cost sharing rules μ^{AS} and μ^{FM} use essentially the same symmetric path $\gamma(t) = (t,t)$, so that it is easily calculated that $\mu^{\mathrm{AS}}(x^*,c) = \mu^{\mathrm{FM}}(x^*,c) = (\frac{2}{3}\left(\mathrm{e}^{30}-1\right), \frac{1}{3}\left(\mathrm{e}^{30}-1\right)$.

Axiomatic Characterization of Fixed-Path Rules Recall demand monotonicity as a weak incentive constraint for cost sharing rules. Despite the attention that the Aumann–Shapley rule received, it fails to meet this standard. To see this consider the following

$$c(y) = \frac{y_1 y_2}{y_1 + y_2}\,, \quad \text{and} \quad \mu_1^{\mathrm{AS}}(x,c) = \frac{x_1 x_2^2}{(x_1+x_2)^2}\,.$$



Cost Sharing, Figure 11
Paths for $\mu^{\mathrm{MS}}, \mu^{\mathrm{AS}}, \mu^{\mathrm{FM}}$



Cost Sharing, Figure 12
Paths for $\mu^{\mathrm{MS}}, \mu^{\mathrm{AS}}, \mu^{\mathrm{FM}}$

Then the latter expression is not monotonic in x_1. One may show that the combination of properties in Theorem 17 are incompatible with demand monotonicity. Now what kind of rules are demand monotonic? The classification of all such rules is too complex. We will restrict our attention to the additive rules with the *dummy* property, which comprises the idea that a player pays nothing if her good is for free:

Dummy If $\partial_i c(y) = 0$ for all y then $\mu_i(x, c) = 0$ for all cost sharing problems $(x, c) \in \mathcal{P}^n$.

Theorem 19 (Friedman [35])

- *A cost sharing rule μ satisfies dummy, additivity and demand monotonicity if and only if it is an (infinite) convex combination of rules generated by fixed paths which do not depend on the cost structure.*
- *A cost sharing rule μ satisfies dummy, additivity and scale invariance if and only if it is an (infinite) convex combination of rules generated by scale invariant fixed paths which do not depend on the cost structure.*

This theorem has some important implications. The Friedman–Moulin rule is the unique serial extension with the properties additivity, dummy and demand monotonicity. As we mentioned before, μ^{FM} is not scale invariant. The only cost sharing rules satisfying all four of the above properties are *random order values*, i. e. a convex combination of marginal vectors of the stand-alone cost game [142]. μ^{SS} is the special element in this class of rules, giving equal weight to each marginal vector. Consider the following weak fairness property:

Equal Treatment Consider $(x, c) \in \mathcal{P}^n$. If $c_x(S \cup \{i\}) = c_x(S \cup \{j\})$ for all i, j and $S \subset N \setminus \{i, j\}$ then $\mu_i(x, c) = \mu_j(x, c)$.

Within the class of random order values, μ^{SS} is the unique cost sharing rule satisfying equal treatment.

Strategic Properties of Fixed-Path Rules [34] shows that the fixed-path cost sharing rules essentially have the same strategic properties as the serial rule. The crucial result in this respect is the following.

Theorem 20 (Friedman [34]) *Consider the demand game $G(\mu, c)$ where μ is a fixed path cost sharing rule and $c \in C^n$ has strictly increasing partial derivatives. Then the corresponding set $\mathcal{O}^\infty$ of action profiles surviving the successive elimination of overwhelmed actions consists of a unique element.*

As a corollary one may prove that the action profile in $\mathcal{O}^\infty$ is actually the unique Nash-equilibrium of the game $G(\mu, c)$, and that it is strong as well. Moreover, [34] shows that this Nash-equilibrium can be reached through some learning dynamics. Then this means that the demand games induced by μ^{FM} and μ^{MS} have strong strategic properties. Notice that the above theorem is only one-way. There are other cost sharing rules, like the *axial serial rule*, having the same strategic characteristics.

Future Directions

So far, a couple of standard stylized models have been launched providing a theoretical basis for defining and studying cost sharing principles at a basic level. The list of references below indicates that this field of research is full in swing, both in theoretical and applied directions. Although it is hard to make a guess where developments lead to, a couple of future directions will be highlighted.

Informational Issues

So far most of the literature is devoted to deterministic cost sharing problems. The cost sharing problems we face in practice are shaped by unsure events. Despite its relevance, this stochastic modeling in the literature is quite exceptional, see [56,138].

The presented models assume the information of costs for every contingent demand profile. Certainly within the continuous framework this seems too much to ask for. Retrieving the necessary information is hindered not only by technical constraints, but leads to new costs as well. [48] discusses data envelopment in cost sharing problems. A stochastic framework will be useful to study such *estimated* cost sharing problems. Other work focusing on informational coherence in cost sharing problems is [126]. Related work is [4], discussing mixtures of discrete and continuous cost sharing problems.

Budget Balance

In this overview, the proposed mechanisms are based on cost *sharing* rules. Another stream in implementation theory – at the other extreme of the spectrum – deals with cost *allocation* rules with no restrictions on the budget. [89] compares the size of budget deficits relative to the overall efficiency of a mechanism.

Performance

Recall the performance indices measuring the welfare impact of different cost sharing rules. [90] focuses on the continuous homogeneous production situations, with cost functions of specific types. There is still a need for a more general theory. In particular this could prove to be indispensable for analyzing the quality of cost sharing rules in a broader set-up, the heterogeneous and Bayesian cost sharing problems.

Non-linear Cost Sharing Rules

Most of the axiomatic literature is devoted to the analysis of cost sharing rules as linear operators. The additivity property is usually motivated as an accounting convention, but it serves merely as a tool by which some mathematical representation theorems apply. Besides the practical motivation, it is void of any ethical content. As [88] underlines, there are hardly results on non-additive cost sharing rules – one of the reasons is that the mathematical analysis becomes notoriously hard. But – as a growing number of authors acknowledges – the usefulness of these mathematical techniques alone cannot justify the contribution of the property.

I thank Hervé Moulin as a referee of this article, and his useful suggestions.

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of

Rowena Lohman
Cornell University, Ithaca, USA

Article Outline

Glossary

Aseismic Occurring without detectable radiated seismic energy.

Cascadia The region of the Pacific Northwest dominated by the Cascade Range and affected by subduction of the Juan de Fuca plate beneath North America.

Coseismic Occurring during an earthquake.

Elastic A form of behavior of a solid when subjected to stress. Elastic solids deform in response to stress by an amount proportional to a constant known as the "rigidity". When any applied stress is removed, an elastic solid recovers its original shape.

Geodesy The study of the shape and area of the Earth, including large-scale variations that affect the rotation dynamics of the planet of the whole, down to smaller length scales of earthquakes, landslides, etc.

Forward model A description of what a model of some process would predict about behavior of the system, e. g., how a given distribution of subsurface slip on a fault during an earthquake should affect observations of ground deformation at the surface.

GPS Global Positioning System. A network of satellites that transmit a signal that can be used by receivers (small transportable and/or permanent affixed to the ground) to infer three-dimensional positions.

InSAR Interferometric Synthetic Aperture Radar. The combination of Synthetic Aperture Radar imagery (generally acquired from airborne or satellite-based platforms) to infer changes in ground deformation, digital elevation models, variations in atmospheric water vapor, etc.

Interseismic deformation Occurs in the time period between earthquakes, usually associated with gradual increase in elastic stress to be released in future earthquakes.

Inverse theory The approach to determining the values for parameters of a given physical model that best describe observations of the system of interest.

Leveling The field of geodesy involved in the determination of variations in angle from horizontal between nearby fixed points on the Earth's surface, usually converted to changes in elevations.

Locked zone The portion of the fault zone that does not slip during the interseismic period, therefore accumulating stress and eventually rupturing coseismically.

Paleoseismology The study of individual earthquakes that occurred in the past, usually before the advent of instrumental recordings of seismic events.

Plate tectonics The theory governing how discrete plates on the Earth's surface move relative to each other over geologic time.

Postseismic deformation Deformation occurring in the hours to years following an earthquake.

Seismic cycle The combination of strain build-up and release that occurs on plate margins and along faults within plates, accommodated by processes within the coseismic, postseismic and interseismic time scales.

Seismogenic The region of a fault zone that is capable of producing earthquakes. Also refers to effects caused by an earthquake.

Subduction The process by which one tectonic plate descends beneath another, usually accompanied by volcanism and seismicity.

Triangulation The field of geodesy related to measuring horizontal angles and changes in angles between networks of fixed points.

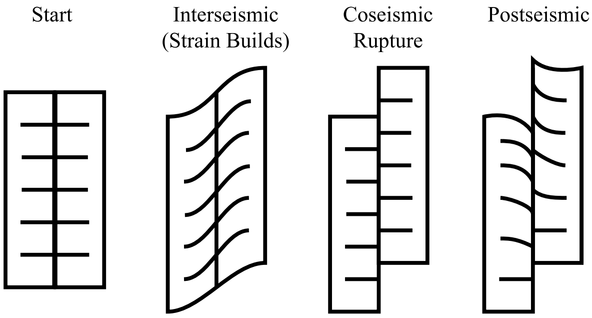
Trilateration The field of geodesy related to measuring distance and changes in distance between networks of fixed points.

Viscoelastic A material behavior that is a combination of viscous and elastic behavior, resulting in some permanent deformation when the material is subjected to changes in stress.

Viscosity A material property describing its ability to flow in response to an applied stress. A measure of the response of a material to a stress, resulting in permanent deformation. The deformation rate of a viscous material depends on both the viscosity and applied stress.

Definition of the Subject

The seismic cycle consists of the processes associated with the accumulation and release of stress on seismogenic faults. The cycle is commonly divided into 3 periods: the coseismic interval for events occurring during an earthquake, the postseismic interval after an earthquake, and the interseismic period in between earthquakes (Fig. 1). Some of this deformation during these different periods is related directly to the motion on the fault during the earthquake – the ground is translated in one direction or another, there is crushing of rock, rotation or heaving of blocks of earth, and landslides triggered by the shaking. There is also ground deformation that results because of secondary effects – movement of ground water within the crushed and strained rock, cascades of earthquakes triggered by stress changes during the first event, continued slip on the fault interface, as well as flow of deeper, more ductile layers of the crust and mantle in response to the changes in stress. By examining these different behaviors and studying crustal deformation we can learn more about the underlying cause.



Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 1
Cartoon illustrating map view (view from overhead) of ground deformation during the seismic cycle for a strike-slip fault (after [73]). Similar models exist for other fault types

Earthquakes and other motion along fault zones are some of the ways that the Earth's crust accommodates far-field forcings due to plate tectonic motions. One of the prime features of interest as we study the seismic cycle is the magnitude of motion along these fault zones at different temporal and length scales. However, the only place where we can directly observe this motion is within the shallowest (< several meters) parts of the fault zone, through maps of features that are offset across the fault. The field of paleoseismology involves the search for information about previous earthquakes on a fault zone, often through trenches dug across the fault and the use of radiogenic dating to determine how frequently earthquakes have occurred in the past.

In order to infer what is occurring throughout the whole seismogenic zone (often the upper ∼15 km within the continental crust), we rely on an arsenal of tools that include seismology (the study of how seismic waves travel through the earth) and geodesy (the study of changes to the shape of the earth's surface). In this chapter, we will explore how we can draw conclusions about fault zone slip at depths far greater than are directly accessible to us, based on how the earth's surface deforms during, before and after earthquakes.

Introduction

Ground shaking due to earthquakes can be felt over most of the Earths' surface, both on land and underwater. Earthquakes are also associated with volcanic activity, landslides and tsunami – they are often concentrated near discrete tectonic plate boundaries but also occupy diffuse zones where the Earth's crust is deforming [12,57]. The seismic energy that is released during an earthquake passes through deep portions of the Earth and helps us to learn about material properties we could not illuminate any other way, including details of the structure of the Earth's crust, core and everything in between. However, the destructive cost of large earthquake requires that the primary goal of earthquake research is that of determining when and where damaging earthquakes will occur [99]. To achieve this goal, we first have to understand what happens during each earthquake, i. e., where it was located, how big it was, how it's location relates to the distribution of previous earthquakes, etc.

One of the most common methods that we use to study earthquakes relies on the feature most apparent to humans – the rapid and often destructive movements of the ground that occur during the earthquake. Seismology studies how the ground shakes during earthquakes and how we can use that information to better understand seismogenesis. However, this ground shaking is also always accompanied by some amount of permanent deformation of the ground. After all, the primary driving force behind most earthquakes is the slow motion of tectonic plates relative to each other. In this chapter we will not cover seismology, although combinations of seismic data and observations of geodetic displacements are often very powerful tools. Instead, we cover the geodetic observations of ground deformation during earthquakes and some of the methods that we use to interpret this deformation in terms of what actually happened on and around the fault zone.

Highlights of Earthquake Geodesy

Geodesy is defined as the branch of mathematics concerned with the shape and area of the Earth. In this chapter we will examine how the use of geodesy to quantify changes in the shape of the Earth can help us learn about earthquakes. We begin with a brief history of how the use of geodesy to study earthquakes has evolved, along with a description of some of the more interesting individual earthquakes and other seismic cycle behaviors that have been observed geodetically. We then explain the mechanics of how we use these measurements of surface deformation to understand processes deep beneath the Earth's surface.

Observations of Coseismic Displacements

The history of earthquake geodesy begins even before we really understood what earthquakes were. The key observations began when scientists began to associate earthquakes with observable deformation of the terrain. In Charles Lyell's Principles of Geology [46], he noted that earthquakes often accompany abrupt changes in the ground surface. The 1819 Ran of Cutch, India [64] and 1855 Wairarapa, New Zealand earthquakes were some of the first events where the accompanying ground deformation was observed. In 1835, during Charles Darwin's voyage on the *H.M.S. Beagle*, he experienced a large earthquake near Concepcion, Chile. During his reconnaissance of the area, he noted that the coastline had risen several meters in areas, exposing barnacles that had previously been underwater. He also found fossils hundreds of meters above sea level, indicating that numerous earthquakes had raised the cliffs over many millennia.

Several large earthquakes in the second half of the 19th century helped to advance the theory that earthquakes were caused by motion on faults. The 1872 Owens Valley, California, earthquake [19], the 1888 Amuri/Marlborough, New Zealand, earthquake [50], the 1891 Nobi, Japan, earthquake [36] and the 1893 Baluchistan earthquake [21] were each accompanied by visible deformation of the ground surface. These observations, and the fact that much of the deformation was consistent with regional, long-term topographic relief, helped counter arguments that earthquakes were primarily caused by volcanic activity [48].

Around the same time interval, the practice of surveying was coming into more widespread use, notably in India where Britain was involved in mapping the areas under its control. Surveyors installed permanent "monuments" or benchmarks, which they could then return to and re-survey at a later date. The May 17, 1892 Tapanuli, Sumatra, earthquake occurred during a triangulation survey by JJA Muller [58]. They noted changes in their surveyed angles between benchmarks that were consistent with two meters of deformation on a branch of the great Sumatran fault. In the foothills of the Himalaya, triangulation/leveling surveys measured deformation due to the 1897 Assam earthquake [64] and the 1905 Kangra earthquake [53]. In Italy, the 1915 Avezzano earthquake [94] was also spanned by early geodetic surveys.

In North America, the first great earthquake to be surveyed was the 1906 earthquake that destroyed most of the city of San Francisco, CA [40]. HF Reid [72] used three sets of triangulation surveys across San Andreas Fault to show that there had been approximately 3.2 meters of slip across the fault. During the 1920s and 1930s, there was a great deal of leveling work done in Japan which captured deformation associated with the 1927 Tango earthquake, and the 1944 and 1946 earthquakes associated with oceanic plate subduction in southwestern Japan [63,93]. Tide gauges along the coasts have also proved useful in earthquake studies, especially near subduction zones.

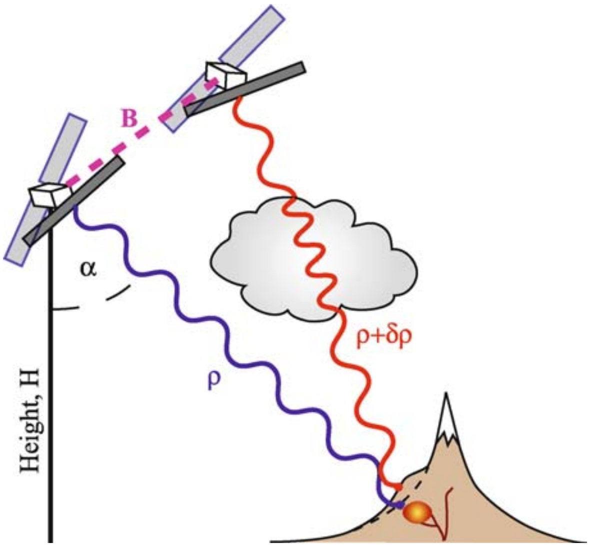
There was a boom in the use of the three main ground-based geodetic techniques (triangulation, trilateration and leveling) in the middle of the twentieth century, with observations of the 1940 Imperial Valley and 1962 Tehachapi earthquakes in California and the first observation of shallow interseismic creep on faults in the San Francisco Bay Area and in the Salton Trough/Imperial Valley region in Southern California. Next, the development of space-based geodesy began to allow for more precise and spatially extensive surveys of areas before and after earthquakes. Very Long Baseline Interferometry (VLBI) stations scattered around the world placed strong constraints on the relative motion of individual tectonic plates, as did the widespread use of Global Positioning System (GPS) [22,83].

GPS can be used either in continuous mode at permanent stations, which allows for high precision observations that can catch temporal changes in deformation, or in survey/campaign mode, where researchers take GPS receivers out to fixed benchmark stations in the field (sometimes previously studied using earlier surveying methods). Some of the first large earthquakes to be studied using GPS were the Ms 6.6 Superstition Hills, CA, earthquake in 1987 [39] and the 1989 Mw 7.1 Loma Prieta, CA earthquake [3]. The precise locations and descriptions of ground deformation allowed researchers to begin to examine how individual earthquakes fit in with the long-term topography, including the estimation of possible recurrence intervals [35,41].

InSAR The advent of Interferometric Synthetic Aperture Radar (InSAR), and it's application to the 1992 Landers, California, earthquake [17,49], ushered in a new era of geodesy with its unparalleled spatial density of deformation observations [23,76]. Synthetic Aperture Radar (SAR) images are acquired from a variety of platforms that send out radar signals, including satellites and airplanes (Fig. 2), and contain information about the phase and amplitude of the reflected return from the earth's surface.

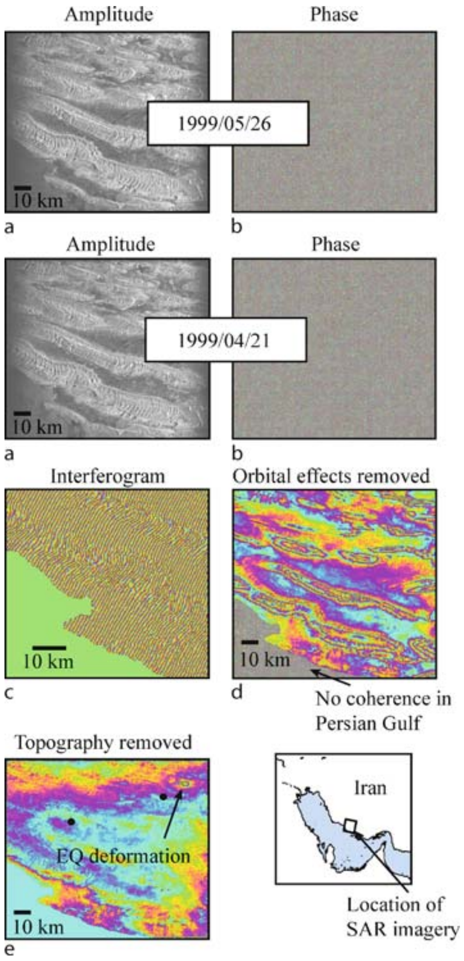
A SAR interferogram is the difference in phase between two SAR images, and reflects a variety of factors that change the path length between the satellite and the ground. After correcting for some of these factors, such as topography (Fig. 3), the resulting interferometric phase is a function of any ground deformation that occurred between the two SAR acquisitions, in addition to variations in atmospheric water vapor, the ionosphere, etc. [11,20,100]. The high spatial resolution of InSAR (pixels commonly 5 m × 20 m or smaller) combined with its large areal coverage (~100 km) produces images with so many pixels that they can become unwieldy to deal with computationally, especially when multiple interferograms are studied at once. Most researchers use various downsampling methods to reduce the number of data points considered without significantly reducing the amount of information retained [43].

The interferometric phase is only sensitive to ground deformation towards or away from the satellite, in a direction known as the satellite line of sight (LOS). Also, since the interferometric phase can only be measured as a fraction of the radar wavelength, an interferogram does not immediately give us an absolute measurement of the magnitude of ground deformation (Fig. 4). We need to add up the interferometric "fringes" to solve for the total deformation field. This "unwrapped" deformation field, along with information about the line-of-sight direction, can be combined in attempts to model the earthquake source parameters, or for models of deformation throughout other parts of the seismic cycle.



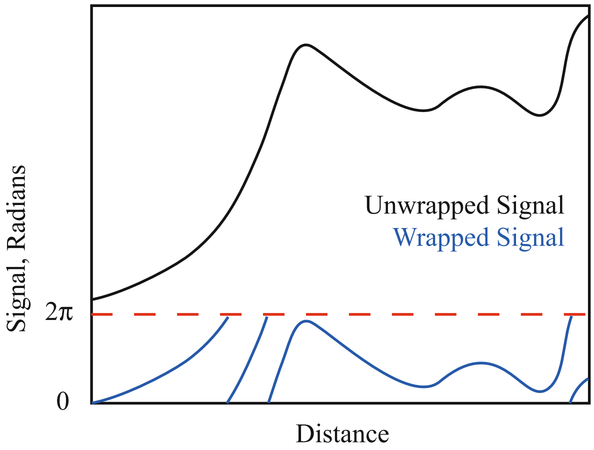
Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 2
Formation of a Synthetic Aperture Radar (SAR) interferogram: Two satellite radar images of the ground surface, separated by a spatial baseline, *B*, are combined to solve for the $\delta\rho$, the difference in line length (ρ) between the satellite and the ground along the satellite viewing direction (α). Knowledge of the satellite orbital path and the relative distance between the two image acquisitions (*B*) is necessary to convert $\delta\rho$ to elevation. If the two images are obtained simultaneously, or over a small time interval, the interferogram will only reflect topographic relief throughout the imaged area. However, if changes in ground surface elevation (e. g., the volcanic inflation shown in this figure between the *blue* and *red*), or changes in the atmosphere/ionosphere (e. g., water vapor content) occur between the two image acquisitions, this will also be reflected in the final interferogram

InSAR observations have improved the spatial complexity of these observations, allowing over a dozen large earthquakes to be studied in detail by a wide range of observers. Some noteworthy events that had various portions of their coseismic-postseismic activity covered by combinations of InSAR and GPS include the 1992 Landers, CA, earthquake [13,17,49], the 1995 Antofagasta, Chile, earthquake [70,77], the 1997 Hector Mine, CA earthquake [85], the 1999 Chi-Chi, Taiwan earthquake [8,98], the 2003 Bam, Iran earthquake [18], and the 2005 Nias–Simeulue earthquake [28]. In other cases, InSAR can help to determine the location of small- to moderate-sized earthquakes in areas with little other geophysical or field-based information [44].



Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 3

Overview of steps in forming and interpreting an interferogram. An interferogram requires the combination of two sets of amplitude a and phase b observations from two separate image acquisitions (here, on two different dates separated by a month over an area along the Persian Gulf, Iran). While phase in the individual SAR images appear to be random noise, when the two images are combined, the phase changes vary coherently to form the interferogram in c. If we remove the effects of the satellite orbital geometry (the "curved earth effect"), we are left with d, which reflects both topography, ground surface deformation and any atmospheric changes between the two image acquisitions. The area in the *lower left* still looks like white noise due to the fact that water (here, the Persian Gulf) changes its reflectivity over short time scales and the phase does not remain coherent. If we remove the effects of topography e we are left with a map that clearly shows the effects of a small Mw 5 earthquake that occurred during this time interval (*black dots* show the seismically-determined locations for this event). Other features are due primarily to changes in atmospheric water vapor



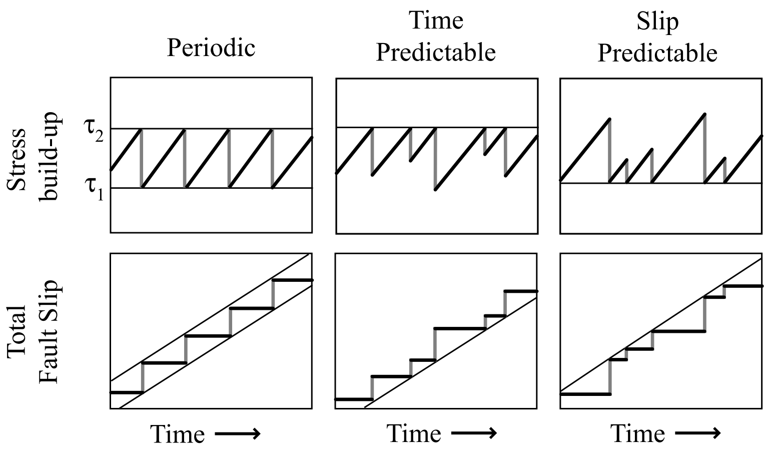
Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 4

Illustration of how the inherent 2π ambiguity affects the observed deformation. The "true" ground deformation vs. distance profile (*black* signal) would appear as the segmented *blue curve* ("*wrapped*" signal) when viewed using InSAR, since interferometry only retains information about the relative phase within a 2π cycle, not about the absolute phase, or number of cycles between the satellite and the ground. Reconstructing the original deformation field requires a process known as phase unwrapping, and there will also be an ambiguity as to the absolute value of the deformation field as a whole

Observations Throughout the Seismic Cycle

Early Models As the body of information about earthquakes grew, scientists were able to begin hypothesizing about the processes controlling their occurrence. Reid's observations of the 1906 San Francisco earthquake led him to propose his elastic rebound theory [73], where he hypothesized that the crust behaves like an elastic solid driven from the far field at a constant rate, which ruptures in earthquakes at periodic intervals to allow the two blocks to slide past each other (Fig. 1). In the interseismic period, the ground deforms smoothly in a manner that depends on the relative plate velocities, the thickness of the elastic plate, the elastic plate rigidity, etc. The size of the largest potential earthquake on a fault would depend on the length and depth of the elastic zone, and the timing until the next earthquake would depend on how much strain had built up since the last one.

This simple model, where each earthquake releases all of the built-up stress along the fault zone at a regular interval, does not seem to hold in the real world. On most faults, the magnitude of fault slip and rupture area appears to vary significantly between earthquakes (Fig. 5). Additionally, large amounts of accelerated deformation and other types of postseismic behavior are observed to



Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 5

Cartoon illustrating theories governing the temporal distribution of large earthquakes [88], each assuming a constant increase in stress vs. time in the interseismic interval (*black lines*), and coseismic behavior (*gray*) that depends on the accumulated stress in various ways. In the periodic model [73], earthquakes occur at constant intervals and always have the same magnitude, releasing the same amount of built-up stress. In the time-predictable model, earthquakes always occur when a maximum stress, τ_2, is reached, but the slip in each event varies. The time of the next earthquake depends on how much stress was released in the previous event. In the slip-predictable model, earthquakes occur at varying times, but always release the amount of built-up stress down to the minimum level, τ_1. The amount of slip, therefore, depends on the time since the previous earthquake

occur immediately after earthquakes, indicating that stress release is not accommodated in a simple manner. Observations such as these can help us improve and expand on the models that we utilize to explain earthquake occurrence.

Postseismic Behavior Earthquakes may primarily release built-up strain due to plate motions, but they also produce stress increases in both the near-field within the crust and within the underlying mantle. Observations of postseismic deformation, which is driven by the preceding coseismic stress changes [25,79,92], span a wide range of behaviors that may be explained by equally large range of constitutive properties. For some shallow strike-slip earthquakes, the observed postseismic deformation is as large as the fault slip during the earthquake [38,86].

Observed postseismic behaviors include poroelastic deformation [13,33], where fluid flow following gradients in coseismic stress changes results in ground deformation, frictional afterslip [5,28,55,81,82] and viscoelastic relaxation of the lower crust [25,26,68,74,79]. Afterslip is sometimes triggered not only on the fault that caused the earthquake, but also on surrounding faults within the stress field [1,12]. Another very noticeable consequence of an earthquake is the series of aftershocks following it, which may be triggered by combinations of stress changes as the lower crust relaxes after an earthquake as well as those due to motion during the earthquake itself [90].

In cases where the coseismic slip distribution (and it's associated stress change) is well-constrained by combinations of geodetic and seismic data, we can explore models of crustal and mantle properties, or place bounds on laboratory-derived rock mechanics laws [7], in order to fit the postseismic response to the coseismic stress change. For instance, the distribution of afterslip places constraints on the frictional behavior of the fault zone [32,55]. However, any such study requires good understand of the processes occurring during the earthquake itself.

Interseismic Behavior Although it is usually less dramatic than deformation occurring during and immediately after earthquakes, interseismic deformation can also tell us a great deal about the fault zone. The depth of the "locked" or "coupled" zone that will eventually rupture seismically [24,29], the rate at which stress is accumulating along the fault zone [59,92], and even variations in crustal elastic properties when rocks of different types are brought into contact across the fault zone [14], can all be addressed by examination of interseismic deformation across a fault. In addition, data types that span a finite amount of time, such as InSAR or campaign GPS observations, will always contain some amount of interseismic strain that may need to be removed before studying measurements spanning an earthquake. The steadiest interseismic deformation is mainly due to flow of the lower crust and mantle beneath the elastic upper crust, but there are also observations of steady creep in the shallowest portions of several strike-slip fault zones [31,37,47,73].

Transient Behavior One of the most intriguing fault behaviors observed recently are isolated deformation events that are often not directly associated with an earthquake at all. These "slow" or "silent" earthquakes have been observed around the world in subduction zones, especially within the Cascadia subduction zone ([51,54], Fig. 6), Japan [27,56,65], Mexico [45], and Chile [64]. Along-strike variations in the amount of plate convergence that is taken up by these aseismic slip processes vs. large coseismic events may persist over very long timescales, as is indicated by the correlation of potentially aseismic "seismic gaps" in subduction zones and gravity anomalies [89,95]. Although most transient fault zone activity has been noticed along subduction zones, there are also observations of transient aseismic creep along the San Andreas Fault [60] and within the Imperial Valley, CA [42]. Further observations will help us understand how great of a contribution combinations of steady interseismic and transient aseismic behaviors make to the release of plate motion across many of the major tectonic boundaries around the world.

Figure after [54]

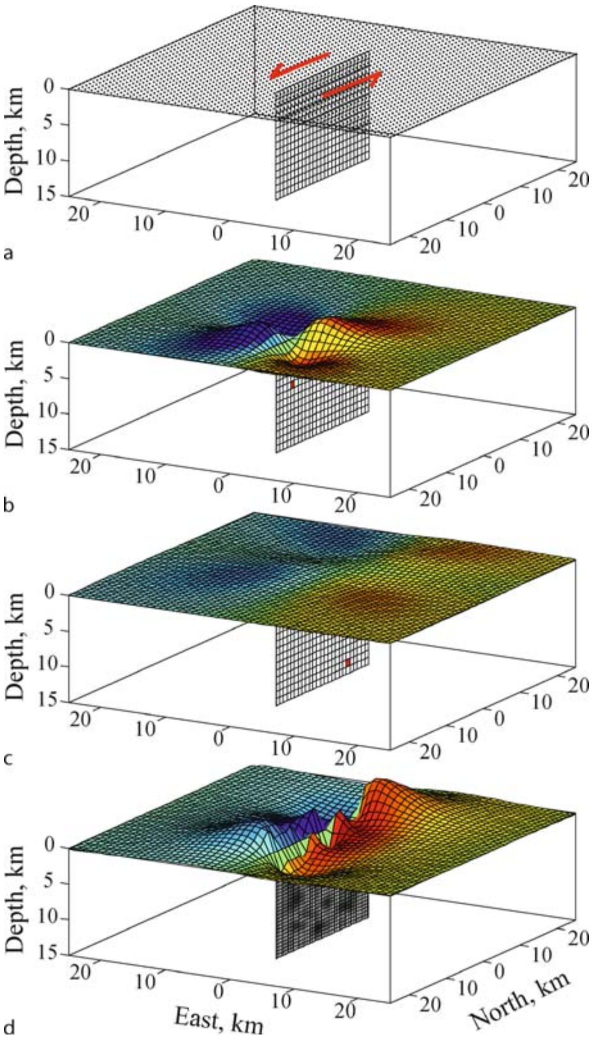
Modeling of Geodetic Observations

Overview of Inverse Theory

All of the observations discussed above involve measurements of surface deformation. We can learn nothing about processes occurring below the surface, within fault zones, without the ability to infer how those observations were generated. Inverse theory spans the range of problems relating to identifying which model of real-world behavior is consistent with observed data. Some of the simplest inverse problems include that of fitting a line to a series of data points, or even calculating the mean value of a set of observations. Good treatments of the field of inverse theory and it's applications to geophysical problems in general can be found in books by Parker [66] and Menke [52], as well as in key papers by Backus and Gilbert [4] and Tarantola and Valette [91].

Before a geophysical inversion can be performed (i. e., determining the size of an earthquake based on ground deformation) the "forward model" must be defined and understood. A forward model is a description of how we believe the system of interest, here, the Earth's crust, will behave in response to the process we are studying (i. e., fault slip). For inversions for fault slip, the forward model is our best guess at how the deformation field produced by motion on the fault surface will propagate through the solid earth to the ground surface where we can observe it. Laboratory, seismological and field observations support the idea that the crust behaves as an elastic solid on the short timescales associated with earthquakes and their immediate aftermath, although parts of the crust deform viscously at longer time scales under prolonged stress. The response of the elastic crust surrounding a plane that undergoes fault slip can be described mathematically [62]. Figure 7 shows the predicted ground deformation for strike-slip motion on fault "patches" at varying depths. The ground deformation response is linear, i. e., the deformation from multiple sources is just the sum of deformation from the individual fault patches. Therefore, we can predict the expected ground deformation from arbitrarily complicated fault zone geometries and slip distributions.

In an inverse problem, we consider the behavior of a forward model or family of forward models from a num-



Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 7

Predicted ground surface deformation for a vertical, left-lateral strike-slip fault a, using Okada [62]. Fault slip on a shallow fault patch (*red*, panel b) produces a larger amount of deformation over a smaller area than does fault slip on a deeper region of the fault plane c. Here, *deformation of the grid* indicates vertical deformation and *color* indicates the amount of northward (*red*) or southward (*blue*) deformation. The amount of total deformation from a complicated fault slip distribution is achieved by summing the components from all parts of the fault d

ber of possible sources that could potentially explain our data, and we find the combination these sources that best fits the data. In this section, the family of forward models is represented by slip on a fault plane that has been divided up into a number of fault patches, and the best-fit model would be the distribution of fault slip magnitude along this fault plane that best matches the observed ground deformation.

Linear vs. Nonlinear Inverse problems can be divided up into two major families: Linear and Nonlinear. In a linear problem, we solve for the sum of forward models that best fits the data, without any size constraints on the individual contributions from each forward model (fault patch). One example of a linear problem is where we find the best-fit fault slip distribution on a fixed fault plane, without any constraints such as requiring that the fault slip has a positive or negative sign (i. e., right-lateral vs. left lateral). Linear problems are essentially extensions of the problem of fitting a line to a set of data, and are quite easy to solve [52].

Nonlinear problems exist when the functional shape and form of the predicted data varies with the parameter choice. An inversion for the location of the fault plane itself, where quantities such as the x, y, z, location or fault plane strike and dip are varied, is very nonlinear. The process of solving a nonlinear problem involves finding a model that best fits the data in some pre-defined way, usually by finding the model that produces the lowest sum of squared residuals with the data (least-squares fit). Nonlinear problems may have multi-dimensional misfit functions with poorly defined or multiple minima, and the only way to find the absolute or "global" minimum is by exhaustively searching the parameter space.

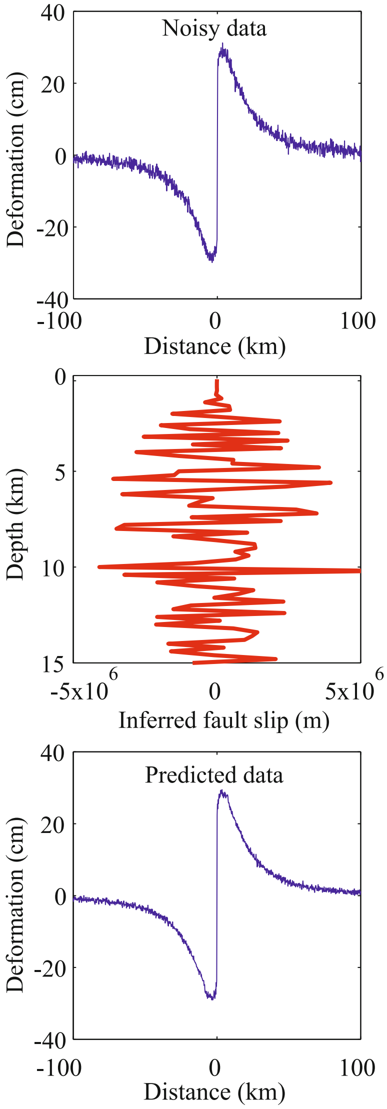
Methods for searching the parameter space in a nonlinear problem fall into two main camps. Gradient-based methods determine the slope and gradient of the misfit surface (often in many dimensions) and follow it downhill in an iterative way. These methods work well if the misfit surface has a single, well defined minimum. If the search begins near one of the local minima, it is possible that the true, global minimum will never be found. Global methods involve variations that range from simply sampling the parameter space very densely, to iterative methods that track many initial samples or families of samples in gradient-based searches. One method that performs very well in the ~9-dimensional parameter space of finding the best-fit fault plane and slip that fits data for a small earthquake is the Neighborhood Algorithm [44,78]. In the Neighborhood Algorithm (NA), the misfit values at many initial points are used to iteratively focus in on regions of the parameter space with lower misfit values. The NA method has the strength of being able to track and define multiple minima instead of just choosing one. A survey of several other nonlinear optimization methods applied to earthquake location problems can be found in Cervelli [6].

