Foreword

The Nolph and Gokal *Textbook of Peritoneal Dialysis* in its third edition covers the history of peritoneal of dialysis from its early beginnings to the present and updates the many advances since the second edition was published. This book continues to represent a major source of knowledge about this dialysis therapy.

Two of the previous editors, Drs. Ram Gokal and Karl D. Nolph, are now retired from their full-time academic careers, and Drs. Ramesh Khanna and Ray Krediet, who were co-editors of the second edition, have skillfully assumed the total responsibility for editing this third edition. They have graciously included the names of Drs. Nolph and Gokal in the title of the third edition, and I thank them for this honor. Drs. Gokal and Nolph were the two co-editors of the first edition.

The 31 chapters included in this scholarly and comprehensive review of the history, science, and clinical practice of peritoneal dialysis should be a valuable resource for all those who have an interest in the therapy from any perspective.

The science reviewed includes peritoneal membrane structure and function, the peritoneal microcirculation, solute and water transport via the peritoneal membrane and lymphatics, animal models of peritoneal dialysis, pharmacological manipulation of transport, pharmacokinetics during peritoneal dialysis, and the chemistry and physiologic effects of various peritoneal dialysis solutions.

Epidemiology and demographic studies are included in chapters dealing with the current status of the therapy, survival outcome comparisons with patients on peritoneal and hemodialysis, and peritoneal dialysis in developing countries.

Clinical chapters review what is known about peritoneal dialysis in the elderly, long-term patients, children, and diabetics. The challenges of anemia, fast transport, achieving adequacy and volume control, changing peritoneal morphology and function, maintaining good quality of life, peritonitis, ultrafiltration failure, protein-energy malnutrition, renal osteodystrophy, cardiovascular disease and inflammation, vascular calcification, and other noninfectious complications are reviewed extensively in separate chapters. There are also individual chapters on peritoneal dialysis access and exit-site care, connectology, and automated peritoneal dialysis. There is a chapter dealing with intraperitoneal chemotherapy. A very important chapter is the one dealing with the nephrology nurse's role in organizing and managing a peritoneal dialysis program.

The completeness of the reviews and the breadth of topics imply that the book should be useful for medical students, medical residents, nephrology fellows, nephrologists (both clinical and academic), researchers (clinical, translational and basic), nurses, dieticians, social workers, bioengineers, pharmacologists, epidemiologists, and many others.

The authors of each chapter are highly qualified to write their respective chapters and most of the authors are among the top leaders in area of knowledge they review.

This book is being published at a time when, in my opinion and that of many others, peritoneal dialysis is underutilized. It is a therapy with a long list of advantages for many patients. It is also, for many, a good therapy with which to commence chronic dialysis therapy. One of the reasons for underutilization is clearly lack of knowledge of and lack of experience with peritoneal dialysis among nephrologists. Although nephrology training programs are expected to provide education and experience with peritoneal dialysis to their nephrology fellows, many programs are poorly equipped and/or motivated to do a good job in this regard. My hope is that this book, which contains state-of-the-art knowledge about peritoneal dialysis, will be a useful tool for those involved in worldwide efforts to increase understanding of peritoneal dialysis and what it has to offer many patients.

Chapter 1
History of Peritoneal Dialysis

D. Negoi and K.D. Nolph

The concept of the uremic syndrome caused by blood and tissue accumulation of toxic substances normally excreted in the urine was an established idea in the middle of nineteenth century [1, 2]. In the late 1800 s, renal insufficiency and concurrent uremic intoxication were treated only by simple and ineffective measures such as blood letting, dietary changes, digitalis, infusion of normal saline followed by forced diuresis, purgation, and diaphoresis [1, 3]. The period of time surrounding the beginning of the twentieth century was marked by intense research and growth in scientific knowledge that allowed the birth of clinical dialysis, a lifesaving therapy for patients with renal failure.

The Discovery of Principles of Dialysis: Diffusion and Ultrafiltration. Thomas Graham and Henri Dutrochet

The development of peritoneal dialysis in early 1900 s as a form of renal replacement therapy was made possible by remarkable progress in science and medicine that took place in the eighteenth and nineteenth centuries. In the field of physical chemistry, it was Thomas Graham (1805–1869) who completed vast work that included the discovery of laws of diffusion of gases (Graham's law: the rate of diffusion of a gas is inversely proportional to the square root of its molecular weight), investigation of osmotic force, and separation of chemical or biological fluids by dialysis [4–7]. His work represents the theoretical foundation upon which clinical dialysis could later develop. Graham was born in Glasgow, Scotland; his father wanted him to study theology and enter the Church of Scotland. He became a student at the University of Glasgow in 1819, were he was attracted by the field of chemistry and attended lectures in chemistry against his father's wishes. His passion and dedication for this science caused him later to alienate his father. Graham became professor of chemistry at numerous colleges, his lectures being attended by aspirants in chemistry and medicine, as their training was similar during that time. Between 1846 and 1861, he published an important series of papers in the *Philosophical Transactions of the Royal Society:* "The motion of gases" in 1846, followed by "The motion of gases part II" 3 years later, "The Bakerian lecture on osmotic force" in 1854, and "Liquid diffusion applied to analysis" in 1861 [4]. His studies led him to the innovative distinction between "crystalloids" and "colloids," which he defined based on their ability to diffuse through a semi-permeable membrane and crystallize. He introduced the concept of "semi-permeable" membrane and redefined the term *dialysis*. In his experiments, he separated solutions containing sugar or gum arabic from water, using sheets of vegetable parchment impregnated with starch, acting as a "dialytic septum." He noted that sugars can cross the semi-permeable membrane and called them crystalloids, as opposed to gum arabic, which did not cross the vegetable, semi-permeable membrane, and called these types of substances colloids. He wrote: "The molecules are moved by force of diffusion. . . It may perhaps be allowed to me to apply the convenient term *dialysis* to the method of separation by the method of diffusion through a system of gelatinous matter" [4]. As mentioned by Gottschalk, prior to this new meaning given to the term *dialysis*, this was used "to describe dissolution of strength or weakness of the limbs, coming from the Greek, to part asunder" [4].

Graham also suggested that animal tissue could be used as a functioning semi-permeable membrane and showed that the rate of diffusion of different molecules is inversely related to the molecular size. He also demonstrated that urea, which is present in the urine, can be dialyzed through semi-permeable membranes. Because of these brilliant

discoveries that proved that solutes can be "dialyzed" or separated from a fluid using a semi-permeable membrane, he is considered to be the "father of modern dialysis."

Prior to Graham, it was René Henri Joachim Dutrochet (1776–1846) who introduced the term *osmosis* to describe the movement of water through membranes that hamper the passage of solutes but allow the passage of water down concentration gradients of salts [5]. This is an early description of osmotic induced ultrafiltration. Some authors consider Dutrochet as being the "grandfather of dialysis" because he discovered the principle that explains osmotic ultrafiltration [5].

The Peritoneal Cavity and the Peritoneal Membrane

Egyptian morticians observed the peritoneal cavity as early as 3000 B.C. and recorded their observation in the Ebers papyrus [8, 9]. They described it as a "definite entity in which the viscera were somehow suspended" [8]. In the Roman times it was Galen, the Greek physician, who made thorough descriptions of the peritoneal cavity and peritoneum, which he observed by treating injuries of the gladiators [9].

Extensive knowledge of the peritoneal cavity started to accumulate in the last half of the nineteenth century, as the abdomen was often explored due to developments in abdominal surgery (see Table 1.1). In the early 1860 s, von Recklinghausen [10, 11] comprehensively described the peritoneal cavity, even proposing it was lined entirely by mesothelial cells and noting the lymphatic drainage. In 1877**,** Georg Wegner**–** from the Surgical Clinic of the University of Berlin – published his "surgical comments on the peritoneal cavity" [12]. His observations were the results of experiments in rabbits where he injected hypertonic solutions of sugar, salt, or glycerin in an animal's peritoneal cavity and found that intraperitoneal fluid volume increased. When hypotonic solutions were injected in the peritoneum, their volume decreased. In 1893, Beck described the peritoneal mesothelium and possible connections of the peritoneal cavity with lymphatics [13] and Kolossow described paths between the mesothelial cells, which he did not believe were connected with the lymphatic system [13]. The famous English physiologist E.H. Starling and his collaborator from Guy's Hospital in London, A.H. Tubby, specifically studied the transport of fluids and solutes across the peritoneal membrane and published their result at the end of nineteenth century [14]. They determined that solute exchange was primarily between solutions in the peritoneal cavity and blood, lymphatic transport being considered negligible. They reproduced Wegner's results and also studied the transport of indigo carmine and methylene blue and concluded that, as with water, they can cross the peritoneal membrane in both directions.

Further insight into peritoneal physiology was acquired in the early years of the twentieth century. Some of the most well-known works during that period of time are those published by Cunningham, Putnam, and Engel. Cunningham [8, 15] studied the absorption of glucose from the peritoneal cavities of rats in 1920 and reviewed extensively the peritoneal structure and function in 1926. At the same time, Putnam described the dog peritoneum "as a dialyzing membrane" and brought more evidence that the peritoneum was a semi-permeable membrane that allowed bidirectional water and solute transport on the basis of the principles of osmosis and diffusion. His experiments were complex, including observations on dwell time, flow rate, fluid removal, and exchange of various solutes [16]. Advanced animal studies were done by Engel, who published his conclusions in 1927 [17]. He showed that animals could not tolerate extensive ultrafiltration and that solute clearance is directly proportional with its molecular size, the flow rate of the intraperitoneal fluid, peritoneal surface area, and blood flow. These were the times when the first attempts of therapeutic peritoneal dialysis were done in humans.

Table 1.1 Pioneering animal studies of the peritoneal membrane

Investigator	Findings	Date
Recklinghausen [10, 11]	Described mesothelium and lymphatic drainage	1862–1863
Wegner [12]	Transport of solutes and water across the peritoneum	1877
Beck [13]	Described mesothelium	1893
Kolossow [13]	Described intermesothelial paths	1893
Starling and Tubby [14]	Transport of solutes and water across the peritoneum	1894
Cunningham [8, 15]	Peritoneal transport and structure	1920–1926
Putnam [16]	Described the peritoneum "as a dialyzing membrane"	1923
Engel [17]	Peritoneal transport	1927

The Birth of Clinical Dialysis

In 1913–1914, Abel, Rowntree, and Turner developed a device they called the "artificial kidney" or "vivi-diffusion apparatus" using semi-permeable collodium membranes specifically designed to substitute the role of the kidneys in eliminating toxic substances when these organs are failing [4, 18]. Although they experimented with this apparatus only in animals, their intention was to develop a method of extracorporeal dialysis that could be used in humans. Their work was terminated in 1914 because of World War I. The first human hemodialysis was done in 1924 in Germany by Georg Haas, who apparently was unaware of Abel's work in the United States [6]. Also in Germany, Heinrich Necheles had great interest in "external" dialysis, and was searching for a better dialysis membrane for his dialyzers [19]. His work with goldbeater's skin, which was a commercial preparation of visceral peritoneum from calves' abdomen, must have stimulated Ganter to perform peritoneal dialysis [19].

First Attempts at Peritoneal Dialysis – Georg Ganter (1923)

Georg Ganter from Würtzburg, Germany is credited with the first publication regarding application of peritoneal dialysis to treat uremia. He was aware of the hemodialysis attempts of his contemporaries, and was captivated by the idea of using a patient's own natural membranes for dialysis. He considered that application of external dialysis at the bedside would be complicated due to difficulties in establishing the extracorporeal circuit and toxic effects of the hirudin, which was used as anticoagulant [20].

In 1923, Ganter published the result of his investigations in humans and animals in his only paper, entitled "On the elimination of toxic substances from the blood by dialysis" [21]. He described his 1918 attempt to remove uremic toxins in a young man with glomerulonephritis using pleural lavage. He removed a pleural effusion and replaced the fluid with a single infusion of 750 mL of a sodium chloride solution and noted clinical improvement. The patient still died a few days after discharge, probably because Ganter did not recognize that uremic toxins will build up again [7]. He then carried out experiments on rabbits and guinea pigs made uremic by ligation of ureters and found that intraperitoneal instillation of saline solution improved the symptoms of uremia and blood urea nitrogen levels. In order to perform fluid exchanges, he used drainage tubes implanted in the peritoneal cavity and instilled saline solutions in volumes of approximately 50 mL, which were left in the peritoneal cavity for about 3 h. After this period of time the fluid was drained, with an average volume of 10–30 mL being recovered. The procedure was then repeated up to four times. He found that, after each exchange, there was almost complete equilibration of nonprotein nitrogen in the dialysate with blood concentrations and that some of the instilled fluid was absorbed. He also noted improvement in the animal's uremic symptoms after peritoneal lavage: their appetite and activity level were improved after each exchange. Ganter used this procedure in a woman with acute uremia from bilateral ureteral obstruction due to uterine carcinoma: her condition improved transiently after a single intraperitoneal infusion of 1.5 L of physiologic saline. In another patient with a coma due to diabetic ketoacidosis, he instilled 3 L of saline intraperitoneally, and the patient's mental status improved transiently.

His unprecedented clinical experience with intermittent peritoneal dialysis was limited, but he envisioned that this procedure could become a new form of therapy and recognized a few aspects of primary importance in its applicability: adequate access is extremely important to maintain good inflow and outflow, peritoneal infection is the most common complication and the use of sterile solutions can help prevent this complication, a large volume of dialysate is necessary in order to remove the uremic toxins, and he suggested 1–1.5 L per exchange. Dwell time also influences solute clearance and it was considered necessary that the fluid remain in the peritoneal cavity until the equilibrium between the blood and dialysate is reached. Additionally, he recommended the use of hypertonic solutions to promote fluid as well as toxin removal.

Unfortunately, Ganter did not continue research in the field of peritoneal dialysis, which evolved very slowly in the following years, probably because most of the attempts were unsuccessful in saving the life of patients.

Early Experience in Peritoneal Dialysis (1923–1950)

In 1950, Odel and his colleagues [22] summarized and analyzed the published experience with peritoneal lavage (dialysis) between 1923 and 1948 and formulated some recommendations based on published results and their own experience. They found only five papers published on this topic from 1923 to 1938 (including Ganters' paper) and as many as 33 papers between 1946 and 1948. No papers were published during World War II (1939–1945), but the

number of fatal renal failure cases caused by trauma in both civilian and military patients brought this problem to the center of attention and stimulated research. They identified 101 reported patients treated by peritoneal lavage, including three patients treated by the authors. Sixty-three of the patients had reversible causes of renal failure, 32 had irreversible renal lesions, and two had an indeterminate diagnosis. Of the 101 patients reported in that 25-year period, only 36 survived: 32 patients with reversible uremia, two of the patients considered to have irreversible renal lesions, and two of those with indeterminate renal diagnosis. The most common causes of death were pulmonary edema (40%), uremia (33%), and peritonitis (15%).

The peritoneal dialysis technique was applied in a very diverse way: 22 of the reported patients received intermittent treatments, with 1–6 lavages for exchanges of 15 min to 6 h duration and 75 of the patients received continuous treatment of 1 to 21 days duration. In four cases the type of intraperitoneal lavage was unknown. There was also a great variety of solutions used for peritoneal lavage with 14 different types reported: different concentrations of sodium chloride and dextrose solutions, Ringer's, Rhoads', Hartmann's two modified Tyrode's, "A," "P," modified "P" solutions, Kolff's and two unknown.

Rubber catheters introduced in the peritoneal cavity with the help of trocars, as well as glass or stainless steel tubes with multiple perforations, were used for inflow of the dialysis fluid into the peritoneal cavity, while mushroom-tip catheters of large bore, or stainless steel sump drains "similar to those perforated suction tubes used in operating rooms" were used for drainage of the peritoneal fluid from the peritoneal cavity. Catheter complications were very common and difficult to deal with: these included leakage of fluid, especially around the rigid tubes, bacterial contamination of the tubes, outflow obstruction caused by pocketing of the omentum, visceral perforation caused by the rigid tubes, and intra-abdominal hemorrhage. Other complications were noted: depletion of plasma proteins, sometimes to critical levels, in addition to derangements of the acid–base, electrolytes, and water balance. Odel and his colleagues were convinced that composition of the fluid used for dialysis was of the greatest importance and the main cause of experimental and clinical peritoneal dialysis failure was related to the imbalance of water and electrolytes. They advocated the use of a solution that would not change the normal electrolyte composition of the plasma, would permit maximal diffusion of waste products from the blood, would permit mild dehydration (moderately hypertonic solution), and would not irritate the peritoneum (the solution needs to have a pH close to that of the plasma).

It is worth noting that the early investigators were aware of the fact that peritoneal lavage aided in removal of metabolic waste products, but the concept of adequate dialysis had yet to be discovered. Frequently, the duration of dialysis was too short, or if time of dialysis was longer, the amount of dialysis fluid was not sufficient to achieve sufficient removal of waste products.

Although mortality with peritoneal lavage was high, it offered hope for effective therapy in some patients, especially in patients with reversible causes of renal failure, who were able to recover renal function before the peritoneal dialysis procedure failed.

Of the papers published after World War II, the most important are considered to be those of doctors Howard Frank, a surgical intern, Arnold Seligman, trained in chemistry, and Jacob Fine, their mentor and chief of service at Beth Israel Hospital in Boston. They worked under contract with the "Office of Scientific Research and Development" (OSRD), the federal agency created by President Franklin D. Roosevelt in 1941 to promote research for military purposes in medicine and weapons technology [23]. Their task was to work on treatments for acute renal failure in trauma patients, and because they wanted to avoid the use of anticoagulants they opted for peritoneal lavage as a good possibility. As the literature regarding the use of natural membranes was limited at the time they embarked on their project, the team began by doing very elegant studies of peritoneal irrigation in non-nephrectomized and nephrectomized uremic dogs [24]. They calculated the optimal flow rate and volume of peritoneal irrigation fluid in order to obtain the maximum urea clearance and to prevent uremia, compared the blood urea clearance by peritoneal irrigation with clearance through the kidneys, and experimented with irrigation of various parts of the gastrointestinal tract and pleural cavity, which proved to be ineffective means of urea removal. The irrigation fluid used was Ringer's solution containing glucose, which was later changed to a Tyrode's solution, in their search for the right solution. Their uremic, nephrectomized dogs survived for 3–10 days with peritoneal dialysis and none of them died of uremia, but rather of peritonitis. Their method involved the use of two catheters introduced into the peritoneal cavity, one of them used for inflow of irrigation fluid and the other one for drainage. Continuous irrigation of the peritoneal cavity was done for 20 h daily for 2 days and 8–12 h daily thereafter, with the outflow rate being modified in order to prevent overdistension of the peritoneal cavity. Encouraged by the results of their experimental work in dogs, in 1945 they decided to try the treatment on a patient who presented to the emergency room at Beth Israel Hospital with acute renal failure from sulfathiazole administration [23, 25]. Their treatment was successful and the patient recovered after 7 days of dialysis, using the same technique as described before. This technique can be called an "intermittently continuous irrigation," because the fluid was introduced in the peritoneal cavity by continuous irrigation, but there were periods of time when the irrigation was stopped and so peritoneal dialysis did not take place. It is interesting that their papers do

not make any reference to the first successful use of continuous peritoneal dialysis in a patient with urinary tract obstruction by Wear, Sisk, and Trinkle, and they were probably unaware of this achievement [22, 26]. Fine's group's success became known immediately and gave an impulse to others to use their technique. Motivated by their own accomplishment, they continued work on peritoneal dialysis and tried to perfect their work. They treated 18 more patients, but only four survived [22]. They found that peritonitis was the greater risk associated with the procedure, and the main reason for considering this method was still in the investigational phase [27]. They improved the irrigation fluid by decreasing the sodium chloride concentration to 0.74% to reduce the risk of hyperchloremia, added gelatin, and increased the glucose concentration to increase the fluid tonicity so they were able to control edema. Bicarbonate was used in the irrigation fluid to combat acidosis. The bicarbonate solution was sterilized separately and added to the solution before irrigation was initiated. Their closed system was bulky and seemed complicated, and the procedure required the constant attendance of a nurse (see Figs 1.1 and 1.2). The dialysis solution was sterilized and

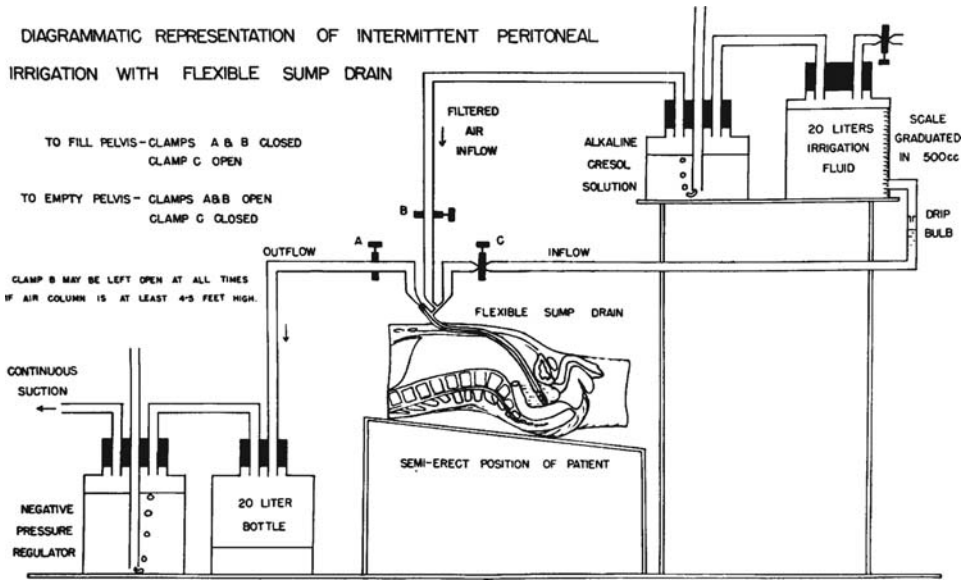

Fig. 1.1 Schematic representation of closed system used by Frank, Seligman, and Fine (From Annals of Surgery 1948, with permission)

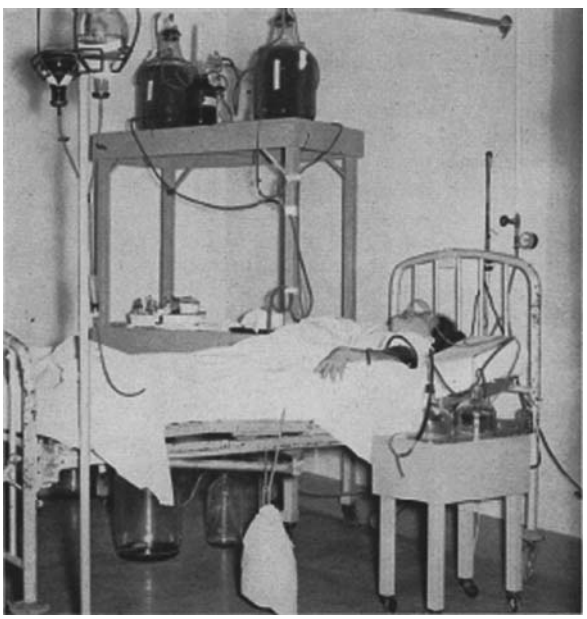

Fig. 1.2 Closed system used by Frank, Seligman, and Fine (From Annals of Surgery, 1948 with permission)

administrated from special 20-L Pyrex bottles, which required a large autoclave and were difficult to manipulate. The access was somewhat improved by introduction of a flexible sump drain that could be used as a two-way system if a separate inflow tube was not available. Most of the patients were treated with continuous flow technique, but they also used intermittent peritoneal lavage in some of the patients, with 0.5–2-L fill volumes depending on patient tolerability and 15 min to 3 h dwell time [27]. After finishing his internship, Frank remained at Beth Israel Hospital as a thoracic surgeon and member of the faculty at the Harvard Medical School and Arnold Seligman went to John Hopkins University School of Medicine, where he followed both a surgical and chemistry career [23].

The next major step in the development of peritoneal dialysis was the work done by Arthur Grollman, from Southwestern Medical School in Dallas, Texas [28]. It is interesting that, in reality, Grollman did not believe in the value of peritoneal dialysis for treatment of acute renal failure, which he thought could be managed by conservative measures if they were properly applied [28]. His main interest was actually to find a simple way to prolong life of nephrectomized dogs, which he used to study the role of kidneys in hypertension [29] His procedure involved the instillation by gravity of the irrigating fluid in the peritoneal cavity of the dogs, using a needle introduced in the peritoneal cavity through the flank [28]. The fluid was left in the abdomen for variable periods of time, and then removed using the same size needle connected by an adapter to a rubber tube. The drainage was followed by refilling. The procedure was carried out twice daily in the morning and late afternoon and kept the dogs alive for 30–70 days after bilateral nephrectomy, compared to the previously reported average of 10 days. Although he called this technique an intermittent peritoneal lavage, it was actually a continuous type of peritoneal dialysis in the way we classify it today, because he did not have periods of a "dry" abdomen. He called it intermittent because it did not involve continuous instillation of the dialysis fluid, but rather the fluid was left to dwell in the peritoneal cavity for various periods of time. He considered that more frequent exchanges were not necessary to prolong a dog's life, but could further decrease the level of urea and other catabolites. His kinetic studies showed that urea reaches equilibrium in 2 h after filling the peritoneal cavity of dogs with 1 L of fluid containing different concentrations of glucose. He also paid attention to the volume of fluid removed with peritoneal lavage using various concentrations of glucose in the dialysis solutions and using variable periods of time. In humans, he found equilibrium time for urea, electrolytes, creatinine, and glucose after 2 h, using 2–3 L instillation volumes of dialysis solution. He described the use of his method in five human patients. The dialysis fluid composition was modified based on patient needs and "intermittent" exchanges of 2 h duration were done for 16–48 h. The access used was for the first time a plastic tube, "to which omentum does not attach itself" [28]. The single plastic catheter was kept in place for the entire procedure and was used for both inflow, when it was attached through a needle to the infusion bottle, and outflow, when it was connected to an adapter and rubber tube for drainage. One of his patients survived, two others had some improvement in their clinical condition but died after peritoneal dialysis was stopped, and the other two did not improve at all with peritoneal dialysis. He did not have any peritonitis in humans; there was one episode in a dog dialyzed for 70 days, due to a break in the aseptic technique. Grollman considered his method superior to the continuous lavage previously described because of its simplicity and possibly increased efficiency in removal of the waste products. His technique did not require "the complex apparatus, multiple incisions, and constant attention necessary when one utilizes a constant perfusion technique as advocated by previous investigators" [28]. Additionally, he considered that continuous irrigation can create a "channeling" of the fluid between the inflow and outflow and be less efficient in urea removal due to decrease in available surface for exchange.

The Modern Era of Peritoneal Dialysis

The modern era of peritoneal dialysis started with Morton Maxwell in 1959 [30]. Maxwell started training in renal physiology with Homer Smith at the New York University School of Medicine in 1948. After he joined the staff of the VA Hospital in Los Angeles, California, he purchased a Kolff twin-coil kidney machine and started using it. He found this procedure "formidable" and expensive, with narrow applicability due to necessity of dedicated medical staff with special training, who had to work long hours to prepare the machine, deliver the treatment, and clean up after a 6-h-long session [31]. He turned his attention to peritoneal dialysis and found Grollman's technique promising in its simplicity and worked on refining it. One of the obstacles he wanted to eliminate was the laborious way of extemporaneous preparation of dialysis solutions. Access-related complications were also a great limiting factor in peritoneal dialysis and he started experimenting with different catheters. Maxwell introduced a semi-rigid nylon catheter with a curved tip and numerous tiny distal perforations, which, similar to plastic catheters, caused less omental reaction than the rubber and metal tubes. Because it was semi-rigid, it did not have the tendency to kink as did other plastic catheters developed in the early 1950 s, and, by decreasing the diameter and increasing the number of very

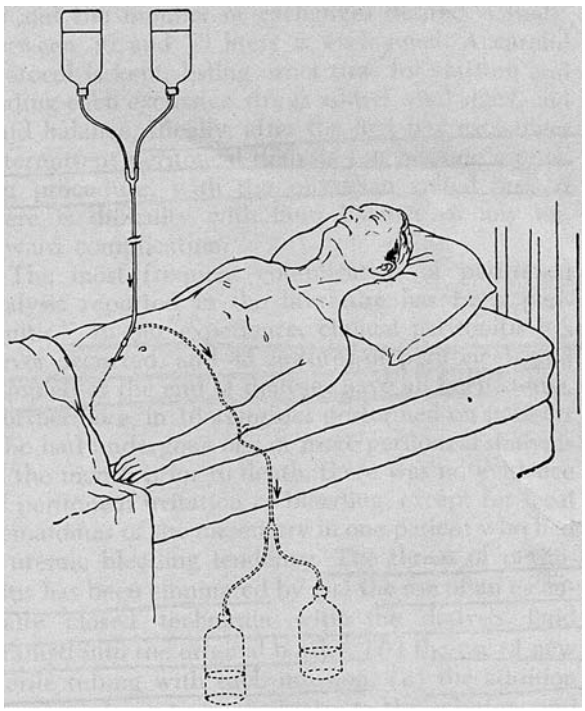

Fig. 1.3 Maxwell's paired bottle technique (From JAMA 1959, with permission)

small perforations in the distal end, he prevented portions of the omentum from entering the catheter and this resulted in better performance. He convinced the Don Baxter Company of Glendale, California, and Cutter Laboratories of Berkeley, California, to produce a standard dialysis solution in 1-L sterile glass bottles, special Y-type administration tubing, and the new type of catheter [29, 30]. The peritoneal dialysis procedure involved insertion of the catheter into the peritoneal cavity through an incision of the abdominal wall, below the umbilicus, using a 17 French Duke trocar set [31]. Then the catheter was attached to the Y-tubing, previously connected to 2 L of warmed dialysis solution (see Fig. 1.3). The paired bottles were hung above the bed level and the dialysis fluid was allowed to flow into the peritoneal cavity. The tubing was clamped when the bottles were empty with some fluid still present in the administration tubing, and the bottles were then lowered onto the floor. After 1 h dwell time, the clamps were removed and the fluid was permitted to flow out of the peritoneal cavity. When the drainage was complete, a new pair of dialysate bottles was connected to the catheter using new tubing. This "intermittent" procedure was continued for 12–36 h as required buy the clinical situation and proved to be "mechanically successful" in 76 instances [31]. Maxwell and his colleagues specifically reported only six cases in their classical paper, with five survivors and one death after transient improvement with dialysis. Those patients who recovered had acute renal failure, barbiturate poisoning, intractable edema, hypercalcemia, and acute on chronic renal failure due to ureteral blockage.

The new dialysis solution contained sodium in a concentration of 140 mEq/L, chloride 101 mEq/L, calcium 4 mEq/L, magnesium 1.5 mEq/L, dextrose 15 g/L, and, for the first time, lactate 45 mEq/L. The lactate was replacing bicarbonate in the dialysis solution, eliminating the problem of precipitation of calcium salts. Potassium was excluded from the commercial dialysis solution because most of the patients with acute renal failure had hyperkalemia, but, if needed in patients with low serum potassium levels, it could be added to one of the bottles using a hypodermic syringe. The 1-L bottles were much easier to handle than the large carboys introduced by Fine's group and generally used up to that point. If there was need for addition of other substances to the dialysis solution (potassium, dextrose, prophylactic antibiotics, heparin), they were added to one of the two bottles used for each exchange, a maneuver that, from their perspective, decreased the risk of peritonitis. Actually, they reported that in their experience peritonitis never occurred, although in fact the risk of contamination was still increased because the system was disconnected with each exchange.

Their experience in patients with chronic renal failure was unsatisfactory, but they imagined that with further improvement of the technique, peritoneal dialysis could become more efficient so that it could be applied for shorter sessions of 6–8 h duration. Theoretically, chronic patients could be admitted to the hospital at certain intervals and receive the peritoneal dialysis treatment, "in the same manner patients with refractory anemia are given transfusions at

the present time" [31]. Although the procedure was still not ready for use in the treatment of chronic uremia, the fact that now it became a simpler nursing procedure and the dialysis solution was commercially available in 1-L bottles allowed it to be accepted and used more commonly as a treatment for acute renal failure. The new catheter used by Maxwell seemed to have fewer complications than previously used catheters and became widely used.

At the same time, at the U.S. Navy Hospital in Oakland, California, Paul Doolan and his team started research in dialysis, being stimulated once more by war casualties due to acute renal failure and hyperkalemia in the Korean War (1950–1953) [32]. Their goal was again to find a simple way to dialyze patients on the battle field or at the bedside, and found that peritoneal dialysis applied using Grollman's intermittent flow technique was most appropriate. In the same year, 1959, they published their experience with the use of intermittent peritoneal lavage in ten patients [33]. They used dialysis solutions that were prepared in the hospital, with a lower content of sodium (128 meq/L), glucose used as an osmotic agent, and bicarbonate 28 mmol/L added as a buffer and, to avoid precipitation of calcium salts, they administered calcium parenterally. Potassium was added to the dialysis fluid as required by the clinical situation. Doolan and Murphy developed a polyvinyl chloride catheter with a straight intra-abdominal segment with multiple side holes, transverse ridges, and spiral grooves to avoid kinking and omental obstruction. William Murphy was the president of the Cordis Corporation and manufactured this catheter, but it did not become widely used because it was difficult to insert, sometimes even requiring laparotomy. Nevertheless, Doolan and his group used the catheter to successfully carry out intermittent flow peritoneal dialysis. The work of Maxwell and Doolan and the introduction of plastic catheters and commercially available "rinsing" solutions contributed to the widespread acceptance of peritoneal dialysis in the early 1960 s as a clinically feasible technique.

Long-Term Peritoneal Dialysis

The first chronic renal failure patient treated with long-term peritoneal dialysis was Mae Stewart, a 33-year-old black woman from San Francisco who had complications from a recent childbirth [32, 34]. In late 1959, she was referred to see Dr. Richard Ruben at Mt. Zion Hospital in San Francisco for management of her renal failure. Previously that year, Ruben had worked with Doolan at Oakland Naval Hospital, where he acquired the skills necessary to perform peritoneal dialysis. He started Stewart on peritoneal dialysis with the help of his colleagues, doctors A.E. Lewis and E. Hassid. She improved after the first dialysis session, with a decrease in serum creatinine form 20 to 13 mg/dL, but after a week her condition deteriorated again. They decided to leave the catheter in place in case they might need to use it again. As it turned out, the patient had small, shrunken kidneys and chronic renal failure due to glomerulonephritis, so her uremic symptoms returned after several days. She continued to receive in-hospital, weekly peritoneal dialysis treatments, using the same catheter left in place, so the Murphy-Doolan catheter was the first one used for chronic peritoneal dialysis. She was allowed to go home between treatments, where she was able to continue to take care of her family. Sometimes during treatments, she was disconnected from the closed system after inflow and was allowed to ambulate.