Smoothing The specific problem of inverting for fault slip on a particular fault plane has an interesting twist to it that is shared by many geophysical inverse problems. Just as an inversion for the best-fit line to data usually requires at least two data points, other inversions also effectively require the existence of more data than unknown quantities. For fault-slip problems the question does not boil down to simple numbers of data points vs. the number of fault patches – parts of the fault plane are better-resolved than others, and some data points contribute more information than is provided by their neighbors. For instance, if we had a thousand GPS receivers within 100 feet of the fault zone, but extended our target fault plane down to 100 km, the GPS data would be able to tell us little about what was going on at depth, even if we only divided the fault plane up into a few fault patches. Conversely, data points very close together and far from the fault contribute essentially the same information about what occurred – combining them can help to reduce noise, but it does not help us to isolate variations in fault slip along the fault.

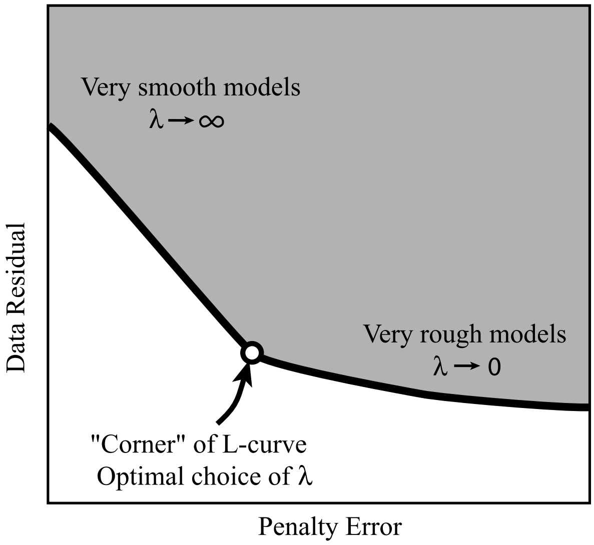
Because of these inherent variations in resolution, both in model and data, an inversion can run into problems if we simply solve for the best-fit fault slip distribution on a finely-divided fault plane. Since the forward models for two fault patches at great depth are very similar on the surface, the inversion cannot determine the relative strength of fault slip that should be assigned to each. The difference between [0 1] and [-1000 1001] is very small when you propagate it up to the surface, often smaller than the noise in the data (or even machine precision!). Therefore, the "best-fit" model would have unrealistically large variations that have nothing to do with what really occurred during the earthquake (Fig. 8). This effect is often known as "checkerboarding". While some of the features in the inferred slip distribution are related to the earthquake, much of the complexity is due to the attempt of the inversion to fit noise within the data.

There are several methods for dealing with this effect, all of which place some bounds on how large or spatially rough the variations in fault slip can be. The simplest method (although one of the hardest to optimize) is to parametrize the fault plane in a way that the fault patches are never so small that there are large tradeoffs in their predicted surface deformation [70]. The extreme of this would be to only use one fault patch. In most cases where we have a lot of data, this solution would not fit the data well nor tell us much about the earthquake.

Another method is to place a penalty during the least squares inversion on fault slip solutions that are very large (usually involving large variations) or that are spatially rough. These "regularized" inversions result in spatially smooth slip distributions that usually fit the data almost as well as the rough, unregularized inversions. Regularization always involves some choice of how much weight needs to be placed on the roughness penalty vs. the fit to the data, which can be a difficult procedure. Too large of a penalty weight and the slip distribution will be too smooth and will not fit the data (the logical extension of this is the single fault patch model discussed above). Too small of a weighting and the slip distribution will be arbitrarily rough, with unrealistic changes in sign throughout the fault zone.



Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 8
Example of how noisy data can affect fault slip inversion. *Top:* Deformation from a vertical strike slip fault, with added noise. *Middle:* Best fit slip distribution inferred from noisy data. The large fluctuations mostly cancel each other out at the surface, producing (*bottom*) predicted data that matches both the underlying deformation signal and the noise



Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 9
Typical L-curve. Each *point* on the curve corresponds to a slip distribution inferred using a different value of λ. In most cases, the "penalty error" will be a measure of model roughness

There are two main families of methods for choosing the appropriate smoothing weight (apart from random guessing, which often performs surprisingly well!). In general, as the amount of regularization is increased, the fault slip distribution becomes smoother and the fit to the data worsens. Ideally, we would choose the value where the proportion of the slip distribution that is just fitting data noise is as small as possible, without smoothing so much that we fit neither the noise nor the underlying signal due to the earthquake. The first method requires choosing the smoothing weight from a plot of data fit vs. model roughness, often referred to as an "L-curve" because of the characteristic shape of such curves (Fig. 9). The smoothing value at the corner of the "L" generally fits the data well without being "too rough". This type of parameter choice is slightly arbitrary and not easy to automate, but it does allow the researcher to include some intuition about characteristics of the earthquake.

The other family relies on the concept that a good choice of smoothing would be able to reproduce another, independent set of data spanning the earthquake fairly well. Too much smoothing and the slip model would fit neither the original nor the additional data sets well. If the choice of smoothing were too small, the resulting complex slip distribution would mainly be fitting noise in the original data set and would not, therefore, fit the independent noise in the second data set.

Of course, we rarely have the luxury of multiple data sets – if they do exist, we should use them for the main inversion! Data resampling procedures, known variously as the bootstrap, jacknife or cross-validation [10] are used to simulate the existence of multiple, independent data sets in cases where only one exists. Du et al. [9] compared cross-validation and other techniques for choosing smoothing parameters for geodetic data spanning the 1983 Borah Peak earthquake. Another powerful parameter choice method is the Akaike Bayesian Information Criterion (ABIC) that can be used to choose smoothing weights or other inversion characteristics [1,30,97].

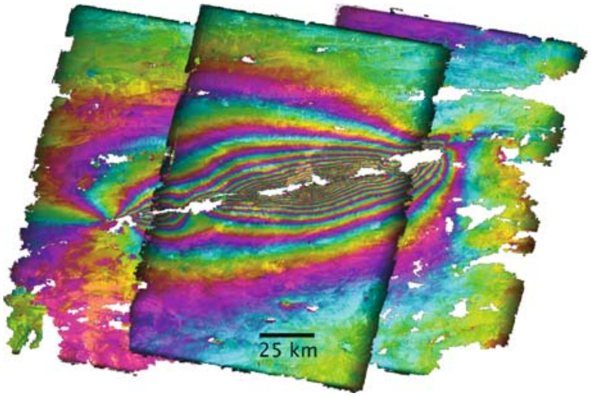
Noise Although finding the best-fit model to our data is certainly important, knowing how confident we are in that estimate is just as crucial. Studies of postseismic behavior, for instance, rely on good estimates of the coseismic slip distribution [25], and are improved further when we know what constraints we can place on that slip distribution. A variety of techniques exist for estimating these confidence limits – for linear problems, and when we know the character of the noise (magnitude, spatial correlation), it is quite simple to propagate data errors through to error bounds on the inversion results [52]. However, for nonlinear problems, and for cases where we are not quite sure how much of our signal is noise (usually the case with InSAR data), we need to rely on other methods for estimating the noise.

The same data resampling procedures described above can be used to generate multiple sets of inversion results that should reflect the noise structure of the data, even when it is not understood ahead of time. For nonlinear problems, such as the 3-D location of the best fit fault plane and earthquake mechanism for a particular earthquake, knowledge about the data noise can be used to construct multiple synthetic data sets that can then each be inverted using the nonlinear method of choice. Any conclusions about the problem (i. e., error bounds on fault slip) should be drawn from the ensemble as a whole [44].

Case Examples

Here we examine case examples for two earthquakes. In each case, we review the data and discuss characteristics of the inferred slip distributions.

Mw 7.6 Manyi, Tibet, Earthquake The 1997 strike-slip earthquake that occurred Tibet produced a very long rupture (170 km) with up to 7 meters of offset. It was such a long rupture that it takes three overlapping SAR tracks (Fig. 10) to cover its full length! Here, we show the effects



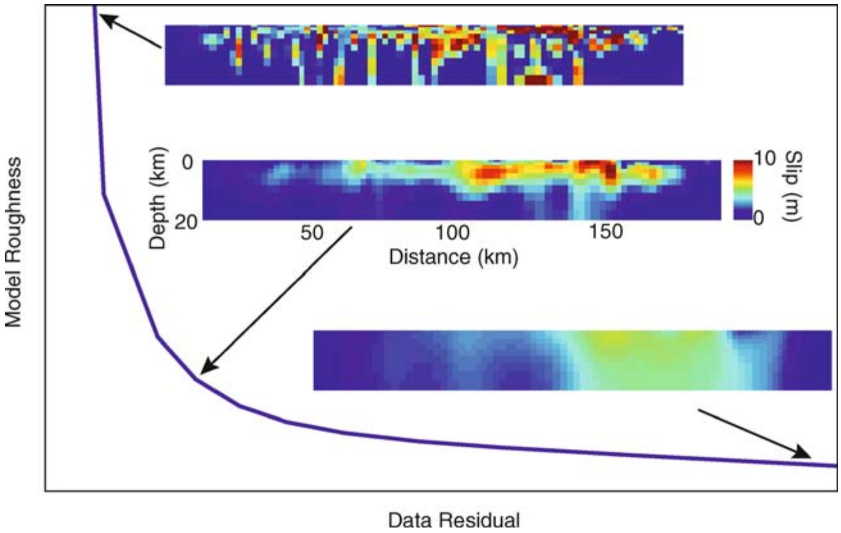
Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 10
Three overlapping interferograms spanning the 1997 Manyi earthquake

of variations in the spatial smoothing weights (λ) on an inversion of the deformation field for fault slip. Figure 11 illustrates the differences in inferred slip distributions for various magnitudes of λ, resulting in a spectrum between very smooth slip distributions that do not fit the data very well, to impossibly rough slip distributions that only fit the data marginally better than the "optimal" model (center panel). Our optimal model predicts up to 10 meters of fault slip with most slip occurring in the upper 10 km. Here, we chose the optimal value of λ using cross-validation, but the other methods discussed above can also be applied to this problem.

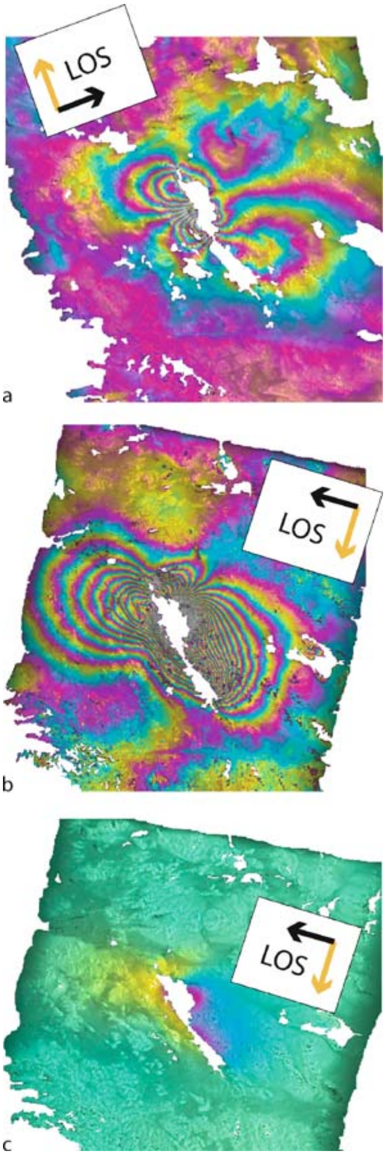
Asymmetries in the profiles of deformation across the fault during the Manyi earthquake have led some researchers to think that the elastic behavior of the crust may be different on one side of the fault vs. the other [67]. The magnitude of horizontal ground motion for a straight, vertical, strike-slip fault should be symmetric across the fault, if there are no other complications. However, variations in fault plane dip can affect the resulting ground deformation as much as variations in crustal properties, requiring that such studies carefully consider the fault geometry used in their inversions.

Mw 7.1 Hector Mine, CA, Earthquake The 1999 Hector Mine earthquake [16,85] occurred in the Mojave Desert of Southern California, and was widely studied due to it's proximity to large population centers and the San Andreas fault, it's very complete data coverage (GPS, InSAR, seismic data), and the fact that it occurred only a few years after another very large earthquake on a neighboring fault (1992 Landers earthquake). The combination of the two earthquakes within such a short time interval suggests that series of earthquakes may occur separated by long intervals of quiescence instead of events always occurring at semi-regular time intervals of strain buildup and release [61,69].

In Fig. 12, we show a subset of the available InSAR data spanning the Hector Mine earthquake. Both continuous and campaign GPS data were also recorded on either side of the Y-shaped rupture. In Fig. 13, we show the re-



Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 11
L-curve for the Manyi EQ, showing slip distributions inferred using 3 different values of smoothing, each with the same color scale. Small λ (*top panel*) produces an unrealistically rough slip distribution, whereas very large λ (*bottom panel*) produces a smooth model that doesn't fit the data



Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 12
Three representations of the Hector Mine EQ. a "Ascending" and b "descending" wrapped interferograms, where the satellite is moving in the direction indicated by the *yellow arrow* and viewing in the direction of the *black arrow*. Note how the same deformation field looks very different depending on the viewing direction. Color cycles correspond to ~3 cm of deformation. c Unwrapped version of interferogram in b. Now the color scale corresponds to 3 meters and spans the entire dynamic range of the data

sults of inverting the GPS and all the InSAR data for the best-fit fault slip distribution, with up to 6 meters of fault slip. Note how the maximum fault slip is not at the surface, but peaks at a few km depth. If we plot the average slip vs. depth (Fig. 14), the profile clearly shows how the shallow slip deficit is robust even given the amount of noise in the data.

Future Directions

The spatial and temporal coverage of geodetic data sets such as InSAR and GPS is increasing to the point where we can observe new types of fault zone behavior and solve for characteristics on a scale and precision that could hardly have been imagined a few decades ago. As we increase our ability to understand and describe the kinematics of crustal deformation, we can begin to explore the dynamic processes driving seismic and volcanic deformation in tectonically active regions around the world. Three of the main fields that show the most promise in the near future are discussed below:

Transient Deformation and Slow, Silent Earthquakes

The episodic slow slip events that show up with amazing regularity (∼14 months) in Cascadia ([51,54], Fig. 6), and that are also observed in Japan [27,56,65] and Mexico [45], are some of the most exciting new types of fault zone behavior that scientists have observed in recent years. The idea that earthquakes contained energy that was released by slower ruptures was noticed using seismic data far earlier than it was ever observed geodetically (1960 Chilean earthquake [34]). The slow slip events are often associated with heightened levels of spatially-correlated, low-level seismicity, or seismic tremor [87]. Currently, the process that allows these slow earthquakes to initiate and propagate at the observed speeds is still unknown, although they may be occurring at depths where dehydration of subducted sediments becomes important.

Apart from their intrinsic interest (since we always seek to explain processes that we do not understand), these slow/silent events release a not insignificant amount of the accumulated strain across the fault boundaries. In some ways this is a boon to people living nearby – any plate tectonic motion that is accommodated aseismically means that there is that much less accumulated strain that could be released in a destructive earthquake. However, there are indications that aseismic slip events are often closely followed by earthquakes [42,75], indicating that the changes in stress during the slow event can push other, nearby, regions past the brink until they rupture coseismically. This, also, can be seen in a positive light – perhaps close monitoring of aseismic deformation along active plate boundaries can serve as an early warning system, or at least a signal to raise the forecasted earthquake hazard whenever heightened activity is observed.

Reduction or Modeling of Atmospheric Noise

One of the largest hurdles for researchers approaching InSAR data is the atmospheric noise present in all interferograms. GPS data is affected by this problem as well, but the atmospheric signal can be solved for or averaged out due to the long observation times allowed by GPS. An area of active research is the modeling and removing of the atmospheric noise signal from InSAR data, using a variety of tools that range from other satellite-based observations of atmospheric water vapor content to simplistic models of correlations between elevation and interferometric phase [96].

The first-order layering of the atmosphere results in profiles of water vapor that tend to decrease vs. elevation in a manner that often appears essentially linear when two SAR images are combined in an interferogram. However, lateral variations with distance from water bodies and gradients from one side of a mountain belt to the other, result in the fact that the appropriate elevation vs. signal can vary quite a bit across a typical SAR image. For some target problems, such as the location of a small earthquake or the fault slip distribution for an earthquake in a relatively flat area, these elevation-dependent signals will likely affect the inversion to only a limited extent. However, in studies where the signal of interest is correlated with elevation, such as fold growth or subsidence caused by lake loading, great care should be taken when removing overly simple models of atmospheric water vapor from the data.

A more promising, albeit still problematic, approach is the modeling of water vapor content based on observations from satellite-based platforms. Water vapor measurements are made by a variety of satellites, but two in particular have the spatial scale and temporal resolution that make them potentially very useful in InSAR applications. The Moderate Resolution Imaging Spectroradiometer (MODIS) instruments on both the Terra and Aqua satellites acquire almost daily observations over most of the Earth's surface at fairly high resolution (1 km spacing). They are not acquired at exactly the same time as the SAR images, but they can still be used to track seasonal trends or to seek individual features that may persist between the SAR and MODIS image acquisition times. While these cannot be used to quantitatively remove the atmospheric signal, they can be very useful from a qualitative standpoint in determining whether a particular interferometric signal may or may not be tectonic in origin.

The Medium Resolution Imaging Spectrometer (MERIS) is physically located on the same satellite (ENVISAT) that acquires much of the SAR imagery used today. Since MERIS observations are made at essentially the same time as the SAR imagery, they see the same atmosphere and can not only be used in the same qualitative way as MODIS, but also show promise of allowing the actual removal of atmospheric contributions to the interferometric phase. Some difficulties lie in the fact that MERIS and MODIS measurements of atmospheric water vapor can only be made in cloud-free images, and that "double-bounce" effects of the signal bouncing off the base of both visible and invisible clouds can bias the observations and introduce spurious water vapor features. Still, these satellite-based methods show great promise. The most robust method for reducing the contribution from atmospheric noise to our inversions remains the use of multiple independent data sets, whenever available.

Data Assimilation

As mentioned in Sect. "Highlights of Earthquake Geodesy", the vast quantity of data now available to us can prove troublesome – if it takes hours to perform one forward model of a possible earthquake scenario with the available data, then the inverse problem quickly becomes unmanageable (or at least can begin to extend past the length of a normal graduate thesis). Parallel computing methods and the rapid decrease in cost for computing resources now makes the operation of large, multi-processor machines feasible within individual research departments. These large machines allow us to approach inverse problems with the "big hammer" of stochastic, or Monte Carlo, methods, which rely on the use of many randomly generated simulations of a system [6]. However, the expected continuing increase of both spatial and temporal coverage of deformation observations requires that we need to continue developing new tools that allow us to capitalize on data time series as well as individual snapshots of ground deformation.

Kalman filters and related methods are one very powerful tool now in widespread use, especially within the GPS community [51,84]. The incorporation of InSAR data into such methods is slightly more difficult, in part because of the large number of data points, but also because of the varying character of noise between interferograms and difficulties in dissociating the description of noise vs. modeling of the geophysical signal of interest. Data assimilation methods developed in the atmospheric sciences, which also deal with data sets of varying spatial and temporal scales and resolutions, are a potentially rich source of tools that the geodetic community can explore in the near future.

Cryosphere Models

ROGER G. BARRY
NSIDC, CIRES, University of Colorado, Boulder, USA

Article Outline

Glossary

Cryosphere All forms of terrestrial snow and ice.

Newtonian viscous body A body whose stress at each point is linearly proportional to its strain rate at that point.

Definition of the Subject

The cryosphere comprises all terrestrial forms of snow and ice – snow cover, floating ice, glaciers, ice sheets, frozen ground and permafrost. It is a critical element of the climate system because of its high reflectivity, its insulating effects on the land and ocean, and its storage of water on short and long time scales. Numerical models of components of the cryosphere have been developed over the last 30 years or so, and some elements of these are now incorporated in coupled climate models and earth system models.

Introduction

Currently there are no comprehensive models of the entire cryosphere. Rather there is a wide range of models of components of the cryosphere – snow cover, floating ice, glaciers, ice sheets, frozen ground and permafrost – and various components are treated with varying degrees of detail in coupled atmosphere-ocean-land models. Cryospheric processes are generally parametrized in such earth system models.

Models developed for each of the main cryospheric components are discussed in turn.

Snow Cover

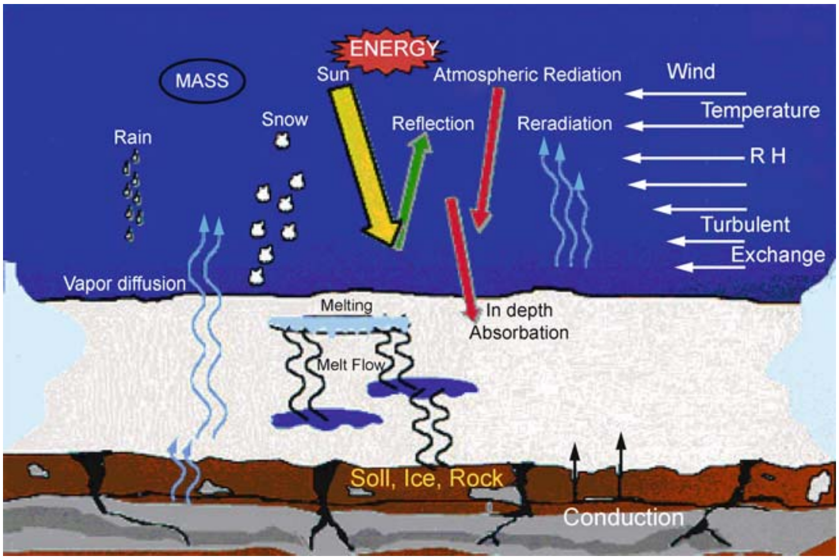
Snow cover is observed in situ at hydrometeorlogical stations, from daily depth measurements, (monthly) snow courses and in special automated networks such as the western United States Snow Telemetry (SNOTEL) network of snow pressure pillows. Its extent is also observed and mapped daily (since June 1999) over the Northern Hemisphere from operational satellites of the National Oceanic and Atmospheric Administration (NOAA) in the USA. Snow covers about 47 million km^2 at maximum in January and there is only a small area in South America in July. Hemispheric snow water equivalent estimates are routinely made from passive microwave data (1979-present) with a 25-km resolution (Armstrong et al. [4]).

There are numerous models of the formation and disappearance of snow cover. Many have a hydrological focus aimed at estimating seasonal runoff. Some use simple temperature degree-day formulations while others incorporate a full energy balance calculation. Dozier and Painter [14] examine the use of multispectral and hyperspectral remote sensing to estimate the snow's spectral albedo, along with other properties such as grain size, contaminants, temperature, liquid water content, and depth or water equivalent.

The U.S. Army Cold Regions Research and Engineering Laboratory Model SNTHERM (SNow THERmal Model) is a 1-D energy balance model for snow and soil that is forced by meteorologically determined surface fluxes [41]. It simulates in-snow properties and processes, such as heat conduction, water flow, melt, vapor flow, compaction, grain growth, and solar absorption (see Fig. 1). The output provides snow depth, profiles of snow temperature, water content, density, grain size, and surface fluxes of sensible heat and evaporation. Surface boundary conditions require: incoming solar and longwave radiation; wind speed, air temperature and humidity at some reference height; and precipitation. The model will estimate solar and longwave radiation from cloud cover, if data on these variables are not available. Lower boundary conditions include soil textural properties (currently clay or sand used as defaults), wetness and temperature profile.

A comparative study of three snow models with different complexities was carried out by Jin et al. [39] to assess how a physically detailed snow model can improve snow modeling within general circulation models. The three models were (a) SNTHERM; (b) a simplified three-layer model, Snow–Atmosphere–Soil Transfer (SAST), which includes only the ice and liquid-water phases; and (c) the snow submodel of the Biosphere –Atmosphere Transfer Scheme (BATS), which calculates snowmelt from the energy budget and snow temperature by the force–restore method. SNTHERM gave the best match to observations with the SAST simulation being close. BATS captured the major processes in the upper layers of a snow pack where solar radiation is the main energy source and gave satisfactory seasonal results.

CROCUS is a model of the Centre d'Etudes de la Neige, Grenoble [10]. It is a 1-D physical model that determines mass and energy balance for a snow cover and is used for operational avalanche forecasting. The snow cover is represented as a pile of layers parallel to the



Cryosphere Models, Figure 1
The snowpack energy balance as characterized by SNTHERM (US Army Corps of Engineers)

ground. Energy exchanges are projected orthogonally to the slope. The model describes the evolution of the internal state of the snow cover as a function of meteorological conditions. The variables describing the snow cover are temperature, density, liquid water content, and snow type of each layer. To match the natural layers, the thickness and number of layers are adjusted by the model. The model simulates the heat conduction, melting/refreezing of snow layers, settlement, metamorphism, and percolation. It simulates dry and wet snow metamorphism with experimental laws derived from laboratory data. Snow grains are characterized by their size and type. This allows an accurate albedo of the snow cover to be calculated.

Bartelt and Lehning [7] also present a 1-D physical model of the snow pack (SNOWPACK) with equations for heat transfer, water transport, vapor diffusion and mechanical deformation. New snow, snow drift and ablation are treated. The snow layers are treated in terms of height, density and microstructure (grain size, shale and bonding). The model is used for avalanche warnings in Switzerland.

Interception Models

A physically-based snowfall interception model that scales snowfall interception processes from branch to canopy is now available [25]. It takes account of the persistent presence and subsequent unloading of intercepted snow in cold climates. To investigate how snow is intercepted at the forest stand scale, measurements of wind speed, air temperature, above- and below-canopy snowfall, accumulation of snow on the ground and the load of snow intercepted by a suspended, weighed, full-size conifer were collected from spruce and pine stands in the southern boreal forest. Interception efficiency is found to be particularly sensitive to snowfall amount, canopy density and time since snowfall. Further work resulted in process-based algorithms describing the accumulation, unloading and sublimation of intercepted snow in forest canopies (Pomeroy et al. [70]). These algorithms are unique in that they scale up the physics of interception and sublimation from small scales, where they are well understood, to forest stand-scale calculations of intercepted snow sublimation.

Blowing Snow Models

Physically-based treatments of blowing snow and wind are used to develop a distributed model of blowing snow transport and sublimation over complex terrain for an Arctic tundra basin by Essery et al. [18]. A reasonable agreement with results from snow surveys is obtained when sublimation processes are included. Sublimation typically removes 15–45% of the seasonal snow cover. The model is able to reproduce the distributions of snow mass, classified by vegetation type and landform, which can be approximated by lognormal distributions. The representation used for the downwind development of blowing snow with changes in wind speed and surface characteristics is shown to have a moderating influence on snow redistribution.

Spatial fields of snow depth have power spectra in one and two dimensions that occur in two frequency intervals separated by a scale break between 7 and 45 m [84]. The break in scaling is controlled by the spatial distribution of vegetation height when wind redistribution is minimal and by the interaction of the wind with surface concavities and vegetation when wind redistribution is dominant.

In mountainous regions, wind plays a prominent role in determining snow accumulation patterns and turbulent heat exchanges, strongly affecting the timing and magnitude of snowmelt runoff. Winstral and Marks [90] use digital terrain analysis to quantify aspects of the upwind topography related to wind shelter and exposure. They develop a distributed time-series of snow accumulation rates and wind speeds used to force a distributed snow model. Terrain parameters were used to distribute rates of snow accumulation and wind speeds at an hourly time step for input to ISNOBAL, an energy and mass balance snow model. ISNOBAL forced with accumulation rates and wind fields generated from the terrain parametrizations accurately models the observed snow distribution (including the formation of drifts and scoured wind-exposed ridges) and snowmelt runoff. By contrast, ISNOBAL forced with spatially constant accumulation rates and wind speeds taken from the sheltered meteorological site at Reynolds Mountain in southwest Idaho, a typical snow-monitoring site, overestimated peak snowmelt inputs and tended to underestimate snowmelt inputs prior to the runoff peak.

Avalanche Models

Avalanches range in size from sluffs with a volume of $< 10\,\text{m}^3$ to extreme releases of 10^7–$10^8\,\text{m}^3$; corresponding impact pressures range from $< 10^3$–10^6 Pa. There are two main types – loose snow avalanches and slab avalanches. Commonly, they begin with the failure of snow layers with densities less than $300\,\text{kg m}^{-3}$. An avalanche path comprises a starting zone, the track, and a runout–deposition zone. Loose snow avalanches are initiated when the angle of repose is exceeded – about 45°. The angle increases as temperatures rise due to increased cohesion. Slush avalanches can occur on slopes <10°. Downslope propagation continues to the kinetic angle of repose at about 17° [52,69]. Slab avalanches occur when a cohesive slab is released over an extensive plane of weakness on slopes of 35–40°. Slab thicknesses are 0.1–4 m and have a mean density of $\sim 200\,\text{kg m}^{-3}$. Bed surface temperatures are near 0°C.

The variables of interest for forecasting are velocity, run-out distance and impact pressure. The acceleration of an avalanche is resisted by surface friction, air drag at the front and upper boundary, and ploughing at the advancing front and underneath surface. According to Perla [69], maximum velocities range from 20–$30\,\text{m s}^{-1}$ for path lengths up to 500 m and slope angles of 25–35°. The mean run-out length on 67 Colorado avalanche paths was 380 m (Bovis and Mears [9]). On occasion, the run-out may cross a valley floor and continue up the facing slope. Impact pressures are a maximum at 1–2 m above the surface and range in value from about 1–10×10^5 Pa (Perla [69]).

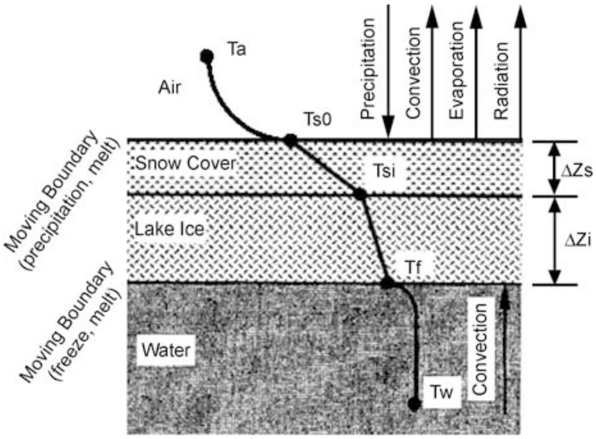
Land Surface Schemes in GCMs

Snow cover is treated in Land Surface Models (LSMs), but snow and ice albedo parametrizations differ widely in their complexity [5]. A Snow Model Intercomparison was conducted using 24 snow cover models developed in ten different countries [17]. The models differ as to being multilayer or not, the inclusion of a soil model, variable heat conductivity, variable snow density, and the treatment of liquid storage. Only four of the models met all five criteria.

27 atmospheric general circulation models (GCMs) were run under the auspices of the Atmospheric Model Intercomparison Project (AMIP). The AMIP models reproduce a seasonal cycle of snow extent similar to the observed cycle. However, GCMs tend to underestimate autumn and winter snow extent (especially over North America) and overestimate spring snow extent (especially over Eurasia). The majority of models displays less than half of the observed interannual variability. No temporal correlation is found between simulated and observed snow extent, even when only months with extremely high or low values are considered [20]. The second generation AMIP-II simulations gave better results [21].

Floating Ice

Lake ice formation is dependent on the density characteristics of fresh water, which reaches a maximum density at 4°C. As a water body cools in the autumn it becomes isothermal at 4°C. Further cooling of the surface allows a less dense layer to form and eventually frazil ice or sheet ice forms depending on the wind conditions. Snow accumulation on lake ice depresses the ice surface below the water level, causing the snow to become saturated and leading to the formation of white snow-ice (in contrast with the black lake water ice). In rivers the flow motion leads to frazil ice, which builds up into pancakes. A 1-D energy balance model of lake ice growth is described by Liston and Hall [47] that treats lake-ice freeze-up, break-up, total ice thickness and ice type (Fig. 2). The model is



Cryosphere Models, Figure 2
The elements of a model of lake ice [47]

forced by daily atmospheric data on precipitation, wind speed and air temperature.

Sea ice grows thermodynamically by freezing of sea water at near –1.8°C due to the salinity, by the accumulation of snow cover on its surface, and by dynamic processes such as ridging and rafting. It decays thermodynamically, by wave action and by export to areas of warmer ocean. Ice types include new ice, young ice, first year and multi-year ice (World Meteorological Organization [91]). Typical first year ice thickness in the spring in the Arctic is about 1.5–2 m; multi year unridged ice may be 3–4 m thick. Ridging produces keels that may extend to 20–30 m depth. Ice draft (below the sea surface) is measured by upward looking sonars that are moored or deployed on submarines in the Arctic. Ice extent and concentration – the fractional coverage of ice – are determined by aerial reconnaissance, and primarily by satellite remote sensing (optical, passive microwave, synthetic aperture radar, scatterometry and laser altimetry). Weekly or 10-day charts of ice conditions are produced by national operational ice services (see [94]).

Modeling sea ice in either a stand-alone model or a GCM involves the solution of the following equations [19]:

i. for momentum, to obtain the ice velocity fields;
ii. for thermodynamic processes to obtain net ice growth/melt; and
iii. conservation equations including deformation ands transport of ice, plus the thermodynamic sources and sinks.

Ice dynamics is based on five stresses: wind stress, water stress, internal ice stress, Coriolis force, and the stress from the tilt of the sea surface. The Coriolis force and the tilt term are an order of magnitude less than the other three terms. The air and water stresses assume a constant turning angle of 25° in the Arctic and –25° in the Antarctic [28]. Internal ice stress is highly variable depending on ice conditions. It can be negligible when the ice cover is not compact and there are "free-drift" conditions, but it can be the largest force when there is thick, compact ice cover. The force due to ice resistance to deformation involves the relationship between stress and strain rate, which is termed the rheology (Flato [19]). Early work assumed that stress is linearly dependent on strain rate as in a linear viscous fluid [12]. Pritchard et al. [71] used an elastic-plastic rheology where the stress is linearly dependent on strain up to a yield strength where failure occurs. Hibler [27] developed a viscous-plastic model with an elliptical yield curve; the pre-yield stress states are linearly related to the strain rate. Advances by Hunke and Dukowicz [35] address the response of the ice on the timescales associated with wind forcing through an elastic viscous-plastic (EVP) rheology. The model was modified so that it reduces to the viscous–plastic model at these timescales, whereas at shorter timescales the adjustment process takes place by a mathematically efficient elastic wave mechanism. Recently, Lagrangian [33,45] sea ice models using a granular rheology have been developed (Tremblay and Mysak [83]; Overland et al. [65]). They have advantages in that they model individual sea ice "floes", but are also computationally intensive and are still in their infancy.

Ice dynamics have been extensively treated by Hibler [27]. He couples the dynamics to the ice thickness characteristics by allowing the ice interaction to become stronger as the ice becomes thicker and/or contains a lower area percentage of thin ice. The dynamics in turn causes high/low oceanic heat losses in regions of ice divergence/convergence. The ice is considered to interact in a plastic manner with the plastic strength depending on the ice thickness and concentration. These in turn evolve according to continuity equations that include changes in ice mass and percent of open water due to advection, ice deformation and thermodynamic effects. Anisotropic dynamic behavior of sea ice has also been investigated [13,30], though such approaches are computationally intensive and currently are not commonly used in models. The standard model treats sea ice as a visco–plastic material that flows plastically under typical stress conditions but behaves as a linear viscous fluid where strain rates are small and the ice becomes nearly rigid. The standard viscous–plastic model has poor dynamic response to forcing on a daily timescale. Models do not generally account for high-frequency (sub-daily) inertial and tidal effects on dynamics, though research has shown that such effects can be important in the evolution of the ice cover [26,43]. The thermodynamics and dynamics are coupled through the ice thickness distribution. Essentially, deformation leads to pressure ridging and the formation of open water areas while thermodynamic processes act to ablate ridges and remove open water by ice formation in winter and create thinner ice/open water in summer. Thus, deformation acts to spread out the thickness distribution by promoting thick and thin ice categories while thermodynamic processes work towards a central ice thickness value [28].

Sea ice models typically feature processes of ice thermodynamics and dynamics although the earliest studies essentially used only thermodynamic ice growth and decay. The steady state Stefan relationship is written after Hibler and Flato [29]:

$$\rho_{\mathrm{I}} L \frac{\mathrm{d}H}{\mathrm{d}t} \approx \frac{k_{\mathrm{i}}}{H}(T_{\mathrm{m}} - T_{\mathrm{B}}) \, ,$$

where L = latent heat of fusion, T_{m} = melting point of the ice, T_{B} = upper boundary temperature of the ice, H = ice thickness, k_{i} = ice conductivity and ρ_{I} = ice density. Ice growth/melt at the underside is a result of the difference between the upward ocean heat flux and the heat conducted away from the ocean/ice interface into the ice. The first 1-D model of sea ice thermodynamics was developed by Maykut and Untersteiner (1971) [51]. A fuller treatment was made by Parkinson and Washington [66]. The model had four layers – ice, snow, ocean, and atmosphere – and 200 km horizontal resolution.

The incorporation of detailed thermodynamic processes includes the presence of snow on the sea ice, leads and polynyas, melt ponds, the effect of internal brine-pocket melting on surface ablation, the storage of sensible and latent heat inside the snow-ice system, and the transformation of snow into slush ice when the snow-ice interface sinks below the waterline due to the weight of snow. Models with enthalpy conservation improve the thermodynamic component of sea ice models [8]. These are starting to be included in larger-scale climate models.

An intermediate one-dimensional thermodynamic sea ice model developed by Ebert and Curry [15] includes leads and a surface albedo parametrization that interacts strongly with the state of the surface, and explicitly includes meltwater ponds (see Fig. 3). Four important positive feedback loops were identified: (1) the surface albedo feedback, (2) the conduction feedback, (3) the lead-solar flux feedback, and (4) the lead fraction feedback. The destabilizing effects of these positive feedbacks were mitigated by two strong negative feedbacks: (1) the outgoing longwave flux feedback, and (2) the turbulent flux feedback. A review of thermodynamic models is given by Steele and Flato [80].

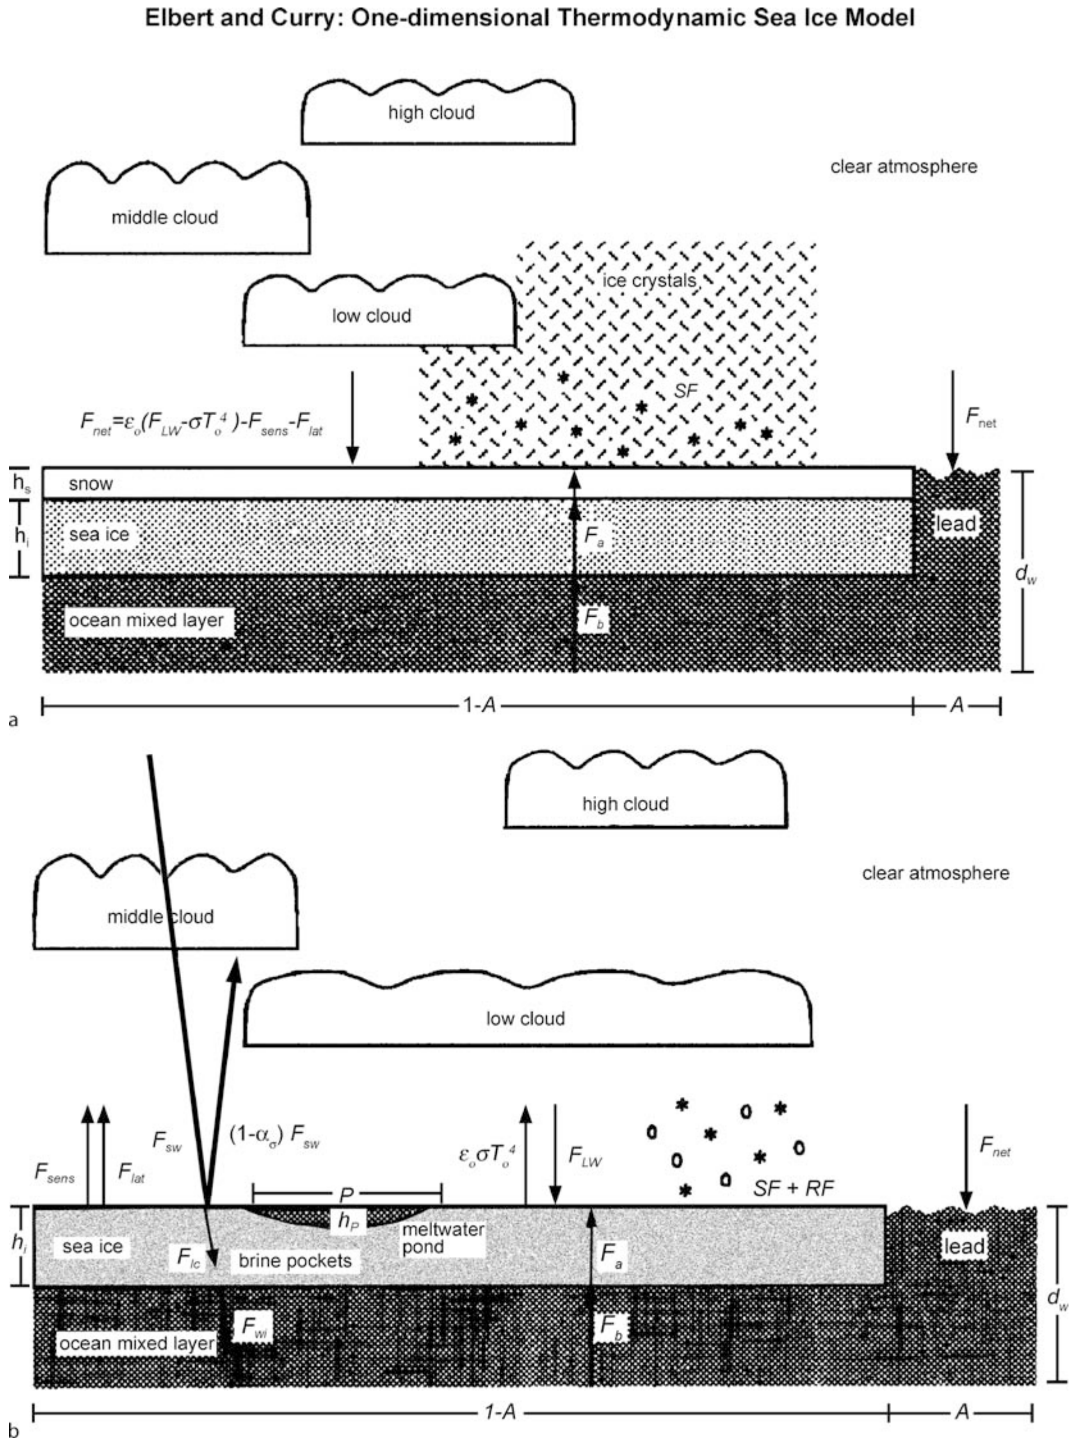
Conservation equations are needed for ice area (concentration) and ice volume (thickness).

$$\begin{aligned} \partial h/\partial t &= -\nabla \bullet (\boldsymbol{u} h) + S_h \\ \partial A/\partial t &= -\nabla \bullet (\boldsymbol{u} A) + S_A \, , \end{aligned}$$

where $\boldsymbol{u}$ is the ice velocity vector and S_h and S_A are source terms for mean ice thickness and concentration, respectively. The second equation must also have the constraint that the area $A \leq 1$. The ice strength is parametrized only in terms of ice thickness h and A [27].

An atmospheric GCM was coupled to a global 1-degree, 20-level ocean GCM with dynamic and thermodynamic sea ice by Washington and Meehl [86] and run with increasing atmospheric CO_2. The Coupled Model Intercomparison Project (CMIP) allows a comparison of predicted Arctic sea ice [53]. Of the 12 models, only seven include sea ice motion and only four of these have a prognostic solution to the momentum equation. Apart from errors and approximations in the sea ice representation, the models also suffer from errors in the atmospheric and oceanic forcing fields. While the northern hemisphere ice extent in winter is well simulated overall, the ice thickness does not capture the proper spatial distribution with thicker ice toward North America and Greenland and thinner ice in the Eurasian basin. The simulations for the southern hemisphere show a wider range of extents and thickness. Flato [19] examines the sea ice extent simulated by two GCMs for AD 1900–2100 with the 'business as usual' scenario of greenhouse gases and aerosol concentrations. Both show a progressive decrease in ice in both hemispheres although the two models differ significantly in the initial southern hemisphere ice extent.

Martin and Gerdes [50] make a comparison of sea ice drift results from different Arctic Ocean Model Intercomparison Project (AOMIP) sea ice-ocean coupled models and observations for 1979–2001. The models are capable of reproducing realistic drift pattern variability. However, one class of models has a realistic mode at drift speeds around 3 cm s^{-1} and a short tail toward higher speeds. Another class shows unrealistically a more even frequency distribution with large probability of drift speeds of 10 to 20 cm s^{-1}. Reasons for these differences lie in discrepancies of wind stress forcing as well as sea ice model characteristics and sea ice-ocean coupling. Hunke and Holland [36] underscore the sensitivity of Arctic sea ice and ocean to small changes in forcing parameters. A comparison of three sets of forcing data, all variants of



Cryosphere Models, Figure 3
The configuration of a one-dimensional thermodynamic model of sea ice **a** winter; **b** summer [15]

National Centers for Environmental Prediction (NCEP) forcing, give significant differences in ice thickness and ocean circulation using a global, coupled, sea ice-ocean model.

A study of GCMs used for the IPCC Fourth Assessment Report shows that while they produce reasonably similar ice extents in the Arctic, their equilibrium ice thickness values have a wide range due to differences in downwelling infrared radiation [16]. Holland et al. [32] found that in some scenarios of future CO_2 concentrations the sea ice cover can respond non-linearly with large decreases in extent within only 5–10 years, indicating that the current fitted to observations linear trends may not hold in the future. Stroeve et al. [81] showed that the IPPC models substantially underestimate the observed decline in Arctic sea ice extent compared to observations over the past 50 years. Hence their application in future scenarios is questionable.

Johnson et al. [40] examine the simulated sea ice concentration from nine ice-ocean numerical models in the AOMIP. The models have similar characteristics in winter (100% cover is produced), and most models reproduce an observed minimum in sea ice concentration for September 1990.

An assessment of coupled climate models with respect to the development of Arctic sea ice thickness during the 20th century is examined by Gerdes and Koeberle [22]. Model behavior is compared with results from an ocean–sea ice model using the AOMIP atmospheric forcing for the period 1948–2000. The hindcast exhibits virtually no trend in Arctic ice volume over its integration period 1948–2000. Most of the coupled climate models show a negative trend over the 20th century that accelerates towards the end of that century.

Glaciers

Glaciers are built up from snow that persists over many years. Initial densification leads to firn (densities of 400–830 kg m^{-3}) and at some depth, where the air passages between grains are sealed off (∼15–70 m according to wetness), to glacier ice with a density of 830–917 kg m^{-3} [67]. The glacier has upper accumulation and lower ablation areas, that are annually varying, and the ice slowly flows downhill towards the glacier terminus. Some glaciers occasionally display surges when the ice advances rapidly for a year or two and then stabilizes or retreats.

Glacier models consider either the mass balance and the rate of change of total mass, or the glacier dynamics and interactions between the ice and the bed. The flow velocity is modeled along the centerline of the glacier.

Glacier flow is determined from a relation between the shear strain rate (ε_{xy}) and shear stress (τ_{xy}) known as Glen's flow law [23]:

$$\overset{\bullet}{(\varepsilon_{xy})} = A\tau_{xy}^{n} ,$$

where $n \sim 3$. A depends on ice temperature, impurities and crystal orientation.

Recommended values of A decrease from 6.8×10^{15} s^{-1} kPa^{-3} at 0°C to 3.6×10^{-18} at −50°C (see Table 5.2 in [67]). Stress causes ice to deform by extension/compression, and shear leading to rotation.

Ice flows only by internal deformation when the bed is frozen, but where temperate conditions exist at the base, sliding becomes important. The sliding law relates basal velocity, shear stress, water pressure and the glacier bed characteristics. Weertman's [88] theory of sliding involved regelation and plastic deformation. Regelation operates over small bumps in the bed (<1 m dimension). All the ice is at pressure melting point. There is excess pressure on the upstream side of the bump so that the ice there is colder than on the downstream side. This causes heat to flow towards the upstream side through the bump and surrounding ice. The heat transferred melts ice on the upstream side and melt water flows around the bump, refreezing on the downstream side because it is colder than the ice there. Ice also deforms plastically. Near a bump, the longitudinal stress in the ice and, therefore, the strain are above average. The greater the distance over which the stress is enhanced, the greater is the ice velocity. This mechanism works best over larger bumps. Both processes are equally effective at the "controlling obstacle" size, about 1–10 cm.

Paterson [67] shows that the sliding velocity:

$$u = \text{constant}\,(\tau^{0.5}/R)^{4} ,$$

where R = roughness and τ = basal shear stress.

Water from surface ablation penetrates to the glacier bed and has been shown to lift the ice by as much as 40 cm on the Unteraargletscher, Switzerland (Iken et al. [38]). During rapid uplift events the glacier velocity increased 3–6 times. When the water pressure at the bed exceeds a certain value (the separation pressure) that depends on the bed roughness, cavities form in the lee of bumps. When the water pressure exceeds a second critical value, sliding becomes unstable.

A numerical ice flow model has recently been used to study the advance of tidewater glaciers into a deep fiord [56]. The results suggest that irrespective of the calving criterion and the accumulation rate in the catchment, the glacier cannot advance into deep water (>300 m) unless sedimentation at the glacier front is included.

Using a first-order theory of glacier dynamics, Oerlemans [61] related changes in glacier length to changes in air temperature. He constructed a temperature history for different parts of the world from 169 records of glacier length. The reconstructed warming in the first half of the 20th century is 0.5°C. The warming signals from glaciers at low and high elevations appear to be very similar.

Ice Sheets

There are currently two major ice sheets in Greenland and Antarctica, but during the Last Glacial Maximum about 20,000 years ago there were massive ice sheets over northern North America and Fennoscandia. The Antarctic ice sheet covers 12.4 million km^2 and reaches thicknesses in excess of 4500 m; it represents a sea level equivalent of 64.3 m. The Greenland ice sheet has an area of 1.8 million km^2 and a maximum thickness of 3200 m; it has a sea level equivalent of 7.5 m. Both ice sheets have a parabolic profile and gentle slopes (1–2°) away from the margins. Greenland has a suite of snow facies; from the interior outward these are: the dry-snow zone, percolation zone, wet-snow zone, superimposed ice zone, and the ablation area. The equilibrium line is between the ablation area and the higher zones. At its base, Greenland is close to sea level except for fringing coastal mountains, through which the ice reaches the sea in some 20 major outlet glaciers. Antarctica is mostly dry snow and is little affected by melting except at the margins and in the Antarctic Peninsula. In the Antarctic there are major ice shelves (e. g. the Ross Ice Shelf and the Filchner–Ronne Ice Shelf) that buttress large sections of the ice sheet (see Fig. 4) and extend around 44% of the coastline of the continent.

The major problems in ice sheet dynamics, following Paterson (see p. 238 in [66]), are (i) to calculate the distribution of ice thickness and velocity that will maintain a steady state, given the accumulation and ablation rates and surface temperature. The flow parameters, ice thickness at the ice divide, and geothermal heat flux must be specified. Flow lines, the time that ice takes to travel along them, and the age of the ice at different depths, can be calculated from the velocity distribution. (ii) to determine how the system will react to changes in accumulation, ablation or surface temperature.

The earliest ice sheet models assumed that ice deformed as a Newtonian viscous body. Orowan [64] and Nye [59] assumed that ice behaved as a perfectly plastic material, but Glen [23] established the relationship between strain rate and stress in ice as non-linear (see above).

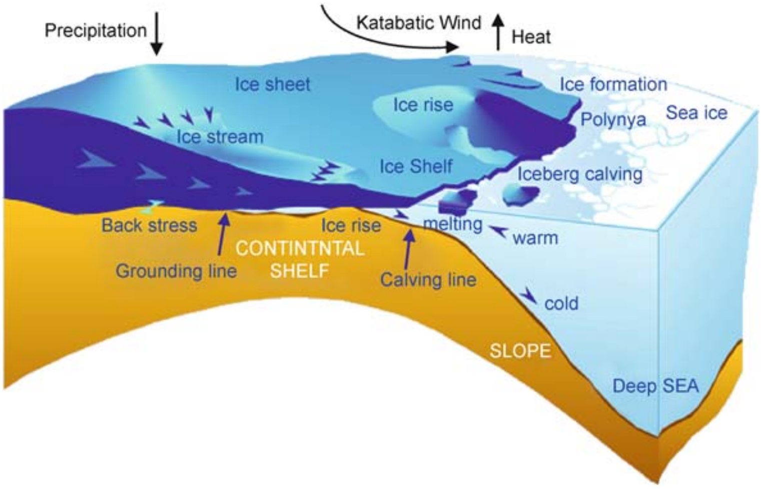
The surface profile of an ice sheet on a horizontal bed of half width L, thickness h and thickness at the centre H is:

$$h^2 = \frac{2\tau_0}{\rho g}(L - x) ,$$

where ρ = density, g = acceleration due to gravity, τ_0 = the basal shear stress (∼0–100 kPa), and $(L - x)$ is the distance from the edge measured along a flow line. The equation describes a parabola. The ice thickness at the centre is $H = (2\tau_0 L/\rho g)^{0.5}$.

The mass balance (B) can be expressed in a mass conservation equation as:

$$B = \frac{\partial q}{\partial x} : + \frac{\partial h}{\partial t} ,$$



Cryosphere Models, Figure 4
Schematic of an ice sheet and shelf showing the processes at work (after Wikipedia)

where h = ice thickness, t = time, and the flux $q = h\,\boldsymbol{u}$, where $\boldsymbol{u}$ is the velocity averaged over the ice thickness (see p. 246 in Paterson [67]).

If the flow term $\partial q/\partial x$ is small, then the surface elevation will vary in response to the local accumulation/ablation, which will determine the profile. 'Balance velocities' are steady state velocities that are calculated from accumulation rate and ice thickness. Paterson [67] shows that for a 1000 km radius circular ice sheet, of perfectly plastic ice with a yield stress of 199 kPa, an accumulation rate of 150 mm of ice/year, and ablation by iceberg calving at the margin, the ice in the centre would be 4700 m thick. Balance velocities would increase from 1,5 m a^{-1} at 100 km from the centre to 45 m a^{-1} at 900 km and the travel time for ice to move from the center to the edge would be 150,000 years.

In Greenland and Antarctica much of the ice transport is accomplished by fast flowing ice streams – regions where the ice flow is much faster than on either side. Most occupy deep channels with beds below sea level and terminate either as a floating glacier tongue (an outlet glacier) or become part of an ice shelf. Morgan et al. [54] indicate that while ice streams and outlet glaciers account for only 13% of the coastline of Antarctica, they drain about 90% of the accumulation of the interior.

A hierarchy of land ice models is presented by van der Veen and Payne [85]. The simple lamellar flow model, involves a balance between driving stress and basal drag. The surface and bed topography must be nearly level for lamellar flow, which is a good approximation to conditions in the interior of an ice sheet. In cases where an ice stream is bounded by a rock wall or stagnant ice on one or both sides, lateral drag needs to be incorporated. The proportion of driving stress that is supported by drag at the bed is termed the shape factor [60]; it is less than one for narrow ice streams. An important issue in Antarctica is the interaction between the ice sheet and ice shelves. The peripheral ice shelves are thought to exert a back stress that stabilizes the inland ice sheet where it is grounded below sea level, as in most of West Antarctica [82]. Where the bedrock slopes down towards the ice sheet interior, the grounding line is unstable; If the grounding line initially retreats, the ice at the grounding line becomes thicker due to the bedrock slope, and the creep thinning (thinning associated with along-flow gradients in the ice velocity) increases causing the grounding line to retreat further – a positive feedback. The dynamics of ice sheet grounding lines is examined by Schoof [76]. A boundary layer theory for ice flux through the transition zone shows that the flux increases sharply with ice thickness at the grounding line. He finds that marine ice sheets have well-defimed, discrete equilibrium profiles, and steady grounding lines cannot be stable on reverse bed slopes. Also, marine ice sheets with overdeepened beds may undergo hysteresis with variations in sea level, accumulation rate, bed slipperiness and ice viscosity.

Two general types of an ice sheet model have been developed. One is prognostic, based on the original work by Budd et al. [11]; the other category is diagnostic, addressing specific aspects of ice sheet processes. Prognostic models involve four sets of equations (van der Veen and Payne [85]). These are: (i) diagnostic equations for the horizontal velocity components as functions of local ice geometry and ice rheology (Glen's law); (ii) prognostic equations for the evolution of internal ice temperature, given appropriate boundary conditions at the upper and lower ice surfaces; (iii) a diagnostic equation for ice vertical velocity via the divergence of the horizontal velocity; and (iv) a prognostic equation for ice thickness based on the snow accumulation, snow/ice melt and the divergence/convergence of horizontal ice flow. The effects of bedrock depression under the changing weight of the ice load must also be taken into account. Such models have been used to reconstruct ice sheet history over glacial cycles, as well as to assess the responses to future climate change.

Diagnostic models do not address time evolution of the ice sheet and treat the internal stress regime in much greater detail, particularly the contributions of longitudinal and lateral stresses. Recently, models have been developed that do not assume negligible vertical shear. Huybrechts and de Wolde [38] have combined prognostic model elements with a detailed diagnostic model to study the multi-century behaviour of the Antarctic and Greenland ice sheets. A fully dynamic 3-D thermo-mechanical ice sheet model was coupled to a two-dimensional climate model.

A model validation exercise was undertaken by the European Ice Sheet Modeling Initiative (EISMINT). Payne et al. [68] examined the effects of thermo-mechanical coupling while MacAyeal et al. [49] test ice shelf models for the Ross Ice Shelf. Overall, the models agreed in the main features that were simulated.

Frozen Ground and Permafrost

The surface layers of soil and rock may be seasonally or perennially frozen. Perennially frozen ground or permafrost is frozen for at least two successive summers. The ground need not contain ice but may be rock below 0°C. Ground ice may be segregated, in veins, or massive in occurrence. The spatial extent of permafrost ranges from

The flowchart of a model processing the effects of snow cover on frozen soil, used to study the timing, duration, number of days, and areal extent of near-surface soil freeze/thaw status [92]

continuous (>90% of the surface is underlain), to discontinuous (50–90% of the surface), sporadic (10–50%) and isolated (<10%). Continuous permafrost is associated with mean annual temperatures below about –7°C. Its thickness ranges from a few meters up to 1500 m in Yakutia. Subsea permafrost also occurs offshore in the Eurasian shelf seas and in the Beaufort Sea; it is a relic of previous glacial intervals when the sea bed was exposed by sea level lowering of up to 135 m under low temperature conditions.

Ground temperatures are largely determined by heat conduction, although in areas of seasonal freezing and discontinuous permafrost localized circulation of groundwater may need to be considered. The thermal properties of the ground vary with the mineral composition, organic content, moisture content (as vapor, water and ice), and temperature, as well as the overlying vegetation and snow cover. A frozen soil algorithm has been developed [92] to detect the near-surface soil freeze/thaw cycle over snow-free and snow-covered land in the United States (see Fig. 5).

The conductive heat transfer is given [89] as:

$$G = -K(\mathrm{d}T/\mathrm{d}z)$$

where K = the thermal conductivity ($W\ m^{-1}\ K^{-1}$).

For steady state conditions, the temperature at depth T_z is written:

$$T_z = T_s + (G/K)z$$

where T_s = surface temperature.

The heat conduction equation is:

$$\partial T/\partial t = \kappa \partial^2 T/\partial z^2$$

where κ = thermal diffusivity ($\mathrm{m}^2\ \mathrm{s}^{-1}$), the coefficient of heat diffusion. To simulate soil freezing and thawing processes, soil water phase change has to be considered (for details, see Lunardini [48]).

Permafrost models can be broadly classified as either equilibrium or process-based transient models according to their underlying methodology. Equilibrium models are based on empirical and semi-empirical relationships between permafrost occurrence and topoclimatic factors (altitude, slope, aspect) and mean air temperature, freezing and thawing indices, and snow cover. They are often used to predict the lateral "boundaries" of permafrost distribution, or to estimate "average" geocryological parameters. thawing indices, snow cover and solar radiation, for example [77]. A 'frost index' model was developed by Nelson and Outcalt [55] for the Arctic and has been applied to mountain areas [31]. A wide spectrum of explicit equilibrium permafrost models is available to estimate the thickness of the active layer. The simplest approaches are based on several variations of the analytical Stefan solution to the heat conduction problem with phase change. These methods have been used to estimate regional-scale active layer thickness [56,79]. Kudryavtsev et al. [42] developed a more comprehensive equilibrium permafrost model with analytical solutions that has been adapted and used with Geographical Information System (GIS) technology to estimate active layer thickness at regional [74,78] and circum-arctic [2] scales. The advantages of equilibrium models are their relative simplicity and low data requirements. The major drawback of such models is their inability to resolve seasonal and inter-annual variability [77], which is frequently required for ecological and hydrological studies in the Arctic. These limitations have led to recent spatial adaptations of process-based transient numerical models.

Process-oriented transient models detail one-dimensional heat transfer in soils with phase change driven by either surface temperature [24] or the energy balance components [46]. They account for the major physical processes governing development of the ground thermal regime, simulate soil freezing/thawing processes, and provide insight into the response of soil thermal regime to changes in environmental conditions. These models can provide good results for simulating active layer thickness and permafrost temperatures when driven with known boundary conditions and forcing parameters measured at site-specific locations [73,93]. Recently, such one-dimensional heat transfer models with phase change have been used to simulate regional-scale soil thermal regime [62,63]. However, their adaptation from point-specific to regional-scale is not a straightforward process. It requires simplification, careful selection of climate forcing data, and treatment of surface and subsurface parameters with largely unknown distributions over the modeled domain.

Most GCMs do not treat permafrost dynamics. However, Nikolsky et al. [58] show that in the Community Land Model (CLM3) GCM improvements can be made to the representation of permafrost dynamics and their climate feedbacks. They do this by increasing the total soil depth by adding new layers, incorporating a surface organic soil layer, and modifying the model's numerical scheme to include unfrozen water dynamics and more realistic treatment of the model phase changes between ice and water.

The Community Climate System Model (CCSM) has a 5-layer snow model over a 10 layer 3.4 m deep soil model that treats thermal and hydrologic frozen soil processes. A projection made for the 21st century shows severe degradation of the permafrost in the Northern Hemisphere.

Some models address only the active layer that is the top layer of soil that thaws during the summer and freezes again during the autumn. The thaw depth can be analyzed by the Stefan solution for heat transfer in a medium with phase change (Anisimov et al. [3]):

$$z = [(2n\lambda t T)/(\rho w L)]^{0.5}$$

where z = active layer thickness (m), n = the ratio of seasonal ground surface and air temperature degree-day sums, λ = thermal conductivity of thawed soil (W m^{-1} K^{-1}), t = warm season duration > 0°C (s), T = mean warm season temperature (°C), ρ = soil density (kg m^{-3}), w = relative water content (decimal proportion) and L = latent heat of fusion (J kg^{-1}).

A dynamic 3-D terrain model is currently being developed and tested in Svalbard (Humlum [34]). The model takes topographic data, terrain surface characteristics (geomorphology and vegetation) and meteorological variables (air temperature, wind speed and direction, and cloud cover) as input and provides output on phenomena such as terrain surface net radiation balance, snow cover thickness and duration, glacier mass, active layer thickness, stable permafrost thickness and the amount of summer melt water discharge.

A stochastic model was developed by Anisimov et al. [3] and used to calculate the probability density function of active-layer thickness (ALT). Equations for the mean, variance, and higher moments of ALT were derived by applying stochastic averaging to a semi-empirical model of seasonal thawing. The stochastic model was applied in a case study in the Kuparuk River basin, north-central Alaska.

Shiklomanov et al. [77] compare three models of active layer thickness (ALT) for northern Alaska. One model (NSIDC) is very accurate in the topographically homogeneous Coastal Plain but overestimates (ALT) in the Brooks Range Foothills. The UAF-GIPL 2.0 model reproduced site-specific active layer values well but overestimated ALT on the Coastal Plain. Large differences in ALT fields mainly result from differences in model approaches for characterizing largely unknown spatial distribution of surface (vegetation, snow) and subsurface (soil properties and moisture) conditions.

Data set limitations are a major problem (Anisimov et al. [3]). A permafrost model, forced with available climate data sets, was used to calculate the large-scale characteristics of permafrost in northern Eurasia. Zonal-mean air and ground temperatures, depth of seasonal thawing, and area occupied by near-surface permafrost in Eurasia north of 45° N were analyzed. The 0.5–1.0 °C difference in zonal-mean air temperature between the data sets translates into a 10–20% uncertainty in estimates of near-surface permafrost area, which is comparable to the extent of changes projected for the following several decades.

GCMs have been used to simulate changes in permafrost conditions with global warming. Anisimov and Nelson [1] were the first to study this. Most recently, Saito et al. [74] use a coupled global climate model at high horizontal resolution (0.5° land mesh) with a five-layer, 4.0 m deep soil to evaluate changes in the distribution of frozen ground and subsurface hydrothermal regimes under global warming. Two types of frozen ground were classified according to monthly soil temperatures: "permafrost" for regions with a maximum active layer thickness less than 4 m and "seasonally frozen ground." Approximately 60% of present-day permafrost would degrade into seasonally frozen ground by 2100 in the circum-Arctic basins.

Future Directions

In the next 5–10 years we can expect to see more comprehensive treatment of cryospheric processes in climate models. Already, steps are being taken to incorporate ice sheet processes and to enhance the treatment of frozen ground and permafrost. Increased model resolution will place new demands for cryospheric data sets for boundary conditions and as validation data. Mountain glaciers, as well as lake ice, will need to be incorporated especially in regional climate models.

Glossary

WT1D The one-dimensional Wavelet Transform as defined in [53]. See also ▶ Numerical Issues When Using Wavelets.

WT2D The two-dimensional Wavelet Transform.

Discrete ridgelet trasnform (DRT) The discrete implementation of the continuous Ridgelet transform.

Fast slant stack (FSS) An algebraically exact Radon transform of data on a Cartesian grid.

First generation discrete curvelet transform (DCTG1) The discrete curvelet transform constructed based on the discrete ridgelet transform.

Second generationdiscrete curvelet transformx (DCTG2) The discrete curvelet transform constructed based on appropriate bandpass filtering in the Fourier domain.

Anisotropic elements By anistropic, we mean basis elements with elongated effective support; i. e. length > width.

Parabolic scaling law A basis element obeys the parabolic scaling law if its effective support is such that width ≈ length^2.

Definition of the Subject

Despite the fact that wavelets have had a wide impact in image processing, they fail to efficiently represent objects with highly anisotropic elements such as lines or curvilinear structures (e. g. edges). The reason is that wavelets are non-geometrical and do not exploit the regularity of the edge curve.

The Ridgelet and the Curvelet [16,17] transforms were developed as an answer to the weakness of the separable wavelet transform in sparsely representing what appears to be simple building atoms in an image, that is lines, curves and edges. Curvelets and ridgelets take the form of basis elements which exhibit high directional sensitivity and are highly anisotropic [9,18,32,68]. These very recent geometric image representations are built upon ideas of multiscale analysis and geometry. They have had an important success in a wide range of image processing applications including denoising [42,64,68], deconvolution [38,74], contrast enhancement [73], texture analysis [2], detection [44], watermarking [78], component separation [70,71], inpainting [37,39] or blind source separation [6,7]. Curvelets have also proven useful in diverse fields beyond the traditional image processing application. Let's cite for example seismic imaging [34,42,43], astronomical imaging [48,66,69], scientific computing and analysis of partial differential equations [13,14]. Another reason for the success of ridgelets and curvelets is the availability of fast transform algorithms which are available in non-commercial software packages following the philosophy of reproducible research, see [4,75].

Introduction

Sparse Geometrical Image Representation

Multiscale methods have become very popular, especially with the development of the wavelets in the last decade. Background texts on the wavelet transform include [23,53,72]. An overview of implementation and practical issues of the wavelet transform can also be found in ► Numerical Issues When Using Wavelets.

Despite the success of the classical wavelet viewpoint, it was argued that the traditional wavelets present some strong limitations that question their effectiveness in higher-dimension than 1 [16,17]. Wavelets rely on a dictionary of roughly isotropic elements occurring at all scales and locations, do not describe well highly anisotropic elements, and contain only a fixed number of directional elements, independent of scale. Following this reasoning, new constructions have been proposed such as the ridgelets [9,16] and the curvelets [17,18,32,68]. Ridgelets and curvelets are special members of the family of multiscale orientation-selective transforms, which has recently led to a flurry of research activity in the field of computational and applied harmonic analysis. Many other constructions belonging to this family have been investigated in the literature, and go by the name contourlets [27], directionlets [76], bandlets [49,62], grouplets [54], shearlets [47], dual-tree wavelets and wavelet packets [40,46], etc.

Throughout this paper, the term 'sparsity' is used and intended in a weak sense. We are aware that practical images and signals may not be supported in a transform domain on a set of relatively small size (sparse set). Instead, they may only be compressible (nearly sparse) in some transform domain. Hence, with a slight abuse of terminology, we will say that a representation is sparse for an image within a certain class, if it provides a compact description of such an image.

Notations

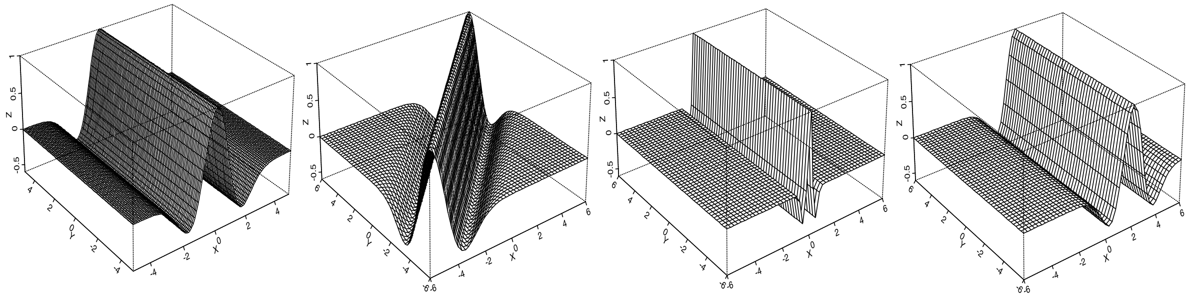
We work throughout in two dimensions with spatial variable $\mathbf{x} \in \mathbb{R}^2$ and $\boldsymbol{\nu}$ a continuous frequency-domain variable. Parentheses (., .) are used for continuous-domain function evaluations, and brackets [., .] for discrete-domain array indices. The hat ˆ notation will be used for the Fourier transform.

Ridgelets

The Continuous Ridgelet Transform

The two-dimensional continuous ridgelet transform in $\mathbb{R}^2$ can be defined as follows [10]. We pick a smooth univariate function $\psi : \mathbb{R} \to \mathbb{R}$ with sufficient decay and satisfying the admissibility condition

$$\int |\hat{\psi}(\nu)|^2/|\nu|^2 \, d\nu < \infty \,, \qquad (1)$$



Curvelets and Ridgelets, Figure 1

Few Ridgelets examples – The second to fourth graphs are obtained after simple geometric manipulations of the first ridgelet, namely rotation, rescaling, and shifting

which holds if, say, ψ has a vanishing mean $\int \psi(t)\mathrm{d}t = 0$. We will suppose a special normalization about ψ so that $\int_0^\infty |\hat{\psi}(\boldsymbol{\nu})|^2 \boldsymbol{\nu}^{-2}\mathrm{d}\boldsymbol{\nu} = 1$.

For each scale $a > 0$, each position $b \in \mathbb{R}$ and each orientation $\theta \in [0, 2\pi)$, we define the bivariate *ridgelet* $\psi_{a,b,\theta} : \mathbb{R}^2 \to \mathbb{R}$ by

$$\begin{aligned}\psi_{a,b,\theta}(\mathbf{x}) &= \psi_{a,b,\theta}(x_1, x_2)\\ &= a^{-1/2} \cdot \psi((x_1 \cos\theta + x_2 \sin\theta - b)/a)\,;\end{aligned} \tag{2}$$

A ridgelet is constant along lines $x_1 \cos\theta + x_2 \sin\theta = \text{const}$. Transverse to these ridges it is a wavelet. Figure 1 depicts few examples of ridgelets. The second to fourth panels are obtained after simple geometric manipulations of the ridgelet (left panel), namely rotation, rescaling, and shifting.

Given an integrable bivariate function $f(\mathbf{x})$, we define its ridgelet coefficients by

$$\mathcal{R}_f(a, b, \theta) := \langle f, \psi_{a,b,\theta}\rangle = \int_{\mathbb{R}^2} f(\mathbf{x})\overline{\psi}_{a,b,\theta}(\mathbf{x})\,\mathrm{d}\mathbf{x}\,.$$

We have the exact reconstruction formula

$$f(\mathbf{x}) = \int_0^{2\pi}\int_{-\infty}^{\infty}\int_0^{\infty} \mathcal{R}_f(a, b, \theta)\psi_{a,b,\theta}(\mathbf{x})\frac{\mathrm{d}a}{a^3}\mathrm{d}b\frac{\mathrm{d}\theta}{4\pi} \tag{3}$$

valid almost everywhere for functions which are both integrable and square integrable. This formula is stable and one can prove a Parseval relation [16].

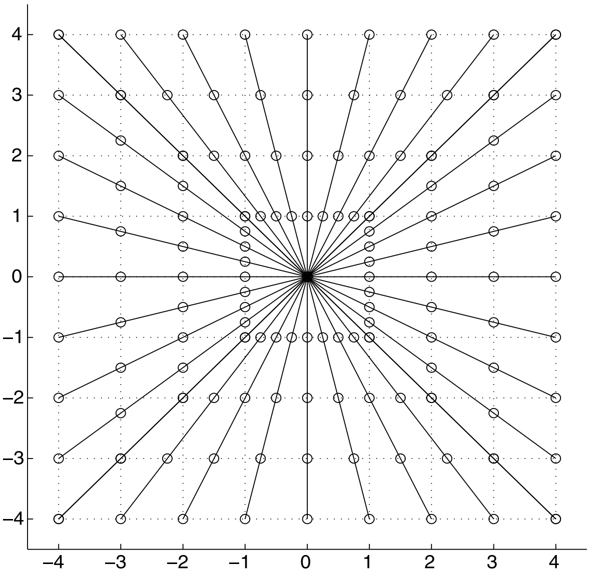
Ridgelet analysis may be constructed as wavelet analysis in the Radon domain. The rationale behind this is that the Radon transform translates singularities along lines into point singularities, for which the wavelet transform is known to provide a sparse representation. Recall that the Radon transform of an object f is the collection of line integrals indexed by $(\theta, t) \in [0, 2\pi) \times \mathbb{R}$ given by

$$Rf(\theta, t) = \int_{\mathbb{R}^2} f(x_1, x_2)\delta(x_1 \cos\theta + x_2 \sin\theta - t)\,\mathrm{d}x_1\mathrm{d}x_2\,, \tag{4}$$

where δ is the Dirac distribution. Then the ridgelet transform is precisely the application of a 1-dimensional wavelet transform to the slices of the Radon transform where the angular variable θ is constant and t is varying. Thus, the basic strategy for calculating the continuous ridgelet transform is first to compute the Radon transform $Rf(t, \theta)$ and second, to apply a one-dimensional wavelet transform to the slices $Rf(\cdot, \theta)$. Several digital ridgelet transforms (DRTs) have been proposed, and we will describe three of them in this section, based on different implementations of the Radon transform.