She was kept on intermittent or "periodic" peritoneal dialysis for 7 months, and the catheter was replaced only once at 3 months after starting the treatment. Intraperitoneal antibiotics were administered occasionally to prevent the occurrence of peritonitis. Later during the treatment, the patient developed pericarditis, refused to continue further treatments, and died. Mae Stewart was the first patient maintained on chronic dialysis; she started treatment in January 1960 several months before Clyde Shields started chronic hemodialysis in Seattle in March 1960. Ruben and his collaborators wrote a report of this case and submitted it to the New England Journal of Medicine, but the manuscript was rejected for publication.

During the early 1960 s, many centers were trying to use "periodic" peritoneal dialysis in patients with end-stage renal failure. The results were disappointing mainly because of frequent episodes of peritonitis due to access infection or contamination during the repeated maneuvers of changing the bottles [35]. Survival was commonly limited to only few months. As the nylon catheters were found to be unsatisfactory for long-term use, many attempts in different centers were being made to design a safe and easy method to insert an access device that would permit reliable dialysate flow and limit the infectious and mechanical complications. During that time, significant results in chronic dialysis were accomplished at the University of Washington in Seattle, where Belding Scribner and Wayne Quinton were able to maintain end-stage renal disease patients on chronic hemodialysis. However, the number of patients was much higher than what they could accommodate, and also some of the patients were running out of sites for hemodialysis access, requiring other forms of chronic therapy. Scribner, the same as others during that time, thought that peritoneal dialysis could be a good alternative to hemodialysis and invited Dr. Fred Boen, an Indonesian physician working in Holland, to come to Seattle and work on peritoneal dialysis [36, 37]. Boen had become known for his work on the kinetics of peritoneal dialysis, which was the subject of his M.D. thesis and was later published [38]. In January 1962, Boen and his team in Seattle began a program of long-term peritoneal dialysis, one of the first in the world. Around the

same time, John Merrill started doing chronic peritoneal dialysis in Boston, at the Peter Bent Brigham Hospital, Harvard Medical School. Both groups presented their 3 months experience in April 1962 at the American Society for Artificial Internal Organs Meeting in Atlantic City, New Jersey [39–41]. At the same meeting, Dr. J. Garrett from the Albany Medical College, New York, mentioned that he had maintained a patient on intermittent dialysis for 9 months [42]. The Seattle group developed the first automatic peritoneal dialysis machine, which was designed with the goal of minimizing the risk of contamination of the dialysis solution at the time of each exchange and also to reduce the need for nursing attendance [40]. They returned to the closed system developed earlier by Frank, Seligman, and Fine and designed a similar but automatic one. The sterile dialysis solution was contained in 20-L carboys from where it was pumped into an elevated reservoir where the fill volume was preset, usually at 2 L. From there the fill volume would enter in the peritoneal cavity using gravity flow. The inflow, dwell, and outflow times were monitored by the system's timers, which controlled the opening of the clamps and made the procedure automatic. They used a dwell time of 30 min. The disadvantage of the system was that the 20-L glass bottles were bulky and difficult to handle and, again, required special equipment for preparation and sterilization of the dialysis solution. The advantage was that it eliminated the need for frequent system openings during each exchange by replacing the individual 1-L bottles with large carboys containing the sterile dialysis solution; this way they decreased the risk of peritonitis by contamination. Later, they used a 48-L carboy, which made it possible to use a single container and a completely closed system for each dialysis session.

Boen's group, the same as Merrill's group in Boston [41], tried to use a permanent, indwelling peritoneal device in order to make frequent access into the peritoneal cavity easier. Their idea was to create an artificial and permanent conduit or channel through the abdominal wall, which would allow easy passage of a catheter into the peritoneal cavity and eliminate the need for repeated paracentesis.

Boen's access was the modification of a system developed by Garrett [40]. It was initially a Teflon hollow tube, replaced later by a silicon rubber, which was surgically implanted in the abdominal wall with one exit at the skin and the other one in the peritoneal cavity (see Fig. 1.4). The hollow tube had two perpendicular discs, one located just below the peritoneum in the peritoneal cavity and the other one in the abdominal wall. This tube allowed the repeated introduction of a catheter into the peritoneal cavity. At the end of the treatment, the catheter was withdrawn from the tube, which was then capped. The cap looked like a button at the skin surface and Boen's device was later called "Boen's button" or the "silastic button." Others tried to create a subcutaneous access button, which required cannulation through multiple stab wounds in the skin [43]. The overall performance of these buttons turned out to be poor. Merrill reported the use of such a device in five patients who received two to 17 dialysis treatments [41]; one of the patients had acute renal failure and did not recover, two patients were dialyzed intermittently for 2 months and the other two for 3 months. One of them was even able to do eight dialysis treatments at home, with the help of her spouse. None of the patients developed clinical peritonitis, but all of them had technical failure of the access device: occlusion of the lumen due to fibrous tissue or omentum, bowel penetration, or disruption of the conduit. Garrett was also not getting good results with his button device, even after further improvements [42].

Kevin Barry and his team from the Walter Reed Army Institute of Research, Washington, D.C., considered the permanent, artificial intra-abdominal conduit as a viable access option, and in order to make it easier to insert without

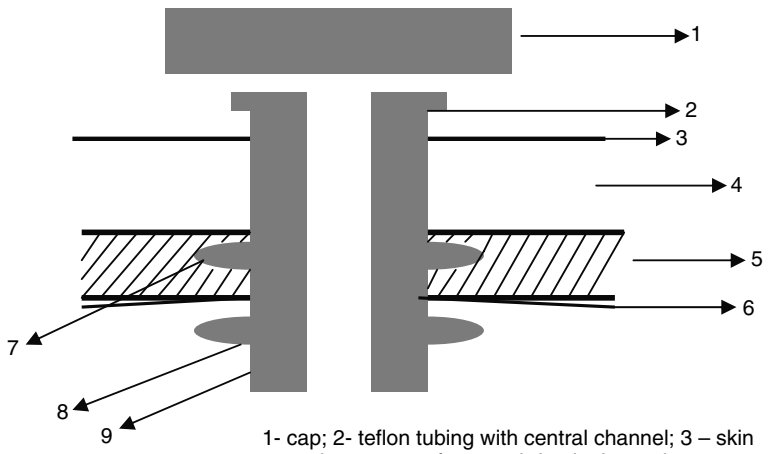

Fig. 1.4 Schematic representation of the "Boen's Button

the need of a surgical procedure, they developed a flexible, polyvinyl cannula implanted with the help of a trocar [44, 45]. The cannula had a balloon at the intraperitoneal end, which kept the device in place after it was expanded by infusion of saline. This device was able to accommodate the standard, nylon catheter. They recruited 116 investigators from several countries to participate in trials involving these polyvinyl cannulae [45]. Frequent complications were noted, including fluid leaks, separation of the intraperitoneal balloon, massive bleeding, and bowel perforation. This device has never gained popularity. Norman Lasker was one of those who used the Barry pericannula with some success [46, 47], but abandoned this method later in favor of the Roberts and Weston stylet catheter [47].

Other investigators were trying to find ways to use implanted, indwelling catheters without the need for artificial conduits. Gutch, for instance, from the Medical Service and Dialysis Unit of the V.A. Hospital in Lincoln, Nebraska, experimented with long-term catheters of different materials and found that silicon catheters were the least irritating and caused the least protein loss in the dialysis fluid [48, 49]. He reported the use of such silicone catheters for as long as 17 months, which was a significant achievement in survival of peritoneal dialysis patients; of note, this group preferred to dialyze patients daily, rather than two or three times a week, which was the common dialysis schedule during that time. Insertion of the catheter was done as usual, through a 24 French trocar.

In 1964, Boen and his group became convinced that chronic indwelling conduits or catheters of any material were not practical for long-term peritoneal dialysis because of frequent episodes of peritonitis and adhesion formation causing technical difficulties and poor general condition [50]. Their experience in humans was limited to only two patients, but none of them did well using Boen's button; their research in rats had demonstrated that polyethylene, Teflon, or silastic indwelling tubes inevitably produced adhesions and infections. As a result, Boen started using the "repeated puncture technique": a new puncture and a new nylon catheter were used each time the patient was dialyzed. Using this technique in combination with the closed sterile dialysis system and their automatic cycling machine, their second patient had no peritonitis for more than 8 months, compared with the development of peritonitis after 10 weeks when using Boen's button. The patient was dialyzed once weekly for 14–22 h and maintained a good quality of life. The trocar used for the repeated puncture was the one described by McDonald [51, 52]. Dr. Harold McDonald was a urologist who became familiar with peritoneal dialysis while training at the Peter Bent Brigham Hospital in Boston, with John Merrill's group in the early 1960 s. There he witnessed an unsuccessful event of catheter insertion for peritoneal dialysis and became interested in developing a tool that could facilitate catheter placement and resolve the pericatheter leakage. He designed a smaller, 14 French trocar, with a triface pointed tip. The common catheters used at that time were 11 French in size and were introduced using a 24 French Duke or Ochner paracentesis trocar. This new trocar made a smaller hole in the abdominal wall for catheter insertion, which helped in diminishing leakage around the catheter.

The Tenckhoff Catheter

In 1963, Henry Tenckhoff, a German physician, accepted a fellowship position at the University of Washington in Seattle, where he replaced Charles Mion, who was returning to France [36]. Tenckhoff also developed his interest in nephrology and dialysis while working in Boston with John Merrill. He could not nurture his interest for dialysis in Germany, and decided to return to the United States to continue working in dialysis. In 1964, Boen's team started training patients for home intermittent peritoneal dialysis using the repeated puncture technique and the Seattle, automatic closed system [36, 53]. The patients were trained in the hospital and then sent home with the dialysis equipment; the dialysis solution was prepared in the hospital, sterilized in the 40-L glass containers, and delivered to the patient's home at regular intervals. Dialysis was done weekly, usually on weekends. Tenckhoff had to go to the patient's home and insert the peritoneal dialysis catheter and start the dialysis treatment, which was carried out for 20–22 h each session. After this time, the patient with the help of the spouse, would terminate the treatment, turn off the machine, and remove the catheter. Initially they used the McDonald trocar to insert the catheter, but afterwards they started using the Weston and Roberts stylet catheter, which helped further in reducing the problems of bleeding and leakage. The procedure was simple and allowed long-term survival without peritonitis. In 1965, the Seattle group had treated one patient at home for 1 year, and another patient was treated using the same technique, but in the hospital, for 2 years. Soon it became clear that more than once weekly treatments were needed for the home peritoneal dialysis patient, and Tenckhoff had to go now twice a week to the patient's residence to start dialysis. Although the previous experience with permanent, indwelling catheters was not favorable, Tenckhoff recognized that, in order to make home peritoneal dialysis a viable procedure, a safe, permanent access to the peritoneal cavity was crucial [54]. Of the previously designed catheter, he believed that the Palmer–Quinton catheter was most appropriate for chronic use, with some improvements.

Russell Palmer, a Canadian physician from Vancouver, was one of the first to do hemodialysis in North America, starting in 1946 [55]. In the early 1960 s he also became interested in peritoneal dialysis and became familiar with the work done in Seattle, including with the work of Wayne Quinton in developing the silicone arteriovenous fistula for hemodialysis. He asked Quinton to help him design a permanent peritoneal dialysis access and, after experimenting with different materials, they decided to use silicon rubber. Their final product was an 84-cm-long catheter, with a lumen of 2 mm [56]. The intraperitoneal portion was coiled and had numerous perforations extending 23 cm from the tip. At the middle of the length of the catheter, there was a triflange step for placing the catheter in the deep fascia and peritoneum. The catheter was introduced surgically in the peritoneal cavity through a midline incision located about 5 cm below the umbilicus. From this level, the extraperitoneal portion was tunneled under the skin and the exit site was in the left upper quadrant. This long, tunneled portion was designed to decrease the risk of infection due to migration of bacteria from the skin. The external portion of the catheter was capped between dialysis treatments. Although this design was innovative and allowed peritoneal dialysis treatments for more than a year, peritonitis continued to occur [57].

Tenckhoff took this catheter a step further and designed the access that is even today most commonly used for peritoneal dialysis [58]. The most important improvement was the addition of two Dacron felt cuffs, obviating the need for the triflange step, which was eliminated from the new design [54]. At that point it was recognized that Dacron felt attached to the catheters improves tissue fixation, permits tissue ingrowth, and this way creates a barrier that reduces the chances of infection. McDonald also created a permanent silicon peritoneal catheter equipped with a Teflon velour skirt in the subcutaneous tissue and a Dacron sleeve in the intramural portion [59]. After extensive animal studies, Tenckhoff and Schechter decided that they would use a silicon catheter, of 40 or 75 cm length [54]. Two Dacron felt cuffs were attached to the silastic catheter in two places, dividing the catheter into three portions: the intraperitoneal portion was a straight 20-cm tube with 60 perforations in the area15 cm from the tip. Some of the catheters also had a curled intraperitoneal section, similar to the one described by Palmer. One of the Dacron felt cuffs was located in the peritoneal cavity, abutting the parietal peritoneum. The intramural section was also tunneled under the skin, but in an arcuate pattern and varied in length from 45 to 10 cm. They shortened this segment as they felt that the presence of the two cuffs closed the catheter sinus tract at both sides and thus decreased the risk of bacterial invasion. The second cuff was placed in the subcutaneous tissue just beneath the skin. They also recommended the arcuate tunnel so that the external part of the catheter and the sinus were directed caudally. In 1968, Tenckhoff and Schechter presented their 4-year experience in eight patients: one catheter had been used without complication for as long as 14 months in one of the patients [54]. Although the Tenckhoff catheter has not completely eliminated the risk of peritonitis, it was a major breakthrough and became the most important factor in promoting peritoneal dialysis in other centers.

The Growth of and Disappointment with Intermittent Peritoneal Dialysis

The next limiting steps in the widespread use of home peritoneal dialysis was represented by the difficulties in providing the adequate supply of sterile peritoneal dialysis fluids to the increasing number of patients using this technique and patients' problems in handling the large and heavy bottles [60]. The Seattle group was still preparing the dialysate in their hospital's "fluid factory" and was shipping the 40-L containers to the patients' homes. Charles Mion in France was using smaller, 10-L plastic containers connected in series for closed-circuit peritoneal dialysis [61]. The next proposal was to design a machine that could make sterile dialysate in the home of the patients, obviating the need for shipping large quantities of dialysate. Harold McDonald from the Department of Surgery – Urology, State University of New York, Downstate Medical Center, Brooklyn, New York, created a system that used tap water and dialysate concentrate, which could be integrated in an automatic peritoneal dialysis machine for hospital or home use [62]. Cold tap water, after going through a purifying and warming system, was mixed with the dialysate concentrate, and the resulting dialysis solution was further sterilized by passing through a 0.22-μ millipore filter before entering the peritoneal cavity. McDonald presented his system at the American Society for Artificial Internal Organs Meeting in 1969 [62]. At the same meeting, Tenckhoff presented the first system of water purification, which was developed by the Seattle group [60]. The latter experimented with different methods of water or dialysate purification, including bacterial filtration, heat sterilization, and UV-light irradiation, and found that heat sterilization using a pressure boiler tank was the only way to achieve perfect sterilization. This system was further improved and allowed production of large quantities of safe, sterile dialysate in the hospital and at home; its disadvantages were the large weight and bulkiness, high cost, and requirement for high pressure and temperatures to operate. As a result of progress made in water treatment technology, Tenckhoff and his team were able to design a new, much smaller and extremely efficient and safe system [63]. This system used the reverse osmosis method to produce large quantities of sterile, pyrogen-free water from tap water and contributed to the increase in the number of home peritoneal dialysis patients, making the

Seattle center one of the largest centers for home intermittent peritoneal dialysis in the 1970 s. In 1973, they reported the experience of 12,000 peritoneal dialysis treatments in 69 patients [61]. In 1977, 161 dialysis patients had been on dialysis at this center. The other large peritoneal dialysis center in North America at that time was in Toronto, Canada, [61]. In Europe, Charles Mion, formerly trained in Seattle, was directing the third most important center in the world, which was located in Lyon, France [64].

Dimitrios Oreopoulos accepted a position at the Toronto Western Hospital in 1970, to manage a four-bed intermittent peritoneal dialysis program with approximately 16 ambulatory patients [64]. He acquired knowledge about peritoneal dialysis while training in Belfast, Ireland, where he was using the Deane prosthesis to establish access. At the beginning of his experience in Toronto, he was able to maintain patients on peritoneal dialysis for up to 20 months, and their chronic peritoneal dialysis patient population increased steadily to close to 40 patients in a few years. At the same time, one of Oreopoulos' former colleagues from Belfast, Dr, Stanley Fenton, started working at the Toronto General Hospital. Fenton had trained in Seattle with Scribner and Tenckhoff after leaving Belfast and before coming to Toronto. He had a few Tenckhoff catheters, which he showed to Oreopoulos who tried them and was so impressed with the results that he abandoned the Deane prosthesis and converted all patients to Tenckhoff catheters. Having this reliable permanent peritoneal access available, Oreopoulos began sending patients home with reverse osmosis systems. During the early 1970 s. the president of American Medical Products visited Toronto and introduced a simpler cycler machine to Oreopoulos, the one designed by Lasker.