The RectoPolar Ridgelet Transform A fast implementation of the Radon transform can be proposed in the Fourier domain, based on the projection-slice-theorem. First the 2D-FFT of the given image is computed. Then the resulting function in the frequency domain is to be used to evaluate the frequency values in a polar grid of rays passing through the origin and spread uniformly in angle. This conversion from Cartesian to Polar grid could be obtained by interpolation, and this process is well known by the name gridding in tomography. Given the polar grid samples, the number of rays corresponds to the number of projections, and the number of samples on each ray corresponds to the number of shifts per such angle. Applying one dimensional inverse Fourier transform for each ray, the Radon projections are obtained.

The above described process is known to be inaccurate due to the sensitivity to the interpolation involved. This implies that for a better accuracy, the first 2D-FFT employed should be done with high-redundancy.



Curvelets and Ridgelets, Figure 2
Illustration of the pseudo-polar grid in the frequency domain for an *n* by *n* image ($n = 8$)

An alternative solution for the Fourier-based Radon transform exists, where the polar grid is replaced with a pseudo-polar one. The geometry of this new grid is illustrated in Fig. 2. Concentric circles of linearly growing radius in the polar grid are replaced by concentric squares of linearly growing sides. The rays are spread uniformly not in angle but in slope. These two changes give a grid vaguely resembling the polar one, but for this grid a direct FFT can be implemented with no interpolation. When applying now 1D-FFT for the rays, we get a variant of the Radon transform, where the projection angles are not spaced uniformly.

For the pseudo-polar FFT to be stable, it was shown that it should contain at least twice as many samples, compared to the original image we started with. A by-product of this construction is the fact that the transform is organized as a 2D array with rows containing the projections as a function of the angle. Thus, processing the Radon transform in one axis is easily implemented. More details can be found in [68].

One-Dimensional Wavelet Transform To complete the ridgelet transform, we must take a one-dimensional wavelet transform (WT1D) along the radial variable in Radon space. We now discuss the choice of the digital WT1D.

Experience has shown that compactly-supported wavelets can lead to many visual artifacts when used in conjunction with nonlinear processing, such as hard-thresholding of individual wavelet coefficients, particularly for decimated wavelet schemes used at critical sampling. Also, because of the lack of localization of such compactly-supported wavelets in the frequency domain, fluctuations in coarse-scale wavelet coefficients can introduce fine-scale fluctuations. A frequency-domain approach must be taken, where the discrete Fourier transform is reconstructed from the inverse Radon transform. These considerations lead to use band-limited wavelet, whose support is compact in the Fourier domain rather than the time-domain [28,29,68]. In [68], a specific over-complete wavelet transform [67,72] has been used. The wavelet transform algorithm is based on a scaling function ϕ such that $\hat{\phi}$ vanishes outside of the interval $[-\nu_c, \nu_c]$. We define the Fourier transform of the scaling function as a re-normalized B_3-spline

$$\hat{\phi}(\nu) = \frac{3}{2} B_3(4\nu),$$

and $\hat{\psi}$ as the difference between two consecutive resolutions

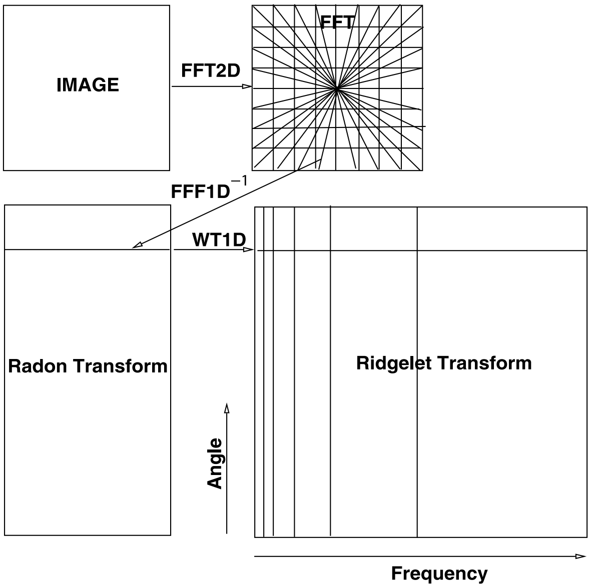
$$\hat{\psi}(2\nu) = \hat{\phi}(\nu) - \hat{\phi}(2\nu).$$

Because $\hat{\psi}$ is compactly supported, the sampling theorem shows than one can easily build a pyramid of $n + n/2 + \cdots + 1 = 2n$ elements, see [72] for details.

This WT1D transform enjoys the following useful properties:

- The wavelet coefficients are directly calculated in the Fourier space. In the context of the ridgelet transform, this allows avoiding the computation of the one-dimensional inverse Fourier transform along each radial line.
- Each sub-band is sampled above the Nyquist rate, hence, avoiding aliasing –a phenomenon typically encountered by critically sampled orthogonal wavelet transforms [65].
- The reconstruction is trivial. The wavelet coefficients simply need to be co-added to reconstruct the input signal at any given point. In our application, this implies that the ridgelet coefficients simply need to be co-added to reconstruct Fourier coefficients.

This wavelet transform introduces an extra redundancy factor. However, we note that the goal in this implementation is not data compression or efficient coding. Rather, this implementation would be useful to the practitioner whose focuses on data analysis, for which it



Curvelets and Ridgelets, Figure 3
Discrete ridgelet transform flowchart. Each of the 2*n* radial lines in the Fourier domain is processed separately. The 1-D inverse FFT is calculated along each radial line followed by a 1-D nonorthogonal wavelet transform. In practice, the one-dimensional wavelet coefficients are directly calculated in the Fourier space

is well-known that over-completeness through (almost) translation-invariance can provide substantial advantages.

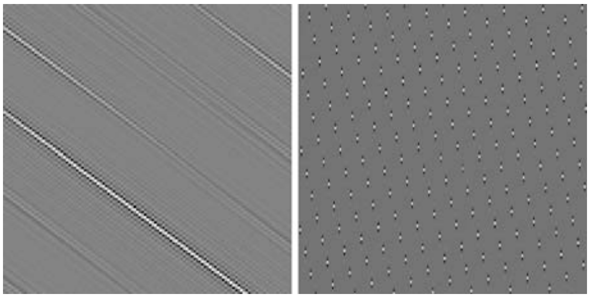
Assembling all above ingredients together gives the flowchart of the discrete ridgelet transform (DRT) depicted in Fig. 3. The DRT of an image of size $n \times n$ is an image of size $2n \times 2n$, introducing a redundancy factor equal to 4.

We note that, because this transform is made of a chain of steps, each one of which is invertible, the whole transform is invertible, and so has the exact reconstruction property. For the same reason, the reconstruction is stable under perturbations of the coefficients.

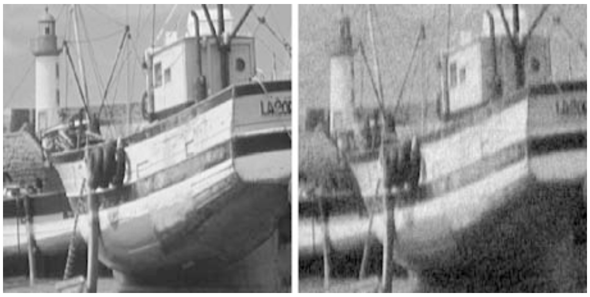
Last but not least, this discrete transform is computationally attractive. Indeed, the algorithm we presented here has low complexity since it runs in $O(n^2 \log n)$ flops for an $n \times n$ image.

The Orthonormal Finite Ridgelet Transform

The orthonormal finite ridgelet transform (OFRT) has been proposed [26] for image compression and filtering. This transform is based on the finite Radon transform [55] and a 1D orthogonal wavelet transform. It is not redundant and reversible. It would have been a great alternative to the previously described ridgelet transform if the OFRT were not based on an awkward definition of a line. In fact, a line in the OFRT is defined algebraically rather that geometrically, and so the points on a 'line' can be arbitrarily and randomly spread out in the spatial domain. Figure 4 shows the back-projection of a ridgelet coefficient by the FFT-based ridgelet transform (left) and by the OFRT (right). It is clear that the backprojection of the OFRT is nothing like a ridge function.



Curvelets and Ridgelets, Figure 4
The backprojection of a ridgelet coefficient by the FFT-based ridgelet transform (*left*), and by the OFRT (*right*)



Curvelets and Ridgelets, Figure 5
Part of original noise-free `Boat` image (*left*), and reconstruction after hard thresholding its OFRT coefficients (*right*)

Because of this specific definition of a line, the thresholding of the OFRT coefficients produces strong artifacts. Figure 5 shows a part of the original image `Boat`, and its reconstruction after hard thresholding the OFRT of the noise-free `Boat`. The resulting image is not smoothed as one would expect, but rather a noise has been added to the noise-free image as part of the filtering !

Finally, the OFRT presents another limitation: the image size must be a prime number. This last point is however not too restrictive, because we generally use a spatial partitioning when denoising the data, and a prime number block size can be used. The OFRT is interesting from the conceptual point of view, but still requires work before it can be used for real applications such as denoising.

The Fast Slant Stack Ridgelet Transform

The Fast Slant Stack (FSS) [3] is a Radon transform of data on a Cartesian grid, which is algebraically exact and geometrically more accurate and faithful than the previously described methods. The back-projection of a point in Radon space is exactly a ridge function in the spatial domain (see Fig. 6). The transformation of an $n \times n$ image is a $2n \times 2n$ image. n line integrals with angle between $\left[-\frac{\pi}{4}, \frac{\pi}{4}\right]$ are calculated from the zero padded image on the y-axis, and n line integrals with angle between $\left[\frac{\pi}{4}, \frac{3\pi}{4}\right]$ are computed by zero padding the image on the x-axis. For a given angle inside $\left[-\frac{\pi}{4}, \frac{\pi}{4}\right]$, $2n$ line integrals are calculated by first shearing the zero-padded image, and then integrating the pixel values along all horizontal lines (resp. vertical lines for angles in $\left[\frac{\pi}{4}, \frac{3\pi}{4}\right]$). The shearing is performed one column at a time (resp. one line at a time) by using the 1D FFT. Figure 7 shows an example of the image shearing step with two different angles ($5\frac{\pi}{4}$ and $-\frac{\pi}{4}$). A DRT based on the FSS transform has been proposed in [33]. The connection between the FSS and the Linogram has been investigated in [3]. A FSS algorithm is also proposed in [3], based on the 2D Fast Pseudo-polar Fourier transform which evaluates the 2-D Fourier transform on a non-Cartesian (pseudo-polar) grid, operating in $O(n^2 \log n)$ flops.

Figure 8 left exemplifies a ridgelet in the spatial domain obtained from the DRT based on FSS implementation. Its

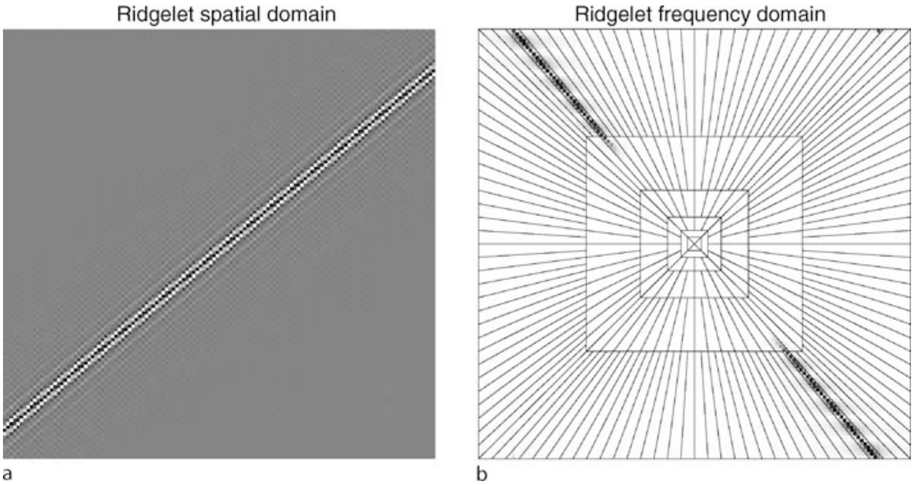
Curvelets and Ridgelets, Figure 7
Slant Stack Transform of an image



Curvelets and Ridgelets, Figure 8
a Example of a ridgelet obtained by the Fast Slant Stack implementation. b Its FFT superimposed on the DRT frequency tiling

Fourier transform is shown on Fig. 8 right superimposed on the DRT frequency tiling [33]. The Fourier transform of the discrete ridgelet lives in an angular wedge. More precisely, the Fourier transform of a discrete ridgelet at scale j lives within a dyadic square of size $\sim 2^j$.

Local Ridgelet Transforms

The ridgelet transform is optimal for finding global lines of the size of the image. To detect line segments, a partitioning must be introduced [9]. The image can be decomposed into overlapping blocks of side-length b pixels in such a way that the overlap between two vertically adjacent blocks is a rectangular array of size b by $b/2$; we use overlap to avoid blocking artifacts. For an n by n image, we count $2n/b$ such blocks in each direction, and thus the redundancy factor grows by a factor of 4.

The partitioning introduces redundancy, as a pixel belongs to 4 neighboring blocks. We present two competing strategies to perform the analysis and synthesis:

1. The block values are weighted by a spatial window w (analysis) in such a way that the co-addition of all blocks reproduce exactly the original pixel value (synthesis).
2. The block values are those of the image pixel values (analysis) but are weighted when the image is reconstructed (synthesis).

Experiments have shown that the second approach leads to better results especially for restoration problems, see [68] for details. We calculate a pixel value, $f[i_1, i_2]$ from its four corresponding block values of half-size $m = b/2$, namely, $B_1[k_1, l_1]$, $B_2[k_2, l_1]$, $B_3[k_1, l_2]$ and $B_4[k_2, l_2]$ with $k_1, l_1 > b/2$ and $k_2 = k_1 - m, l_2 = l_1 - m$, in the following way:

$$\begin{aligned} f_1 &= w(k_2/m)B_1[k_1, l_1] + w(1 - k_2/m)B_2[k_2, l_1] \\ f_2 &= w(k_2/m]B_3[k_1, l_2] + w(1 - k_2/m)B_4[k_2, l_2] \\ f[i_1, i_2] &= w(l_2/m)f_1 + w(1 - l_2/m)f_2 . \end{aligned} \tag{5}$$

where $w(x) = \cos^2(\pi x/2)$ is the window. Of course, one might select any other smooth, non-increasing function satisfying, $w(0) = 1, w(1) = 0, w'(0) = 0$ and obeying the symmetry property $w(x) + w(1 - x) = 1$.

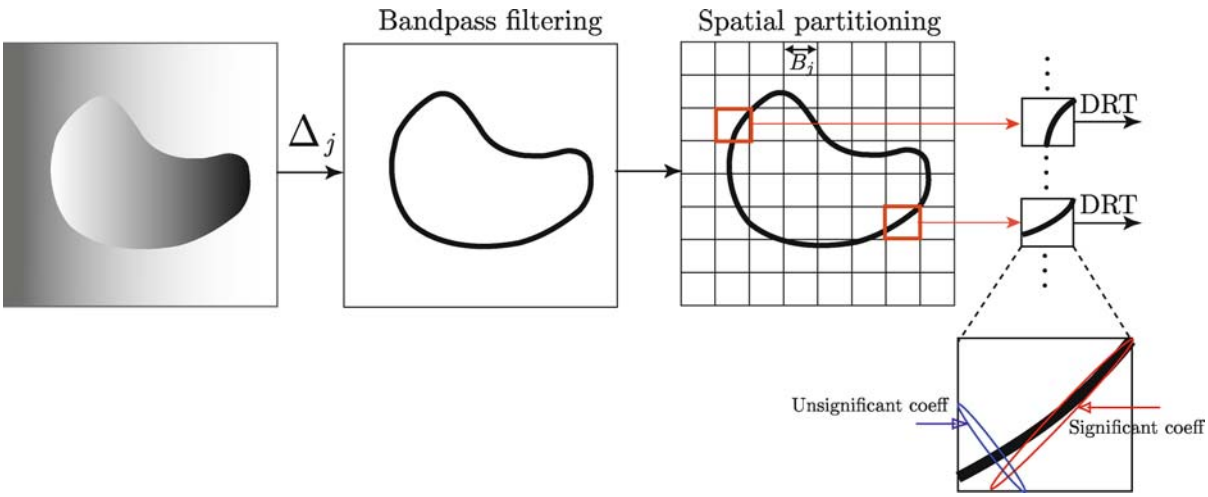
Sparse Representation by Ridgelets

The continuous ridgelet transform provides sparse representation of both smooth functions (in the Sobolev space W_2^2) and of perfectly straight lines [11,31]. We have just seen that there are also various DRTs, i. e. expansions with countable discrete collection of generating elements, which correspond either to frames or orthobases. It has been shown for these schemes that the DRT achieves near-optimal M-term approximation – that is the non-linear approximation of f using the M highest ridgelet coefficients in magnitude - to smooth images with discontinuities along straight lines [16,31]. In summary, ridgelets provide sparse presentation for piecewise smooth images away from global straight edges.

Curvelets

The First Generation Curvelet Transform

In image processing, edges are curved rather than straight lines and ridgelets are not able to efficiently represent such



Curvelets and Ridgelets, Figure 9
Local ridgelet transform on bandpass filtered image. At fine scales, curved edges are almost straight lines

images. However, one can still deploy the ridgelet machinery in a localized way, at fine scales, where curved edges are almost straight lines (see Fig. 9). This is the idea underlying the first generation curvelets (termed here CurveletG1) [18].

First Generation Curvelets Construction The CurveletG1 transform [18,32,68] opens the possibility to analyze an image with different block sizes, but with a single transform. The idea is to first decompose the image into a set of wavelet bands, and to analyze each band by a local ridgelet transform as illustrated on Fig. 9. The block size can be changed at each scale level. Roughly speaking, different levels of the multiscale ridgelet pyramid are used to represent different sub-bands of a filter bank output. At the same time, this sub-band decomposition imposes a relationship between the width and length of the *important* frame elements so that they are anisotropic and obey approximately the parabolic scaling law width $\approx$ length^2.

The First Generation Discrete Curvelet Transform (DCTG1) of a continuum function $f(\mathbf{x})$ makes use of a dyadic sequence of scales, and a bank of filters with the property that the bandpass filter Δ_j is concentrated near the frequencies $[2^{2j}, 2^{2j+2}]$, i. e.

$$\Delta_j(f) = \Psi_{2j} * f, \quad \widehat{\Psi}_{2j}(\boldsymbol{\nu}) = \widehat{\Psi}(2^{-2j}\boldsymbol{\nu}) .$$

In wavelet theory, one uses a decomposition into dyadic sub-bands $[2^j, 2^{j+1}]$. In contrast, the sub-bands used in the discrete curvelet transform of continuum functions has the nonstandard form $[2^{2j}, 2^{2j+2}]$. This is nonstandard feature of the DCTG1 well worth remembering (this is where the approximate parabolic scaling law comes into play).

The DCTG1 decomposition is the sequence of the following steps:

- *Sub-band Decomposition.* The object f is decomposed into sub-bands.
- *Smooth Partitioning.* Each sub-band is smoothly windowed into “squares” of an appropriate scale (of side-length $\sim 2^{-j}$).
- *Ridgelet Analysis.* Each square is analyzed via the DRT.

In this definition, the two dyadic sub-bands $[2^{2j}, 2^{2j+1}]$ and $[2^{2j+1}, 2^{2j+2}]$ are merged before applying the ridgelet transform.

Digital Implementation It seems that the isotropic “à trous” wavelet transform (▶ Numerical Issues When Using Wavelets), [72] is especially well-adapted to the needs of the digital curvelet transform. The algorithm decomposes an n by n image $f[i_1, i_2]$ as a superposition of the form

$$f[i_1, i_2] = c_J[i_1, i_2] + \sum_{j=1}^{J} w_j[i_1, i_2],$$

where c_J is a coarse or smooth version of the original image f and w_j represents ‘the details of f’ at scale 2^{-j}. Thus, the algorithm outputs $J + 1$ sub-band arrays of size $n \times n$.
A sketch of the DCTG1 implementation is given in Algorithm 1.
The side-length of the localizing windows is doubled *at every other* dyadic sub-band, hence maintaining the fundamental property of the curvelet transform which says

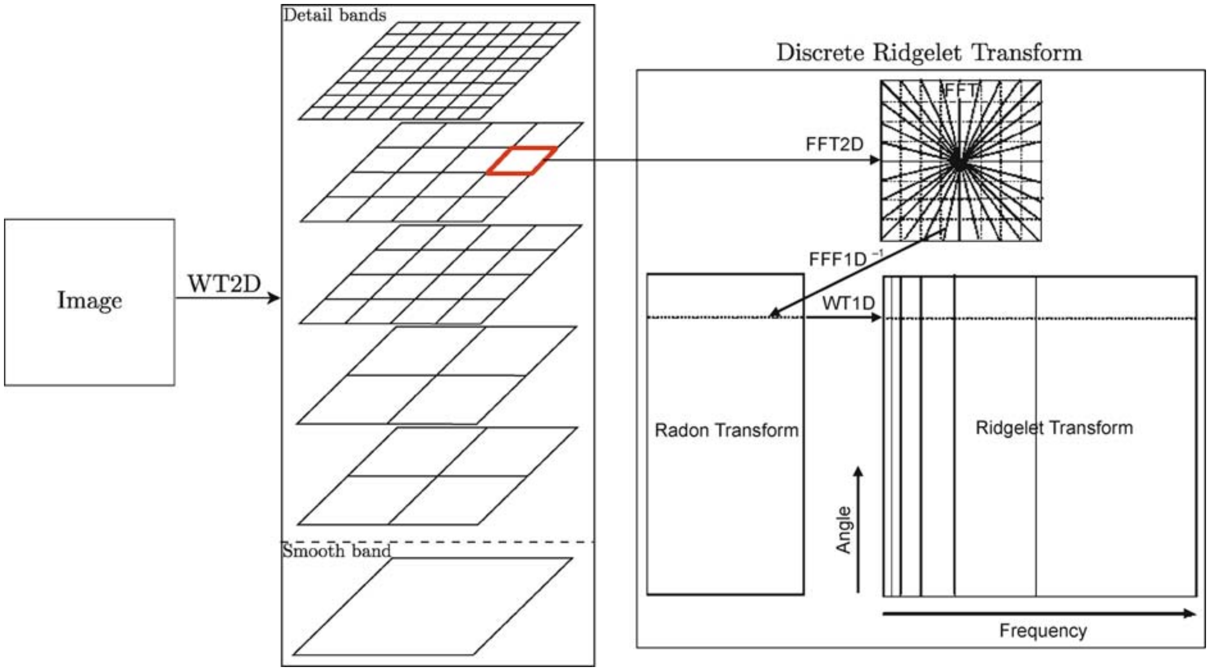
```
Require: Input $n \times n$ image $f[i_1, i_2]$, type of DRT (see above).
Apply the à trous isotropic WT2D with $J$ scales,
Set $B_1 = B_{\min}$,
for $j = 1, \ldots, J$ do
    Partition the sub-band $w_j$ with a block size $B_j$ and apply the DRT to each block,
    if $j$ modulo $2 = 1$ then
        $B_{j+1} = 2B_j$,
    else
        $B_{j+1} = B_j$.
    end if
end for
```

Curvelets and Ridgelets, Algorithm 1
DCTG1

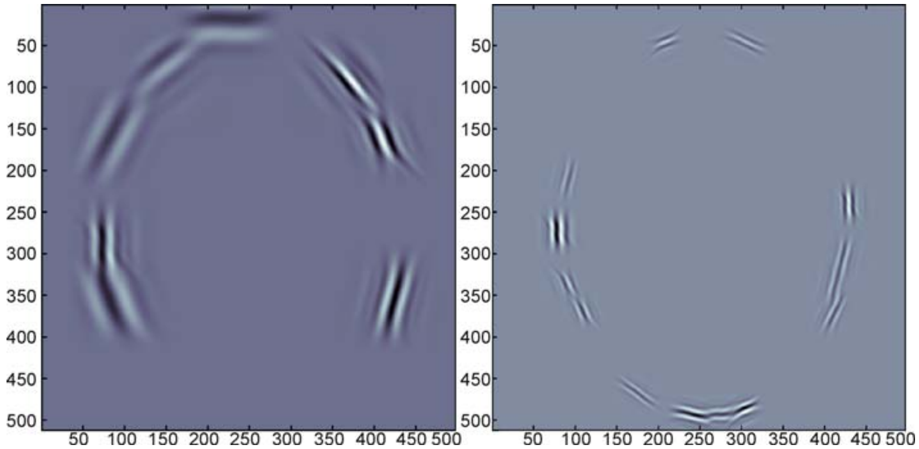
that elements of length about $2^{-j/2}$ serve for the analysis and synthesis of the jth sub-band $[2^j, 2^{j+1}]$. Note also that the coarse description of the image c_J is left intact. In the results shown in this paper, we used the default value $B_{\min} = 16$ pixels in our implementation. Figure 10 gives an overview of the organization of the DCTG1 algorithm.

This implementation of the DCTG1 is also redundant. The redundancy factor is equal to $16J + 1$ whenever J scales are employed. The DCTG1 algorithm enjoys exact reconstruction and stability, as each step of the analysis (decomposition) algorithm is itself invertible. One can show that the computational complexity of the DCTG1 algorithm we described here based on the DRT of Fig. 3 is $O(n^2(\log n)^2)$ for an $n \times n$ image.
Figure 11 shows a few curvelets at different scales, orientations and locations.

Sparse Representation by First Generation Curvelets The CurveletG1 elements can form either a frame or a tight frame for $L_2(\mathbb{R}^2)$ [17], depending on the WT2D used and the DRT implementation (rectopolar or FSS Radon transform). The frame elements are anisotropic by construction and become successively more anisotropic at progressively higher scales. These curvelets also exhibit directional sensitivity and display oscillatory components across the 'ridge'. A central motivation leading to the curvelet construction was the problem of non-adaptively representing piecewise smooth (e. g. C^2) images f which have discontinuity along a C^2 curve. Such a model is the so-called cartoon model of (non-textured) images. With the CurveletG1 tight frame construction, it was shown in [17] that for such f, the M-term non-linear approximations f_M of f obey,



Curvelets and Ridgelets, Figure 10
First Generation Discrete Curvelet Transform (DCTG1) flowchart. The figure illustrates the decomposition of the original image into sub-bands followed by the spatial partitioning of each sub-band. The ridgelet transform is then applied to each block



Curvelets and Ridgelets, Figure 11
A few first generation curvelets

for each $\kappa > 0$,

$$\|f - f_M\|_2 \leq C_\kappa M^{-2+\kappa} , \quad M \to +\infty .$$

The M-term approximations in the CurveletG1 are almost rate optimal, much better than M-term Fourier or wavelet approximations for such images, see [53].

The Second Generation Curvelet Transform

Despite these interesting properties, the CurveletG1 construction presents some drawbacks. First, the construction involves a complicated seven-index structure among which we have parameters for scale, location and orientation. In addition, the parabolic scaling ratio width $\approx$ length^2 is not completely true (see Subsect. "First Generation Curvelets Construction"). In fact, CurveletG1 assumes a wide range of aspect ratios. These facts make mathematical and quantitative analysis especially delicate. Second, the spatial partitioning of the CurveletG1 transform uses overlapping windows to avoid blocking effects. This leads to an increase of the redundancy of the DCTG1. The computational cost of the DCTG1 algorithm may also be a limitation for large-scale data, especially if the FSS-based DRT implementation is used.

In contrast, the second generation curvelets (CurveletG2) [15,20] exhibit a much simpler and natural indexing structure with three parameters: scale, orientation (angle) and location, hence simplifying mathematical analysis. The CurveletG2 transform also implements a tight frame expansion [20] and has a much lower redundancy. Unlike the DCTG1, the discrete CurveletG2 implementation will not use ridgelets yielding a faster algorithm [15,20].

Second Generation Curvelets Construction

Continuous Coronization The second generation curvelets are defined at scale 2^{-j}, orientation θ_l and position $\mathbf{x}_\mathbf{k}^{j,l} = R_{\theta_l}^{-1}(2^{-j}k_1, 2^{-j/2}k_2)$ by translation and rotation of a mother curvelet φ_j as

$$\varphi_{j,l,\mathbf{k}}(\mathbf{x}) = \varphi_j(R_{\theta_l}(\mathbf{x} - \mathbf{x}_\mathbf{k}^{j,l})) , \tag{6}$$

where R_{θ_l} is the rotation by θ_l radians. θ_l is the equi-spaced sequence of rotation angles $\theta_l = 2\pi 2^{-\lfloor j/2 \rfloor} l$, with integer l such that $0 \leq \theta_l \leq 2\pi$ (note that the number of orientations varies as $1/\sqrt{\text{scale}}$). $\mathbf{k} = (k_1, k_2) \in \mathbb{Z}^2$ is the sequence of translation parameters. The waveform φ_j is defined by means of its Fourier transform $\hat{\varphi}_j(\boldsymbol{\nu})$, written in polar coordinates in the Fourier domain

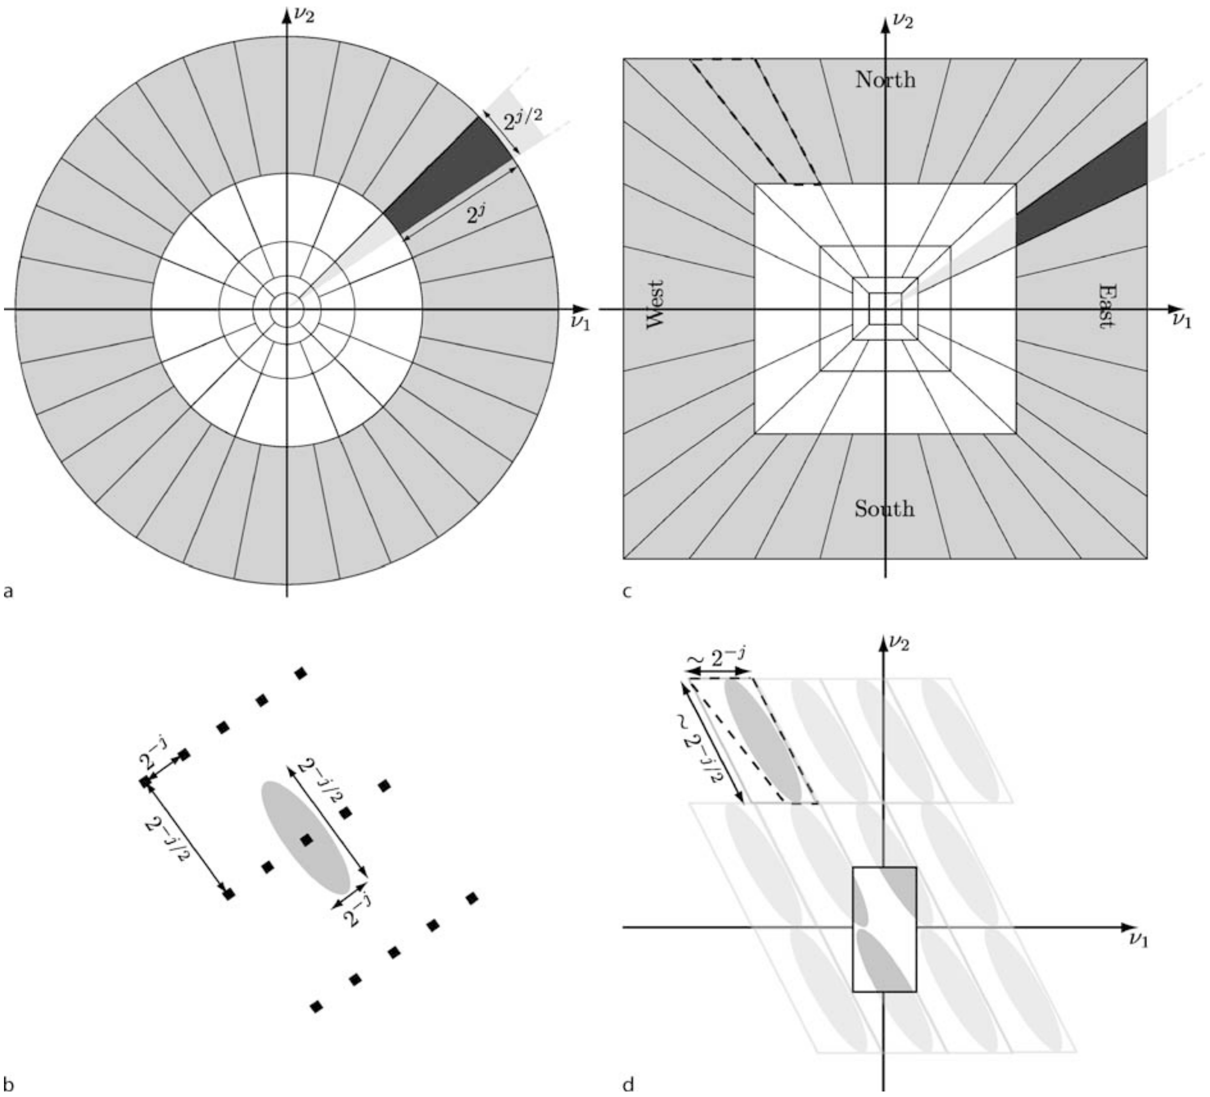
$$\hat{\varphi}_j(r, \theta) = 2^{-3j/4} \hat{w}(2^{-j} r) \hat{v} \left(\frac{2^{\lfloor j/2 \rfloor} \theta}{2\pi} \right) . \tag{7}$$

The support of $\hat{\varphi}_j$ is a polar *parabolic wedge* defined by the support of $\hat{w}$ and $\hat{v}$, the radial and angular windows (both smooth, nonnegative and real-valued), applied with scale-dependent window widths in each direction. $\hat{w}$ and $\hat{v}$ must also satisfy the partition of unity property [15]. See the frequency tiling in Fig. 12a.

In continuous frequency $\boldsymbol{\nu}$, the CurveletG2 coefficients of data $f(\mathbf{x})$ are defined as the inner product

$$c_{j,l,\mathbf{k}} := \langle f \varphi_{j,l,\mathbf{k}} \rangle = \int_{\mathbb{R}^2} \hat{f}(\boldsymbol{\nu}) \hat{\varphi}_j(R_{\theta_l} \boldsymbol{\nu}) e^{i \mathbf{x}_\mathbf{k}^{j,l} \cdot \boldsymbol{\nu}} \mathrm{d}\boldsymbol{\nu} . \tag{8}$$

This construction implies a few properties: (i) the CurveletG2 defines a tight frame of $L_2(\mathbb{R}^2)$, (ii) the effective length and width of these curvelets obey the parabolic



Curvelets and Ridgelets, Figure 12

a Continuous curvelet frequency tiling. The *dark gray* area represents a wedge obtained as the product of the radial window (annulus shown in *gray*) and the angular window (*light gray*). b The Cartesian grid in space associated to the construction in a whose spacing also obeys the parabolic scaling by duality. c Discrete curvelet frequency tiling. The window $\hat{u}_{j,l}$ isolates the frequency near trapezoidal wedge such as the one shown in dark gray. d The wrapping transformation. The *dashed line* shows the same trapezoidal wedge as in c. The parallelogram contains this wedge and hence the support of the curvelet. After periodization, the wrapped Fourier samples can be collected in the rectangle centered at the origin

scaling relation $(2^{-j} = \text{width}) = (\text{length} = 2^{-j/2})^2$, (iii) the curvelets exhibit an oscillating behavior in the direction perpendicular to their orientation. Curvelets as just constructed are complex-valued. It is easy to obtain real-valued curvelets by working on the symmetrized version $\hat{\varphi}_j(r,\theta) + \hat{\varphi}_j(r,\theta+\pi)$.

Discrete Coronization The discrete transform takes as input data defined on a Cartesian grid and outputs a collection of coefficients. The continuous-space definition of the CurveletG2 uses coronae and rotations that are not especially adapted to Cartesian arrays. It is then convenient to replace these concepts by their Cartesian counterparts. That is concentric squares (instead of concentric circles) and shears (instead of rotations), see Fig. 12c.

The Cartesian equivalent to the radial window $\hat{w}_j(\boldsymbol{\nu}) = \hat{w}(2^{-j}\boldsymbol{\nu})$ would be a bandpass frequency-localized window which can be derived from the difference of separable low-pass windows $H_j(\boldsymbol{\nu}) = \hat{h}(2^{-j}\nu_1)\hat{h}(2^{-j}\nu_2)$ (h is a 1D low-pass filter):

$$\hat{w}_j(\boldsymbol{\nu}) = \sqrt{H_{j+1}^2(\boldsymbol{\nu}) - H_j^2(\boldsymbol{\nu})},\ \forall j \geq 0\,, \quad \text{and} \quad \hat{w}_0(\boldsymbol{\nu}) = \hat{h}(\nu_1)\hat{h}(\nu_2)\,.$$

Another possible choice is to select these windows inspired by the construction of Meyer wavelets [20,57]. See [15] for more details about the construction of the Cartesian $\hat{w}_j$'s.

Let's now examine the angular localization. Each Cartesian coronae has four quadrants: East, North, West and South. Each quadrant is separated into $2^{\lfloor j/2 \rfloor}$ orientations (wedges) with the same areas. Take for example the East quadrant ($-\pi/4 \leq \theta_l < \pi/4$). For the West quadrant, we would proceed by symmetry around the origin, and for the North and South quadrant by exchanging the roles of ν_1 and ν_2. Define the angular window for the lth direction as

$$\hat{v}_{j,l}(\boldsymbol{\nu}) = \hat{v}\left(2^{\lfloor j/2 \rfloor}\frac{\nu_2 - \nu_1 \tan\theta_l}{\nu_1}\right), \tag{9}$$

with the sequence of equi-spaced slopes (and not angles) $\tan\theta_l = 2^{-\lfloor j/2 \rfloor} l$, for $l = -2^{\lfloor j/2 \rfloor}, \ldots, 2^{\lfloor j/2 \rfloor} - 1$. We can now define the window which is the Cartesian analog of $\hat{\varphi}_j$ above,

$$\hat{u}_{j,l}(\boldsymbol{\nu}) = \hat{w}_j(\boldsymbol{\nu})\hat{v}_{j,l}(\boldsymbol{\nu}) = \hat{w}_j(\boldsymbol{\nu})\hat{v}_{j,0}(S_{\theta_l}\boldsymbol{\nu}), \tag{10}$$

where S_{θ_l} is the shear matrix. From this definition, it can be seen that $\hat{u}_{j,l}$ is supported near the trapezoidal wedge $\{\boldsymbol{\nu} = (\nu_1, \nu_2) | 2^j \leq \nu_1 \leq 2^{j+1}, -2^{-j/2} \leq \nu_2/\nu_1 - \tan\theta_l \leq 2^{-j/2}\}$. The collection of $\hat{u}_{j,l}(\boldsymbol{\nu})$ gives rise to the frequency tiling shown in Fig. 12c. From $\hat{u}_{j,l}(\boldsymbol{\nu})$, the digital CurveletG2 construction suggests Cartesian curvelets that are translated and sheared versions of a mother Cartesian curvelet $\hat{\varphi}_j^D(\boldsymbol{\nu}) = \hat{u}_{j,0}(\boldsymbol{\nu}), \varphi_{j,l,\mathbf{k}}^D(\mathbf{x}) = 2^{3j/4}\varphi_j^D\left(S_{\theta_l}^T\mathbf{x} - \mathbf{m}\right)$ where $\mathbf{m} = (k_1 2^{-j}, k_2 2^{-j/2})$.

Digital Implementation The goal here is to find a digital implementation of the Second Generation Discrete Curvelet Transform (DCTG2), whose coefficients are now given by

$$c_{j,l,\mathbf{k}} := \left\langle f\varphi_{j,l,\mathbf{k}}^D \right\rangle = \int_{\mathbb{R}^2} \hat{f}(\boldsymbol{\nu})\hat{\varphi}_j^D(S_{\theta_l}^{-1}\boldsymbol{\nu})e^{iS_{\theta_l}^{-T}\mathbf{m}\cdot\boldsymbol{\nu}}\mathrm{d}\boldsymbol{\nu}\,. \tag{11}$$

To evaluate this formula with discrete data, one may think of (i) using the 2D FFT to get $\hat{f}$, (ii) form the windowed frequency data $\hat{f}\hat{u}_{j,l}$ and (iii) apply the the inverse Fourier transform. But this necessitates to evaluate the FFT at the sheared grid $S_{\theta_l}^{-T}\mathbf{m}$, for which the classical FFT algorithm is not valid. Two implementations were then proposed [15], essentially differing in their way of handling the grid:

- A tilted grid mostly aligned with the axes of $\hat{u}_{j,l}(\boldsymbol{\nu})$ which leads to the Unequi-Spaced FFT (USFFT)-based DCTG2. This implementation uses a nonstandard interpolation. Furthermore, the inverse transform uses conjugate gradient iteration to invert the interpolation step. This will have the drawback of a higher computational burden compared to the wrapping-based implementation that we will discuss hereafter. We will not elaborate more about the USFFT implementation as we never use it in practice. The interested reader may refer to [15] for further details and analysis.
- A grid aligned with the input Cartesian grid which leads to the wrapping-based DCTG2.

The wrapping-based DCTG2 makes a simpler choice of the spatial grid to translate the curvelets. The curvelet coefficients are essentially the same as in (11), except that $S_{\theta_l}^{-T}\mathbf{m}$ is replaced by $\mathbf{m}$ with values on a rectangular grid. But again, a difficulty rises because the window $\hat{u}_{j,l}$ does not fit in a rectangle of size $2^j \times 2^{j/2}$ to which an inverse FFT could be applied. The *wrapping* trick consists in periodizing the windowed frequency data $\hat{f}\hat{u}_{j,l}$, and reindexing the samples array by wrapping around a $\sim 2^j \times 2^{j/2}$ rectangle centered at the origin, see Fig. 12d to get a gist of the wrapping idea.

The wrapping-based DCTG2 algorithm can be summarized as in Algorithm 2.

The DCTG2 implementation can assign either wavelets or curvelets at the finest scale. In the CurveLab toolbox [75], the default choice is set to wavelets at the finest scale, but this can be easily modified directly in the code.

```
Require: Input $n \times n$ image $f[i_1, i_2]$, coarsest decomposition scale, curvelets or wavelets at the finest scale.
Apply the 2D FFT and obtain Fourier samples $\hat{f}[i_1, i_2]$.
for each scale $j$ and angle $l$ do
    Form the product $\hat{f}[i_1, i_2]\hat{u}_{j,l}[i_1, i_2]$.
    Wrap this product around the origin.
    Apply the inverse 2D FFT to the wrapped data to get discrete DCTG2 coefficients.
end for
```

Curvelets and Ridgelets, Algorithm 2
DCTG2 via wrapping

We would like to apologize to the expert reader as many technical details are (deliberately) missing here on the CurveletG2 construction. For instance, low-pass coarse component, window overlapping, windows over junctions between quadrants. This paper is intended to give an overview of these recent multi-scale transforms, and the genuinely interested reader may refer to the original papers of Candès, Donoho, Starck and co-workers for further details (see bibliography).

The computational complexity of the wrapping-based DCTG2 analysis and reconstruction algorithms is that of the FFT $O(n^2 \log n)$, and in practice, the computation time is that of 6 to 10 2D FFTs [15]. This is a faster algorithm compared to the DCTG1. The DCTG2 fast algorithm has participated to make the use of the curvelet transform more attractive in many applicative fields (see Sect. "Stylized Applications" for some of them). The DCTG2, as it is implemented in the CurveLab toolbox [75], has reasonable redundancy, at most ~ 7.8 (much higher in 3D) if curvelets are used at the finest scale. This redundancy can even be reduced down to 4 (and 8 in 3D) if we replace in this implementation the Meyer wavelet construction, which introduces a redundancy factor of 4, by another wavelet pyramidal construction, similar to the one presented in Sect. "One–dimensional Wavelet Transform" which has a redundancy less than 2 in any dimension. Our experiments have shown that this modification does not modify the results in denoising experiments. DCTG2 redundancy is anyway much smaller than the DCTG1 one which is $16J + 1$. As stated earlier, the DCTG2 coefficients are complex-valued, but a real-valued DCTG2 with the same redundancy factor can be easily obtained by properly combining coefficients at orientations θ_l and $\theta_l + \pi$.

The DCTG2 can be extended to higher dimensions [21]. In the same vein as wavelets on the interval [53], the DCGT2 has been recently adapted to handle image boundaries by mirror extension instead of periodization [25]. The latter modification can have immediate implications in image processing applications where the contrast difference at opposite image boundaries may be an issue (see e. g. the denoising experiment discussion reported in Sect. "Stylized Applications").

We would like to make a connection with other multiscale directional transforms directly linked to curvelets. The contourlets tight frame of Do and Vetterli [27] implements the CurveletG2 idea directly on a discrete grid using a perfect reconstruction filter bank procedure. In [51], the authors proposed a modification of the contourlets with a directional filter bank that provides a frequency partitioning which is close to the curvelets but with no redundancy. Durand in [35] recently introduced families of non-adaptive directional wavelets with various frequency tilings, including that of curvelets. Such families are non-redundant and form orthonormal bases for $L_2(\mathbb{R}^2)$, and have an implementation derived from a single nonseparable filter bank structure with nonuniform sampling.

Sparse Representation by Second Generation Curvelets It has been shown by Candès and Donoho [20] that with the CurveletG2 tight frame construction, the M-term nonlinear approximation error of C^2 images except at discontinuities along C^2 curves obey

$$\|f - f_M\|_2 \leq CM^{-2}(\log M)^3 \ .$$

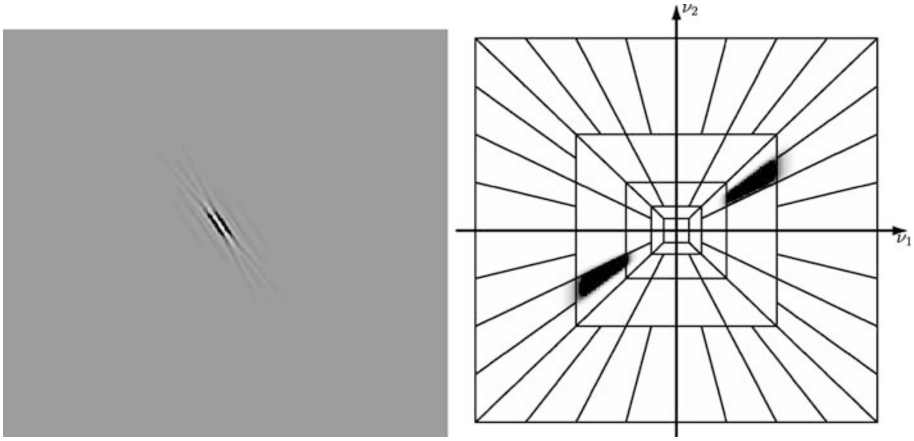
This is an asymptotically optimal convergence rate (up to the $(\log M)^3$ factor), and holds uniformly over the $C^2 - C^2$ class of functions. This is a remarkable result since the CurveletG2 representation is non-adaptative. However, the simplicity due to the non-adaptivity of curvelets has a cost: curvelet approximations loose their near optimal properties when the image is composed of edges which are not exactly C^2. Additionally, if the edges are C^α-regular with $\alpha > 2$, then the curvelets convergence rate exponent remain 2. Other adaptive geometric representations such as bandlets are specifically designed to reach the optimal decay rate $O(M^{-\alpha})$ [49,62].

Stylized Applications

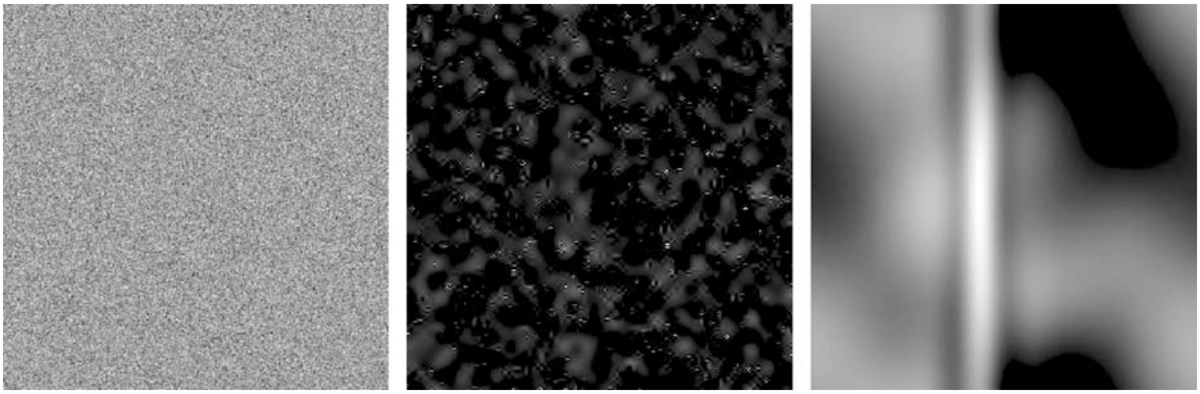
Denoising

Elongated Feature Recovery The ability of ridgelets to sparsely represent piecewise smooth images away from discontinuities along lines has an immediate implication on statistical estimation. Consider a piecewise smooth image f away from line singularities embedded in an additive white noise of standard deviation σ. The ridgelet-based thresholding estimator is nearly optimal for recovering such functions, with a mean-square error (MSE) decay rate almost as good as the minimax rate [12].

To illustrate these theoretical facts, we simulate a vertical band embedded in white Gaussian noise with large σ. Figure 14 (top left) represents such a noisy image. The parameters are as follows: the pixel width of the band is 20 and the signal-to-noise ratio (SNR) is set to 0.1. Note that it is not possible to distinguish the band by eye. The wavelet transform (undecimated wavelet transform) is also incapable of detecting the presence of this object; roughly speaking, wavelet coefficients correspond to weighted averages over approximately isotropic neighborhoods (at different scales) and those wavelets clearly do not correlate very well with the very elongated structure (pattern) of the object to be detected.



Curvelets and Ridgelets, Figure 13
An example of second generation real curvelet. *Left*: curvelet in spatial domain. *Right*: its Fourier transform



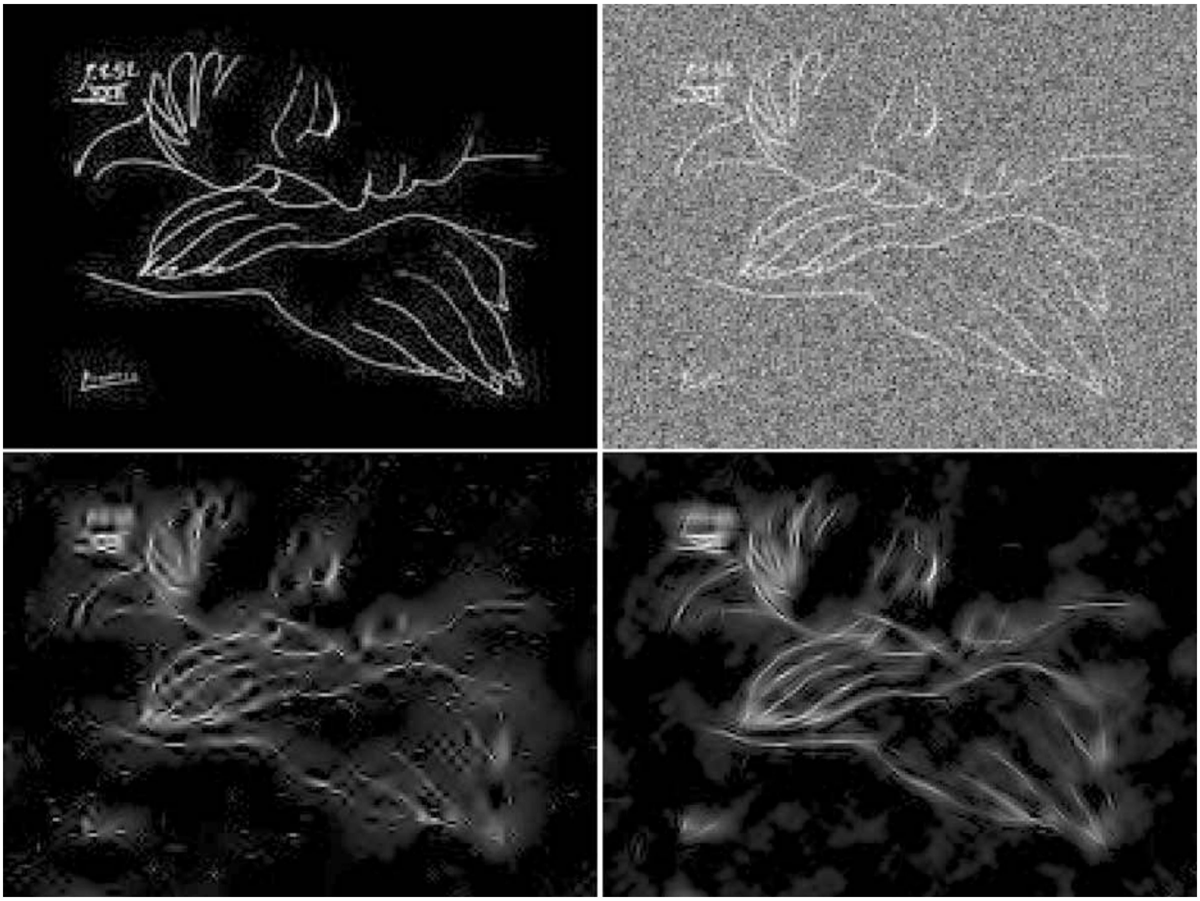
Curvelets and Ridgelets, Figure 14
Original image containing a vertical band embedded in white noise with relatively large amplitude (*left*). Denoised image using the undecimated wavelet transform (*middle*). Denoised image using the DRT based on the rectopolar Radon transform (*right*)

Curve Recovery Consider now the problem of recovering a piecewise C^2 function f apart from a discontinuity along a C^2 edge. Again, a simple strategy based on thresholding curvelet tight frame coefficients yields an estimator that achieves a MSE almost of the order $O(\sigma^{4/3})$ uniformly over the $C^2 - C^2$ class of functions [19]. This is the optimal rate of convergence as the minimax rate for that class scales as $\sigma^{4/3}$ [19]. Comparatively, wavelet thresholding methods only achieves a MSE of order $O(\sigma)$ and no better. We also note that the statistical optimality of the curvelet thresholding extends to a large class of ill-posed linear inverse problems [19].

In the experiment of Fig. 15, we have added a white Gaussian noise to "War and Peace", a drawing from Picasso which contains many curved features. Figure 15 bottom left and right shows respectively the restored images by the undecimated wavelet transform and the DCTG1. Curves are more sharply recovered with the DCTG1.

In a second experiment, we compared the denoising performance of several digital implementations of the curvelet transform; namely the DCTG1 with the rectopolar DRT, the DCTG1 with the FSS-based DRT and the wrapping-based DCTG2. The results are shown in Fig. 16, where the original 512×512 `Peppers` image was corrupted by a Gaussian white noise $\sigma = 20$ (PSNR = 22dB).

Although the FSS-based DRT is more accurate than the rectopolar DRT, the denoising improvement of the former (PSNR=31.31dB) is only 0.18 dB better than the latter (PSNR=31.13dB) on `Peppers`. The difference is almost undistinguishable by eye, but the computation time is 20 higher for the DCTG1 with the FSS DRT. Consequently, it appears that there is a little benefit of using the



Curvelets and Ridgelets, Figure 15

The Picasso picture `War and Peace` (*top left*), the same image contaminated with a Gaussian white noise (*top right*). The restored images using the undecimated wavelet transform (*bottom left*) and the DCTG1 (*bottom right*)

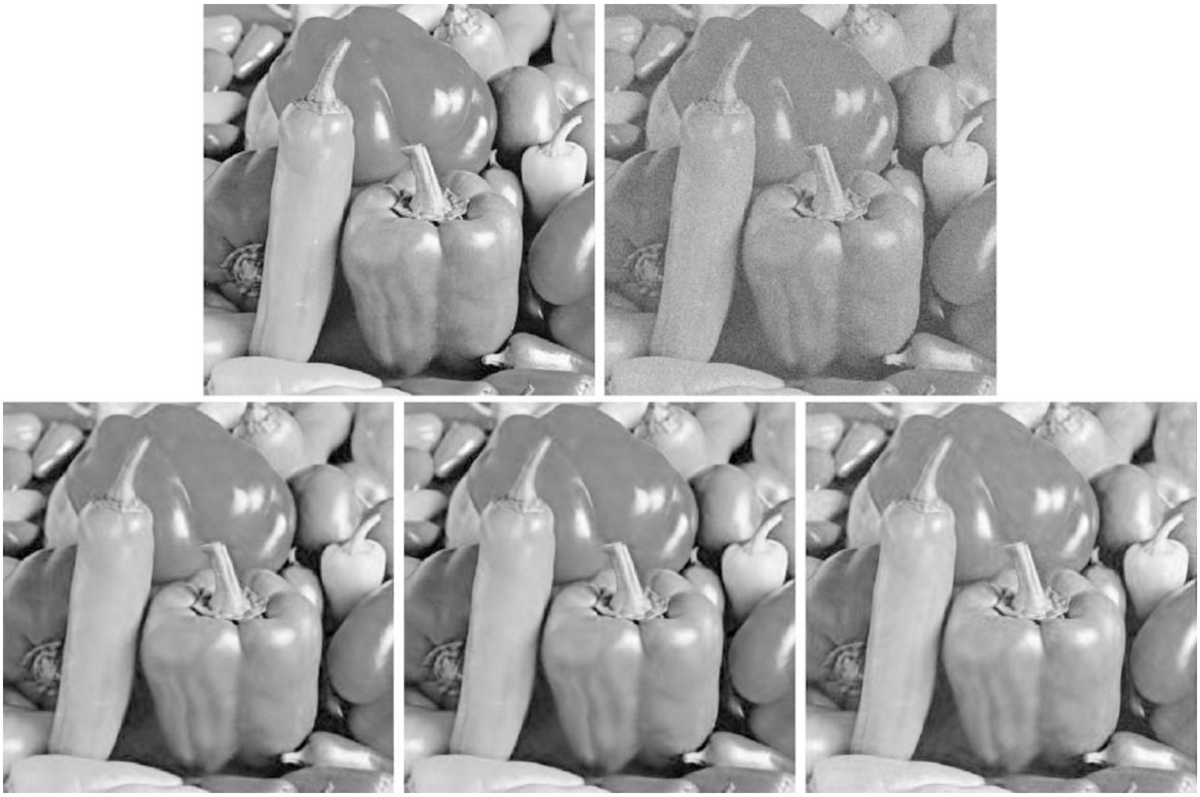
FSS DRT in the DCTG1 for restoration applications. Denoising using the DCTG2 with the wrapping implementation gives a PSNR=30.62 dB which is ~ 0.7 dB less than the DCTG1. But this is the price to pay for a lower redundancy and a much faster transform algorithm. Moreover, the DCTG2 exhibits some artifacts which look like 'curvelet ghosts'. This is a consequence of the fact that the DCTG2 makes a central use of the FFT which has the side effect of treating the image boundaries by periodization.

Linear Inverse Problems

Many problems in image processing can be cast as inverting the linear degradation equation $y = Hf + \varepsilon$, where f is the image to recover, y the observed image and ε is a white noise of variance $\sigma^2 < +\infty$. The linear mapping H is generally ill-behaved which entails ill-posedness of the inverse problem. Typical examples of linear inverse problems include image deconvolution where H is the convolution operator, or image inpainting (recovery of missing data) where H is a binary mask.

In the last few years, some authors have attacked the problem of solving linear inverse problems under the umbrella of sparse representations and variational formulations, e.g. for deconvolution [19,24,38,41,74] and inpainting [37,39]. Typically, in this setting, the recovery of f is stated as an optimization problem with a sparsity-promoting regularization on the representation coefficients of f, e.g. its wavelet or curvelet coefficients. See [37,38,39,74] for more details.

In Fig. 17 first row, we depict an example of deconvolution on `Barbara` using the algorithm described in [38] with the DCTG2 curvelet transform. The original, degraded (blurred with an exponential kernel and noisy) and restored images are respectively shown on the left, middle



Curvelets and Ridgelets, Figure 16

Bottom right: denoised with DCTG2 using the wrapping implementation

and right. The second row gives an example of inpainting on `Claudia` image using the DCTG2 with 50% missing pixels.

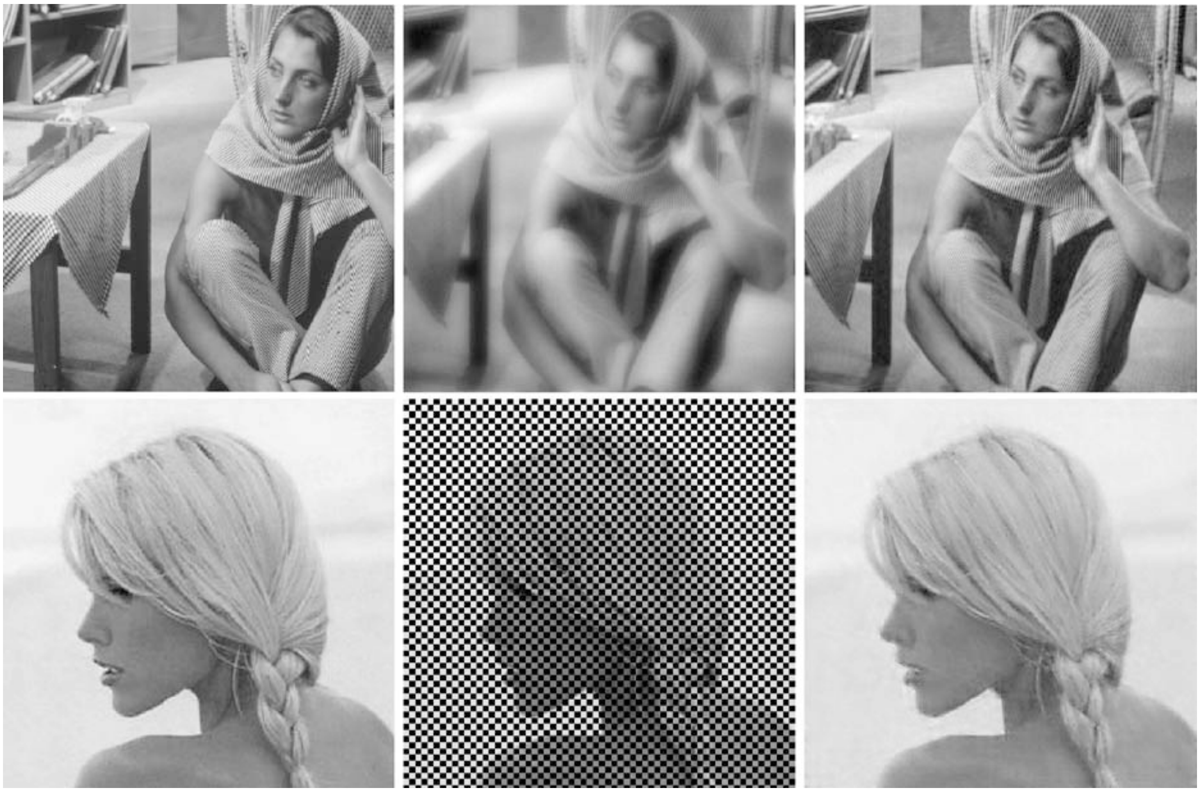
Contrast Enhancement

The curvelet transform has been successfully applied to image contrast enhancement by Starck et al. [73]. As the curvelet transform capture efficiently edges in an image, it is a good candidate for multiscale edge enhancement. The idea is to modify the curvelet coefficients of the input image in order to enhance its edges. The curvelet coefficients are typically modified according to the function displayed in the left plot of Fig. 18. Basically, this plot says that the input coefficients are kept intact (or even shrunk) if they have either low (e. g. below the noise level) or high (strongest edges) values. Intermediate curvelet coefficient values which correspond to the faintest edges are amplified. An example of curvelet-based image enhancement on `Saturn` image is given in Fig. 18.

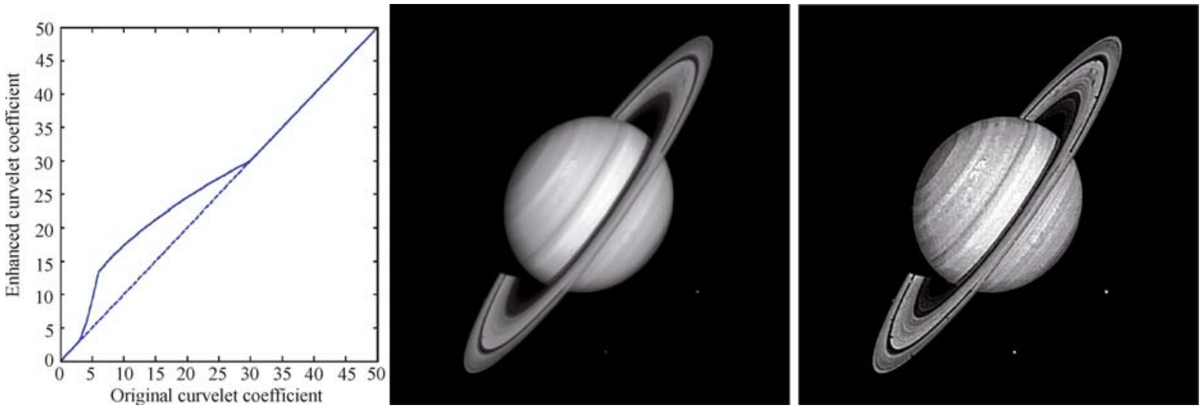
Morphological Component Separation

The idea to morphologically decompose a signal/image into its building blocks is an important problem in signal and image processing. Successful separation of a signal content has a key role in the ability to effectively analyze it, enhance it, compress it, synthesize it, and more. Various approaches have been proposed to tackle this problem.

The Morphological Component Analysis method (MCA) [70,71] is a method which allows us to decompose a single signal into two or more layers, each layer containing only one kind of feature in the input signal or image. The separation can be achieved when each kind of feature is sparsely represented by a given transformation in the dictionary of transforms. Furthermore, when a transform sparsely represents a part in the signal/image, it yields non-sparse representation on the other content type. For instance, lines and Gaussians in a image can be separated using the ridgelet transform and the wavelet transform. Locally oscillating textures can be separated from the piecewise smooth content using the local discrete cosine trans-



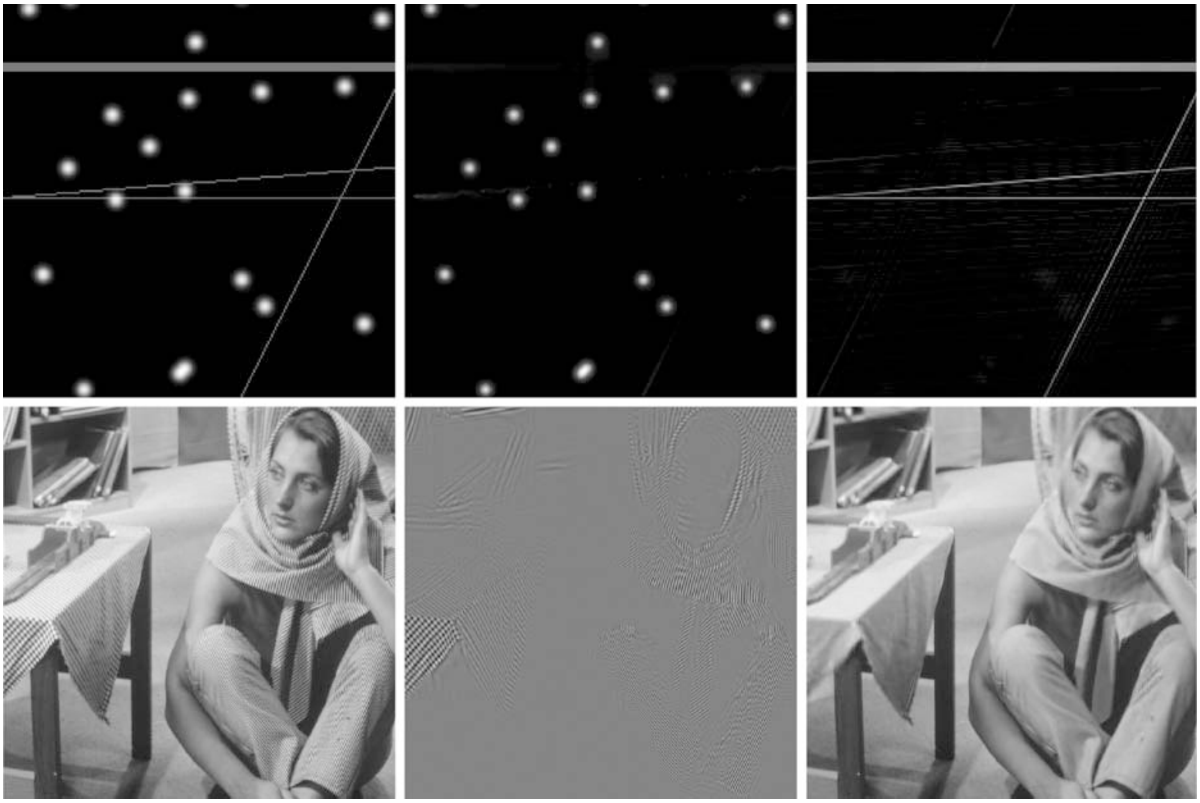
Curvelets and Ridgelets, Figure 17
Illustration of the use of curvelets (DCTG2 transform) when solving two typical linear inverse problems: deconvolution (*first row*), and inpainting (*second row*). First row: deconvolution of `Barbara` image, original (*left*), blurred and noisy (*middle*), restored (*right*). Second row: inpainting of `Claudia` image, original (*left*), masked image (*middle*), inpainted (*right*)



Curvelets and Ridgelets, Figure 18
Curvelet contrast enhancement. Left: enhanced vs original curvelet coefficient. Middle: original `Saturn` image. Right: result of curvelet-based contrast enhancement

form and the curvelet transform [70]. A full description of MCA is given in [70].

The first row of Fig. 19 illustrates a separation result when the input image contains only lines and isotropic Gaussians. Two transforms were amalgamated in the dictionary; namely the à trous WT2D and the DRT. The left, middle and right images in the first row of Fig. 19 represent respectively, the original image, the reconstructed



Curvelets and Ridgelets, Figure 19
First row, **from *left* to *right*: original image containing lines and Gaussians, separated Gaussian component (*wavelets*), separated line component (*ridgelets*). *Second row*, from *left* to *right*: original `Barbara` image, reconstructed local discrete cosine transform part (*texture*), and piecewise smooth part (*curvelets*)**

component from the à trous wavelet coefficients, and the reconstructed layer from the ridgelet coefficients. The second row of Fig. 19 shows respectively the `Barbara` image, the reconstructed local cosine (textured) component and the reconstructed curvelet component. In the `Barbara` example, the dictionary contained the local discrete cosine and the DCTG2 transforms.

Future Directions

In this paper, we gave an overview of two important geometrical multiscale transforms; namely ridgelets and curvelets. We illustrate their potential applicability on a wide range of image processing problems. Although these transforms are not adaptive, they are strikingly effective both theoretically and practically on piecewise images away from smooth contours.

However, in image processing, the geometry of the image and its regularity is generally not known in advance. Therefore, to reach higher sparsity levels, it is necessary to find representations that can adapt themselves to the geometrical content of the image. For instance, geometric transforms such as wedgelets [30] or bandlets [49,50,62] allow to define an adapted multiscale geometry. These transforms perform a non-linear search for an optimal representation. They offer geometrical adaptivity together with stable algorithms. Recently, Mallat [54] proposed a more biologically inspired procedure named the grouplet transform, which defines a multiscale association field by grouping together pairs of wavelet coefficients.

In imaging science and technology, there is a remarkable proliferation of new data types. Beside the traditional data arrays defined on uniformly sampled cartesian grids with scalar-valued samples, many novel imaging modalities involve data arrays that are either (or both):

- acquired on specific “exotic” grids such as in astronomy, medicine and physics. Examples include data defined on spherical manifolds such as in astronomical imaging, catadioptric optical imaging where a sensor overlooks a paraboloidal mirror, etc.

- or with samples taking values in a manifold. Examples include vector fields such as those of polarization data that may rise in astronomy, rigid motions (a special Euclidean group), definite-positive matrices that are encountered in earth science or medical imaging, etc.

The challenge faced with this data is to find multiscale representations which are sufficiently flexible to apply to many data types and yet defined on the proper grid and respect the manifold structure. Extension of wavelets, curvelets and ridgelets for scalar-valued data on the sphere has been proposed recently by [66]. Construction of wavelets for scalar-valued data defined on graphs and some manifolds was proposed by [22]. The authors in [63][see references therein] describe multiscale representations for data observed on equispaced grids and taking values in manifolds such as: the sphere, the special orthogonal group, the positive definite matrices, and the Grassmannian manifolds. Nonetheless many challenging questions are still open in this field: extend the idea of multiscale geometrical representations such as curvelets or ridgelets to manifold-valued data, find multiscale geometrical representations which are sufficiently general for a wide class of grids, etc. We believe that these directions are one of the hottest topics in this field.

Most of the transforms discussed in this paper can handle efficiently smooth or piecewise smooth functions. But sparsely representing textures remains an important open question, mainly because there is no consensus on how to define a texture. Although Julesz [45] stated simple axioms about the probabilistic characterization of textures. It has been known for some time now that some transforms can sometimes enjoy reasonably sparse expansions of certain textures; e. g. oscillatory textures in bases such as local discrete cosines [70], brushlets [56], Gabor [53], complex wavelets [46]. Gabor and wavelets are widely used in the image processing community for texture analysis. But little is known on the decay of Gabor and wavelet coefficients of "texture". If one is interested in synthesis as well as analysis, the Gabor representation may be useless (at least in its strict definition). Restricting themselves to locally oscillating patters, Demanet and Ying have recently proposed a wavelet-packet construction named WaveAtoms [77]. They showed that WaveAtoms provide optimally sparse representation of warped oscillatory textures.

Another line of active research in sparse multiscale transforms was initiated by the seminal work of Olshausen and Field [59]. Following their footprints, one can push one step forward the idea of adaptive sparse representation and requires that the dictionary is not fixed but rather optimized to sparsify a set of exemplar signals/images, i. e. patches. Such a learning problem corresponds to finding a sparse matrix factorization and several algorithms have been proposed for this task in the literature; see [1] for a good overview. Explicit structural constraints such as translation invariance can also be enforced on the learned dictionary [5,58]. These learning-based sparse representations have shown a great improvement over fixed (and even adapted) transforms for a variety of image processing tasks such as denoising and compression [8,36,52], linear inverse problems (image decomposition and inpainting) [61], texture synthesis [60].

Article Outline

Glossary

Cell Structural and functional elementary unit of all life forms. The cell is the smallest unit that can be characterized as living.

Eukaryotic cell Cell that possesses a nucleus, a small membrane-bounded compartment that contains the genetic material of the cell. Cells that lack a nucleus are called *prokaryotic cells* or *prokaryotes*.