Norman Lasker [47, 65] was another pioneer in peritoneal dialysis, who had visited Seattle and studied the automated systems developed by Tenckhoff. He considered they were superior over the manual technique and the wider application of peritoneal dialysis could be facilitated if simpler machines would be available. With the help of Gottscho Packaging Equipment Company, he designed a simpler "peritoneal dialysis cycler." Ira Gottscho was a business man whose daughter died of kidney disease and he established a foundation in her memory. Lasker's peritoneal cycler was simple, efficient, and easy to use: it used gravity principles and eliminated pumps, and used commercially available 2-L bottles of dialysis solution and presterilized disposable tubing and bags. By connecting four bottles, an 8-L reservoir was obtained each time [47, 65].

Oreopoulos was the first to see the value of Lasker's work and had 40–45 patients use his cycler [64]. Another innovation was also available in Canada: in 1973–1974, Baxter provided dialysis solution (Dianeal) in plastic bags and all patients started using this product, which became available in the United States in 1978.

The high cost of care of dialysis patients was an additional factor that held back the dissemination of peritoneal dialysis. In the United States, new renal care legislation was approved in 1972 and Medicare started to cover medical expenses of end-stage renal disease patients in 1973 [47, 66], making peritoneal dialysis affordable. This modality was available not only in the hospital, but also as a home therapy, being delivered intermittently, usually three to four times a week for about 10 h per session [67]. As more experience started to accumulate, it became evident that real long-term success could not be achieved with intermittent peritoneal dialysis. In a 1979 analysis of the outcomes of chronic peritoneal dialysis therapy at the Seattle center, it was found that the cumulative technical survival rate was 72% for 1 year, 43% for 2 years, and only 27% for 3 years [68]. One of the leading causes of intermittent peritoneal dialysis failure was inadequate dialysis. Different approaches had been investigated in humans and animal models to increase the efficiency of intermittent peritoneal dialysis and summarized by Gutman also in 1979 [69]: increase of dialysate flow rate from the standard of 4 L/h to 12 L/h allowed only modest increase in clearance and was expensive, and increases in the dwell volumes over 3 L were uncomfortable for the patients. Other modalities explored were the use of tris-hydroxymethyl aminomethane (THAM) to increase the permeability of the peritoneal membrane, use of vasodilators to increase the effective surface area of the peritoneum, or the use of hypertonic solutions to increase solute removal by solvent drag [69]. None of these methods found applicability and intermittent peritoneal dialysis remained inferior to hemodialysis in terms of achievable small solute clearance. For this reason, peritoneal dialysis was considered a "second-hand" therapy for chronic renal failure until a new form of peritoneal dialysis was born in Austin, Texas.

Continuous Ambulatory Peritoneal Dialysis (CAPD)

In 1975, a young, otherwise healthy patient entered the chronic hemodialysis program directed by Jack Moncrief at the Austin Diagnostic Clinic in Austin, Texas [67]. Each arteriovenous fistula that was created in this patient failed, and in the absence of a hemodialysis access, he was advised to move to Dallas, where an intermittent peritoneal dialysis program was available. He refused to relocate and his doctors were in the situation of losing this young father of four children due to the impossibility of providing life-saving dialysis therapy.

One of Moncrief's collaborators was Robert Popovich [67], a young biomedical engineer formerly trained in Seattle under Belding Scribner and Albert Babb. The case of their unfortunate patient was reviewed during a routine weekly meeting and the team decided to try peritoneal dialysis but in a new form, which would allow complete equilibration of plasma urea with peritoneal fluid and thus maximum urea removal with each dwell. They calculated what was the minimum volume of dialysis fluid required to remove the urea generated daily on a 1 g/kg protein diet, knowing that dialysate urea equilibrates with plasma urea in 2 h. In a 70-kg man who eats 1 g of protein per kilogram of body weight, daily urea generation will be 7,000 mg per day. They decided that a level of 70 mg/dL for the blood urea nitrogen was desired. If at equilibrium dialysate urea concentration will be 70 mg/dL, then 10 L of dialysate are required daily in order to remove the generated urea and maintain a constant plasma urea concentration. The commercial dialysate solutions were available in 2-L glass bottles. Their prescription was for 2-L fill volumes, dwell time of at least 3 h, and a total of five exchanges per day. This prescription was applied to the patient using a Tenckhoff catheter as access, and improved and controlled the patient's chemistries, volume, and clinical status [67]. Moncrief and Popovich called this procedure the "portable/wearable equilibrium peritoneal dialysis technique" and they submitted the results of their first application of the technique as an abstract to the American Society of Artificial Organs in 1976 [67, 70]. This abstract was not accepted for presentation, probably because the name was confusing. In January 1977, Moncrief and Popovich attended the National Institute of Health Contractors Meeting, where they met Karl Nolph [71], who was practicing nephrology at the University of Missouri in Columbia, Missouri. Nolph became interested in the new technique and decided to start collaboration with the Austin group. During their initial discussions, they agreed that "continuous ambulatory peritoneal dialysis" (CAPD) might be a more appropriate name for the new modality [71]. They published the experience with nine patients treated for 136 patient weeks in a classical article that established the use of CAPD [72]. The procedure was simple and involved the continuous presence (i.e., all day long, 7 days a week) of dialysis solution in the peritoneal cavity. Manual exchanges were done 4–5 times a day, and the dialysis catheter was capped between the exchanges, allowing participation in daily activities. The dialysis was called "portable" or "internal" and did not require the presence of a machine [72]. Other advantages of CAPD were identified: it allowed continuous, steady state chemistries after a few weeks because there was constant removal of waste products from the body; the procedure could be done by the patient unaccompanied at home or "anywhere" dietary restriction was not necessarily severe (later it has been recognized that sodium restriction is actually very important); CAPD was better tolerated from the cardiovascular perspective; and larger molecule clearance was significantly higher compared with hemodialysis. CAPD did not eliminate one of the most important problems encountered in peritoneal dialysis, namely peritonitis. On the contrary, the risk of peritonitis was higher because of increased number of connections per day. Their patients had peritonitis, on average, every 10 weeks [72].

Two further modifications of the technique contributed to the decrease of peritonitis rates and facilitated worldwide acceptance of CAPD: the first was the use of dialysate in plastic bags, introduced by Oreopoulos in Canada, and the second was the introduction of the innovative Y-set connector system by Buoncristiani in Italy [64, 71, 73, 75].

CAPD with Plastic Bags

In 1976, Jack Rubin [64, 71], one of the fellows trained at Toronto Western Hospital under Dr. Oreopoulos, was accepted by Dr. Nolph to come for further training and research at the University of Missouri in Columbia, Missouri. He became involved in the emerging CAPD program and was impressed with the new technique. A year later, he returned to Toronto and tried to convince Oreopoulos to adopt this new, continuous procedure that seemed to be better than the typical intermittent peritoneal dialysis. Because of the high peritonitis rates, he was hesitant to introduce it, until one of his patients, who had been on intermittent peritoneal dialysis for about 2 years, had to be admitted with complications related to uremia. She was severely underdialyzed, and Oreopoulos decided to give CAPD a try: she was started on CAPD on September 27, 1977 [64]. Her improvement was so dramatic that he decided to convert all his almost 40 home intermittent peritoneal dialysis patients to CAPD and was able to do this in only a few weeks [71, 73]. Patients' acceptance was excellent and the patient population continued to grow at a fast rate at his center [64]. Because, at the time, dialysis solutions were available in plastic bags were only available in Canada, they adopted a slightly different technique: after filling the peritoneal cavity with 2 L of dialysis solution, the tubing connecting the bag with the dialysis catheter was clamped and the plastic bag was wrapped around the patient, without disconnecting the bag from the catheter. After 6 h, the empty bag was placed on the floor, the tubing was unclamped, and the dialysate was allowed to drain by gravity. When the drainage was complete, the bag was disconnected from the system and a new bag was connected to the permanent catheter to repeat the cycle. They initially used the standard Y-set for acute peritoneal dialysis. The unused arm of the Y-tube was closed and tightly wrapped with the bag, making the

tubing system bulky and uncomfortable. Oreopoulos was trying to improve the tubing by eliminating the redundant part and create a straight tube with a Luer connector for connection with the catheter at one end and a spike for connection with the plastic bag at the other end. After consulting with his Baxter representative, he realized they had the straight tube available from the reverse osmosis machine [64]. They started using this tube and developed the Toronto Western Hospital Technique for CAPD, known also as the "spike technique" [73, 74]. With this technique, their rate of peritonitis was decreased to one episode every 10.5 patient months [74]. As a result of this remarkable improvement and with substantial pressure from the groups in Columbia, Missouri, and Austin, Texas, and also from the National Institutes of Health, the Food and Drug Administration (FDA) finally approved the use of the plastic bags in the United States in October 1978 [64, 71].

The Y-Set and "Flush Before Fill" Technique

In the 1980 s, Dr. Umberto Buoncristiani [73] from Perugia, Italy, published incredible results with an innovative Y-set, which resulted in a significant drop in the peritonitis rates to one episode to every 40 patient-months [73]. Buoncristiani was searching for an original technique in part because his patients were refusing to switch from the intermittent modality to the more efficient CAPD, as they found the "wearable bag" distasteful [75]. He was more concerned about the high rate of peritonitis and was also trying to develop a system to decrease the risk of infection. He realized that the "contaminating act" takes place at the time when a connection is made between a new bag and the transfer set, followed by the filling phase, when the infused fluid carries bacteria into the peritoneal cavity [75]. He reintroduced the Y-tubing, connected with one arm to the catheter, and the other two arms of the "Y" to bags, one containing dialysate and the other one empty. With this technique, after the connections are made, before the draining is started, some fresh dialysate is washed out into the drainage bag, flushing with it any bacteria that might have contaminated the tubing at the time of the connection. This is followed by drainage of dialysate into the empty bag and then filling of the abdominal cavity with the new solution. After the infusion is finished, the two bags are disconnected and the Y-set is filled with an antiseptic. This technique is known as "flush before fill" or "flush after connect," and the system is known as "the disconnect system" [73, 75]. The results were impressive, but they were not easily accepted in North America. The Italian group carried out a prospective, randomized controlled study to compare the Y-set with the standard spike system [76]. Their results were published in 1983 and were again remarkable: the peritonitis rate was one episode every 33 patient-months in the Y-set group, compared to one episode every 11.3 patient-months in the standard system [76]. A multicenter, randomized clinical trial was then carried out in Canada [77] and the results confirmed the Italian experience: their Y-connector group had one episode of peritonitis in 21.53 patient-months compared to one episode in 9.93 patient-months in the standard system group [77]. Subsequently, the Y-set technique has been accepted worldwide as standard.

With these changes, the use of CAPD increased considerably all over the world, a trend that continued through the early 1990 s.

Automated Peritoneal Dialysis (APD)

The use of machines for peritoneal dialysis was left behind for a while, as the CAPD technique proved to be much simpler and efficient than intermittent peritoneal dialysis [78]. After long-term use of CAPD, new problems have been discovered: patients were losing motivation after long periods of time using manual peritoneal dialysis; adequate dialysis was difficult to attain after the residual renal function was lost, especially in large patients, requiring an increase in the total volume of daily dialysis solution; recurrent peritonitis, especially due to touch contamination, continued to remain a problem and one of the main causes of technique failure. Interest in using the machines for peritoneal dialysis was re-established in early 1980 s.

Diaz-Buxo and his collaborators [79] introduced an automated cycler to deliver three exchanges at night, during sleep. In the morning before disconnection, the machine filled the peritoneal cavity with fresh dialysate to be drained at night, when the patient connected again to the machine. The main goal of this modality was to reduce the number of manually performed connections, and thus decrease the risk of touch contamination and peritonitis. This procedure was also a continuous one, as the fluid was always present in the peritoneal cavity and it was thus called "continuous cyclic peritoneal dialysis" (CCPD). The dwell time was supposed to be for at least 3 h, allowing complete equilibration, and small solute clearance was comparable with CAPD. Basically, the CCPD schedule was a reversal of the CAPD schedule, with the three shorter dwells performed at night and one long dwell during the day.

Around the same time, Price and Suki [80] described an "automated modification of prolonged-dwell peritoneal dialysis" (PDPD) [80], which was comparable to CAPD in improving blood chemistries and had lower peritonitis rate than CAPD, similar to results reported by Diaz-Buxo [79].

The continuous development of simpler cyclers and patient preferences has driven an increase in the use of cyclers over the years. This technique became more appealing for physicians after the development of the peritoneal equilibration test (PET) as a tool of defining peritoneal transport characteristics of individual patients [81]. Cycler-based prescription made it easier to deliver increased number of short time dwells for high transporters and maintain them on peritoneal dialysis. Later, the CANUSA study [82] showed a strong, positive correlation of the total small solute clearance with survival. National Kidney Foundation – Dialysis Outcome Quality Initiative (NKF – KDOQI) guidelines were published in 1997 and recommended a target weekly Kt/V of 2.0 for CAPD and 2.1 for CCPD, based on results of the CANUSA study [83]. The need to achieve these high targets drove an increase in APD utilization, because the use of automated machines allowed easier delivery of higher daily dialysate volumes. Subsequent reanalysis of the CANUSA study [84] showed that the decrease in the solute clearance over time was caused by uncompensated loss of residual renal function, suggesting that lower peritoneal clearance targets might be appropriate. This was confirmed by another landmark study, the ADEMEX study in 2002 [85]. Even so, APD use has increased significantly since its reintroduction, probably because it allows positive changes in the lifestyle of dialysis patients.

Peritoneal Dialysis Catheters

The Tenckhoff catheter remains the gold standard for peritoneal dialysis access and is the most widely used [58]. Individual dialysis centers' preferences for dialysis catheters are based on their particular experience and availability of other catheters. Various improvements were tried over the years in many centers, with the purpose of finding the best design with the lowest rates of mechanical and infectious complications.

In Toronto, Dr. Oreopoulos, in collaboration with Gabor Zellerman, attached three silicon discs to the intraperitoneal segment in order to prevent obstruction and migration of the catheter [39, 64]. This catheter was further improved and two variations were described a few years later [86]: Toronto Western Hospital – type 1 and 2. The first type was a double cuff straight catheter with two silicone discs attached to the intraperitoneal segment, and the type 2 was further equipped with a Dacron disc and a silicone ring at the base of the intraperitoneal cuff, which was meant to improve the seal at the peritoneal hole and prevent leaks [86].

In 1980, Ash et al. [87] introduced a "column disc catheter," which was abandoned later in favor of the "T-fluted" Ash catheter [88]. In 1983, the Valli catheter was described: the intraperitoneal segment was enclosed and protected from omental obstruction by a silastic balloon with many holes, which also was supposed to help self-positioning [89].

The permanently bent intramural segment, known as the "swan neck" [90], decreased the risk of external cuff extrusion and it was introduced by Twardowski et al. in 1986. Two somewhat similar designs were introduced later: the Cruz (pail-handle) catheter in 1992 and the "Swan neck with elongated superficial cuff (Moncrief–Popovich)" in 1993 [39]. Twardowski and his collaborators at the University of Missouri, Columbia, Missouri, introduced several more modifications [39]: a Swan neck Missouri catheter has a slanted flange and bead attached below the deep cuff, to improve catheter fixation and decrease leaks; the Swan neck presternal catheter was introduced in 1992 and has a long, tunneled segment with the exit site located in the presternal area. This design was intended to decrease the rate of peritonitis.

Conclusion

Development of peritoneal dialysis has been a fascinating intellectual, scientific, and medical journey. Table 1.2 illustrates the most important moments in the history of peritoneal dialysis, and the most important scientists who made the development of this life-saving treatment possible and applicable to patients afflicted with severe kidney disease. In recent years, there has been a trend for a decrease in peritoneal dialysis utilization, a trend that is more pronounced in the United States and Canada. As a peritoneal dialysis modality, APD is becoming the preferred one, with most of the new peritoneal dialysis patients opting for cycler therapy. At the end of 2004, there were 1,371,000 dialysis patients worldwide and 11% of them were on peritoneal dialysis. Thirty percent of the 149,000 global peritoneal dialysis patients and 60% of the U.S. patients were on APD [91]. The decrease of peritoneal dialysis utilization is thought to be multifactorial, but there is no doubt for those who use it that it remains a very important tool in an integrated renal replacement program. Patient survival in peritoneal dialysis seems to be better on the first

Table 1.2 Milestones in the development of clinical peritoneal dialysis

Investigator	Description	Date
Ganter [20, 21]	First human peritoneal dialysis	1923
Wear, Sisk, and Trinkle [22, 26]	First successful treatment of ARF with PD	1938
Frank, Seligman, and Fine [23–25, 27]	Seminal studies of PD in ARF in animals and humans	1946–1948
Grollman [28]	Long-dwell PD for uremia in animals and humans	1951
Maxwell [31]	IPD for ARF, commercially available dialysis solutions, and nylon catheter	1959
Doolan [33]	IPD for ARF, PVC catheter	1959
Ruben [32, 34]	First long-term IPD for CKD	1959
Boen [36, 37, 40]	First program of long-term PD First automatic peritoneal dialysis machine	1962
Boen [50]	Repeated puncture technique	1964
Tenckhoff [54]	Tenckhoff catheter	1968
Popovich and Moncrief [72]	CAPD	1978
Oreopoulos [64]	CAPD with plastic bags	1977
Buoncristiani [75]	"Flush before fill"	1980
Diaz-Buxo [79] Price and Suki [80]	APD/CCPD	1981

ARF – acute renal failure, PD – peritoneal dialysis, IPD – intermittent peritoneal dialysis, PVC – polyvinyl chloride, CKD – chronic kidney disease, CAPD – continuous ambulatory peritoneal dialysis, APD – automated peritoneal dialysis, CCPD – continuous cyclic peritoneal dialysis.