Domains of life *archaea*, *bacteria* and *eukarya* – or in English *eukaryotes*, and made of eukaryotic cells – which constitute the three fundamental branches in which all life forms are classified. Archaea and bacteria are prokaryotes. All multicellular organisms are eukaryotes, but eukaryotes can also be single-cell organisms. Eukaryotes are usually classified into four kingdoms: animals, plants, fungi and protists.

Motility Spontaneous, self-generated movement of a biological system.

Cytoskeleton System of protein filaments crisscrossing the inner part of the cell and which, with the help of the many proteins that interact with it, enables the cell to insure its structural integrity and morphology, exert forces and produce motion.

Amoeboid motility Crawling locomotion of a eukaryotic cell by means of protrusion of its leading edge.

Molecular motor Motor of molecular size. In this context, protein or macromolecular complex that converts a specific source of energy into mechanical work.

Filament Here, extended unidimensional structure made of an assembly of repeated protein units that hold together via physical interactions (without covalent bonds). A filament will be either a single *polymer* (or here *biopolymer*), a linear assembly of such polymers, or a linear assembly of molecular motors.

Active gel Cross-linked network of linear or branched polymers interacting by physical means, and that is dynamically driven out of equilibrium by a source of energy.

Definition of the Subject

We, as human beings, are made of a collection of cells, which are most commonly considered as the elementary building blocks of all living forms on earth [5]. Whether they belong to each of the three domains of life (*archaea*, *bacteria* or *eukarya*), cells are small membrane-bounded compartments that are capable of homeostasis, metabolism, response to their environment, growth, reproduction, adaptation through evolution and, at the cellular as well as multicellular level, organization. In addition, spontaneous, self-generated movement – also known as *motility* – is one of the properties that we most closely associate with all life forms. Even in the case of apparently inanimate living forms on macroscopic scales, like most plants and fungi, constitutive cells are constantly remodeling their internal structure for the entire organism to perform its metabolism, growth and reproduction [29]. In animals like human beings, cell motility is at the basis of most – if not all – essential processes participating in their lifetime, from their development, maintenance, to eventual death. It is indeed crucially involved for example in embryonic development (where individual as well as collective motions of cells underly morphogenesis), wound healing and recovery from injuries (where cellular migration is essential for tissue repair and regeneration), as well as immune response and most of disease progressions. There, on a biomedical point of view, cellular motility is involved in processes as diverse as neutrophils (white blood cells) and macrophages (cells that ingest bacteria) progressions, axonal regrowth after injuries, multiple sclerosis and cancer metastases. In addition, motility defects of the animal cells themselves can lead to a variety of inherited health problems, including male infertility, deafness and chronic inflammatory diseases.

Introduction

Cell movement was observed and reported for the first time as early as 1674, when Anthony van Leeuwenhoek brought a glass bead that served him as a primitive microscope close to a drop of water taken from a pool. His astonishment was immediate, as he later reported: "… the motion of these animalcules in the water was so swift and various, upwards, downwards and round about, that it was wonderful to see …" [29]. The organisms he saw were probably ciliated *protozoa* – unicellular non-photosynthetic eukaryotic organisms – a fraction of a millimeter in length, swimming by the agitated but coordinated motion of sometimes thousands of hairlike cilia on their surface (see Fig. 1). Despite this very early observation, only relatively recent advances of the past few decades in microscopy, molecular biology and biochemistry have enabled the discovery of the basic underlying molecular mechanisms by which cells are able to feel their environment, exert forces and move in a directed way in search for nutrients or any other task they need to perform. The cytoskeleton, defined as the system of protein filaments that enable the cell to insure its structural integrity and morphology, exert forces and produce motion, was first observed by H. E. Huxley and J. Hanson in

1953, when they discovered the double array of filaments in cross-striated muscles using electron-microscopy techniques [93,110,111]. In parallel with A. F. Huxley and R. Niedergerke, but independently, they published the next year the "sliding-filament model", which explains muscle contraction via the relative sliding of two different types of filaments, originally called "thick" and "thin" filaments [109,115] (see Fig. 2). This, with the help of further genetic, biochemical and crystallographic studies, dated the beginning of a scientific understanding of the subcellular mechanisms that underly cell motility.

In addition to the characterization of the biochemical composition and organization of these subcellular structures, tremendous advances in the past two decades on both physical micro-manipulation and fluorescence-microscopy techniques have enabled the characterization of the processes involved with minute details. On the one hand, thanks to the help of micro-pipettes, atomic-force microscopes and optical tweezers, one can characterize the forces that cells are able to exert as well as their responses to applied stimuli. On the other hand, fluorescence-microscopy techniques provide information on the microscopic dynamics of single molecules in vivo. Finally, combined with biochemistry and gene-expression control, as well as the micro-fabrication of bio-mimetic artificial systems in in vitro assays, these techniques have enabled the study of simplified systems, where some specific aspects of the processes involved can be characterized separately.

In addition to these biochemical and behavioral characterizations, understanding the generic principles that underly cell motility needed an integrated approach to explain how this complex molecular machinery can self-organize and lead to a coherent, purposeful movement at the cellular level. Nothing better than a eukaryotic cell can indeed be categorized as a complex system, in that its behavior integrates the coordinated interplay of more than ten thousand different protein types, numbering together millions and representing 60% of its dry mass [5]. The cytoskeletal machinery is made of hundreds of different molecular players. For example, in 2003, about 160 proteins were known to bind to actin, one of the major biopolymers participating in cell structure and dynamical behavior [53]. Knowledge about this biomolecular machinery is constantly evolving, and its undergoing complexity can be appreciated by consulting up-to-date information on available databases[1]. Therefore, understanding this complexity and describing how it is integrated at the cellular level was made by biophysical studies, both on experimental and theoretical grounds, which helped to identify the generic principles behind cell motility. At the molecular level first, the conversion of chemical energy stored in covalent bounds into mechanical work relies on out-of-equilibrium thermodynamic principles and asymmetrical properties – or polarity – of the structures involved, and happens in a highly-fluctuating environment of brownian particles [13,233]. On larger length scales, the appearance of coordinated motion in large collections of proteins relies on collective phenomena, self-organi-

[1] See, for example, http://www.cytoskeletons.com/database.php.

zation and dynamical symmetry breakings [129]. On yet larger length scales, swimming of microorganisms has attracted the attention of physicists for years [228,263], and morphogenesis and pattern formations in cellular tissues rely on self-organization phenomena, as was envisioned for the first time by Turing in 1952 [141,269]. Therefore, in addition to biophysical experimental techniques, variety of theoretical physics' disciplines spanning the theory of stochastic processes, statistical physics, out-of-equilibrium thermodynamics, hydrodynamics, nonlinear dynamics and pattern formation have contributed and still contribute to our understanding of cell motility.

The present article will mainly focus on the eukaryotic cytoskeleton and cell-motility mechanisms. Bacterial motility as well as the composition of the prokaryotic cytoskeleton will be only briefly mentioned. The article is organized as follows. In Sect. "The Diversity of Cell Motility", we will first present an overview of the diversity of cellular motility mechanisms, which might at first glance be categorized into two different types of behaviors, namely "swimming" and "crawling". Intracellular transport, mitosis – or cell division – as well as other extensions of cell motility that rely on the same essential machinery will be briefly sketched. In Sect. "The Cell Cytoskeleton", we will introduce the molecular machinery that underlies cell motility – the cytoskeleton – as well as its interactions with the external environment of the cell and its main regulatory pathways. Sections "Other Cytoskeleton-Associated Proteins" to "The Prokaryotic Cytoskeleton" are more detailed in their biochemical presentations; readers primarily interested in the theoretical modeling of cell motility might want to skip these sections in a first reading. We will then describe the motility mechanisms that rely essentially on polymerization-depolymerization dynamics of cytoskeleton filaments in Sect. "Filament-Driven Motility", and the ones that rely essentially on the activity of motor proteins in Sect. "Motor-Driven Motility". Finally, Sect. "Putting It Together: Active Polymer Solutions" will be devoted to the description of the integrated approaches that have been developed recently to try to understand the cooperative phenomena that underly self-organization of the cell cytoskeleton as a whole.

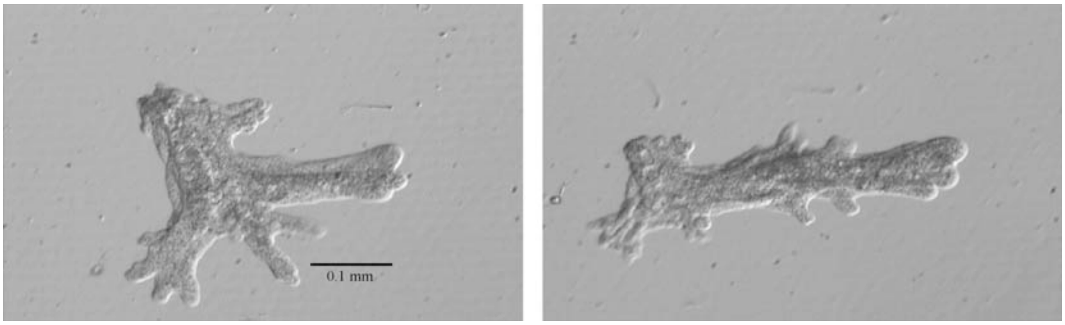
The Diversity of Cell Motility

Swimming

At the cellular level, viscous hydrodynamic forces are several orders of magnitude higher than inertial forces. Therefore, simple reciprocal motions cannot produce forward motion, and cellular swimming patterns need to be asymmetric in space and time for the cell to advance. This hydrodynamic problem faced by cells attempting to swim have been eloquently summarized by Purcell as "life at low Reynolds number" [228]. To solve this problem, bacteria use the rotation of a short helical or corckscrew-shaped *flagellum*, which is a relatively rigid structure made of a collection of hundreds of identical protein subunits called *flagellins* [20]. The swimming of a single bacterium can be impressively rapid, as bacteria such as *Escherichia coli* - the common intestinal bacterium – swim at speeds of 20 to 30 micrometers per second, for the cell itself is only about two-micrometer long and half a micrometer in diameter. The bacterium possesses multiple flagella that gather together during swimming, and can fly apart as the bacterium switches direction. Other bacteria such as *Vibrio cholerae* - the causative agent of cholera – use a single flagellum located at one of their pole, but the propulsion mechanism relies always on the presence of a rotary molecular motor located in the cell membrane, and which is sensitive to modifications of the chemical environment of the cell. Under normal conditions, the bacterium changes direction in an intermittent chaotic way by reversing the rotational direction of its motors, a phenomenon known as *tumbling*. When placed in a concentration gradient of nutrients however, the cell can adapt its tumbling frequency to swim towards nutrient-rich regions, a phenomenon known as *chemotaxis* [181].

Even though it shares the same name, the eukaryotic flagellum shares little structures and propulsion mechanisms with its bacterial counterpart. It is indeed at least ten times larger than a bacterial flagellum in both diameter and length, and instead of being a rigid passive structure animated by a remote motor, it bears its motor activity along its length. Propulsion occurs by the propagation of a bending wave along the flagellum as a result of the relative sliding of a group of about 10 long parallel filaments, which are engulfed in the cell's plasma membrane and are animated by hundreds of motor proteins in a coordinated manner. Eukaryotic cells also use another type of protrusions to swim, the *cilia*, which are much like flagella in their internal structure, but which are shorter and work usually in numbers, covering sometimes the whole cell surface as in the case of paramecia or other ciliated protozoa (see Fig. 1). Their beating pattern is then coordinated at the cellular level, most often in a wave-type of manner known as the *metachronal wave*. Beating cilia are also found in animals, as for example in humans where ciliated cells play major roles in several organs like the brain, the retina, the respiratory tract, the Fallopian tube and the kidney [117].

Other strategies of swimming include the elegant movement used by *Eutreptiella* - called *metaboly* – which



Cytoskeleton and Cell Motility, Figure 3

consists in gradually changing the contour of the cell surface to locally increase the drag exerted by the viscous fluid around and move the cell forward [67]. Other organisms like most motile species of *Chrysophytes* – a group of marine photosynthetic protozoa – possess a flagellum attached at their front instead of their back. The flagellum is covered with stiff hairs projecting from its side that allow the cell to move forward as a planar wave propagates from the base to the tip of the flagellum [29]. Finally, one should mention yet another type of motility – namely *walking* – in which cells use also cilia and flagella animated in a coordinated manner to enable the cell to literally "walk" over surfaces. Walking motility relies on the same essential biochemical structures as the ones employed in swimming with collections of cilia.

Crawling

Cell crawling is the common mechanism employed by most eukaryotic animal cells as they move through animal tissues, constituted of other cells or filaments of the extracellular matrix [5,29]. In contrast to swimming cells, crawling cells in general do not employ conspicuous motile organelles that are external to the cell, and which can be studied in isolation. In general however, they either move by means of wormlike cycles of extensions and contractions of their cell body or of some specific protrusions, or slide without visible means of protrusion, a process also referred to as *gliding*. Most of crawling mechanisms rely on the protrusion of specific dynamic extensions at the leading edge of the cell, but gliding seems to rely sometimes on different mechanisms [67,96]. Even though gliding mechanisms are widespread in bacteria, algae and parasitic protozoa, we still do not know for sure the molecular machinery as well as the essential mechanisms that underly these different phenomena [29,96].

The best characterized crawling mechanism is the so-called *amoeboid motility*, referring to the locomotion of all eukaryotic cells that move by means of protrusion of their leading edge. Originally, the term was referring uniquely to the crawling mechanism of *Amoeba proteus*, a particular species of *amoebae*, whose protrusions are stubby three-dimensional projections called *pseudopodia*[2] (see Fig. 3)[3]. But other types of protrusions exist, that are classified with respect to their shape and dimensional organization. Two-dimensional protrusions are the flat veil-shaped projections called *lamellipodia*, as they occur in fibroblasts' or fish epidermal keratocytes' motility for wound healing[4]. One-dimensional projections are the long thin projections called either *filopodia* or *microspikes*, and which occur for example in neuronal-growth-cone progressions[5]. Filopodia usually protrude as small extensions of a lamellipodium, and are used by the cell to extend its lamellipodium in a given direction [136,257] (see Fig. 4). To

[2] Note that some zoologists also use the term "pseudopodia" or "pseudopods" rather generally to refer to a variety of cell-surface protrusions. These include the different types of protrusions described here as playing a role in amoeboid motility, but also the long extended processes that some cell types use only as feeding apparatus, like *axopodia*.

[3] A short video of a locomoting *Amoeba proteus* can be seen on the following website: http://www.bms.ed.ac.uk/research/others/smaciver/A.prot.Loc.mov.

[4] Fibroblasts are the cells that synthesize and maintain the extracellular matrix in most animal connective tissues. They provide a structural framework (stroma) for many tissues, and play a crucial role in wound healing. Keratocytes are epithelial cells that have been characterized in the epidermis of fish and frogs, and that have been named so because of their abundant keratin filaments. They are specialized in wound healing, and are one of the most spectacular example of fast and persistent locomotion in cells, with velocities up to 30 μm/min [5,158].

[5] Growth cones are structures that are found at the tip of axons and dendrites, by means of which neuron cells extend.

these must be added the spherical membrane protrusions called *blebs*, which occur as a result of cortical contractility, and which have been proposed recently to participate in the initiation of lamellipodium formation and the elaboration of cell polarity for directed motion [211], as well as in the amoeboid motility itself for example in *Dictyostelium*, a model species of *amoebae* [289]. Finally, one should mention a motility mechanism that can be classified as *rolling*, in which some organisms such as *helizoa* use coordinated shortening and lengthening of long radiating needlike extensions called *axopodia* to roll over surfaces. Axopodia happen also to be sticky extensions that are most often used for catching preys in numerous protozoa.

Depending on authors, the process of amoeboid motility can be decomposed into three to five steps that occur simultaneously. First the cell makes a protrusion, where the membrane is pushed forward by means of the polymerization of cytoskeletal filaments. Then the protrusion adheres to the substrate via the formation of anchoring points, and subsequent contraction of the cell cytoskeleton drags the cell body forward. Finally at the rear end, the cell de-adheres and retracts [156,192]. Of these five steps, the two last ones – namely de-adhesion and retraction – involve similar structures and mechanisms as the formation of the anchoring points and cell body drag, which led originally Abercrombie to describe his observation as a three-step cycle [1]. The speed of amoeboid motility can range from less than a micrometer per hour to more than one micrometer per second, depending on cell type and stimulation[6].

Extensions of Cell Motility

In addition to moving the whole cell body, the machinery that is responsible for cellular movement can be employed for quite different tasks, which are as essential to the cell survival and reproduction as its motility per se. As we have earlier stated, even in the case of macroscopically non-aminated live forms, the constitutive cells need constantly to displace their internal organelles for their metabolism to be maintained [241]. When looked under the light microscope, mitochondria, vesicles, lysosomes and ingested particles display a rapid and sporadic movement that is interspaced with relatively long periods of quiescence. Velocities are typically of the order of micrometers per second, as the fastest known organelle transport is performed in the

a to h Fluorescence micrographs of mitosis in fixed newt lung cells stained with antibodies to reveal the microtubules (MT, *green*) see Sect. "Biopolymers", and with a dye (Hoechst 33342) to reveal the chromosomes (*blue*). The spindle forms as the separating astral MT arrays, associated with each centrosome (a to c), interact with the chromosomes. Once the chromosomes are segregated into daughter nuclei (f and g), new MT-based structures known as stem-bodies form between the new nuclei (g). These play a role in cytokinesis (h), the actual cleavage of the two daughter cells. Source: reprinted from [237] with permission from The American Association for the Advancement of Science

green algae *Chara*, whose chloroplasts are transported at velocities that can achieve 60 micrometers per second [39]. Of all cell types, the need for organelle transport is best illustrated by the mammalian motor neurons whose longest extensions – the axons – even though typically only a few micrometers in diameter, can reach lengths up to one meter. Characteristic times that would be required for a mitochondrion to naturally diffuse that distance in such a geometry range from 10 to 100 years. Instead, membrane vesicles and organelles are actively transported in both directions at speeds of about one to five micrometers per second, which allows the whole journey to be made in just a few days [29]. Finally, the probably most-spectacular event of intracellular transport occurs during the essential process of eukaryotic mitosis, by which duplicated chromosomes are segregated from the mother cell and delivered to each of the nascent daughter cells. For this process to occur, major structural reorganizations of the whole-cell cytoskeleton are needed, during which a large and complex cellular structure – the *mitotic spindle* - assembles and drives the chromosomes apart in a coordinated manner [193] (see Fig. 5).

Cell motility can also occur by means of molecular machineries located outside the cell that needs to move. This is the case in particular for mammalian pathogene bacteria such as *Listeria monocytogenes* and *Shigella* and *Rick-*

ettsia species, but also for some viruses like *vaccinia virus*. These organisms propel themselves within and across the cells they invade by utilizing the cytoskeleton of their hosts [41,83,87,266]. Among these organisms, *Listeria* in particular has become a model organism for studying actin-based motility, a simplified version of the whole amoeboid motility, and which can be seen as a representation of just the first step of this complex process in the original Abercrombie description [36,194,222]. Other particular systems use different specific structures from purely cell-cytoskeleton-based motility. Among these, vertebrate skeletal muscles contrast with standard cellular motility, in that they are structured in enormous multinucleated cells that evolved specifically to generate extremely rapid, repetitive and forceful movements. The cytoplasm of these giant cells is crammed full of a highly-organized, almost-crytsalline array of cytoskeletal filaments, whose only function is to produce contractile forces [29,113]. Another essential event of cell division, namely *cytokinesis* – the actual cleavage of the two daughter cells – also involves the contraction of relatively-sliding cytokeletal filaments, this time under the form of a dividing ring [82].

Finally, other types of cells use mechanisms that do not rely on their cytoskeleton for their motility. Of the most spectaculars is the motility based on the stored mechanochemical energy in some supra-molecular springs, which can then contract at velocities as high as eight centimeters per second [179]. Yet another mechanism relies on some stored purely-elastic energy that allows some insect-eating plants to catch their preys. This is the case for example of the Venus flytrap *Dionaea muscipula*, whose leafs can close in about 100 ms, one of the fastest movements in all plant kingdom. To achieve such a performance, the plant relies on a snap-buckling instability, whose onset is actively controlled by the plant after the arrival of a fly has triggered some biochemical response via the disturbance of mechano-sensitive hairs located inside the trap [69].

The Cell Cytoskeleton

The eukaryotic *cytoskeleton* is defined as the system of protein filaments that enable the cell to insure its structural integrity and rigidity, regulate its shape and morphology, exert forces and produce motion. As a framework that insures structural integrity, the cytoskeleton is mainly constituted of a cohesive meshwork of protein filaments that extend throughout the cytoplasm of the cell. But being the essential structure that produces movement at the cellular level, and thereby needing to be highly adaptable to extracellular stimuli or rapid environmental changes, the cytoskeleton has evolved into a highly-dynamic structure. In fact, cytoskeletal filaments constantly grow and shrink, associate and dissociate via multiple linkages, organize on large scales into a dynamic network, and serve as an intricated set of tracks to motor proteins that transport cargos from one part of the cell to the other, or slide filaments with respect to one another to produce contractile forces. This section is devoted to the biochemical description of this very-complex structure. In addition, its interaction with the cell's external world and its regulatory pathways will be briefly presented, as well the prokaryotic cytoskeleton which, even though biochemically different, appears more and more to resemble its eukaryotic counterpart on a functional point of view.

Biopolymers

How can a eukaryotic cell, with a diameter of 10 microns or more, be spatially organized by cytoskeletal proteins that are typically 2000 times smaller in linear dimensions? The answer lies in *polymerization*, this ability of the elementary protein subunits (called *monomers*) to assemble via physical interactions into extended linear structures that are made of a large number of them, typically thousands (called thereby *polymers*, or here more precisely *biopolymers*). There are three types of biopolymers in a given eukaryotic cell, namely *actin filaments*, *microtubules* and *intermediate filaments* (see Fig. 6). Although they are classified according to their respective thickness, more interesting for cellular structures and functions are their rigidity, which at thermodynamic equilibrium is characterized by their persistence length L_p [7] [81].

Actin filaments – or F-actin – have a persistence length that is usually accepted to be of the order of 15 to 17 μm [81,210], even though it has been reported that actin rigidity should depend on the way it is decorated, ranging from 9 ± 0.5 μm for bare F-actin to 20 ± 1 μm for tropomyosin-bound actin filaments in skeletal-muscle structures [119]. Actin filaments are two-stranded helical polymers, 5 to 9 nm in diameter, and are built from dimer pairs of globular-actin monomers – or G-actin – that are polar in nature [5,29]. The two halves of an actin monomer are separated by a cleft that can bind adenosine triphos-

[7] The persistence length L_p is defined as follows: consider a thin flexible rod of fixed length L, submitted to thermal forces. Its shape is completely specified by the tangent angle $\theta(s)$ in three dimensions along the arc length of the rod [154]. The persistence length L_p is defined as the characteristic arc length above which thermal fluctuations of the angle $\theta(s)$ become uncorrelated. Specifically, $\langle \cos[\Delta\theta(s)] \rangle = \exp(-s/L_p)$, where $\Delta\theta(s)$ is the three-dimensional angle change over the arc length s. L_p is related to the rod's material Young modulus E and its geometrical moment of inertia I by $L_p = EI/k_B T$, where $k_B T$ represents thermal energy [81].

phate (ATP) or its hydrolyzed form adenosine diphosphate (ADP)[8]. This is responsible for the existence of two distinct ends to the whole filament, namely a fast growing end – called "plus end" or "barbed end" – where mostly ATP-bound monomers are located, and a slow growing end – known as "minus end" or "pointed end" – that is rich in ADP-bound monomers. The minus end has a critical actin-monomer concentration that is roughly six times as high as that of the plus end. At steady state, and with the help of monomeric diffusion, this drives the phenomenon of *treadmilling*, a dynamic evolution of the actin filament where actin monomers are added to the plus end, and removed from the minus end at the same rate. During this process, the total length of the treadmilling filament is kept constant, while its center of mass is displaced at a constant velocity, even though each individual polymerized monomer do not move on average[9] (see Fig. 7). For pure actin at physiological concentrations, this process is rather slow and occurs at velocities of the order of a few micrometers per hour. But as we shall see in the following, specialized actin-binding proteins allow the cell to increase this speed substantially, which makes actin forces exerted via polymerization-depolymerization mechanisms one of the key players in cellular motility.

Actin is the most abundant protein in a eukaryotic cell (several grams per liter), and has been highly conserved throughout evolution. It organizes into a variety of structures, namely linear bundles, two-dimensional networks or three-dimensional gels, and is mainly concentrated in a layer located just beneath the plasma membrane and called the *actin cortex*. Of primary importance for cell motility are the two-dimensional highly cross-linked networks that actin forms in lamellipodia, and the linear bundles that are found in filopodia and which protrude from the lamellipodia in a directed way. There, as we shall see in Sect. "Filament-Driven Motility", actin polymerization plays a crucial role in driving cell motility. Finally, one should mention the cortical rings that contract during the process of cytokinesis to cleave the two daughter cells, as well as the formation of *stress fibers*, which are force-producing structures that are attached to anchoring points, and which enable the cell to exert traction forces on the substrate on which the cell is crawling[10] (see Sect. "Cell Anchoring and Regulatory Pathways").

Microtubules are the stiffest of all polymers, with persistence lengths ranging from 100 µm up to 6 mm [213]. They are hollow cylinders with an outer diameter of ≃25 nm and are made of tubulin subunits arranged in 13 adjacent protofilaments. Tubulin is a heterodimer formed of α- and β-subunits, which can bind either

[8] The hydrolysis reaction of ATP (ATP $\rightleftharpoons$ ADP + P_i, where P_i designates inorganic phosphate) breaks a high-energy chemical bond – here a phosphoanhydride bond – to drive many chemical reactions in the cell.

[9] Animated movies of this process can be seen at http://www.uni-leipzig.de/~pwm/kas/actin/actin.html or http://cellix.imba.oeaw.ac.at/actin-polymerisation-drives-protrusion.

[10] Illustrations of these structures can be found at http://cellix.imba.oeaw.ac.at. See also [136,257].

guanosine triphosphate (GTP) or guanosine diphosphate (GDP)[11]. Microtubules share some important properties with actin filaments, in that they are polar, treadmill, and can exert forces [51]. They typically organize radially from a single microtubule-organizing center called the *centrosome*, and connect to the actin cortex with their plus ends towards the cell edge. In addition to giving the cell its structural rigidity and shape, they actively participate in regulating the actin cortex dynamics, focal-adhesion assembly and disassembly, and in some cell types participate in determining the cell polarity and its subsequent migrating direction (see Sect. "Cell Anchoring and Regulatory Pathways").

Intermediate filaments are the most flexible polymers of the cell cytoskeleton, with persistence lengths of the order of 0.3 to 1.0 μm. They range in diameter from 7 to 12 nm, in-between that of actin and microtubules. There are different classes of intermediate filaments such as *vimentin*, *desmin*, *keratin*, *lamin* and *neurofilaments*, and they constitute together a large and heterogeneous family, of which different cells possess different members. Unlike actin filaments and microtubules, they are not polar, do not treadmill, and are therefore thought to contribute essentially to the structural and elastic properties of the cell, but little to its dynamics and motility. One particular example of intermediate-filament structure is the *nuclear lamina*, located just beneath the inner nuclear membrane, and that is responsible for its structural integrity.

Molecular Motors

Molecular motors constitute the subset of proteins and macromolecular complexes that convert a given source of energy into mechanical work [5,103]. The energy they need is generally stored into either of two forms by the cell: high-energy chemical bonds, such as the phosphoanhydride bonds found in ATP and GTP, and asymmetric ion gradients across membranes. Known molecular motors can be classified into roughly five categories, namely (1) rotary motors, (2) linear-stepper motors, (3) assembly-disassembly motors, (4) extrusion nozzles, and (5) prestressed springs. A nice table of the major different cell-movements' categories with the different cellular structures and molecular motors they rely on, can be found in [67].

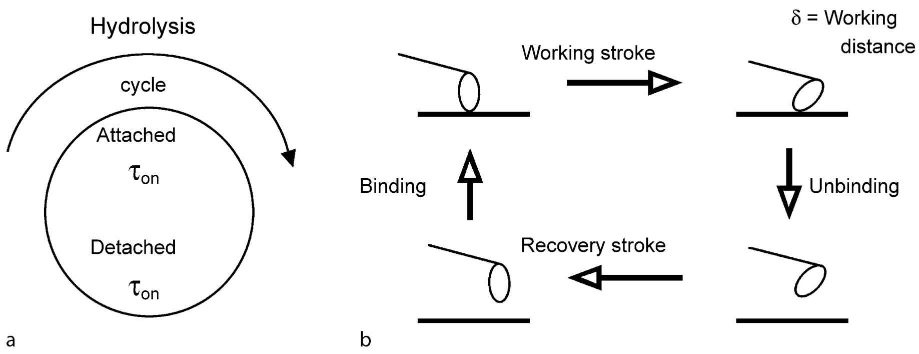
All known biological rotary motors use ion-gradient-based sources of energy, and most of them use electrochemical forces based on hydrogen-ion (or proton) gradients, also known as *proton-motive forces*. This is the case for example for the propulsion motor of bacteria that is responsible for their flagella to rotate [20,181], as well as for the surprising rotary motor F0F1-ATPase that is responsible for ATP synthase in mitochondria and bacteria [290]. This rotary machine usually converts the electrochemical energy stored in proton-concentration gradients, first into mechanical motion, and then back into chemical energy under the form of ATP. But the motor is also reversible, in that it can harness the chemical energy of ATP to produce or maintain the transmembrane electrochemical gradient of proton concentration. This reversibility is best seen in bacteria, when they switch from aerobic to anaerobic conditions [5].

Most of the motors used in amoeboid motility are linear-stepper motors [103,246,258]. We shall therefore focus on this class of motor proteins in the remaining of the present article. They walk on the linear tracks formed by the polymerized cytoskeletal filaments, and can be classified into two different categories, namely *processive* and *non-processive* molecular motors, sometimes designated as "porters" and "rowers" [159]. The processivity is linked to the *duty ratio*, the proportion of time that the molecule spends attached to the filament as compared to the whole motor cycle, namely one ATP-hydrolysis cycle [102] (see Fig. 8). Typically, porters are individual walkers that carry cargos across the cell, and therefore most often participate in intra-cellular traffic. Rowers however work in numbers, and are usually involved in generating contractile forces, like it is the case in skeletal-muscle fibers, stress fibers or contractile rings that form during cytokinesis [82,109,113,115]. Structurally, all these motor proteins can be divided into a motor domain, called the *head*, and a *tail* or *base*. The head is the site of conformational change of the protein during ATP-hydrolysis, and with which the motor attaches to the filament. The tail connects the motor to its cargo or to other motors. Processive motors are (homo-)dimers, such that as one head is attached to the filament, the other can move to a new binding site. In that case, the two tails of the associated monomers wind up together to hold to each other. Non-processive motors can also be found in dimeric forms, one of the two heads being then just unused.

Motor Families

Eukaryotic cytoskeletal motor proteins are divided into three superfamilies, namely *myosins*, *kinesins* and *dyneins*. The motor proteins known longest belong to the myosin superfamily [21], because of their high concentration in skeletal muscles. All myosin motors walk on actin filaments through a general four-step process: binding,

[11] Similarly to ATP, GTP is a stored source of energy for the cell that is consumed via a hydrolysis reaction, here GTP $\rightleftharpoons$ GDP + P_i.



Cytoskeleton and Cell Motility, Figure 8

a ATP-hydrolysis cycle, with the respective durations τ_{on} and τ_{off} of the attached and detached states of the motor. These durations define the duty ratio r as $r = \tau_{on}/(\tau_{on} + \tau_{off})$. b During the attached phase, the head of the motor makes a working stroke of working distance δ. The motor then unbinds from the filament, and makes a recovery stroke during the detached phase. By recovering its initial conformation while detached, the motor avoids stepping backwards and so progresses by a distance equal to the working stroke during each cycle. Source: reprinted from [102] with permission from Nature Publishing Group

power-stroke, unbinding, and recovery-stroke[12] [102] (see Fig. 8). Today, they are classified into 18 different classes, with possibly dozens of different members in each class, even in a single organism. The skeletal-muscle myosins belong to the Myosin II family; they have long tails that form dimeric α-helices and associate into the so-called "thick filaments" originally observed by H. E. Huxley and J. Hanson, while the "thin filaments" are F-actin polymers [93,110,111] (see Fig. 2 and 9). Most myosin molecules are plus-ended directed (to the exception of Myosin VI), and non-processive (to the exception of Myosin V, which is involve in vesicular transport). Their very diverse mechanical features, in terms of step sizes, duty ratios and stepping speeds, are very fine-tuned to their functions[13] [102].

Kinesin proteins share very similar structural features with myosins in their head domain and are therefore thought to have branched from a common ancestor with myosins, but diverge in their tail structures [273]. They walk on microtubules instead of actin filaments, are processive, and are involved mainly in intracellular transport like the transport of organelles along nerve axons[14]. The kinesin superfamily has been divided into 14 families, and a number of "orphans" that are so far ungrouped [189]. Most kinesin motors are plus-ended directed, like the conventional kinesin I that founded the family [274]. Members of the Kinesin-13 family are unconventional, in that they can processively induce microtubule depolymerization, a process that is essential to chromosome segregation during mitosis[15] [107] (see next Section).

Dynein proteins are less well-characterized. It is also unknown whether they share a common ancestor with myosins and kinesins, or whether they are the result of convergent evolution. Two major groups of dyneins exist: axonemal dyneins, which drive the bending of eukaryotic cilia and flagella by inducing the relative sliding of microtubules [226], and cytoplasmic dyneins, which are involved in organelle and vesicular transport, as well as cell division [133]. Most dyneins are minus-ended directed, and interestingly, some dyneins can be non-processive at high, but processive at low ATP concentrations.

Other Cytoskeleton-Associated Proteins

The coordination of the numerous different processes that happen during amoeboid motility rely on a tight regulation of the activity of the cell cytoskeleton, as well as its anchoring to the substrate. In particular, as we shall see below, the protrusion of the leading edge of the cell – the first step of amoeboid motility – relies on the formation of a highly-cross-linked and dynamic network of actin filaments. Its formation and dynamical regulation are carried out with the help of numerous accessory proteins [224,257]. Following Pollard's presentation [223,225] (see Fig. 10), we can focus on the main proteins that are involved in the formation, structure and dynamics of

Dynamical organization of the actin network at the leading edge of a protruding lamellipodium. (1) External cues activate signalling pathways that lead to GTPases and PIP$_2$ activation (2). These then activate proteins of the WASP family (3), which in turn activate Arp2/3 complexes that initiate new filaments as branching from existing ones (4). Each new filament grows rapidly (5), fed by a high concentration of profilin-bound actin stored in the cytoplasm, and this pushes the plasma membrane forward (6). Capping proteins bind to the growing ends, terminating elongation (7). Actin-depolymerizing factor (ADF)/cofilin sever and depolymerize the ADP filaments, mainly in the "older regions" of the filaments (8, 9). Profilin re-enters the cycle at this point, promoting dissociation of ADP and binding of ATP to dissociated subunits (10). ATPactin binds to profilin, refilling the pool of subunits available for assembly (11). the actin network. Nucleation of the network starts after biochemical signals have been integrated via G-protein-linked membrane receptors, namely small GTPases and PIP$_2$ pathways [174] (see Sect. "Cell Anchoring and Regulatory Pathways"). Then members of the Wiscott Aldrich syndrome protein (WASP) family that are anchored to the cell's plasma membrane (like Scar [175]), activate Arp2/3 (for actin-related proteins 2 and 3) complexes that are responsible for the nucleation and maintenance of branching points in the network[16]. Then, in order to promote growth of the actin gel, recycling of G-actin monomers as well as the creation of new F-actin plus ends are stimulated by mainly two types of proteins: (1) Actin-binding proteins – such as profilin – that bind to actin monomers, catalyze the exchange of ADP for ATP, and inhibits ATP hydrolysis, a process that is antagonized by monomer-sequestering proteins – like thymosineβ-4 – that stabilize ADP-bound G-actin. (2) Actin-depolymerizing factors (ADF) – such as cofilin (or ADF/cofilin) – that sever and depolymerize ADP-actin filaments, thereby increasing the pool of available G-actin monomers. The structure of the network is further controlled by capping proteins that can bind to F-actin plus ends to terminate their growth, and thus limit the increase of free-growing plus ends. Finally, cross-linked structures are formed with the help of actin cross-linkers like filamin, and actin-bundling proteins like fascin, fimbrin and α-actinin. α-actinin and filamin are most present in lamellipodium structures, as fimbrin and fascin and most observed in filopodia [257]. Finally, the same as well as other actin-binding proteins (like espin, fascin, fimbrin and villin) exist in other structures where actin-bundles are formed, like bristles, microvilli and stereocilia [234]. In skeletal muscles, tropomyosin strengthens the actin filaments and prevents myosin motors from binding to actin when muscles need to be at rest[17]. For a relatively recent review on the actin-binding proteins, see [53].

Microtubule-associated proteins (MAPs) have been classified into two types, and participate to microtubules' stability and organization. MAPs of Type I are large filamentous proteins that comprise a microtubule-binding domain and a projection domain, thereby controlling the spacing of microtubules. MAPs of Type II have similar structures and cross-link microtubules to membranes, intermediate filaments or other microtubules. In addition, both types of MAPs promote microtubule assembly and stability, and compete with motor proteins for binding sites, such that they participate in microtubule-transport regulation. Other MAPs that do not belong to these classes are denoted XMAPs, as they have been originally identified in the Xenopus-frog eggs. Among these are the plus-end-binding proteins (or +TIPs) that bind to the microtubule growing ends and participate in their stability, and the highly-conserved stathmin or oncoprotein 18 which, instead, destabilizes microtubules [10,249]. The best understood microtubule end-binding proteins are the MCAKs (for mitotic centromere-associated kinesins), also known as Kin I kinesins, which are unusual kinesins in that, instead of moving along the surface of microtubules like other kinesin proteins do, they bind to microtubules' ends and trigger depolymerization in a processive way [47]. In particular, they depolymerize microtubules during mitosis to drive chromosome segregation [180]. For a review, see [104].