2 years of treatment than with hemodialysis [92] and the technique survival at 5 years is around 50–70% [93]. Peritoneal dialysis can no longer be viewed as a second class treatment and with further technological improvement in cyclers and newer, biocompatible peritoneal dialysis solutions, and capability to deliver adequate dialysis in terms of solute and fluid removal, there is a hope that peritoneal dialysis will continue to grow.

Chapter 2
Current Status of Peritoneal Dialysis

R. Mehrotra and E.W. Boeschoten

It was in 1923 that Ganter performed the first peritoneal dialysis (PD) in a woman with renal failure [1]. However, the early experience with intermittent peritoneal dialysis (IPD) was discouraging and led to the belief that PD was not an appropriate renal replacement therapy for patients with end-stage renal disease (ESRD) [2]. The introduction of the concept of continuous ambulatory peritoneal dialysis (CAPD) by Popovich et al. in 1976 [3] was initially met with scepticism, but the successful clinical experience in nine patients at two centers in the United States [4, 5] convinced skeptics about the potential of the technique as a viable alternative to hemodialysis. Over the last decades, PD has grown worldwide to become the third most common modality for renal replacement. In this chapter, we will present a brief overview of the major advances in the care of patients undergoing PD.

PD: The Technique

A major innovation early on was the introduction of sterile plastic bags for dialysate [6]. Since then, the basic PD system consists of a PVC bag containing 1.5–3.0 L of dialysate, a transfer set, and a catheter access to the peritoneal cavity. Significant advances in the technique of PD have occurred during the subsequent decades.

Trends in Connectology

The initial bag-and-spike system was recognized to result in an unacceptably high incidence of peritonitis from touch contamination. In Italy, a double-bag Y-set device was developed that used a disconnect system with a flush before fill technique [7]. The early success in Italy was confirmed in several other centers [8–10] and is now the system of choice for PD. Over 90% of all patients in North America, Europe, Australia, and New Zealand now use these disconnect devices [11, 12]. The increased monetary cost of the twin-bag system is more than offset by the reduction in peritonitis rates [13].

Trends in Catheter Design

Tenckhoff's design of the indwelling silicone rubber catheter with two dacron cuffs was instrumental in making IPD a viable long-term therapy for renal replacement [14] and it still remains the most widely used catheter worldwide [15–17]. Several variations in the catheter design have been introduced and include the number of cuffs (single vs. double), design of the subcutaneous pathway (permanently bent or "swan-neck" vs. straight) and the intra-abdominal portion (straight vs. coiled) [18]. Double-cuff catheters were thought to be associated with a lower incidence of both peritonitis [16, 19, 20] and exit-site infections [21, 22]. However, in a prospective randomized comparison no significant differences between catheters with single or double cuffs could be established with respect to catheter survival, episodes of peritonitis, and exit site infections [23]. The benefit of the swan-neck design was demonstrable in the United States Renal Data System (USRDS) study only after adjusting for possible center effects [16]. Similarly, no convincing evidence exists for the superiority of the coiled design of the intraperitoneal portion of the catheter [18]. Finally, a downward-directed exit site was thought to result in a reduction in the incidence of exit-site infections and peritonitis

[19, 24], but in a prospective comparison, catheter types employing downward and lateral tunnel-tract and exit-site configurations produced equivalent outcomes for infectious and mechanical complications [25].

Innovations in connectology and catheter design have resulted in a 1-year catheter survival of over 80% [24]. The skills of the surgeon or nephrologist involved in the implantation of the catheter and the dedication of the PD team involved in postoperative catheter care now seem to be the most important predictors of cather survival and complications.

Trends in Peritoneal Dialysis Solutions (PDS)

Initially, glucose-based dialysate was the only PDS available. The osmotic agent glucose was buffered with lactate (or, in the early years, with acetate) to produce a low pH of 5.2 to avoid the caramelization during heat-sterilization of the PDS. The limitations of the currently available bioincompatible glucose-based solutions are now widely recognized [26]. The areas of concern are the role of glucose in the nonenzymatic glycation, formation of advanced glycosylation end-products (AGE) and glucose degradation products (GDP), and the unphysiological pH and buffer combinations. Glucose and GDPs are the most likely causative agents being responsible for ultrafiltration failure in PD patients [27–29] (Fig. 2.1). To overcome these and other concerns, alternative solutions have been designed, each targeted to achieve a clinical goal (Table 2.1).

In order to minimize acidity of the peritoneal fluid and reduce GDP production, multibag systems are currently commercially available. In these systems, the buffer is separated from the glucose solution, allowing the glucose to be stored at a very low pH and thus minimizing the formation of GDPs during heat-sterilazation. Low GDP solutions have been marketed and demonstrate improved biocompatibility. Preliminary evidence shows a salutary effect on preservation of residual renal function and retrospective analyses suggest a survival advantage with these solutions [30, 31]. These findings, however, need to be confirmed in prospective, randomized clinical trials.

Icodextrin (Extraneal®) is a glucose polymer that has undergone clinical trials since the early 1990 s. The molecular size of the icodextrin molecule is substantially larger than that of glucose and is removed from the peritoneal cavity slowly via the lymphatics. This allows for sustained ultrafiltration during the long dwells. The use of 7.5% icodextrin for an overnight exchange in patients with CAPD can generate 3.5 times greater ultrafiltration at 8 h than the 1.5% dextrose solution and similar to the 4.25% dextrose solution [32]. The amount of ultrafiltration with icodextrin can be further augmented by adding nitroprusside and this is associated with an increase in urea and creatinine clearances [33]. When used instead of standard glucose solutions for the long daytime dwell in patients on continuous cyclic peritoneal dialysis (CCPD), it generates significantly greater ultrafiltration, increased peritoneal clearance, and increased sodium removal [34, 35]. In high-average and high transporters, the ultrafiltration during the long daytime CCPD dwell with icodextrin is superior to that obtained with 4.25% dextrose [36]. In short-term clinical studies, no

significant adverse effects were noticed although serum maltose levels increased in both CAPD and CCPD patients [32, 37]. In later observations, the development of a skin rash appeared to be the most common treatment-related side effect of the use of icodextrin [38, 39]. There was no increase in the episodes of bacterial peritonitis, and during such episodes no further increase in maltose concentration occurred [40]. In response to an excess of cases of aseptic peritonitis in PD patients using icodextrin, a global recall of some batches of icodextrin PDS was issued in May 2002. Extensive analysis revealed that these cases were due to contamination of dialysate with *Alicyclobacillus* [41]. This problem has been resolved. With the recognition of the importance of ultrafiltration in determining patient outcome, icodextrin PDS are increasingly being used in clinical practice in many countries.

Nutrineal® is a 1.1% amino acid–containing solution with an ultrafiltration capacity equivalent to 1.5% dextrose PDS. Nutrineal® contains no glucose and GDPs and, like icodextrin, has been shown to be more biocompatible to the peritoneal membrane than the conventional PDS [42, 43]. Even though Nutrineal® induces anabolism in malnourished PD patients [44], the clinical benefit of improvement in nutritional status in randomized, controlled trials has been modest [45–47]. Providing a surfeit of calories, as obtained with co-administering amino acid and glucose PDS during night-timing cycling, may enhance the nutritional benefits of these solutions [48].

To gain the maximum benefits of biocompatibility and avoidance of glucose and GDP exposure, it is likely that future developments will focus on a combination of products. More prospective outcome-based studies, particularly focusing on the systemic effects of the new solutions, compared to those obtained by comparing these solutions with conventional PDS, will be required to convince health-care providers to pay the higher costs of the new solutions.

Automated Peritoneal Dialysis

Automated peritoneal dialysis (APD) refers to all forms of peritoneal dialysis employing a cycler to perform the dialysis exchanges. APD regimens include CCPD, IPD, nocturnal intermittent peritoneal dialysis (NIPD), and tidal peritoneal dialysis (TPD). In early experiences with CCPD this modality was shown to be accompanied by lower rates of peritonitis and hospital admissions, whereas it was as effective as CAPD with a Y-connector for patient and technique survival [49]. However, some of the later studies have not been able to confirm the lower incidence of peritonitis in APD patients [50]. The most important advantage of APD compared to CAPD seems the better quality of life and its surrogate, 'patient preference' [50, 51].

Assisted Peritoneal Dialysis

CAPD and APD are home-based dialysis modalities such that patients are trained to perform the treatment themselves. However, in many societies, the elderly, who generally have a higher co-morbidity burden, constitute a progressively larger cohort of incident dialysis patients. These patients are less likely to start or to continue on peritoneal dialysis because they are not able to perform the PD exchanges or to operate the PD cyclers themselves. Many centers have demonstrated the feasibility and safety of assistance for PD treatment by district or private nurses, at the patient's home, for physically dependent or elderly patients [52–54]. However, in a study from France, patients undergoing assisted PD appeared to have a higher risk of peritonitis than family-assisted patients, unless additional regular home visits were organized by the original training center [55]. Therefore, regular home visits by the training center may be necessary to optimize the care provided by the home nurse.

Epidemiology

Patient Numbers on PD

During the 1980 s there occurred a rapid growth in the utilization of PD. This rapid growth continued between 1990 and 1995, with annual global growth rates reaching 15% for the period 1991–1994 [11]. At the end of 1997 the chronic PD population worldwide was estimated to be 115,000, representing 14% of global dialysis patients [56]. However, since then the growth in use of PD has been slower than the increase in the number of patients undergoing maintenance dialysis worldwide [57, 58]. At the end of 2004, 149,000 patients were undergoing PD, representing 11% of the total dialysis population (i.e., 1,371,000). The reasons for this slow-down in the proportion of PD patients seem multifactorial. As the utilization of PD is declining, particularly among the elderly [54, 59], and the elderly are the largest and

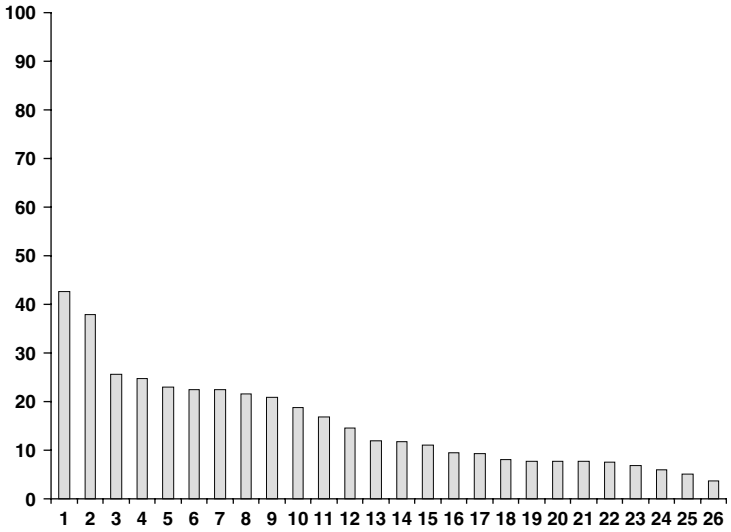

Fig. 2.2 Percentage of prevalent dialysis patients on PD in selected countries worldwide. Data obtained from reference [57]. Index for countries: 1, New Zealand; 2, Iceland; 3, Netherlands; 4, Denmark; 5, Korea; 6, Australia; 7, Sweden; 8, Scotland; 9, Finland; 10, Canada; 11, Norway; 12, Philippines; 13, Italy; 14, Turkey; 15, Israel; 16, Malaysia; 17, Greece; 18, Russia; 19, Taiwan; 20, United States; 21, Uruguay; 22, Czech Republic; 23, Thailand; 24, Chile; 25, Germany; 26, Japan

fastest growing group of patients with chronic disease, barriers to self-care PD may contribute. Also, the burden of unrealistic high solute clearance targets might have reinforced the notion of PD as an 'inadequate' therapy for renal replacement [60]. Finally, institutional changes in the delivery of dialysis therapy – e.g., proliferation of hemodialysis units and corporatization of dialysis care in the United States – are important contributors to this declining trend.

The wide variations in the utilization of PD in different countries are striking [61]. The proportion of patients on dialysis treated with PD varies from 2 to 4% in countries such as Chile, about 5 to 10% in France, Germany, and the United States, 20 to 30% in the Scandinavian countries, The Netherlands, Australia, and Canada, and >75% in Mexico and Hong Kong (Fig. 2.2) [58, 61]. Even within the same country there are wide variations in the use of PD. In the United States, the prevalence of PD in 2004 ranged from 5% in New York to 10.8% in Network 16 (Alaska, Idaho, Montana, Oregon, and Washington) [57]. In Italy, the disparity in use of PD among regions has increased, varying from 0 to 55% [62]. Finally, in France, there are large differences in the use of PD and the percentage of patients treated with PD can vary from 0 to 22% between different towns in the same region [63]. On the other hand, more recently, in Romania, the share of the dialysis pool of incident patients has increased from 10% in 1995 to 29% in 2004 [64]. The reasons for these differences are multiple and complex and are discussed in a subsequent section.

Growth of Automated PD (APD)

While in the 1980 s and the early 1990 s the growth in PD was almost entirely due to the expansion of CAPD programs, it is the growth in automated PD that is sustaining the ongoing increase in the number of patients on PD [58, 65, 66]. This growth has been mainly driven by patient preference and the development of new, simpler cyclers [67]. It is anticipated that the use of APD will continue to expand.

Factors Affecting the Choice of PD

The disparity in the use of PD in different countries and different parts of the same country has stimulated tremendous interest in elucidating the factors that determine the choice of PD as the modality for renal replacement. A large number of factors impact upon this choice (Table 2.2).

Medical and Psychsocial Factors and Patient Education

For technical reasons, PD is the modality of choice in infants and small children with ESRD [68]. The presence of medical contraindications to PD is more frequent than that for maintenance HD [69]. In a recent analysis from the Netherlands Cooperative Study on the Adequacy of Dialysis (NECOSAD) study, previous major abdominal surgery was the most common medical contraindication followed by cystic kidneys, poor lung function, chronic inflammatory

bowel disease, and poor cardiac condition. Poor cardiac condition was the most frequent medical contraindication to HD. Most patients deemed to have a social contraindication to PD were judged by the nephrologist to be incapable of performing the treatment by themselves. The percentage of patients having any contraindication to PD increases with age. However, studies show that up to 70% of adults have neither medical nor social contraindications to either maintenance HD or chronic PD [70–72].

Predialysis care is associated with a greater probability of selection of PD [69, 73–75]. However, if one accounts for the adequacy of education about dialysis modalities, delayed referral may not be as strong an impediment to the selection of home dialysis modalities [71, 76]. Consistent with these observations, adequate predialysis education is associated with a far higher probability of choosing home dialysis [77]. Furthermore, structured, two-step patient education has been shown in a randomized, controlled trial to be associated with significant increase in the proportion of patients that plan to start home dialysis therapy [78].

Physician Bias and Patient Education

Physician bias probably also plays an important role in the utilization of PD [62, 63, 79]. The nature of patient education is dependent on the physician bias, and in nonurgent situations the decisions of patients depend mostly on the information provided by their doctors. In the Dialysis Morbidity and Mortality Study (DMMS), Wave 2, only 25% of the patients who chose HD reported that PD was discussed with them, whereas 68% of the patients who chose PD reported that HD was discussed with them [80]. In fact, 84% of the PD patients but only 47% of the HD patients enrolled in the DMMS Wave 2 study appeared to contribute substantially to the decision about their own dialysis modality. A more recent study from the United States confirms the finding that the majority of patients are not presented with the choice of either chronic PD, home HD, or renal transplantation (66, 88, and 74%, respectively) [71]. An incomplete presentation of treatment options is an important reason for underutilization of home dialysis therapies and probably delays access to transplantation. In societies where such an impediment exists, reimbursement for pre-ESRD education may ensure timely access to different renal replacement therapies.

Economic Factors

The effect of economic factors on the selection of dialysis modality may vary by the region of the world. In Europe and America, it appears that the greater the involvement of the "public" (as opposed to "private") facilities in the provision of dialysis care, the larger the proportion of dialysis patients on chronic PD (Fig. 2.3) [62, 63, 79, 81, 82]. In these areas of the world, the cost of health-care workers in the provision of dialysis therapy is greater than the cost of dialysis supplies. Thus, the delivery of personnel-intense therapy like hemodialysis is more expensive than a therapy that uses a larger amount of supplies, viz., PD [82]. However, in many Asian and African countries, manpower is substantially cheaper than the cost of dialysis supplies, which are often imported from Western countries. This makes hemodialysis more economical than PD in these societies [83]. Manufacture of dialysis solutions in the developing countries has gone a long way in making PD affordable in some of these societies.

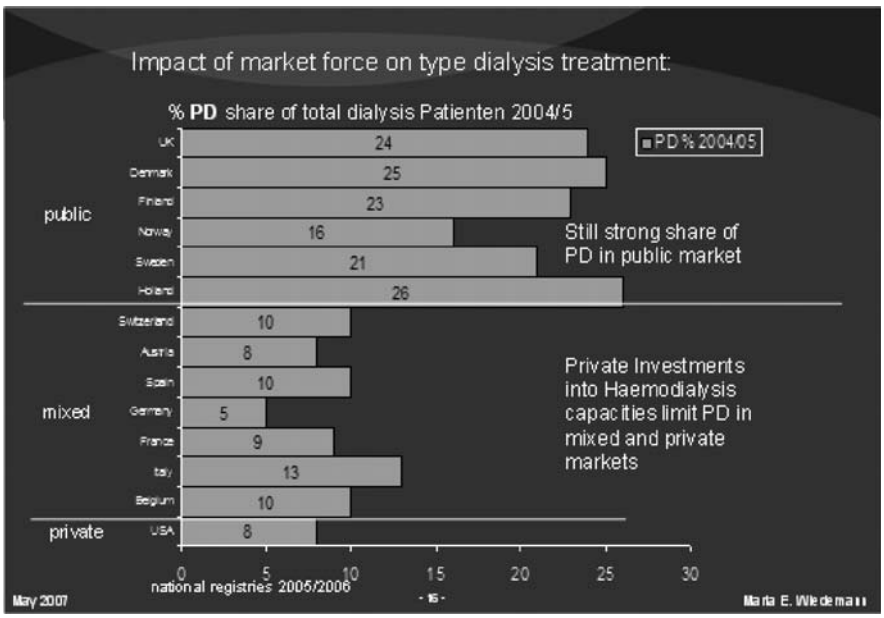

Fig 2.3 Use of PD as a modality for dialysis in various countries during the mid-1990s, based upon the funding of the dialysis provider. The top panel (Japan, USA) shows predominantly private dialysis providers; the middle panel (Germany, Belgium, Austria, Spain, France, Italy) shows a mixture of public and private providers, and the bottom panel (Switzerland, Sweden, Norway, Netherlands, Denmark, Finland, Canada, UK) shows predominantly public providers [81]

Physician reimbursement is significantly influenced by the health-care system and has been identified as a most important determinant of the choice of PD by some [62, 63, 79]. However, financial incentives in Canada (province of Ontario), Germany, and the United States have not translated into a greater utilization of PD [84, 85].

Outcome of PD

HD and PD: Comparative Survival

The current practice of care of the ESRD patient is based on the premise that HD and PD are equivalent therapies. Over the past 20 years, many studies have compared mortality risks in HD and PD [86–94]. Even though at first the results of these studies appear conflicting, some common themes have emerged. First, that the relative risk for death for PD versus HD varies by time over therapy such that most subgroups of patients have a survival advantage during the first 1–2 years of therapy [95]. Second, the lower the co-morbidity burden, the greater is the initial survival advantage associated with PD. In contrast, a higher co-morbidity burden diminishes the advantage of PD and may even be associated with an increased risk after 1–2 years [95]. Not withstanding these conclusions, it remains unclear if any of the differences in the outcomes can be attributed to the dialysis modality and may simply represent residual confounding from the inability of our statistical tools to adjust for differences in the patient characteristics. Given these caveats, patient choice should probably take precedence in the selection of dialysis modality.

Technique Survival

Technique failure is often used to describe the outcome of PD patients and usually implies cessation of use of PD due to transfer to HD, after censoring for death or transplantation. Based on the published studies, technique survival varies considerably in different countries as well as between different centers in the same country [15, 96–101]. The difference in technique success between PD and HD is greatest in the youngest patients and progressively diminishes in the other age groups [102]. Furthermore, some racial groups may have a lower short-term technique survival than others [97] and patients who are referred late are more likely to be transferred to HD than those who are referred early [103]. With improvements in patient selection, training, and aggressive management of complications, it is possible to obtain 1-year technique survival in excess of 80% [104, 105].

If death and transplantation are excluded, infectious complications have been the most common reason for transfer-out from PD [24, 106, 107]. However, with refinements in technology there has been a significant reduction in the rates of infectious complications. This has been paralleled by an increasing recognition of the importance of

small solute clearance and ultrafiltration capacity. Consistent with the importance of ultrafiltration, retrospective studies have demonstrated that it may be possible to prolong the time for which patients are treated with PD with the use of icodextrin PDS [108, 109].

Adequacy of Small Solute Clearances

In the early years of PD it was commonly accepted that subjective clinical judgment was enough for determining that a patient was well dialyzed [110]. Even though the concept of urea kinetic modeling was first extended to PD in the mid-1980 s [111], it was not until the 1990 s that this issue was systematically investigated [112–115]. The multicenter CANUSA study [115] showed that both total weekly Kt/V_{urea} and creatinine clearance (peritoneal + renal) were strong predictors of patient survival, and survival improved continuously with increasing total small solute clearance, without an apparent threshold. Higher dialysis dose, including residual renal function, was also associated with better technique survival and less hospitalization. The similar results from the study of Maiorca et al. [114] supported the CANUSA findings and both provided the evidence for the DOQI guidelines published in 1997 [116]. The DOQI guidelines recommended a target Kt/V_{urea} of 2.0 per week and creatinine clearance of 60 L/week/1.73 m^2 body surface area for CAPD. Somewhat higher levels were recommended for APD. Reanalysis of the CANUSA study, however, revealed that the effect of solute removal on outcome was entirely attributable to the effect of residual renal function [117]. In order to bypass the influence of residual renal function, the effect of the dialysis dose on outcome has been evaluated in four studies of anuric subjects; these studies suggest a minimum threshold of peritoneal Kt/V_{urea} of 1.5–1.7 [118–121]. However, as none of these studies was randomized, confounding cannot be excluded. Consistent with these observational studies, two randomized controlled clinical trials were unable to demonstrate an improvement in survival by increasing the peritoneal small solute clearances within the range currently achieved in clinical practice [122, 123].

Based on these observations, various expert groups now recommend a minimum, total Kt/V_{urea} of 1.7 [60, 124]. Furthermore, it has been recognized that besides solute removal, achievement of euvolemia should be an important goal of adequate dialysis [120, 124].

Residual Renal Function

Not surprisingly, residual renal function (RRF) influences morbidity, mortality, and quality of life in chronic dialysis patients [117, 125–129]. RRF not only contributes to small solute removal, but, probably even more importantly, allows for better volume control and larger-molecular weight solute clearances and continued endocrine and metabolic function [60]. As RRF has a major impact on the outcomes of chronic dialysis patients, its preservation is of major importance.

Decline Rate of Residual Renal Function in PD

Several studies have shown that RRF is better preserved in PD than in HD patients [130–133]. In the NECOSAD study, a large prospective cohort of HD and PD patients in the Netherlands [133], the decline of RRF in HD and PD patients was most pronounced during the first 3 months after the start of treatment. At all time points (0, 3, 6, and 12 months) unadjusted RRF values were higher in PD patients when compared to HD patients. Also after adjustment for baseline variables, PD patients had a 30% higher RRF than HD patients ($p < 0.0001$). Moreover, after adjustment for baseline RRF, the relative difference increased over time, especially during the first 6 months. However, the absolute decrease in both groups was about equal. Proteinuria, a higher diastolic blood pressure, hypotensive episodes in HD, and episodes with dehydration in PD appeared to be associated with a more rapid decline of RRF. In contrast to other studies [134, 135], but in line with the study of de Fijter et al. [136], no detrimental effect of APD on RRF could be found.

Preservation of Residual Renal Function

Considering the importance of RRF to the outcome of dialysis treatment, we need to develop treatment plans that focus on preserving RRF in PD patients [137]. This begins with regular monitoring of RRF and this should be done with a 24-h collection of urine every 1–3 months to measure volume and urea and creatinine clearances. In view of

substantial tubular secretion of creatinine at low GFRs, arithmetic mean of urea and creatinine clearance may be a better measure [138, 139]. Blood pressure should be well controlled and hypotensive episodes should be avoided. Randomized, controlled clinical trials have demonstrated that the benefit of angiotensin converting enzyme inhibitors and angiotensin receptor blockers is seen even at the low levels of glomerular filtration rates reported in patients undergoing PD [140, 141]. The use of diuretics for the preservation of RRF is controversial [142]. Loop diuretics produce an increase in diuresis and may result in a clinically meaningful improvement in fluid balance. However, loop diuretics have no effect on preserving solute clearances [143]. Finally, nephrotoxic agents like aminoglycosides, nonsteroidal anti-inflammtory drugs, and iodinated contrast agents should be avoided as far as possible.

Incremental Peritoneal Dialysis: Are Renal and Peritoneal Clearances Equivalent?

Even though targets have been set for small solute clearance clearances for patients undergoing maintenance dialysis, patients with chronic renal failure are allowed to dwindle to clearances far below the adequacy target before dialysis is initiated [115, 144, 145]. Based on the similar relationship between dietary protein intakes and clearances in pre-dialysis patients and PD patients, the 1997 Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines recommended that the level of small solute clearances considered to provide adequate CAPD at that time (weekly Kt/V_{urea}, 2.0) be considered the level of renal function at which chronic dialysis should be initiated [116, 146]. The PD subcommittee of the KDOQI recommended that chronic dialysis may be initiated in an incremental fashion such that the sum of the renal and dialytic weekly Kt/V_{urea} should remain near 2.0 at all times. Even though scientific evidence for this approach was lacking, "incremental dialysis" seemed rational. In subsequent studies, this approach could not be validated [147, 148]. A reason for this lack of evidence may have been the assumption that renal and peritoneal solute clearance are equivalent. Even when the measured small solute clearances are identical, clearances for middle and larger molecular weight solutes may differ considerably. Furthermore, the kidney has many other metabolic and endocrinologic functions. Therefore, 1 mL/min of solute clearance by the kidney is of more value to the patient than 1 mL/min solute clearance by the kidney [137].

Nutritional Status

Protein energy wasting at the time of initiation of dialysis, and subsequently, is an important surrogate marker of an adverse patient outcome. This observation makes the assessment of nutritional status and prevention of protein energy wasting an important clinical priority.

Prevalence of Protein Energy Wasting

Protein energy wasting is widely prevalent in the PD population [115, 149, 150]. It is estimated that 40% of PD patients have protein energy wasting, with 5–10% of patients demonstrating severe malnutrition [151]. Since peritoneal glucose absorption contributes to the total energy intake of a PD patient, suboptimal protein intakes are probably more important than suboptimal energy intakes as a cause of nutritional decline [151].

The Malnutrition Inflammation Atherosclerosis (MIA) Syndrome

Several studies have shown that malnutrition, inflammation, and atherosclerotic vascular disease are inter-related and each is associated with mortality [152–155]. The combination of these three conditions has been referred to as the MIA syndrome [156]. Several theories have been proposed to explain the supposed links between the three components of the MIA syndrome [155, 157, 158], but the mechanisms involved are not yet clear. Stenvinkel et al. [156] suggested two types of protein energy wasting in ESRD patients: the first type (type 1) is associated with the uremic syndrome per se or factors associated with uremia such as physical inactivity, underdialysis, dietary restrictions, and psychosocial factors. This type is characterized by a modest reduction in serum albumin due to a low dietary intakes. Significant co-morbidity and signs of inflammation are usually not present in type 1 protein energy wasting and this condition may be addressed by eliminating the causative factors. On the other hand, type 2 protein energy wasting, characterized by significant co-morbid conditions, severe hypoalbuminemia, and an inflammatory response evidenced by higher levels of CRP and pro-inflammatory cytokines, may be more difficult to treat.

Losses of Nutrients in the Dialysate

From the beginning of the CAPD era, it has been recognized that PD is associated with protein losses in the dialysate [159–162]. In the guidelines for nutrition in chronic renal failure, these losses have been taken into account [163, 164]. A recent study suggests that APD may be associated with somewhat higher protein losses compared to previous reports in CAPD patients, and the magnitude of these losses may be related to the number of nighttime exchanges and the duration of dwell [165]. Protein and amino acid losses accounted for an average of 15% of total nitrogen appearance, accounting for almost a third of the increase in dietary protein requirements in CPD patients.

Strategies to Improve Protein Energy Wasting in PD Patients

Several interventions have been shown to improve protein energy wasting in dialysis patients [151]. It is unclear, however, if improvement in nutritional status will result in a reduction in morbidity or mortality of our patients. A detailed discussion is beyond the scope of this chapter but are summarized in Table 2.3 and some of the key issues are summarized below.

Residual Renal Function

RRF plays an important role in maintaining the nutritional status of patients on chronic dialysis [115, 149, 166]. In an international study, loss of RRF correlated with muscle wasting and contributed to anorexia and the symptoms of severe malnutrition [149]. Likewise, in the Canadian–USA (CANUSA) multicenter study, after 6 months of initiation of PD there was a progressive decline in nutritional parameters with declining residual renal function [115]. Hence, preserving residual renal function should be an important goal.

Small Solute Clearances

Several cross-sectional studies have shown a relationship between the peritoneal clearances, dietary protein intake, and the nutritional status of patients [167, 168]. In the CANUSA study, during the first 6 months of CAPD, the addition of dialytic clearances resulted in a marked increase in solute clearances. This was associated with significant improvements in several estimates of nutritional status (subjective global assessment, protein catabolic rate, and lean body mass) and these changes were significantly correlated with the estimates of the dose of dialysis [169].

Table 2.3 Recommended interventions to improve nutritional status in PD patients

Treat reversible causes of anorexia
Improve/maintain small solute clearances
Prokinetic agents for gastroparesis
Treat *Helicobacter pylori* infection
Increase supply of nutrients
Nutritional counseling
Appetite stimulants
Oral supplements
Enteral supplements
Intraperitoneal amino acids
Correct metabolic acidosis
Anabolic hormones
Recombinant human growth hormone
Insulin-like growth factor I
Nandrolone acetate
L-carnitine
Potential anti-inflammatory therapies
Treatment of co-morbid conditions

Correction of Metabolic Acidosis

The adverse impact of chronic metabolic acidosis on nutritional status has long been recognized [170]. Two randomized, controlled clinical trials among patients undergoing PD have demonstrated that correction of metabolic acidosis is associated with improvement of nutritional status and reduced hospitalization rates [171, 172].

Use of Intraperitoneal Amino Acid (IPAA) Solutions

Earlier studies with amino-acid solutions enrolled small numbers of patients, were uncontrolled, and used solutions not available commercially. However, three trials supported the use of these solutions. Two metabolic balance studies have demonstrated that IPAA solutions induce anabolism, particularly when a surfeit of calories (as with glucose-based dialysate) is provided [44, 48]. However, subsequent randomized, controlled clinical trials have demonstrated that the nutritional benefits of IPAA solutions may be modest (reviewed in [151]).

Obesity

Early papers on CAPD focused on weight gain during peritoneal dialysis as an undesirable complication [173–176]. Many PD patients experience significant weight gain upon initiation of therapy, but weight usually stabilized thereafter [174, 176]. The weight gain appears to correlate with the daily amount of glucose absorbed from the dialysate [173] and seems to be most prominent in patients who are already obese at the start of treatment [174]. More recently, the impact of obesity on outcomes of dialysis patients has been questioned. Unlike the observations in the general population, in HD patients obesity appears to be associated with improved survival [177]. The advantage associated with obesity in PD patients appears, though, to be less pronounced [178, 179]. In a report from the Australian and New Zealand registry, among patients undergoing PD, obesity was associated with worse outcomes [180] and a higher risk for peritonitis [181]. The effects of weight gain on outcomes of PD patients, thus, need further study.

Cardiovascular Disease

Vascular complications are the major cause of death in patients undergoing PD and include congestive heart failure, myocardial infarction, and cerebrovascular disease. While traditional risk factors like diabetes mellitus, hypertension, smoking, physical inactivity, obesity, and hyperlipidemia contribute substantially to cardiovascular disease in the general population, nontraditional risk factors like inflammation, anemia, and abnormal mineral metabolism are probably also important in dialysis patients [182]. These factors represent only some of the many nontraditional factors that may play a pathophysiologic role in the high cardiovascular burden in dialysis patients.

As discussed above, inflammation, indicated by elevated serum concentrations of acute phase proteins or cytokines, is associated with worse outcome in dialysis patients. Inflammation interacts with many pathophysiologic pathways that lead to vascular damage [183]. Emerging evidence indicates that loss of RRF may be associated with worsened inflammation and left ventricular hypertrophy and they may interact to increase mortality and cardiovascular death risk of PD patients [184].

There is substantial evidence that treatment of anemia in dialysis patients improves quality of life and objective markers of physical and cognitive performance [185, 186]. Furthermore, anemia has been shown to contribute to left ventricular hypertrophy [187]. Even though many epidemiological studies have consistently demonstrated an inverse relationship between hemoglobin levels and mortality, complete correction does not seem to lead to any improvement in survival over partial correction of anemia [188]. A randomized clinical trial of normalization of hemoglobin with erythropoietin in HD patients with cardiovascular disease was stopped prematurely as interim analyses suggested that continuation of the study was unlikely to prove the primary hypothesis [189]. There was a trend towards a higher mortality in the intervention group but this did not reach statistical significance. Thus, based on the current body of evidence, complete correction of anemia cannot be recommended for dialysis patients at this time.