Cell Anchoring and Regulatory Pathways

The two first steps of cell crawling in the Abercrombie classification consist in the protrusion of the leading edge and its adhesion to the substrate [1,156]. Although they were thought to be largely independent processes, evidences are accumulating that adhesion and protrusion are highly interrelated [9,24,90,236]. Protrusion results primarily from actin polymerization at the leading edge of the migrating cell (see Sect. "Filament-Driven Motility"), and is regulated by the small GTPases Rho, Rac and Cdc42 [25,235]. As Rho is known to activate actomyosin contractility, Rac and Cdc42 induce actin polymerization and the formation of actin-filled protrusions such as lamellipodia and filopodia [91]. Through these pathways, the cell can respond to the chemical composition of its environment, an example of chemotaxis: as a function of the gradients of chemoattractants or chemorepellants in its environment, the cell regulates its sites of fastest actin polymerization in order to move towards or away from the source[18] [215]. Of primary importance for the accurate spatial regulation of these processes is the role of microtubules, which in some cell types play a crucial role in determining cell polarity and directional migration [136,204,236,255,256]. Microtubules have been proposed to activate Rac and Rho, the latest via the release of the GDP-GTP exchange factor GEF-H1 during microtubule depolymerization [143,283].

Adhesion occurs via the formation of adhesion sites, which rely primarily on molecules such as *integrins*, also involved in regulating the cell behavior via different signal-transduction pathways [24,78,190]. An important aspect of that process is that it allows the cell to "feel" the mechanical properties of its environment. This has been shown to be important for the migration of fibroblasts, in that they seem to migrate preferentially towards regions of

[16] In addition to Arp2 and Arp3, which are members of the Actin related proteins (Arp) family in that they have sequences and structures that are similar to actin, the Arp2/3 complex contains five other smaller proteins.

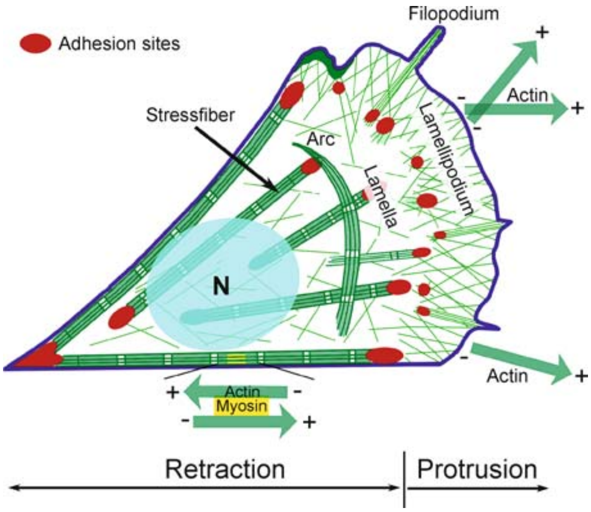
stiff substrates, a process referred to as *durotaxis* [169]. In addition, the mechanical properties of the cell's environment have been proposed to be relevant for tissue-growth directionality, as well as cell differentiation [56,243]. Adhesion sites can be roughly divided into two broad categories, namely *focal complexes*, which locate beneath microspikes or filopodia, and *focal adhesions*, which locate at the termini of stress fibers and serve in long-term anchorage [136] (See Fig. 11). Interestingly, these adhesion sites are also regulated by small GTPases of the Rho, Rac and Cdc42 families: focal complexes are signaled via Rac1 and Cdc42, and can either turnover on a minute time-scale or differentiate into long-lived focal adhesions via the intervention of RhoA [136]. A schematic representation of the integrated role of the small GTPases in regulating cell migration can be seen in Fig. 12. Such regulations are crucial for cell migration to occur optimally. Indeed, whereas adhesion sites are necessary at the leading edge of the cell to provide anchoring points on which the cell can exert traction forces, these need to be released at the rear for the cell to move forward. This results in a biphasic response of the cell-migration speed as a function of adhesive-ligand concentrations, in that too-low or too-high ligand concentrations prevent either the traction forces to be exerted, or the rear to be released [131,156]. How these regulatory pathways lead to a spatio-temporal feedback mechanism between actomyosin regulation and the focal-adhesion system is still under investigation [24,90].



Cytoskeleton and Cell Motility, Figure 11
Schematic representation of the actin cytoskeleton in a polarised fibroblast. The different organisational forms of actin filaments and their relations to adhesion sites to the substrate are depicted: diagonal actin filament meshwork in the lamellipodium, with associated radial bundles that sometimes protrude into filopodia; contractile bundles of actin (stress fibers) in the cell body and at the cell edge; and a loose actin network throughout the cell. Arc-shaped bundles are sometimes observed that move inwards under the dorsal cell surface (arc). The diagram shows an idealized cell: in reality, actin arrays are interconnected in various combinations and geometries. Adhesion sites are indicated in red. The flat region behind the lamellipodium and in front of the nucleus (N) is termed the lamella. At the cell front, in lamellipodia and filopodia, actin filaments are all polarized in one direction, with their fast-growing ends directed forward for producing pushing forces and inducing protrusion; in the cell body, actin filaments form bipolar assemblies with myosin proteins (stress fibers) for retraction. The Prokaryotic Cytoskeleton

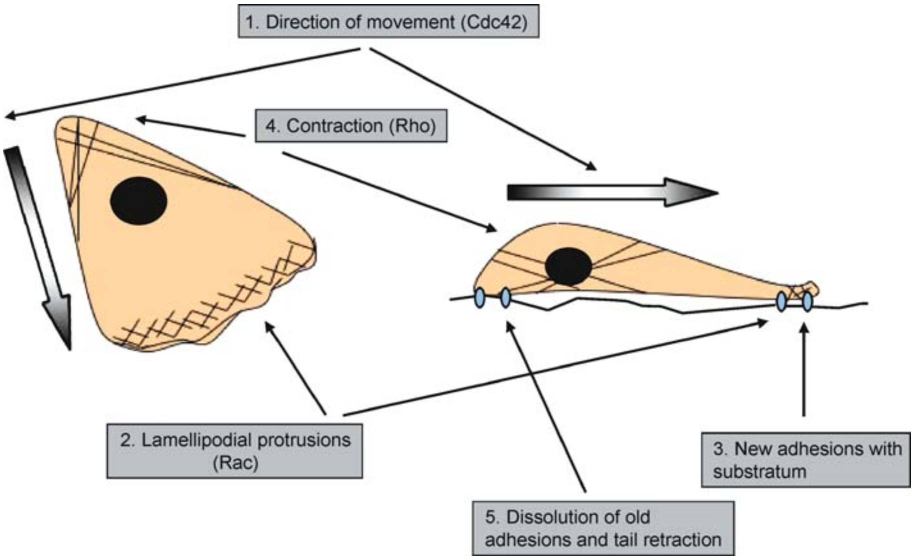
This section is completely independent of the rest of the article. Readers not interested in the biochemical composition of the prokaryotic cytoskeleton might want to skip this section.

As cytoskeletal proteins' structures are highly conserved throughout the three domains of life (archaea, bacteria and eukarya), prokaryotic cytoskeletal proteins differ strongly in their sequences from their eukaryotic counterparts. For this reason, and the fact that prokaryotes have a relatively simple organization as compared to eukaryotic cells, it was long thought that they were lacking a cytoskeleton. It is only in the 1990s that prokaryotic homologs of tubulin, actin and intermediate filaments started to be discovered. The first bacterial cytoskeletal proteins to be brought to knowledge was the protein FtsZ, whose relation to tubulin was discovered independently by three groups in 1992 [43,200,232]. Later, it was found that FtsZ could assemble into protofilaments that can be either straight or curved as a function on the state of the nucleotides, similarly to microtubules [58,104], and that its structure at the level of protein folding was nearly identical to that of tubulin [171,206]. The second prokaryotic cytoskeletal proteins to be discovered were MreB and ParM also in 1992, and were shown to be distant relative of the actin superfamily by sophisticated sequence-alignment techniques [26]. Later, it is only in 2001 that MreB was proven to be capable of self-assembly into cytoskeletal filaments that resemble much closely F-actin structures [126,276]. Finally, an homolog of intermediate filaments has been found recently in the bacterium *Caulobacter crescentus*, but only in this particular species so far [16]. Since it is responsible for giving the bacterium its crescent shape, it was given the name of *crescentin*.

Despite their sequencial differences with their eukaryotic counterparts, prokaryotic cytoskeletal proteins share with them strong homologies in their structural as well as



1. Direction of movement (Cdc42)
4. Contraction (Rho)
2. Lamellipodial protrusions (Rac)
3. New adhesions with substratum
5. Dissolution of old adhesions and tail retraction

Cytoskeleton and Cell Motility, Figure 12

Schematic representation of the integrated roles of Rho, Rac and Cdc42 proteins in regulating cell migration. By inducing actin-filament assembly, filopodia and focal-complexes formations, Cdc42 regulates the direction of migration (1). Rac induces actin polymerization at the cell periphery (2) and promotes lamellipodia protrusion. It also induces the formation of focal complexes at the leading edge (3). Rho plays a role in regulating longer-lived structures, namely activating actomyosin contraction in the stress fibers located in the cell body and at the rear (4), as well as promoting the assembly of focal-adhesion complexes. functional properties [8,188]. They are classified into four groups [253]: (i) Actin homologs are constituted by MreB and MreB homologs, ParM, and MamK. MreBs play an important role in a number of cellular functions, such as regulation of cell shape, chromosome segregation, establishment of cell polarity and organization of membranous organelles. ParM proteins are involved essentially in plasmid partitioning, and MamK is involved in the subcellular organization of membrane-bounded organelles. Similarly to actin, MreB and ParM protein families present polymerization-depolymerization dynamics that are driven by ATP hydrolysis. Less is known about MamK. (ii) Tubulin homologs contain FtsZ and the BtubA/B proteins, which constitute two other families of GTPases as compared to tubulin. As FtsZ is crucially involved in cytokinesis via its ability to form contractile rings and spiral structures, the role of BtubA/B proteins, which are much less widespread in the bacterial kingdom, has less been characterized so far. (iii) The intermediate filaments' homolog crescentin has only been found in *Caulobacter crescentus* and, as for its eukaryotic counterparts, is mainly involved in cell shape and structural integrity. (iv) Finally, the large MinD/ParA superfamily is made of prokaryotic cytoskeletal proteins that have no counterparts in eukaryotes. They however have the ability to organize into polymeric filaments, and present ATPase activity. Proteins of the MinD group are involved in placement of the bacterial and plasmid division sites, whereas proteins of the ParA subgroup are primarily involved in DNA partitioning.

Interestingly, cytoskeletal proteins seem to have been strongly conserved throughout evolution in each of the three separate domains of life, but differ quite substantially across domains [57]. Bacterial FtsZs proteins are 40–50% identical in sequence across species, and share even the same amount of similarities with their archaeal counterparts. Bacterial MreBs are generally 40% conserved. Among eukaryotes, the conservation is even stronger: it reaches 75–85% for tubulin and 88% for actin, one of the most conserved protein in the eukaryotic domain. In the case of archaea, MreB and actin homologs have not yet been identified for sure [57].

Filament-Driven Motility

Many kind of movements in eukaryotic cells are driven by polymerization-depolymerization mechanisms of cytoskeleton filaments, for which motor proteins per se are not required. Instead, the chemical energy stored in high-energy hydrogen bounds (under the form of ATP or GTP) is converted into movement via treadmilling mechanisms [264]. Two types of filaments have this ability, namely microtubules and actin filaments.

Microtubule Growth and Catastrophes

Microtubules are the stiffest of all cytoskeletal filaments, which confers them the ability to organize and stabilize both the cell structure and its transport network for internal communication and distribution. Depending on the cell need, they constantly reorganize or exert forces on the cell membrane or other organelles they transport. This is the case for example during the organization of the mitotic spindle, the structure formed prior to chromosomal segregation during mitosis [248]. There, chromosomes gather in a plane halfway from two microtubule-organizing centers – the centrosomes – that are located at each pole of the future dividing cell, and from which the microtubules tear the chromosome pairs apart [6,118] (see Fig. 6, especially panels C to F). For this mechanism to happen, microtubules constantly exert pulling and pushing forces both on the chromosomes and the cell membrane, a mechanism that allows for correct positioning of the site of cell-division [288]. Coupled with kinesin-motor activity, correct positioning of the centrosomes relies crucially on the ability of microtubules to grow and shrink spontaneously, a dynamics that provides feedback to centrosome positioning and leads to oscillations orthogonal to the cell spindle axis [85,86]. Such a mechanism is also responsible for the correct positioning of the nucleus in the fission yeast *Schizosaccharomyces pompe* [268].

Understanding microtubules' polymerization-depolymerization dynamics started with the first observation that they display phases of relatively slow growth, alternated with phases of rapid shrinkage [191]. Changes from one type of behavior to the other are referred to as *catastrophes* for the conversion from growing to shrinking, and *rescues* for the opposite transition. Observations of this behavior were further made in culture cells [244] and cellular extracts [19], which confirmed the existence of such dynamic instabilities in vivo. During mitotic-spindle formation, it has later been shown that the specialized structures that connect the microtubules to the chromosomes, the *kinetochores*, can "capture" and stabilize growing microtubules, preventing them from undergoing catastrophes [95]. For a review, see [134].

Further characterization of microtubules' biomechanical properties came from experimental studies of the forces produced by their polymerization-based growth. Analyzing force-induced microtubule buckling [50], microtubule forces were characterized as being potentially as high as those produced by motor proteins – typically a few pico-Newtons [123] – and to be able to deform membranes [74] or center asters in mirofabricated chambers [62,101], a mechanism that imitates nucleus positioning in fission yeast. For reviews, see [51,104].

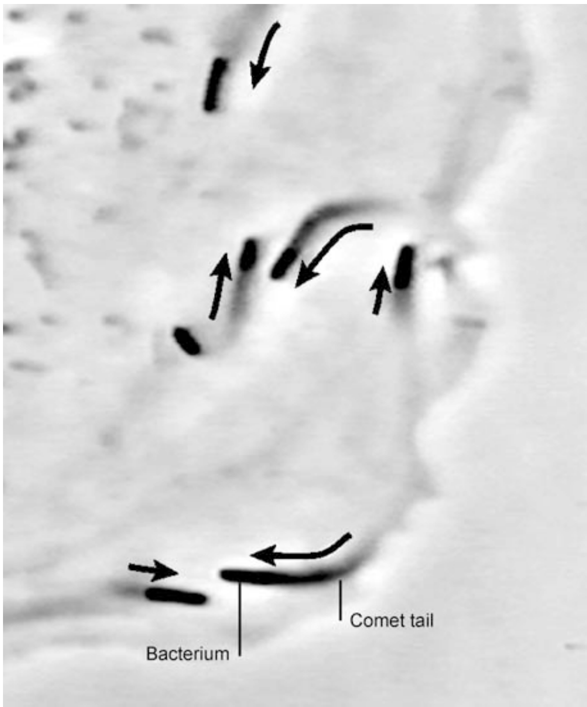
Actin Gels

As earlier stated, the first step of amoeboid motility in the original Abercrombie classification occurs via protrusion of the leading edge of the cell. This mechanism relies mainly on the polymerization dynamics of actin filaments [194,214,225]. Actin polymerization is known to play a primary role at the plasma membrane, where it is nucleated by proteins of the WASP family via Arp2/3 complexes (see Sect. "Other Cytoskeleton-Associated Proteins"). It has also been proposed to be responsible for driving endocytosis and the movement of endosomes, both in cultured cells and yeast [132,186].

Our understanding of eukaryotic actin-based motility has grandly benefitted from the motility mechanism of the bacterium *Listeria monocytogenes*. This pathogene moves at velocities of the order of several micro-meters per minute by nucleating the formation of an actin "comet-tail" that, while polymerizing thanks the host's cytoskeletal machinery, pushes the pathogene forward [265] (see Fig. 13). This particular motility mechanism, studied in in vitro assays, has allowed for the identification of the minimal set of proteins needed to actin-based motility, as well as the role of several of the main actin-related proteins [170,284]. It has also been used as a probe for the cell cytoskeleton network structures and visco-elastic properties in a position-dependent manner [153], and has shed light into the basic elementary principles of actin-based motility [71,87,194,214].

Except for very recent reports [68], nearly no force measurement has yet been done on single actin filaments. Due to their smaller bending rigidity, the corresponding stall force is expected to be orders of magnitude smaller than that of microtubules because of buckling phenomena. Instead, large forces can only be obtained when highly cross-linked actin filaments work as a whole and form a relatively rigid network, as it is the case in filopodia protrusion. Forces generated during actin-based propulsion have been measured on polymerizing actin gels, in particular using in vitro assays based on artificial biomimetic systems. Forces in the range of a few nano-Newtons have been found for gel comets originating from 2-µm-size polystyrene beads [182].

Other bio-mechanical characterizations of actin network's properties concern the study of its gel-like viscoelastic properties. In particular, transitions between a solid-like elastic material and a solution-like viscous material have been observed [73]. These could rely in part on



Cytoskeleton and Cell Motility, Figure 13
***Listeria* bacteria moving in a cell via actin-based motility. the biochemical-dependent mechanical properties of the actin filaments themselves [119], on the generic properties of such semiflexible-filament networks [75], or on the activity of motor proteins that help disentangling the network and thereby lead to its fluidization [106]. It has also been observed that cross-linked actin networks display an increase of their elastic modulus as a function of the stress applied, a nonlinear behavior known as *stress-stiffening* [63,259]. This might explain partly the interestingly rich properties of cellular rheology [99,135], which have been partly reproduced in in vitro measurements [77]. Among these, dynamical scaling of the stress stiffening (see e. g. [76]) has been proposed to be the signature of underlying self-similar mechanical properties of the cell cytoskeleton [18,61]. Finally, the intermediate filaments as well as the biochemical environment or preparation of the actin network have been proposed to play an important role in modulating its rheological properties [75,122]. This might contribute to the observed local changes in the elasticity of the cell as it moves, a crucial aspect for driving its motility [9,73].

Modeling Polymerization Forces

With general thermodynamic considerations, growth velocities of polymerizing filaments can be understood as follows: if k_{on} and k_{off} are the association and dissociation constants for monomers at the polymer tip, and δ is the distance a filament grows under addition of a single monomer, a typical growth velocity of the polymerizing filament is given by: $v = \delta[k_{\text{on}} - k_{\text{off}}]$. When experiencing a force f opposing polymerization, like the cellular membrane resistance at the leading edge of the advancing cell, filament-growth velocity becomes:

$$v(f) = \delta\left[k_{\text{on}} \exp\left(-q\frac{fa_1}{k_B T}\right) - k_{\text{off}} \exp\left((1-q)\frac{fa_1}{k_B T}\right)\right]. \quad (1)$$

In this expression, $k_B T$ represents thermal energy, fa_1 is the most probable work needed to add a monomer in the presence of the force f, and q is a parameter describing how much the force f influences the on-rate as compared to the off-rate. Under these assumptions, the maximal force a given filament can produce via polymerization, or *stall force*, is expressed as $f_s = (k_B T/a_1) \cdot \ln(k_{\text{on}}/k_{\text{off}})$. Even though good overall agreement with experimental data was obtained for individual microtubules while choosing $13a_1 = a$ and $q = 1$ (with a being the size of a tubulin monomer) [50], the so-derived stall force was too large as compared with experimental measurements. This led to revising the dynamics of the microtubule-polymerizing end, proposing $a_1 \simeq a$ and $q \simeq 0.22$ as better fitting parameters, pointing to a rich dynamics of microtubule polymerization [140].

To understand the origin of polymerization forces, the standard microscopic model relies on the ratchet mechanism, a rectified Brownian motion originally introduced in this context by Peskin et al. [219] to explain filopodia protrusion, *Listeria* propulsion as well as protein translocation. Filopodia protrusion in particular is thought to rely essentially on actin-polymerization forces: when reaching the cell membrane, growing F-actin filaments feel a force opposing their growth, and therefore exert a force on the membrane. Because of thermal fluctuations and membrane's as well as actin-filaments' finite bending rigidities, some space is constantly opened between the growing filament and the membrane. From time to time, an additional monomer can thereby be added to the growing filament, which pushes the membrane forward[19]. In the simplest case of a single stiff protofilament, the distribution P of distances x between the filament and the membrane is given by the following Fokker–Planck equation:

$$\begin{aligned}
\partial_t P(x) &= D\partial_x^2 P(x) + f\frac{D}{k_\mathrm{B}T}\partial_x P(x) \\
&\quad + k_\mathrm{on}P(x+\delta) - k_\mathrm{off}P(x) \quad \text{for } x < \delta \\
\partial_t P(x) &= D\partial_x^2 P(x) + f\frac{D}{k_\mathrm{B}T}\partial_x P(x) \\
&\quad + k_\mathrm{on}[P(x+\delta) - P(x)] \\
&\quad - k_\mathrm{off}[P(x) - P(x-\delta)] \qquad \text{for } x > \delta\,,
\end{aligned} \tag{2}$$

where notations are similar to the ones used in Eq. (1), and to which must be added the effective diffusion coefficient D for the distances x between the filament and the membrane. The time-dependence of P is implicit. Using vanishing-current conditions at the leading edge $x = 0$, the stall force can be obtained and is given by an expression analog to that of microtubules models, with $a_1 = \delta$ being the size of a G-actin monomer. Including bending fluctuations of the growing filament, this led to the Elastic Brownian Ratchet Model [195], a generalization of which is the Tethered Elastic Brownian Ratchet Model [197] that considers that some filaments are attached to the membrane via protein complexes (as it has been observed in the *Listeria*-propulsion mechanism for example) and therefore do not exert polymerization forces. When typical parameter values are plugged into these models, single actin-filament force generation is estimated to be of the order of 5–7 pN [198]. Taken into account that at the leading edge several hundreds of actin filaments per micron work together to drive the cell forward, the resulting force is of the order of nanonewtons per micron [197], a force large enough to tackle the membrane load and resistance. However, it has since then been claimed that motor proteins, called *end-tracking motors*, should be required to explain observed forces in the case of *Listeria* propulsion for example [49]. This work has been reviewed in [194].

Lateral interactions between filaments in an actin network have been investigated via models that take into account the branching structure of the network [37,38]. In particular, Autocatalytic Models assume that new branches are generated from existing ones, which leads to a growth velocity that is independent of the load [38]. To investigate the consequences of these models, two approaches have been followed, namely stochastic simulations of the growing actin network, tracking each filament position and orientation [37], and deterministic rate equations that include growth, capping and branching rates, and which led to a comparison between ratchet and autocalytic models [38]. Experimental tests of the two models have been performed in in-vitro systems, using *Listeria* propulsion as well biomimetic systems [271] (see next paragraph). While some *Listeria* studies favored the Tethered Elastic Brownian Ratchet Model [184], some studies using biomimetic systems favored the Autocatalytic Model [285], and several others neither of them. A possible explanation for these apparently contradictory results may be that different experimental studies led to analyzing different regimes of the force-velocity curve.

A Model System for Studying Actin-Based Motility: The Bacterium *Listeria monocytogenes*

As earlier stated, our understanding of eukaryotic actin-based motility has grandly benefited from the motility mechanism of the bacterium *Listeria monocytogenes* (see Sect. "Actin Gels"). While velocities of *Listeria* bacteria in a homogeneous environment are typically constant, some mutants progress in a saltatory manner [155]. This observation has been later reproduced in in vitro motility assays using latex beads coated with the bacterium transmembrane protein ActA (that further recruits Arp2/3) [35], or directly with VCA proteins, a sub-domain of WASP that is responsible for actin-branching and polymerization nucleation [22]. Such biomimetic systems have allowed for the direct measurement of the characteristic polymerization force that is produced by an actin gel [182], and for the overall study of actin-based motility mechanisms in simple and well-controlled conditions [194,222,271].

Theoretical understanding of such actin-based propulsion mechanisms has come from two different angles, namely molecular and mesoscopic, continuum models. We have already reviewed the molecular models that rely on brownian-ratchet mechanisms. They, in particular, have led to force-velocity curves that are consistent with some observations of *Listeria* motion [184,197]. Continuum models describe the actin network as a compressible elastic gel with an elastic modulus of about 5000 Pa [79,182,207] (see also Sect. "Macroscopic Phenomenological Approaches: The Active Gels"). When growing over a curved surface like the bacterium *Listeria* or a coated bead, the gel deforms as it grows by monomer additions on the particle surface, which in turn generates a stress that pushes the particle forward [79,207]. Monomer transport to the inner surface of the growing gel is purely diffusive, with a diffusion constant that has been estimated to be of the order of 2 μm^2/s for actin monomers

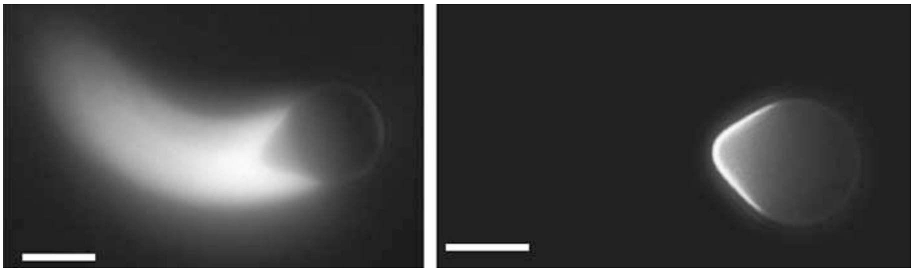
[19] For an animated illustration, see http://www.jhu.edu/cmml/movies/anim/eBRatchet2.swf.

in an ActA-produced gel [221]. When originally initiated on a spherical object like a rigid bead, the growth of the gel layer starts isotropic, but ruptures into a comet-type growth because of mechanical instability. The instability relies on a positive feedback that involves creation of a tensile stress as the gel grows because of geometrical effects, and enhancement of the depolymerization rate or rupture of the gel in regions of enhanced tensile stress [252]. The instability occurs less rapidly with increasing bead size, which explains why movement is more often observed with small beads. This mechanism of tensile-stress accumulation and rupture can also explain the saltatory motion observed with *Listeria* mutants and coated beads in some conditions [22]: rapid phases of motion are due to the sudden rupture of the gel that pushes the particle forward, as slow phases of motion correspond to progressive build-up of lateral tensile stress. Depending on the size of the bead as well as the concentration of proteins at its surface, this dynamic instability can be present or not, which explains the observation of both continuous and saltatory regimes with coated beads as well as *Listeria* bacteria [22,23].

To further explore the properties of the actin gel and the *Listeria*-propulsion mechanism, experiments with soft objects like liposomes [80,270], endosomes [262] and oil droplets [28] have been performed. They show that the actin gel squeezes the object, compressing its sides and pulling its rear, an effect that gives it a pear-like shape (see Fig. 14). Analysis of the contour of the deformed objects provides informations on the distribution of the normal stress on the surface of the object. This could in principle allow for the derivation of the total force exerted on the load in the case for example of oil droplets, where interfacial tension is measurable and normal stress can be deduced from Laplace's law [28]. But in fact, assuming a constant surface tension, the integration of the normal stress over the surface of the droplet gives a zero net value of the force that is independent of the droplet shape, the latest being regulated by the variation of the polymerization velocity with normal stress. Instead, the distribution of actin-polymerization promoters on the surface of the droplet follows the gel elastic deformations, which in turn creates pressure variations inside the droplet, and thereby surface-tension gradients along its surface (see Fig. 14); and these are at the origin of the final non-zero net pushing force [28]. Finally, direct observation of the actin comet during its growth on coated beads has shown that the actin gel constantly undergoes deformations that depend on the protein composition of the motility medium they are placed in [212]. As a function of bead size and the concentration of cross-linkers or regulatory proteins, the bead velocity can be limited either by diffusion of the monomers to the coated surface, by polymerization velocity at the surface of the bead, or by the elastic stress built up in the gel. These findings, supported by experimental results, buttress the idea that actin-based movement is governed by the mechanical properties of the actin network, themselves tightly regulated by the proteins that are involved in actin dynamics and assembly (see Sect. "Other Cytoskeleton-Associated Proteins").

Another Example of Filament-Driven Amoeboid Motility: The Nematode Sperm Cell

Even though, as described above, protrusion of the leading edge in amoeboid motility is most commonly actin-driven, other cells, the nematode sperm cells, use another cytoskeletal protein to drive their motility: the Major Sperm Protein (MSP) [240]. Nematodes constitute one of the most common phyla of all animal kingdom, with over 80.000 different described species, and their sperm is



Cytoskeleton and Cell Motility, Figure 14
Actin-based propulsion with liquid drops. Oil drops are covered with VCA, placed in cell extracts that are supplemented with actin, and observed by fluorescence microscopy. *Left panel*: Note the bright actin comet and the pear-like shape of the droplet due to squeezing forces exerted by the actin gel. Scale bar is 4 µm. *Right panel*: VCA is labeled with fluorescin isothiocyanate (FITC). Note the inhomogeneous distribution of the actin-polymerization promoter on the surface of the droplet. Scale bar is 3 µm. Source: reprinted from [28] with permission from The American Physical Society

thought to be the only eukaryote cell type that do not possess the globular protein G-actin. These cells offer an ideal to study cell crawling since, dislike actin, MSP is a simpler, more specialized protein that do not possess as many regulatory or associated proteins, and in particular is not known to bind any molecular motor (at the exclusion of end-tracking proteins). MSPs being also apolar [31], the nematode motility constitutes one of the simplest of all cytoskeleton-driven motility mechanisms known to operate in vivo [240,286].

Similarly to what has been done with biomimetic systems to study actin-based propulsion, motility assays using vesicles derived from the leading-edge of nematode sperm cells of *Ascaris* species, have shed light into the mechanisms at play [120]. In the presence of ATP, growth of MSP fibers are capable of pushing the vesicle forward, their polymerization being driven by specialized proteins located within the vesicle membrane, a mechanism that ressembles very much the *Listeria*-propulsion mechanism. But, contrary to ATP-driven actin treadmilling, MSPs assemble into apolar filaments and lack a nucleotide binding site for ATP hydrolysis. To power membrane protrusion, it has recently been proposed that motor end-tracking proteins processively polymerize MSP filaments, while keeping the elongating filaments' ends in contact with membrane-associated proteins [48]. For cell progression however, a second force is required, namely a traction force that pulls the cell body forward once the advancing lamellipodium has been anchored to the substrate on which the cell is crawling. In actin-based amoeboid motility, this process is motor-driven, but nematode sperm cells use instead the sensitivity of their MSP to pH, whose decrease provokes reorganization, depolymerization and in fine contraction of the network [121,187,286]. Polarity in the cell is maintained by an influx of protons close to the cell body, which creates a pH gradient in the lamellipodium and powers this process [137].

To quantitatively understand the mechanism underlying this motility, both microscopic and phenomenological models have been proposed. In the proposed microscopic models, mechanisms underlying the traction-force generation by solely cytoskeletal disassembly can be qualitatively understood as follows [27,286]: because of pH gradient, MSP filaments tend to bundle at the front, and split apart and disassemble at the rear [187]. A bundle with N filaments being much stiffer than N isolated individuals (with an effective persistence length of $N^2 L_p$ as each individual has a persistence length L_p), it pushes the cell membrane at the leading edge where filaments are bundled, while splitting filaments exert contractile forces at the rear. Indeed, because of entropic effects, filaments tend to retract once split apart. Finally, even further decrease in pH creates weakening of the attachments and dissociation of the filaments for monomeric MSPs to be recycled at the front [286] (see also [196]). In the proposed phenomenological approach however [124], the sensitivity to pH is described as influencing the equilibrium swelling properties of the gel only. As the gel treadmills towards the rear end where acidic conditions are found, it tends to contract by an isotropic multiplicative factor Λ that is position-dependent. General elasticity theory of continuous media allows to express the strain tensor as:

$$u_{\alpha\beta} = \tfrac{1}{2}(1 - \Lambda^2)\delta_{\alpha\beta} + \tfrac{1}{2}(\partial_\alpha u_\beta + \partial_\beta u_\alpha)\,, \qquad (3)$$

where u_α are the components of the displacement vector (with $\alpha = x, z$). Assuming linear elasticity theory[20], the stress tensor is then obtained as $\sigma_{\alpha\beta} = \lambda u_{\gamma\gamma}\delta_{\alpha\beta} + 2\mu u_{\alpha\beta}$, where λ and μ are the Lamé coefficients, which further leads to a position-dependent tensile stress as was introduced phenomenologically in [27]. While traveling through the lamellipodium, tangential stress builds up, which leads to rupture of the adhesion points once a critical force has been passed, and eventually drags the cell body forward. Therefore, within this framework, only one parameter is directly controlled by the pH – namely Λ – and the pH in particular does not need to influence directly adhesion strength.

Motor-Driven Motility

Generic Considerations

Despite the major role played by polymerization forces in cellular motility, and in particular as we have previously seen in amoeboid motility, a vast amount of diverse motile processes in eukaryotic cells is driven by motor proteins (see Sect. "Molecular Motors"). Theoretical studies of molecular motors started with the cross-bridge model published independently by A. F. Huxley and H. E. Huxley to explain the relative sliding of myosin filaments with respect to actin filaments in cross-striated muscle fibers [108,112]. This approach was later formalized by Hill [97], who introduced the notion of different "states" of a motor protein, each of these corresponding to a thermodynamic-equilibrium state. Interpretation of these different states was given in terms of different conformations of the motor protein and its interaction with the filament, or in terms of the state of the hydrolysis reaction of ATP, or both [54,159]. Justification for considering different thermodynamic-equilibrium states relied on

[20] For an introduction to the elasticity of continuous media, see, e. g., [154].

the observation that for the transient response of muscles, the fastest response was known to be in the range of milliseconds, as thermal equilibrium on molecular characteristic length scales of 10 nm occurs after at most a few hundreds of nanoseconds. In this class of models, progression of the motor along the filament relies on asymmetric transition rates of the particle between the different states, for which asymmetry of the filament and energy consumption by the motor is required. Typically, after one cycle of conformational states, the motor protein has progressed by one or several allowed binding sites on the periodic lattice represented by the cytoskeletal filament. In between, up to five or six different states could be involved [97,172]. Experimental confirmation came later with the direct observation of walking steps displayed by advancing molecular motors [258]. Such observations were first obtained studying kinesin motors in in-vitro motility assays, and later with myosin motors displacing a filament that was attached to two glass beads placed in laser-trap potentials [32]. For a review, see [246].

Another class of models relies on the generalization of Feynman's famous "thermal ratchet", in which the presence of different heat baths (namely thermal baths at different temperatures) can rectify the brownian motion of a given particle and lead to its directed motion [64]. For motor proteins, as we have already discussed, temperature inhomogoneities in the system cannot hold long enough to ground the mechanism. Instead, various different isothermal rectifying models have been discussed to describe the underlying mechanisms of different biophysical processes [13,177]. Among these, one can mention the translocation of proteins and force-generation by linear molecular motors (which includes cytoskeletal motors, but also motors acting on DNA or RNA, like DNA-polymerases, RNA-polymerases and helicases), the ion transport in ion pumps, and the rotary-motor processes such as the one found in the F0F1-ATPase or the bacterial flagellar motor. Such isothermal rectifying processes and their underlying physical principles have been extensively reviewed in [129,233]. They all rely on a Langevin type of description of an overdamped particle of position x, moving in a spatially-periodic potential $W(x)$ that reflects the motor-filament interaction, and subjected to a viscous friction with coefficient ξ and a fluctuating force $f(t)$ that reflects the stochasticity of thermal fluctuations:

$$\xi \frac{\mathrm{d}x}{\mathrm{d}t} = -\partial_x W(x) + f(t) \,. \tag{4}$$

To rectify brownian motion, three different approaches have been mainly followed, namely (i) random forces $f(t)$ whose fluctuations do not satisfy the fluctuation-dissipation (FD) relation, (ii) fluctuating potentials $W(x,t)$ that are time-dependent, and (iii) particle fluctuating between states, where different states indexed by $i = 1, \ldots, N$ reflects different conformations of the protein and interactions with the filament.

In the following, no attempt will be made to extensively present the literature on molecular motors. We shall instead only briefly sketch the generic considerations of the main proposed models, and focus more closely on a particular example of them, the two-state model, which has allowed for an understanding of the appearance of spontaneous oscillations in systems of coupled motors. This generic mechanism has been proposed to underly axonemal beating, the generic mechanism that powers eukaryotic flagellar and ciliary-based motilities.

Phenomenological Description Close to Thermodynamic Equilibrium

Sufficiently close to thermal equilibrium, out-of-equilibrium perturbations can be described using a generic linear-response theory that introduces generalized forces which drive generalized currents [45]. In the context of molecular motors, the generalized forces that drive the system out of equilibrium are the mechanical force f_{ext} acting on the motor (including drag), and the chemical-potential difference $\Delta\mu$ of the chemical reaction ATP $\rightleftharpoons$ ADP + P_i that drives motor power [129,217]. Linear-response theory then gives:

$$v = \lambda_{11} f_{\text{ext}} + \lambda_{12} \Delta\mu \tag{5}$$

$$r = \lambda_{21} f_{\text{ext}} + \lambda_{22} \Delta\mu \,, \tag{6}$$

where the coefficients λ_{ij} are phenomenological response coefficients. Here λ_{11} and λ_{22} can be viewed respectively as a standard and generalized mobilities, and λ_{12} and λ_{21} as mechano-chemical couplings. Onsager relations impose that $\lambda_{12} = \lambda_{21}$, and the Second Law of Thermodynamics insures that the dissipation rate is positive: $T\dot{S} = f_{\text{ext}} v + r\Delta\mu \geq 0$. Whenever both of the two terms that appear in this inequality are positive, the system is passive, but it works as a motor when $f_{\text{ext}} v < 0$, and as generator of chemical energy when $r\Delta\mu < 0$. The latter function is not known for linear motors, but is the common mode of operation of F0F1-ATPase, the protein complex that synthetizes ATP from electro-chemical energy that is stored in proton gradients [5,290] (see Sect. "Molecular Motors"). The reversibility of this rotary engine can be related to the predicted reversibility that comes out of linear-response theory: in the absence of an external force, reversing the chemical potential difference $\Delta\mu$ should reverse the sign of the velocity v without a need for a change in the mechanism.