Abnormal mineral metabolism is common in patients with chronic kidney disease and epidemiologic studies suggest that these abnormalities are associated with a higher cardiovascular risk [190]. It seems that hyperphosphatemia is a much stronger predictor of outcome in dialysis patients than hypercalcemia or hyperparathyroidism [190]. Most of the studies on mineral metabolism in dialysis patients have focused on HD but some recent studies demonstrate a similar risk in PD [191, 192]. There is currently no evidence that correction of abnormalities in mineral metabolism results in improvement in clinical outcomes of dialysis patients.

Table 2.4 Sources of infection of the peritoneal cavity in patients on peritoneal dialysis

Intraluminal
Touch contamination
Periluminal
Catheter-related infections (exit-site/tunnel infections)
Enteric
Iatrogenic (enteric, bacteremic, gynecologic)

Infectious Complications

Infectious complications, particularly peritonitis, have long been the proverbial "Achilles heel" of PD and have long accounted for technique failure [24, 106, 107] and catheter loss [23, 24, 193]. The pathophysiologic bases for peritonitis are summarized in Table 2.4.

As discussed earlier, refinements in connectology and use of the twin-bag systems have led to significant declines in the rates of peritonitis from touch contamination. Over the last decade, advances have been made in reducing catheter-related infections. The first step in preventing catheter-related infections is ensuring that the PD catheter is placed by an experienced operator under sterile conditions. The risk can be further reduced by using exit-site antibiotic prophylaxis by employing either mupirocin or gentamicin [194]. With these advances, the peritonitis rates have declined from about 1.4 episodes per patient-year to 0.5 episodes per patient-year in many centers [195, 196]. Guidelines for prevention, diagnosis, and treatment of infectious catheter-related complications were first published in 1983, have been revised several times, and are evidence based when evidence existed [196]. However, despite a bibliography of more than 9,000 publications on infections as a complication of peritoneal dialysis, the recommendations are hampered with insufficient randomized controlled trials to justify firm pronouncements on several topics being addressed. Therefore, they are not meant to be implemented in every situation. It is strongly advised that each center should examine its own pattern of infection, causative organisms, and sensitivities and adapt the protocols as necessary for local conditions. The guidelines can be considered as an important tool for quality improvement of peritoneal dialysis [197].

Peritoneal Sclerosis

Encapsulating peritoneal sclerosis (EPS) is a rare but life-threatening complication of peritoneal dialysis [198–201]. Most patients have undergone treatment at least 4 years, with the prevalence increasing with longer PD vintage [199]. The mortality rate is high, and in severe cases with complete intestinal obstruction, 60–93% of the patients die [199]. From experiences reported in the literature, optimal management requires a high index of suspicion for the diagnosis of the condition. Appropriate investigations include longitudinal peritoneal equilibration tests and regular measurement of CA125 in the dialysate. A sudden decrease in CA125 concentrations may indicate the development of EPS [202]. CT scanning of the abdomen for detecting fibrosis, thickening of the peritoneum, and calcifications may be helpful. There is no agreement about the therapy of choice for EPS, although it is generally agreed that total parenteral nutrition, steroids, and, sometimes, surgical enterolysis maybe important components [200]. Treatment of EPS with tamoxifen is still controversial [203]. The cause of EPS seems to be multifactorial. Given that only a small proportion of patients develop EPS, it is proposed that genetic factors may set up a predisposition for this life-threatening complication [204]. To address further research on this rare entity, international collaboration in the form of a global registry and DNA bank has recently been proposed [204].

Quality of Life

Studies on the outcome of dialysis treatment usually focus on mortality and morbidity. There is general consensus, however, that the quality of the remaining life is an important outcome parameter as well [205]. It is well known that quality of life (QoL) in new dialysis patients is substantially impaired, both in HD and PD patients [206–212]. In a study of 226 new dialysis patients (120 HD and 106 PD), it was observed that QoL is lower compared to the general population in all QoL dimensions [205]. Multivariate analysis showed that a higher number of co-morbid conditions, a lower hemoglobin level, and a lower RRF were the most important independent risk factors for a lower QoL.

However, these medical factors could explain only a small part of the variations in the observed QoL. Consistent with these observations, studies have shown that psychological and social issues have a significant impact on the QoL of PD patients [213–216]. Kutner et al. found limited evidence for an association between race and perceived health status and QoL in black and white patients starting dialysis (1,679 HD and 1,623 PD) enrolled in the DMMS Wave 2 cohort study [211].

It has been suggested that differences in QoL may become more apparent with increasing dialysis vintage. Longitudinal evaluation of the QoL was recently reported by Merkus et al. [206]. In 250 incident patients enrolled in the NECOSAD study, the physical QoL deteriorated during the first 18 months, both in HD and PD patients, but the deterioration was greater in PD patients. The mental QoL remained stable over time and did not differ between both dialysis modalities. These results are similar to the study by Wu et al. [212], but could not be confirmed by Kutner et al., who compared QoL in 455 HD and 413 PD patients [210]. PD patients' scores appeared to be higher than HD patients' scores with regards to the effects of kidney disease, burden of kidney disease, staff encouragement, and satisfaction with care.

When patients are confronted with the choice of dialysis modality, it is important to realize that there are distinct advantages and disadvantages to each of the modalities. Patients who initiate PD may be able to enjoy a period of time being largely independent of a dialysis facility, and they are more likely to be able to continue their jobs [217].

Future Directions

Over the past two decades, PD has established a niche for itself in the therapy of ESRD. Three different surveys – one each from United States, Canada, and the British Isles – concerning nephrologists' opinions about the optimal distribution of dialysis modalities reported that the optimal percentage of patients treated with PD should be around 30–40% [218–220]. When patients having no contraindication to PD are offered a free choice, 45–50% chose PD [69, 72]. These percentages are considerably higher than the 11% global PD penetration. Thus, much greater attention should be paid to optimal patient education. With the encouraging results with daily home HD, home therapies are likely to receive greater attention in the future. The effect of growth of home HD on the utilization of PD remains to be seen.

Economic Considerations

As discussed earlier, nonmedical factors are the most important determinant of choice of PD, and it is anticipated that these factors will continue to influence the use of this therapy. In the United States, annual costs for the HD patients are significantly higher than that for PD patients [57]. Greater utilization of self-care dialysis reduces overall costs: even after accounting for younger age and lower co-morbidity of the PD population; and annual per-capita Medicare expenditure is $12,000 lower than for in-center HD [221]. With increasing costs of the Medicare ESRD program, this issue is likely to receive greater attention, with a possible push towards greater use of home dialysis.

On the other hand, in developing countries, efforts are underway to reduce the costs associated with PD therapy, particularly by reducing the need to import PDS from the developed countries. The greater the success at outsourcing the production of dialysis solutions, the greater would be the potential to lower the cost of therapy and, hence, the higher the probability of use of PD.

Quality Considerations

Efforts to further improve the outcome of PD, particularly to reduce the cardiovascular disease burden, should continue in the future. To achieve this goal we need evidence-based best practice guidelines like those being released by the International Society for Peritoneal Dialysis, Dialysis Outcomes Quality Initiative (DOQI), European Best Practice Guidelines, and Caring for Australians with Renal Impairment (CARI). It has been shown that the release of guidelines has some effect on clinical practice. Renal replacement therapy is being started in the United States at progressively higher levels of glomerular filtration rate [57]. In the Netherlands, the introduction of the DOQI guidelines resulted in a tendency towards earlier introduction of renal replacement therapy and higher doses of dialysis [222]. The only way to ensure that guidelines actually improve medical outcomes is to emphasize implementation strategies. Furthermore, guidelines should be systematically re-evaluated on their effectiveness in clinical settings.

Chapter 3
Comparing Survival Outcomes in Peritoneal Dialysis and Hemodialysis

K.E. Yeates and P.G. Blake

Since the emergence of peritoneal dialysis (PD) as a widely used, feasible, and successful home-based therapy in the 1980s, there has inevitably been interest in comparing outcomes on this modality with those on hemodialysis (HD). Many studies have been done comparing costs of treatment, quality of life, and hospitalization and results have been variable [1–12]. Most important and most controversial, however, have been the studies that have attempted to compare patient survival on PD to that on HD [13–27].

The background to this controversy is that in most developed countries, PD is less costly for payers and providers than HD [8–12]. Pressure from payers to use PD has therefore been significant and the question that arises is whether survival is equivalent or better and whether the therapy can consequently be deemed to be more cost effective.

Despite the positive attributes of PD, the proportion of incident patients treated with the modality has fallen in many countries over the last decade, most notably in the United States, where the PD prevalence has fallen from 14% in 1995 to 8% in 2002 [28]. This decline has many causes but may partly be driven by a series of U.S. studies suggesting higher mortality on PD, particularly for older patients and those with diabetes [13, 18, 19]. This trend towards a more expensive modality mix emphasizes the importance of resolving the relative benefits of the two modalities.

As this chapter will show, historically, most comparative survival studies have utilized renal registry data [13–23]. Head-to-head randomized controlled trials directly comparing PD to HD survival have never been successfully completed [24]. The literature is therefore imperfect and so is a source of ongoing controversy.

A striking feature of the literature comparing survival between PD and HD is that results seem to differ greatly between different countries or when different methods of analysis are used [13–27]. This confused situation is partly related to different study designs, and the variety of statistical methods that have been applied to compare overall patient survival.

There is some question as to whether it is even valid to compare survival rates in PD and HD or whether newer statistical methods can be used to overcome inherent differences between the two patient populations and modalities [29–32].

In this chapter we review historical and more contemporary survival outcomes between PD and HD. In addition, we will review changes in statistical methodology that have been utilized over time to compare survival between the two treatment modalities and discuss the merits and drawbacks of each study and its design. Lastly, we conclude with a summary of our findings and suggest ways to apply this knowledge to clinical practice.

Points to Consider When Interpreting Survival Analyses in Dialysis Therapy

Two key points need to be remembered when considering the design of studies comparing mortality on PD and HD. First, modality switches from PD to HD are much more frequent than those in the opposite direction [15–20]. Second, almost all studies indicate that PD compares best with HD in the early months and years after onset of end-stage kidney disease (ESKD) as compared to subsequently [15–20] (Fig. 3.1). The cause of this is unclear, though it may be related to better retention of residual renal function on PD or to unrecognized baseline case mix differences between patients on the two modalities. It is often referred to as an example of disproportionate hazards and it greatly complicates comparative survival analysis [20, 29, 31].

We will now consider a variety of factors that have to be taken into account in designing and evaluating studies done in this area.

The Use of Prevalent versus Incident Patients

Some studies that have compared survival between PD and HD have used prevalent patients, some have used incident only, and some have used both [13–20]. Incident studies are preferable, of course, because an early adverse effect will be missed in a purely prevalent study. Because of the disproportionate hazards phenomenon mentioned above, HD, the modality with the higher early mortality, will look misleadingly good in a purely prevalent study. Studies that use prevalent-only patients should therefore be interpreted with caution and likely will not be seen much in the future [13].

As-Treated (AT) versus Intent-to-Treat Analysis (ITT)

Careful consideration of each of these study design methods is important as the choice can have a significant impact on study outcomes in analyses that compare survival in PD and HD.

ITT attributes a patient's death to the treatment that the patient was originally placed on or "intended" to be receiving. AT attributes a patient's death to the therapy that the patient was receiving at the time of their death. ITT has been used in many of the survival analyses and does not allow the researcher to account for switches in therapy. It attributes a patient's death to the initial therapy they received without accounting for the "actual" therapy, or multiple therapies, the patient may have received during their course of treatment.

The different types of analyses try to answer subtly different questions. An ITT analysis asks the most clinically relevant question, which is whether initial modality assignment influences patient survival. This is what a physician needs to know when advising patient about modality choice prior to initiation of dialysis. An AT analysis tries to determine which modality is likely to be associated with better survival while a patient is receiving it. In a sense, the AT analysis compares the actual modalities while the ITT compares two strategies, "HD first" versus "PD first."

Often, the comparative studies use a modified ITT approach with censoring of patients either at the time of any modality switch, including transplantation, or at some designated time period after a switch [15–17].

Most statisticians would suggest that both ITT and AT analyses be performed when comparing outcomes, as each answers a distinct question and because differences in those answers can indicate that more detailed analyses are required. AT models require new complicated statistical models to deal appropriately with modality switches and are likely to yield more accurate results when large administrative datasets are being used.

When to Enter Patients in Comparative Studies

Most studies assign patients to the modality they are being treated with 90 days after initiation of dialysis and the period prior to that is omitted from the comparison [15–19]. Intuitively, it might appear more appropriate to use the

true initial modality to assign patients and to include all treatment time in the analysis. However, in most centers, patients presenting acutely or late are all treated with HD and, because these patients tend to be sicker and to have a worse prognosis, a survival comparison based on initial modality would be biased against HD. Also, deaths in the first 90 days are likely to be more affected by pre-existing co-morbidity than by dialysis modality per se. The notion is that by 90 days these patients will have stabilized or recovered renal function or died and that some will even have switched to PD and that, overall, the comparison will be fairer. It could even be argued that extending the assignation to 120 days might be even fairer in lessening the influence of pre dialysis co-morbid conditions.

In contrast, others argue that the 90-day approach removes from the analysis part of the time period where PD is most successful and this introduces a bias in favor of HD. Furthermore, this is a period when HD patients are most likely to be using venous catheters for blood access and these are associated with significant complications so that omitting this period might again leads to a bias against PD. The 90-day rule is probably a fair compromise. However, it is important that the large influence of this issue on the results of the analysis be clearly understood. Papers by Fenton et al. and by Murphy et al. particularly demonstrate this effect [15, 16, 25] (Fig. 3.2). One U.S. study by Winkelmayer surprisingly reports a bias in the opposite direction, with more deaths on PD in the first 90 days, but the cohort studied was small and comprised only elderly patients and the findings did not quite reach statistical significance and seem out of line with those in other studies [30].

Adjustment for Baseline Confounders

None of the comparative survival studies is randomized and so adjustment for baseline population differences is important. In most, though not all, developed countries, patients treated with PD tend to be younger and healthier than those on HD and so, in countries such as the United States and Canada, an unadjusted analysis will show misleadingly better results for PD [15, 26]. Conversely, in some European countries, PD tends to be used, particularly in older patients considered to be potentially less tolerant of the hemodynamic challenges of HD, and the bias might thus be in the opposite direction [23].

Clearly, adjustment of comparisons for age, sex, and baseline co-morbidity is crucial. However, co-morbidity information is often lacking or inaccurate in registry studies [20, 33]. Many analyses correct for age, sex, and diabetes only [17]. Others do a qualitative "yes/no" correction for conditions such as heart failure, ischemic heart disease, cancer, etc. [15, 16]. Prospective studies typically have more detail available and attempt to quantify co-morbidity by using scoring systems [25, 26, 27]. They may also adjust for functional characteristics, residual renal function, and laboratory measurements [27]. In general, in North American analyses, greater adjustments seem to result in findings that are more favorable to HD, but there are always concerns about the nature and accuracy of the adjustment [27, 31].

A key point about adjustment for co-morbidity is that only baseline data be used. It is completely inappropriate to adjust for data points or events occurring after initiation of dialysis as the modality may be influencing these. For example, outcomes should not be adjusted for residual renal function after initiation of dialysis as this may be better

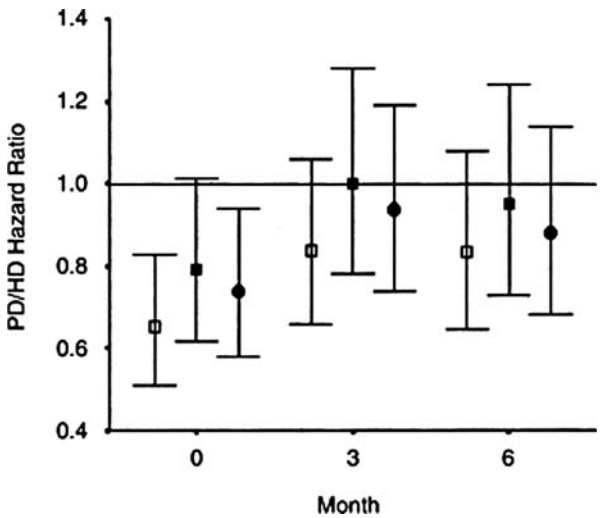

Fig. 3.2 Relative risks of mortality in Canadian PD versus HD patients before and after adjustment and with varying start points from Murphy et al. [25]

preserved on PD than HD and the adjustment may therefore take a key advantage of PD out of the analysis. Similarly, adjustment for serum albumin after initiation is inappropriate because it tends to be systematically lower on PD due to dialysate protein losses and the adjustment would introduce a bias against HD. The "Choices for Healthy Outcomes in Caring for End-stage renal disease" (CHOICE) study, for example, made the error of adjusting for serum C reactive protein levels measured after initiation of the treatments being compared [27, 31].

Adjustments will inevitably be incomplete, even in the most detailed of prospective cohort studies. Factors such as motivation and family support may be critical but are difficult to measure. Only a randomized trial could get around these concerns.

Adjustments are complicated and, recently, awareness has increased about complex interactions between modality and factors such as age, sex, and diabetic status and their effects on survival [20]. This has led to results of comparative studies being expressed separately for diabetics and nondiabetics, younger and older patients, men and women, and even for those with and without heart disease [17–20]. There is a realization that there is not one simple answer to the question of which modality is best and that the answer varies between the different subpopulations with ESKD.