Hopping and Transport Models

Within the first class of models that we have mentioned earlier, namely hopping models between different discrete equilibrium states of the motor-filament system, generic transition rates and periodicity in theses transition rates, related to periodicity of the filament, are generally assumed. Within this framework, one can calculate the mean velocity v and the diffusion coefficient D of the molecular motor from analyzing the generic associated Master Equation [46]. For non-zero mean velocity to occur, at least one of the transitions between states must break detailed balance, a feature that can be associated with chemical energy consumption. In the simplest case of only two possible states of the motor protein, one can derive simple compact expressions for v and D [66]. Their dependence on the external force further leads to the derivation of the force-velocity curve, as well as a simple expression for the stall force, namely the force at which the motor protein ceases to progress on average.

To describe protein trafficking on a filament where many motors are simultaneously engaged, like it is commonly the case for example in organelle transport by kinesin proteins along microtubules, one can reduce the number of states that a motor can occupy to one per filament binding site. Motors are then represented by particles that move on a one-dimensional lattice with homogeneous transition rates, to which attachment and detachment rates from and toward the bulk can be added. This description belongs to a class of driven lattice-gas models that are used to study various transport phenomena, like ionic transport in solids or traffic flow with bulk on-off ramps [247]. In the simplest case of the absence of particle attachment and detachment, the model reduces to the Asymmetric Simple Exclusion Process (ASEP) [250], originally introduced to describe the translation of messenger RNA by ribosomes [173]. Including attachment-detachment rates, the next simplest case describes the space surrounding the filament as a reservoir of uniformly-distributed particles [147,216]. A second possibility is to include the dynamics of unbound particles explicitly, for example on a cubic lattice [161]. Boundary terms can also play an important role, and different possible choices have been considered depending on the biological situation [138].

Consequences of these models are illustrated by various important phenomena. Among these, one can find the followings: anomalous transport due to repeated attachments and detachments [4,161,205], domain walls that separate regions of high and low motor densities in the filament [161,216], phase separation in systems with two motor species [60], and phase transitions when cooperative binding-unbinding is introduced [139]. For a recent review on these collective traffic phenomena, see [40] and references therein.

The Two-State Model

One model that proved to be particularly useful for describing the rectification of brownian motion via coupling to chemical hydrolysis reactions, is the so-called “two-state model”. In this description, the molecular motor switches stochastically between two different interaction states with the filament, that are described by two different asymmetric and l-periodic potentials W_1 and W_2 representing polarity and periodicity of the filament [14,15,128,129,178, 217,218,227] (see Fig. 15a). The dynamics of this system can be conveniently represented in terms of two coupled Fokker–Planck equations that describe the evolution of the probability density $P_i(x,t)$ of the motor to be in state $i = 1,2$ at position x at time t. Explicitly, we have:

$$\begin{aligned} \partial_t P_1 + \partial_x J_1 &= -\omega_1 P_1 + \omega_2 P_2 \\ \partial_t P_2 + \partial_x J_2 &= \omega_1 P_1 - \omega_2 P_2 \,. \end{aligned} \tag{7}$$

The currents $J_i (i = 1,2)$ result from diffusion, interaction with the potentials W_i, and the external force f_{ext}:

$$J_i = \mu_i [-k_B T \partial_x P_i - P_i \partial_x W_i + P_i f_{\text{ext}}] \,. \tag{8}$$

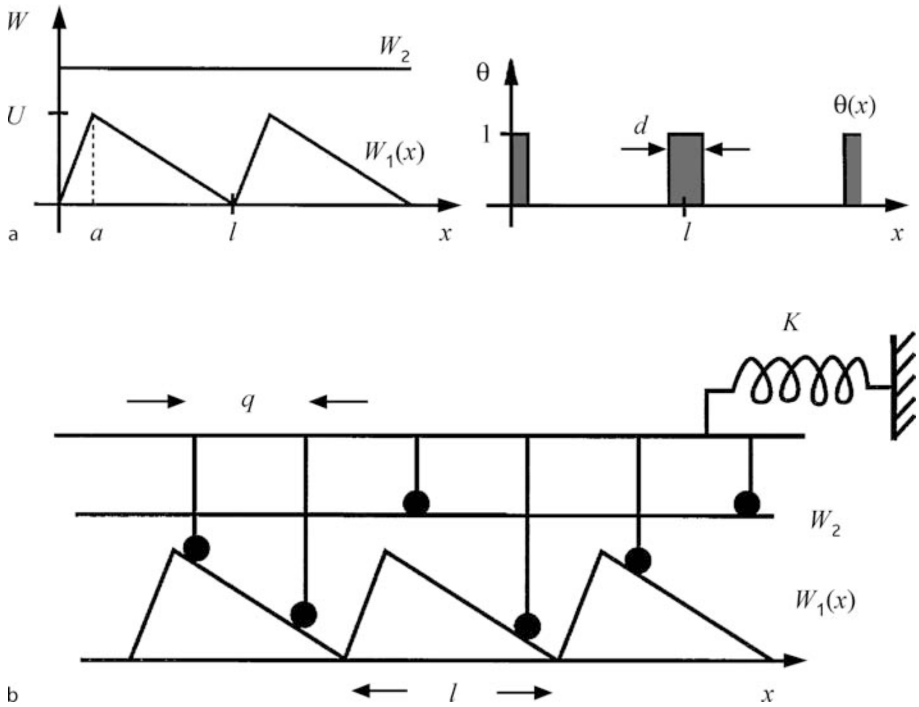
The transition rates $\omega_i(x) (i = 1,2)$ between the two states are driven out of equilibrium by ATP consumption, whose strength can be represented by a single parameter Ω using the following form:

$$\omega_1(x) = \omega_2(x) \exp\left[\frac{W_1(x) - W_2(x)}{k_B T}\right] + \Omega\Theta(x) \,, \tag{9}$$

where $\Theta(x)$ is a l-periodic function of integral one over one period. For $\Omega = 0$, detailed balance is satisfied. Within this formalism, it has been shown that both spatial symmetry and detailed balance need to be broken for directed motion to occur, which has been quantified in terms of an effective potential W_{eff} [227].

Coupled Motors and Spontaneous Oscillations

Directly interesting for eukaryotic cellular motility driven by cilia and flagella, is the motion of motors with respect



Cytoskeleton and Cell Motility, Figure 15

Schematic representation of the two-state model as used in [128] for the calculation of the collective behavior of rigidly-coupled non-processive motors. a, *left panel*: W_1 represents the attached state of the motor to the filament and is therefore asymmetric and *l*-periodic; W_2 represents the detached state where no interaction with the filament occurs. a, *right panel*: Illustration of the *l*-periodic function Θ (*x*) as it appears in Eq. (9) and which represents ATP consumption in the system, here at preferred locations of the motor on the filament, or at preferred configurations of the motor protein for ATP hydrolysis. b Schematic representation of a collection of rigidly-coupled motors with periodicity *q* interacting with the filament, and coupled to its framework by a spring of stiffness *K*. Under some conditions, this model leads to spontaneous oscillations. Both structures and behaviors are reminiscent of skeletal-muscle myofibrils' oscillations or axonemal beating (see Sect. "Axonemal Beating"). Source: reprinted from [128] with permission from The American Physical Society

to their associated cytoskeletal filament when a collection of them is rigidly coupled. Such structures are typical of skeletal-muscle structures (where Myosin II motors associate into the so-called "thick filaments"), or of the axonemal structure that drives oscillatory motions in cilia and flagella. Such systems have been studied using the two-state thermal-ratchet model [127,128], and a crossbridge model [30,97,108,112,279,280]. Here we shall discuss essentially the case of an ensemble of motors that are rigidly linked to each other and walk collectively on a cytoskeletal filament whose interaction with the motors is described by the two-state model [129]. In the case of randomly distributed motors, or motors distributed periodically with a period q that is incommensurate with the filament period l, the probability density $P(\xi, t)$ of finding a particle at position $\xi = x \bmod l$ in either state $i = 1$ or 2, approaches the value $1/l$ in the case of an infinitely-large number of motors. In a mean-field approximation, equations of motion for the probability densities read:

$$\begin{aligned}\partial_t P_1 + v\partial_\xi P_1 &= -\omega_1 P_1 + \omega_2 P_2\\ \partial_t P_2 + v\partial_\xi P_2 &= \omega_1 P_1 - \omega_2 P_2\ .\end{aligned} \tag{10}$$

The force-velocity curve can then be computed using the fact that $f_{\text{ext}} = \eta v - f$, where f_{ext} is the external force applied, η is the friction coefficient per motor protein, and f is the force per motor protein exerted by the potentials:

$$f = -\int_0^a \mathrm{d}\xi (P_1 \partial_\xi W_1 + P_2 \partial_\xi W_2)\ . \tag{11}$$

Expressing P_2 as $P_2 = 1/l - P_1$, and P_1 as a series expansion in powers of the velocity v, one finds a generic series expansion for the force-velocity curve f_{ext} as a function of v in the steady state. As a function of the distance to thermal equilibrium Ω, controlled by ATP consumption by the motors, and which appears as a control parameter for the dynamics with a critical value Ω_c, the curve $f_{ext}(v)$ can be strictly monotonic for $\Omega \leq \Omega_c$, or present some multi-valuated regions for $\Omega > \Omega_c$, where two stable velocity regimes exist for a given external force. For symmetric potentials, the system is quiescent with $v = 0$ at zero force for $\Omega \leq \Omega_c$, but present two possible opposite spontaneous velocities for $\Omega > \Omega_c$, a spontaneous symmetry breaking that is characteristic of second-order phase transitions with characteristic mean-field exponents. Such a reversible spontaneous movement has been observed in a motility assay with NK11 proteins, a mutant of the kinesin protein Ncd that has lost its directionality [55]. In addition, when the external force is varied, a hysteresis is found for $\Omega > \Omega_c$, an experimental observation of which has been reported for a myosin II motility assay under near-stalling conditions induced by electric fields [239]. Numerical simulations of both situations have been performed using the two-state model with a finite number of motors and in the presence thermal noise [17].

Axonemal Beating

The previous and related models have been used to describe the spontaneous oscillations that have been observed in skeletal-muscle myofibrils' oscillations or axonemal beating [72,209,287]. In these cases, it has been proposed that the coupling of the motor backbone to a spring prevents spontaneous steady-state velocities to occur, but instead leads to spontaneous oscillations [128] (see Fig. 15b). In the case of axonemal beating, of most relevance for eukaryotic cell swimming, the elastic force results from bending of the microtubules and leads to self-organization of the dynein motors. This collective behavior has been proposed to explain the bending waves of cilia and flagella [30,176] and analyzed in the framework of the two-state model [33,34]. Close to the oscillatory instability, wave-patterns can be computed, whose frequencies and shapes depend on the filament length and boundary conditions, and which are in good agreement with observed flagellar beating patterns [278].

In the case of cilia however, beating patterns are typically assymetric, like it is at best exemplified in the case of the two cilia of the green alga *Chlamydomonas* [29], an observation that cannot be accounted for by investigating beating patterns at the oscillatory instability only. Using the same underlying model, it has been proposed that this assymetry originates from the presence of transverse external flow that occurs as the organism is swimming [89]. In that case, the cilium tends to beat faster and quite straight in the direction of the flow, whereas it comes back slower and more curved against it, a beating pattern that evokes power and recovery strokes. Hydrodynamics has also been proposed to be responsible for dynamic coupling of adjacent cilia, which results in both spontaneous symmetry breaking and synchronization of their beating pattern [89]. This effect could be at the basis of the observed beating waves that propagate for example on the surface of *paramecia*[21] as they swim, which originate from a constant phase difference in the beating of the adjacent cilia, and which have been called *metachronal waves* [29,88,89]. This could also underly the breaking of symmetry that occurs in mammalian development during gastrulation, and which is responsible for left-right asymmetry. In that case, it has been shown that beating of cilia located in a transiently-formed epithelial chamber known as the *node*, create a directional flow which transports signaling molecules preferentially to one side [29,117,185]. There, beating patterns are unusual in that cilia swirl in vortical fashion rather than beat [208], and hydrodynamic-driven synchronization of these three-dimensional beating patterns has also been studied [281].

Putting It Together: Active Polymer Solutions

The last part of this review is devoted to the presentation of some generic descriptions of the cell cytoskeleton, when considered as a network of long protein filaments that are cross-linked by a variety of smaller proteins. As already discussed, filamentous proteins that are involved in the cell-cytoskeleton dynamics are mostly F-actin and microtubules (made of G-actin and tubulin monomers), with which interact cross-linkers that can be either passive and stationary (such as α-actinin), or active and mobile, consisting then of clusters of molecular motors (mostly myosin and kinesin motors) (see Sect. "The Cell Cytoskeleton"). To model these systems, different complementary approaches have been developed, namely computer simulations [202,203,260], and analytical descriptions that can be roughly divided into three categories, namely microscopic, mesoscopic, and macroscopic or phenomenological hydrodynamic descriptions. The first analytical approaches that have been developed correspond to mesoscopic descriptions. There, starting from a microscopic description of the filaments, the effect of active cross-linkers is described via motor-induced relative velocities of paired filaments, where the form of such velocities is inferred from general symmetry considerations [144,145,148,201,251]. Microscopic approaches start from what is known about the properties of the different molecular players involved and their interactions, and aim

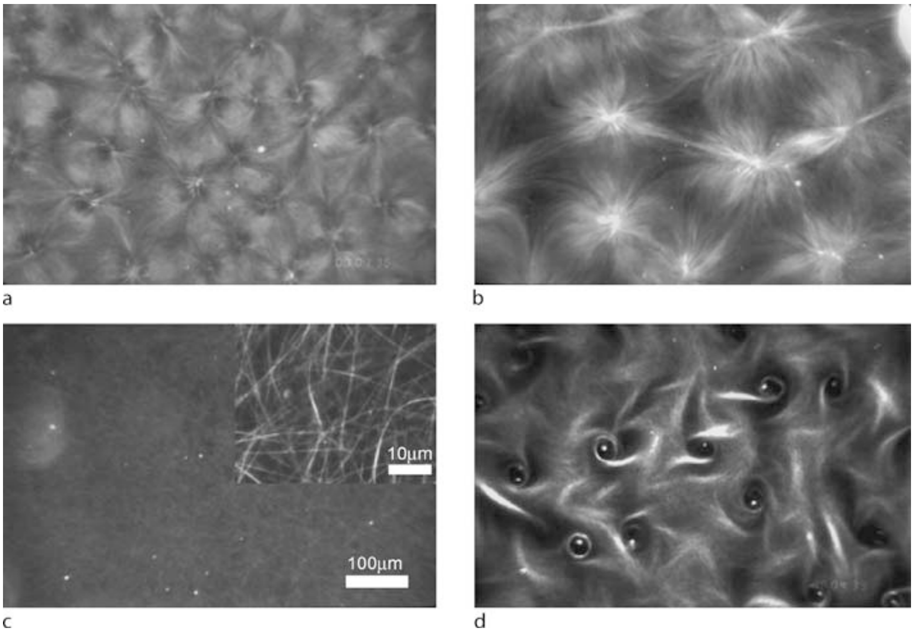
[21] An illustration of a paramecium can be seen in Fig. 1, center.

to build large-scaled coarse-grained theories from statistical physics' principles [2,3,11,12,146,165,166,168]. Finally, macroscopic hydrodynamic approaches have adopted a more phenomenological point of view: they harness the generic symmetry and dynamical properties of the players involved, to derive directly effective continuous theories in terms of a few coarse-grained fields [94,125,130,150, 151,152,157,231,245,254,267,282,295]. Recently, attempts have been made to bridge microscopic to macroscopic models, and compare what results in being similar and different in the two types of approaches [3,164,166].

Interests for describing the cytoskeleton as an ensemble of filamentous polymers actively connected by crosslinkers have come to the scene since self-organizations of motor-filament mixtures were observed experimentally [203,260,272]. Among these, complex patterns that include asters, vortices, spirals and connected poles or networks have been observed in confined quasi-two-dimensional systems in in vitro experiments [203,260] (see Fig. 16). Patterns where shown to be selected in a way that is dependent on motor and ATP concentrations, and numerical simulations based on microscopic models of rigid rods connected by active elements have shown to be capable of reproducing the experimental results [260]. Further experiments were performed on systems that resemble more closely a living cell, and which, while being simplified versions of it, still exhibit some of its behaviors. Along these lines, formations of bipolar spindles that do not contain any microtubule-organizing center were observed using cell extracts [116], and cell fragments that contain only the actin cortex where found to self-propagate on a substrate, with coexistence of locomoting and stationary states [59,277].

Mesoscopic Approaches

Theoretical modeling of the cell cytoskeleton have benefitted from the knowledge accumulated in equilibrium statistical physics of polymer solutions and liquid crystals [44]. However, the cell cytoskeleton is an active medium for which new analysis techniques needed to be developed in order to describe, for example, its ability to actively self-organize, exert forces and create motion. First, theoretical models have aimed to describe pattern formations in sys-



Cytoskeleton and Cell Motility, Figure 16

Different large-scale patterns formed through self-organization of microtubules and kinesin motors as reported in [203]. Initially uniform mixtures of proteins heated to 37°C displayed different patterns after 7 min of self-organization. Patterns are shown at equal magnification; the samples differ in kinesin concentration. a A lattice of asters and vortices obtained at 25 g ml^{-1} kinesin concentration. b An irregular lattice of asters obtained at 37.5 g ml^{-1} kinesin concentration. c Microtubules form bundles at 50 g ml^{-1} kinesin concentration (scale bar, 100 µm); insert: at higher magnification (scale bar, 10 µm). d A lattice of vortices obtained at a kinesin concentration smaller than 15 g ml^{-1}. tems of actively-driven rigid filaments in one-dimensional geometries [144]. Such configurations are represented in vivo for example by stress fibers that are important for cell-force generation, contractile rings that form during cytokinesis, or the formation of filopodia for forward protrusion during amoeboid motility. There, dynamical equations that govern individual filaments were introduced using "mesoscopic" mean-field models, where the relative sliding of paired polar filaments is described by an effective relative velocity that is induced by many individual events of motor activity. General constraints on these relative velocity fields are imposed by symmetry considerations that rely on the orientational polarity of the filaments (see, e. g., [144]). In such systems, polarity sorting [201], contraction [144,251], as well a propagating waves [148] emerge from the models. Interestingly, it has been shown that relative velocity of filaments of the same orientation is important for contraction to occur [144], a phenomenon that has been suggested to rely on motor-density inhomogeneities along the filament that create inhomogeneous filament interactions along their lengths [147]. More generally, the whole bifurcation diagram of this generic one-dimensional model has been established, and motor-distribution dynamics has been introduced that lead to contractile states with the generation of contractile forces, of most relevance for stress fibers' as well as contractile rings' dynamics [145]. Interestingly, the simplest version of these models, when only one possible polymer orientation is considered, has been mapped to hopping models that describe driven-diffusive systems [199]. In the absence of active cross-linkers, the model reduces to a class of hopping models known as the Zero Range Process (ZRP), for which exact analytical solutions of the steady state as well as one-dimensional phase transitions have been described [92]. In the generic case however, the dynamics defines a new class of driven-diffusive systems, which can still be mapped in some cases to the ZRP analytic solution, even though with a different criterium for condensation to occur [199].

Microscopic Approaches

Microscopic approaches to describing the cell cytoskeleton dynamical behavior model explicitly all the considered different processes and interactions that occur between the different molecular players, and aim to derive effective dynamical equations for the different density fields that enter the description, by coarse-graining the microscopic dynamics. Most studies that have done so model the motor-filament system as an ensemble of rigid rods of fixed lengths, which interact via point-like cross-linkers that can induce relative sliding as well as rotational motions [2,3,146,165,166]. Exceptions to this rule are theoretical descriptions of the mechanical response of active-filament solutions to high frequency stimuli [162,168]. There, anomalous fluctuations occur that are dominated by the bending modes of the filaments in combination with the activity of the cross-linkers. Inspired by polymer physics at thermodynamic equilibrium, excluded-volume interactions as well as entanglements are taken into account in the description. In particular, the system exhibits accelerated relaxation at long times due to directed reptation that relies on active phenomena.

Attempts at deriving the motor-mediated interaction between filaments from microscopic descriptions have been performed in [2,3,11,12,165]. See also the review [163]. In [11,12], a generalization of the Maxwell model of binary collisions in a gas is used to describe the dynamics of polar rods whose inelastic and anisotropic interactions reflect the presence of active crosslinkers. Orientational instabilities lead to bundling as well as the formation of asters and vortices patterns. In [2,3,165], filaments are described as rigid rods of fixed length, and hydrodynamics is obtained by coarse-graining the Smoluchowsky equation for rods in solution, coupled via excluded-volume and motor-mediated interactions. There are two main motor-mediated mechanisms for force exchange among filaments. First, active crosslinkers induce bundling of filaments, building up density inhomogeneities. Second, they induce filament sorting as a function of their polarization state. As a result, phase diagrams are derived that show instabilities of the homogeneous states at high filaments' and crosslinkers' densities. In particular, all homogeneous states are rendered unstable by the same mechanism of filament bundling, a fact reminiscent of the effect described in [144] where the interaction between filaments of the same orientation has been shown to be important for contraction to occur. Interestingly, the broken directional symmetry of the polarized state yields an effective drift velocity that describes filament advection. This convective-type term describes a genuine out-of-equilibrium contribution that is structurally not present in phenomenological descriptions based on systematic linear expansions close to thermodynamic equilibrium (see below). Such a term is reminiscent of the one introduced in earlier studies of self-propelled nematic particles [230,254,267], as well as of the explicit flow of the solvent taken into account in [150,151,282]. Other effects of higher-order nonlinear terms have also been discussed in [292,293], where pattern selection between stripe patterns and periodic asters occurs via nonlinear interactions.

Macroscopic Phenomenological Approaches: The Active Gels

The third category of approaches that have been developed to try to understand the dynamical behavior of the cell cytoskeleton as a whole, are effective phenomenological theories which rely on the hypothesis that large length- and time-scales behaviors of the cytoskeleton are largely independent of the microscopic details that underly its dynamics, but depend instead only on a few macroscopic fields that capture the relevant behavior. Sufficiently close to thermodynamic equilibrium, these relevant fields describe the *hydrodynamic modes* (or *slow modes*) of the dynamics, namely the modes whose relaxation rates go to zero at long wavelengths. As for equilibrium systems close to a critical point, such hydrodynamic modes correspond to the *conserved densities* on the one hand, and the *order parameters* that break continuous symmetries on the other hand [45,100]. To write generic theories for the dynamics of these hydrodynamic modes, standard approaches consist in writing systematic expansions in the different couplings that are allowed by the symmetry properties of the system. In the vicinity of a critical point, which occurs generally when a continuous symmetry is spontaneously broken after a second-order phase transition has been traversed, the concept of renormalization group has given a theoretical framework to identify universality classes: starting from the full nonlinear expansions of the underlying stochastic dynamics, only a few relevant parameters matter for the asymptotic scaling laws that occur at the transition [65,100,294]. Even though originally developed to study equilibrium critical points, the renormalization-group concept has allowed for the characterization of some out-of-equilibrium universality classes (see e. g. [70,238,261] and the review [98]).

Away from such remarkable points however, any term allowed by symmetry in a systematic expansion is a priori relevant. The standard approach for systems close to thermodynamic equilibrium consists in writing generalized thermodynamic forces and fluxes that are related to each other by linear-response theory. Constraints on the generic coupling constants to linear order emerge from the spatio-temporal symmetries of the system, and correspond to the Onsager relations and the Curie principle [45]. Inspired by the dynamics of liquid crystals [44,183], a hydrodynamic theory has been developed that describes the cytoskeleton as a visoelastic polar gel, driven out of equilibrium by a source of chemical energy [150,151,152,282,295] (this work has been reviewed in [130]). Among other applications, such or similar approaches have been applied to the description of pattern formation in motor-microtubule mixtures [157,245], as well as the collective dynamics of self-propelled particles [52,94,254,267].

Originally, this hydrodynamic theory has been presented as a generic theory for active viscoelastic materials made of polar filaments, referred to as *active polar gels* [151]. Within the framework of the previously-described general formalism, here applied to the cytoskeleton, conserved quantities are the different number densities that enter the dynamics, namely the number densities of subunits in the gel, of free monomers, and of respectively bound and unbound motors to the filaments. To these must be added the solvent density and the total mechanical momentum. Source terms in the conservation equations correspond to polymerization and depolymerization of cytoskeleton filaments, attachment and detachment of motor proteins to the filaments, and the potential presence of an external force. Order parameters correspond to orientational order parameters that originate from the polarity of the filaments. Namely, they correspond to momenta of the local polarization vector of individual filaments $\boldsymbol{u}$, and most often only the first momentum $\boldsymbol{p} = \langle \boldsymbol{u} \rangle$ is considered that represents the locally-averaged polarity in the gel[22]. To these must be added a crucial parameter that drives the system out of equilibrium, and which originates from the actively-maintained source of chemical energy in the cell, corresponding to out-of-equilibrium concentrations of ATP versus ADP and P_i. This parameter $\Delta\mu$ is expressed as the difference in chemical potentials of ATP versus ADP plus P_i: $\Delta\mu = \mu_{\mathrm{ATP}} - (\mu_{\mathrm{ADP}} + \mu_{\mathrm{P}_i})$. After identification of the different conjugated generalized fluxes and forces, that are split into dissipative and reactive parts as a function of their properties under time-reversal symmetry, the constitutive equations that specify the dynamics are written in terms of a generalized Maxwell model, which describes the viscoelastic dynamical properties of the gel. Under its simplest form and for nonpolar viscoelastic gels, the Maxwell model writes

$$\left(1 + \tau \frac{D}{Dt}\right) \sigma'_{\alpha\beta} = 2\eta \left(v_{\alpha\beta} - \frac{1}{d} \delta_{\alpha\beta} v_{\gamma\gamma} \right) + \bar{\eta} \delta_{\alpha\beta} v_{\gamma\gamma} \,, \tag{12}$$

in d dimensions. Here $v_{\alpha\beta}$ and $\sigma'_{\alpha\beta}$ are the symmetric parts respectively of the velocity-gradient tensor $\partial_\alpha v_\beta$ and the viscous stress tensor, η and $\bar{\eta}$ are respectively the shear and bulk viscosities, and $\tau = E/\eta$ is the viscoelastic relaxation time that is related to the Young elastic modulus E

[22] The next momentum $q_{\alpha\beta} = \langle u_\alpha u_\beta - d^{-1} \, \boldsymbol{p}^2 \, \delta_{\alpha\beta} \rangle$, where d is the dimension of space, is a symmetric traceless tensor of order two that corresponds to nematic order.

and to the shear viscosity η. This relaxation time describes the crossover between an elastic behavior at short times that resembles that of a solid gel and a viscous behavior at long times that resembles that of a fluid[23]. Finally, D/Dt represents a convective corotational derivative that takes into account invariance with respect to translations and rotations in the system. In the general framework of active polar gels close to thermodynamic equilibrium, generic linear couplings are added to this model following the general procedure described above. Extensive presentations of the complete formalism can be found in refs. [130,151], which also include discussions about its limitations and some of its possible extensions. In particular, in [130], extensions that aim to include the contributions of rotational viscoelasticity, of some nonlinear couplings and of passive as well as active sources of noise are briefly discussed. The main developed extension so far concerns the generalizations of this formalism to multi-component active gels that are now being developed [125,167]. These allow in particular to take into account the possible permeation of the cytosol through the cytoskeletal gel, which affects force balance in the system, and which might be of importance for cell motility.

Despite its recent development, this generic theory of active polar gels has been applied to the description of some systems that are of particular relevance for cell motility or experimental situations observed in vitro. Its first application was the study of topological defects in the polarity field of the gel that lead to the formation of patterns such as asters, vortices and spirals [150]. As a function of two dimensionless parameters representing the relative strength of the coupling to the chemical potential $\Delta\mu$ and to the bend and splay moduli of the polar gel, a phase diagram was derived where vortices and asters give rise to rotating spirals via dynamic instabilities. These relate to the spatial patterns that have been observed in vitro [203,260], as well as to the creation of spontaneous motion, of most relevance for cell motility. In a different geometry, namely a cylinder of finite diameter and length, the formalism has been applied to establish a phase diagram of ring formation that contains phases of one or multiple rings, and which can be quiescent or oscillating [295]. This is relevant for understanding the formation and localization of cortical rings that form prior to cytokinesis and for which double-ring formation has been observed with certain plant cells [84]. To understand the generation of active flows that might be of relevance for cell crawling, a generic phase diagram has been derived for a two-dimensional active polar film that is compressible [282]. Compressibility here might refer to different thicknesses in a three-dimensional incompressible gel that is described in two dimensions after integration of the density fields over its thickness. Within this framework, density fluctuations couple generically to polarity splay, and different topological phases of the gel-polarity organization are found that could correspond to some of the previously-observed patterns in the experimental literature. Finally, the description of spontaneous movements of thin layers of active gels has been applied to the study of cell locomotion on a solid substrate that occurs via the protrusion of the actin-filled lamellipodium at the leading edge of the cell [152]. Reducing the lamellipodium description to a two-dimensional gel protruding in one dimension, and with a spatially-dependent thickness, the steady-state thickness profile as well as the flow and force fields have been computed. One particularly striking aspect of cell crawling that is described by this formalism is the presence of a retrograde flow of the gel as the cell is crawling. This aspect has been quantified in earlier experiments performed on fish epidermal keratocytes [275]. It has been shown that while the cell is crawling, treadmilling of actin filaments happens faster than global motion of the cell, such that the actin cortex is moving rearward with respect to the substrate, in a direction opposite to the movement of the cell [42,131,160]. Similar questions have been addressed using different theoretical frameworks in [7,142,242].

Comparisons of the Different Approaches to Describing Active Polymer Solutions

With these different ways of approaching the description of the dynamics of the cell cytoskeleton as a whole, a natural question is to ask to what extent these different approaches are similar and different, and which aspects of the cytoskeleton or cell behavior can be or not described by each of the theories. For answering these questions, connections between the different approaches have been made, first between mesoscopic and hydrodynamic descriptions [149,164]. In [164], a generalization of the mesoscopic model introduced in [144,148] is developed to obtain a set of continuum equations in unconfined geometries. A phase-diagram is derived that results from the stability analysis of the homogeneous state of actively crosslinked polymers, taking into account excluded-volume interactions and estimates of entanglement in two and three dimensions. It is found that an instability occurs as the bundling rate between filaments of the same orientation is

[23] Note that only one relaxation time is assumed to characterize the system, as some experiments suggest that a power-law distribution of relaxation times is better suited to describe cytoskeleton dynamics, potentially because of some scale-invariant dynamical properties in the system [18,61].

increased, which at low filament density happens first via a density-fluctuation instability, and at high filament density via an orientational-fluctuation instability. In the presence of a finite sorting rate between filaments of different orientations, propagating modes appear that reflect oscillatory behavior. In [149], the continuum theory is related to nonlocal descriptions of filament-motor systems, since filaments can transmit stresses over finite distances. The effective parameters of the continuum theory are recovered from the previously-published mesoscopic description [144], even though with missing coefficients that are thought to correspond to microsocpic multi-particle interactions, not described in [144]. Effects of polymerization-depolymarization dynamics via effective source and sink terms in the local filament densities are also discussed (see also [125,167]) – like it is the case in the effective macroscopic theories – as well as the role of polarity. In particular, it is found that nonpolar arrangements of filaments do not exhibit oscillatory instabilities and propagating modes, which might be of relevance for muscle sarcomeric structures. As seen previously, in these systems, spontaneous oscillations that have been observed correspond more to oscillatory instabilities of rigidly-coupled collective motors than to solitary-wave solutions, as they are found in systems of active polar filaments.

Microscopic theories present the advantage of being able in principle to give rise to a full description of a given system with arbitrary precision and specificity, and to take into account the nonlinear effects that are of direct relevance for the system's behavior. However, they rely on the microscopic knowledge that one has on the system under consideration, and are therefore limited by the available information on the different agents. In addition, they end up with effective descriptions that are model-dependent, in that the different parameters of the so-obtained theory, which describe its physical behavior, depend on the interactions that are taken into account at the microscopic level. Also, an important aspect of active cytoskeleton dynamics that is usually not described in such microscopic approaches is the very important phenomenon of treadmilling that relies on polymerization-depolymerization dynamics of cytoskeletal polymers, and which we have seen to be of crucial importance for some mechanisms of cellular motility such as *Listeria* propulsion or nematode-sperm-cell locomotion (see Sect. "Filament-Driven Motility"). However, despite the absence of these effects, which are taken into account effectively in macroscopic hydrodynamic descriptions, such microscopic approaches allow for the derivation of the forces exchanged between the motors and the filaments from microscopic knowledge, while they appear as effective parameters of unknown explicit origin in effective macroscopic descriptions. Thereby, questions can be addressed that concern the role played by the specific physical properties of motor-filament interactions at the microscopic level in controlling the system behavior on large scales. Indeed, the richness of the observed self-organized structures raises the question of how much is generic, and how much is specific in cytoskeleton behavior. For example, experiments have shown that very different self-organizing structures occur with processive as opposed to non-processive motor proteins: at high motor concentrations, microtubule-kinesin mixtures self-organize in a variety of spatial patterns [203,260], as homogeneous states are more robust with acto-myosin systems [106], an effect that can be thought of as the influence of motor processivity on the dynamical large-scale parameters [164].

Extensions and Future Directions

Cell motility is a complex and integrated process that relies on self-organization of the cytoskeleton, carefully and precisely orchestrated by the cell with the help of numerous different types of molecular players. If one includes the subcellular movements that are responsible for intracellular traffic and material exchange between the inner parts and external parts of the cell, cell-motility mechanisms are found to ground the activity of all life forms on earth. When looked under the microscope, motility mechanisms and structural changes of the diverse cell types appear so vast and various that a comprehensive understanding of their underlying mechanisms seems to be an overwhelming challenge. However, as we have seen from the literature covered in the present article, our understanding of cell motility has tremendously progressed over the past two decades. On the one hand, complexity has even further emerged, since the biochemical characterization of the molecular players involved has revealed that at least hundreds of different protein types participate in the structural and dynamical organization of the cell cytoskeleton. On the other hand, despite the existence of such very complex regulation processes that rely on the integrated interplay of the whole set of different molecular players, the characterization of the cell cytoskeleton has revealed that its main structures and functions are due to just a few types of key proteins, namely three types of biopolymers and three superfamilies of molecular motors. Even more striking is the evolutionary conservation of the main molecular players involved in building the cytoskeleton dynamical filaments, both within the eukaryotic domain of life on the direct sequence point of view, and even across the three domains of life when structural and functional properties are considered. These striking observations indicate that the different underlying mechanisms of cell motility all rely on generic principles that can be understood on a biophysical point of view. In addition, further help from micro-manipulation and fluorescence-microscopy techniques, as well as the development of simplified systems based on gene-expression control and biomimetic artificial systems, has enabled the experimental biophysical investigation of the different specific aspects of the processes at play.

The theoretical analyses reviewed in this article have shown that central concepts that underly the cytoskeleton dynamics are self-organization and dynamic instabilities, here grounded on out-of-equilibrium nonlinear dynamics', thermodynamics' and statistical physics' principles. Such concepts are at the basis of all the theoretical approaches that have been developed to understand the mechanisms of diverse phenomena such as polymerization-depolymerization force and movement generation, molecular motors' individual behaviors and collective phenomena, as well as the generic behaviors of active-polymer solutions which lead to a description of the cytoskeleton dynamics as a whole. On all of these topics, microscopic as well coarse-grained effective macroscopic approaches have been developed. As already discussed, they both have their advantages, powers and limitations, and represent important complementary steps in the ultimate goal of an integrated description of the universal principles that underly cell motility.

As we have seen in this article, our understanding of cell motility and cell cytoskeleton dynamics has grandly benefitted from the interplay between experiments and modeling, each for its own reasons guiding the other in its directions of investigation. To further understand the integrated processes at play in cell motility, such fruitful interactions will certainly be further required and developed. On the theoretical point of view, bridges between understanding simplified systems or some particular aspects of cell motility and the phenomenon of cell motility as a whole at the global cellular level, have already started being investigated, but further developments of these two different ways of approaching the cytoskeleton dynamics as well as understanding the links that ultimately relate them are required. Another important aspect whose understanding represents a challenge is the potentially crucial role of noise that has been so far most of the time absent from the macroscopic effective theoretical approaches. Indeed, noise in nonlinear dynamical systems is known to potentially have important constructive effects, whose main representatives are stochastic resonance, coherence resonance and noise-induced transitions, as well as the extensive gallery of different spatially-extended phenomena such as array-enhanced stochastic and coherence resonance, or noise-enhanced synchronization of nonlinear oscillators (see e. g. [220]). Such phenomena have already been recognized to play an important role in some biological cytoskeleton-based pattern formations (see e. g. [105]), and could play a crucial role in driving other cytoskeletal self-organization phenomena, especially close to dynamical instabilities, where the effect of noise is highest. Finally, having at hand the underlying biochemical and biophysical mechanisms of cell forces and motility, a great challenge is to understand self-organization at yet larger scales, namely in animal tissues, where collections of cells present integrated coherent behaviors that drive diverse key processes such as morphogenesis, wound healing, immune response, tumor development and metastases formations. There, the same scheme involving "microscopic" as well as effective "macroscopic" approaches can certainly play an equally major role, "microscopic" approaches then potentially integrating the whole knowledge acquired at the level of a single cell, and partially reviewed in this article.

Acknowledgments

To write this article, I grandly benefited from Karsten Kruse's habilitation thesis, which constituted a very good starting point as an extensive review of the existing biophysical literature on the cytoskeleton. I acknowledge Cécile Sykes and Jean-François Joanny for discussions, careful reading of the manuscript and constructive criticisms and suggestions. I also acknowledge Andrew Callan-Jones for pointing to me important references.