The U.S registry-based and prospective cohort studies have all used the Medicare "Medical Evidence Form 2728" to identify co-morbid disease among study patients. Vonesh et al. found that 45% of patients had no co-morbidity data recorded [20]. This high proportion of patients likely includes those with missing data and those who truly are without co-morbid disease. Furthermore, in 2000, Longnecker et al. performed a validation of co-morbidity data from the CHOICE Study and found that co-morbid conditions are significantly underreported on Form 2728 but that wrongfully attributing a diagnosis to a patient did not frequently occur [33]. Missing co-morbidity data is less likely to be an issue in studies where the co-morbidity data is collected and validated from more than one source.

Time-Dependent Analyses

As already mentioned, the relative mortality risks between patients on HD and PD do not appear to be constant with time on dialysis. Almost all studies suggest PD is at its best in the initial 2 years after initiation of dialysis and that HD is at its best with longer-term patients. Indiscriminate application of the Cox proportional hazards model to such a "disproportionate" situation is clearly inappropriate. Recent studies have therefore done repeated analyses using different start points, i.e., redoing the analysis at 6 months, 12 months, 24 months, etc. (Fig. 3.2). Of course, the adjustments involved must still be based on predialysis baseline characteristics, as explained above. Time-dependent covariates have been used in other types of longitudinal dialysis outcome studies but would be inappropriate in comparative survival studies as adjustment would be made for a time-dependent covariate that is affected by the treatment that is being studied, potentially adjusting out the effect that is being measured.

The use of propensity scores can help to minimize the effects of case-mix differences and the potential for confounding in registry based and observational studies but requires substantial statistical expertise [30, 35]. It is most useful in dealing with situations where there are complex interactions between covariates that influence treatment assignment and also where there may be significant center effects influencing outcomes. This is clearly relevant in PD HD comparisons. Of course, propensity scores do not and cannot remove the biases associated with unidentified confounders. Only a randomized trial can do this.

Methodologic Issues in "Switching" Modalities

As already mentioned, modality switches from PD to HD are much more common than those in the opposite direction and this leads to problems in comparative AT studies. If a patient switches modality and then dies shortly thereafter, it would seem unfair to attribute the death to the new modality. Accordingly, most AT studies allow a "grace period," typically of 90 days' duration, during which deaths are attributed to the previous rather than the new modality. Longer grace periods might be considered but would seem excessive. In one study, the length of such periods did not appear to influence the final results substantially [15].

Other Clinical Points

Other issues that deserve consideration when comparing survival outcomes in PD and HD include within, and between, country differences in patient populations where PD is in high versus low use. For example, in Hong Kong, more than 80% of patients are receiving PD versus HD [36]; whereas the opposite is true in the United States

[37]. This raises the question as to how much one can extrapolate conclusions from comparative studies done in such countries to other jurisdictions. One has to presume that very "selected" populations are receiving the low-use modality in these settings. It also raises concerns about experience with the low-use modality in centers within such countries. There is significant literature suggesting improved outcomes with increased experience in many area of medicine including ESKD [38].

Significant changes that may impact on patient survival and technique failure have occurred in the way PD and HD have been delivered over the past two decades. For example, HD therapy has seen significant technologic advances with the introduction of volumetric HD machines and high flux dialyzers. PD therapy has also experienced similar trends with the introduction of cyclers, Y-set and double-bag systems, and novel dialysis solutions. Both modalities have also experienced a fluctuating emphasis on higher clearance prescriptions and more aggressive use of recombinant erythrocyte stimulating agents and higher hemoglobin targets. In other words, the modalities being compared are themselves in a state of flux and every comparative study may be considered out of date by the time it is published.

The Studies

To date, comparison of PD versus HD survival has occurred through retrospective analysis of registry-based data, prospective cohort studies, and two unsuccessful randomized controlled trials [13–27].

Randomized Trials

In the 1990s, Baxter attempted to enroll patients in a worldwide randomized trial comparing HD and PD. The study was abortive because once interested patients completed the prerandomization education session, the large majority had developed a preference and were no longer willing to undergo randomization. This has been a recurring problem and underlines the point that there is a limit to the types of therapies that patients will accept on a random basis [24].

More recently, the Dutch NECOSAD Study Group aimed to enroll in a randomized trial all new dialysis patients who had no contraindication to either HD or PD at 38 dialysis centers in The Netherlands [24]. The primary and secondary outcomes were quality-of-life adjusted life year (QALY) score and survival, respectively. The study was stopped early due to low enrollment, with only 38 patients agreeing to participate. In the first 2 years, there was only a slight difference in mean QALY score, which favored HD over PD. After 5 years of follow-up there was no persisting difference in quality of life but the hazard ratio for death with HD versus PD was significant at 3.8, suggesting that long-term survival favors PD. However, it could be argued that low study enrollment makes these results difficult to interpret and the small number of patients who agreed to participate in the study may have been "different" from the large number who chose not to be included [24].

Registry-Based Studies

A number of registry based studies have been published since the mid-1990 s reporting patient outcomes, particularly from the United States, Canada, Denmark and the Netherlands [13–23]. In 1995, Bloembergen et al. used Poisson regression to analyze a large sample of prevalent-only patients from the United States Renal Data System (USRDS) for the years 1987–1989 with adjustment for demographic characteristics and showed 19% higher all-cause mortality in prevalent PD patients in the United States as compared to HD [13] (Fig. 3.3). The excess risk of death was significant for patients aged over 55 years and was most pronounced in females and those with diabetes. The methodology used here was unusual. In addition to the prevalent based analysis method, the study only started analyzing patients who had completed 90 days of treatment on 1 January of each of the 3 years concerned and so systematically omitted the majority of the first 12 months of treatment in many patients. This introduced a substantial bias against PD. Vonesh, however, did a similar analysis with the USRDS dataset, but included both incident and prevalent patients from 1990 to 1993, and for these more contemporary cohorts reported no significant difference between PD and HD mortality although there was still a trend favoring HD in older diabetics and PD in younger diabetics [14].

In contradistinction, Fenton et al. published results of an analysis utilizing data from the Canadian Organ Replacement Register (CORR). This involved incident PD and HD patients who initiated therapy between 1990 and 1994, with follow-up for as long as 5 years [15, 16]. After adjustment for baseline differences including age, primary renal disease, center size, and co-morbidity at the initiation of dialysis, and using both an ITT and AT approach, the

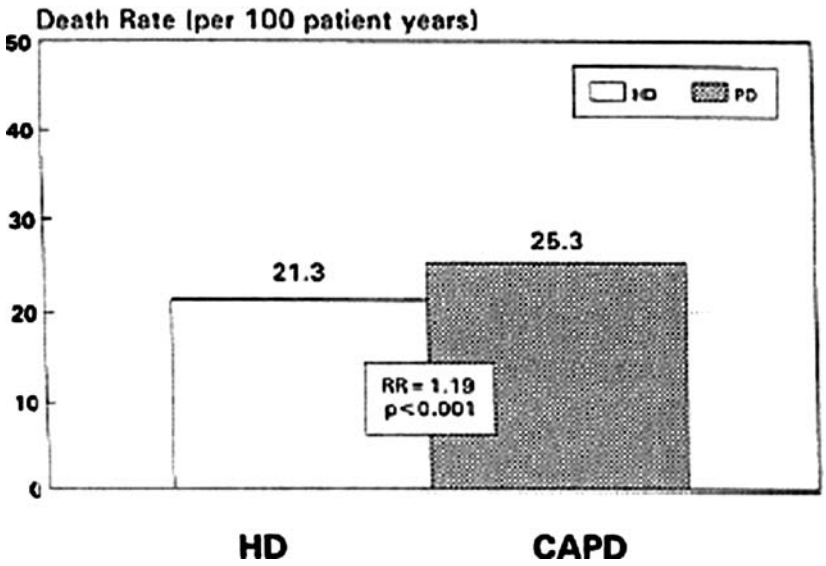

Fig. 3.3 Relative risks of mortality in U.S. PD versus HD patients from Bloembergen et al. [13]

Table 3.1 Relative risks of mortality using ITT and AT models in Canadian PD versus HD patients from Schaubel et al. [16]

	'As-treated' RR	'Intent-to-treat' RR
All patients	0.73 (0.69–0.77)	0.93 (0.87–0.99)
Nondiabetic		
<65 yrs	0.53 (0.46–0.60)	0.84 (0.73–0.96)
≥65 yrs	0.75 (0.65–0.86)	0.95 (0.86–1.05)
Diabetic		
<65 yrs	0.76 (0.65–0.83)	0.90 (0.82–1.10)
≥65 yrs	0.88 (0.75–1.04)	1.04 (0.87–1.24)

authors showed that, in Canada, there was a significant 27% survival advantage for PD patients compared to HD and that this advantage was greater in the first 2 years of dialysis and for younger patients [15, 16] (Table 3.1) (Fig. 3.1).

Comparable U.S results were reported by Collins et al. in 1999 in a study that comprised incident patients from 1994 to 1996 followed for the first 2 years of dialysis [17]. The authors used Poisson regression to compare death rates and adjusted for age, gender, race, and primary renal disease. A Cox model was utilized to evaluate cause-specific mortality with the issue of proportionality addressed through a separation of patients with and without diabetes. This study showed a significant survival advantage for PD over the first 2 years compared with HD in younger patients with and without diabetes and in older nondiabetic patients also (Fig. 3.4). The effect was most apparent, being almost 40%, in the younger nondiabetics. Only in older patients with diabetes did the authors report a survival advantage for HD [17].

These contrasting outcomes caused confusion but the studies did demonstrate a number of consistent findings. The U.S studies clearly showed how incident analyses, such as that by Collins et al., make PD look much better than prevalent ones, such as that by Bloembergen et al. [13, 17]. They also established that, for both countries, the relative

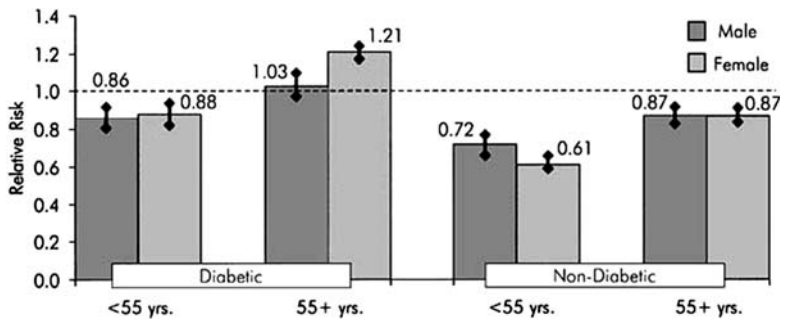

Fig. 3.4 Relative risks of mortality in incident U.S. PD versus HD patients by age and diabetic status from Collins et al. [17]

mortality favored PD initially but then, over 2–3 years, tended to move towards parity or even to favoring HD [13–16]. They also all showed the interaction between age and modality and between diabetic status and modality, when survival is being considered. It became clear that HD looked best in older patients and in diabetics, and that PD looked best in younger patients and in non-diabetics [13–17]. The studies also suggested a difference between outcomes in the United States and Canada and some corroborating evidence from the CANUSA study appeared to support the notion that Canadian patients did better on PD than their U.S. counterparts [39]. This led to extensive debate on whether this was a real finding. Some argued that it might reflect relatively greater experience with PD in the relatively larger PD centers in Canada [38]. However, it also had to be noted that overall ESKD treatment rates were higher in the United States, raising the possibility that U.S. patients might be on average a less healthy population and this might be confounding the analysis [39].

A conclusion from all these studies published between 1995 and 2001 was that PD survival was overall at least as good as that of HD and that the modality had a particular advantage in the early years of ESKD and especially in younger patients. Furthermore, a Danish registry study published in 2002 showed very similar results to those of Fenton et al. and Collins et al. (Table 3.2) [21]. All this gave support to the idea that PD was an excellent initial dialysis modality and the term "integrated dialysis care" was introduced to describe a frequently advocated policy of treating all suitable new ESKD patients with PD, recognizing that many will eventually switch to HD [40, 41].

Subsequent U.S. studies have, however, been less favorable to PD. In 2003, Ganesh et al. and Stack et al. from the same research group published two U.S. registry-based studies that compared mortality differences among PD and HD patients with ischemic heart disease and congestive cardiac failure, respectively [18, 19]. They used Center for Medicare and Medicaid Services Medical Evidence Forms to define co-morbidity data and they linked this to mortality data from the United States Renal Data System (USRDS). These studies were very similar and both were based on the same population of patients and compared outcomes over the first 2 years of dialysis. Given secular trends in the United States during the time period covered from 1995 to 1997, PD patients tended to be younger and healthier when compared to HD patients initiating dialysis. Both studies attempted extensive adjustment for baseline differences in demographic, clinical, and laboratory covariates and used nonproportional Cox regression models with ITT and AT models for comparison. Results were expressed separately for patients with and without diabetes. Ganesh et al. reported a 23% higher mortality in patients with diabetes and cardiac disease who received PD compared with HD [18]. Those patients with diabetes but without cardiac disease also had a higher mortality on PD by 17% when compared with HD. In those patients without diabetes and with cardiac disease, there was a 20% higher mortality on PD. However, for those without cardiac disease or diabetes there was no significant survival difference (Table 3.3). Similarly, Stack et al. reported that after 2 years, mortality was significantly higher for PD patients with congestive heart failure when compared to HD [19]. For patients without congestive heart failure but with diabetes there was also an 11% higher mortality among those who received PD compared with HD. These studies were noteworthy because they were the first to identify explicitly cardiac disease as an important characteristic to consider when determining the effect of dialysis modality on outcomes [18, 19].

Vonesh et al. subsequently published a U.S. registry based study in 2004 that expanded on the previous USRDS studies and adjusted for numerous clinical and demographic patient characteristics [20]. The effect of age was not reported in the previous studies and the Vonesh study therefore provided new data on the interaction of age on survival. The study was also designed to adjust for a cohort effect in order to account for changes in practice patterns in both PD and HD over the study time period of 1995–2000. The large study size with almost 400,000 incident U.S. Medicare dialysis patients also allowed for extensive subgroup analysis. The results showed that among the patients group with no baseline co-morbidity, the adjusted mortality rates for patients without diabetes was significantly higher for HD compared to PD for all age groups [20]. In those with diabetes but no other baseline co-morbidity, mortality

Table 3.2 Relative risks of mortality using ITT and AT models in Danish PD versus HD patients from Heaf et al. [21]

	'As-treated' RR	'Intent-to-treat' RR
All patients	0.65 (0.59–0.72)	0.86 (0.78–0.95)
Age < 55	0.57 (0.45–0.72)	0.90 (0.72–1.13)
Age > 55	0.66 (0.58–0.74)	0.85 (0.76–0.94)

0–24 months	1.01	1.20 (1.10–1.32)	0.69	0.99 (0.93–1.05)

Table 3.4 Relative risks of mortality in U.S. PD versus HD patients by age and diabetic status from Vonesh et al. [20]

		Age	'Intent-to-treat' RR	'As-treated' RR
Non-diabetic	No co-morbidity			
		18–44	1.24 (1.07–1.44)	1.55 (1.30–1.84)
		45–64	1.13 (1.02–1.25)	1.23 (1.10–1.38)
		≥ 65	1.13 (1.05–1.21)	1.18 (1.09–1.28)
Diabetic	No co-morbidity			
		18–44	1.22 (1.05–1.42)	1.45 (1.21–1.74)
		45–64	0.92 (0.85–1.00)	0.98 (0.89–1.07)
		≥ 65	0.86 (0.79–0.93)	0.86 (0.79–0.94)
Non-diabetic	Co-morbidity			
		18–44	1.19 (0.94–1.50)	1.34 (1.03–1.76)
		45–64	1.01 (0.92–1.11)	1.10 (0.98–1.22)
		≥ 65	0.96 (0.91–1.01)	0.98 (0.93–1.04)
Diabetic	Co-morbidity			
		18–44	1.10 (0.92–1.32)	1.35 (1.09–1.68)
		45–64	0.82 (0.77–.0.87)	0.82 (0.78–0.91)
		≥ 65	0.80 (0.76–0.85)	0.82 (0.77–0.87)

was higher on HD among 18–44 year olds but the risk of death was significantly lower on HD for those over 65 years. For the group without diabetes and without baseline co-morbidity, there was no difference in adjusted mortality rates. For those with diabetes and co-morbidity at baseline there was higher mortality for PD among over 65 years but no difference for younger patients (Table 3.4) [20]. Both the Vonesh and Collins studies used an interval Poisson model whereas Ganesh and Stack et al. utilized Cox models. Both models should be considered acceptable and appropriate for survival analyses that compares PD and HD and, if used correctly, will not impact differently on survival outcomes.

The Ganesh and Stack study findings have not been reproduced outside the United States but have given rise to concern that PD is less effective in older and sicker patients, particularly when cardiac disease is involved. It is possible that some modality selection bias may underlie these findings but they have given rise to concern about PD use in cardiac patients in the United States, and to a lesser extent elsewhere. There are theoretical concerns that the systemic absorption of the hypertonic glucose in PD solutions may have adverse metabolic consequences in patients with cardiac disease. It is possible that this effect might be more pronounced and apparent in a U.S. ESKD population, where obesity and diabetes are particularly prevalent.

Prospective Cohort Studies

Three noteworthy prospective cohort studies have been done comparing survival between PD and HD [25–27]. A Canadian study by Murphy et al., published in 2000, enrolled 822 incident patients from 11 dialysis centers across Canada with almost half on PD and half on HD in the period of March 1993 to November 1994 [25]. The study was well designed with a long follow-up period to January 1998, using a Cox model for ITT and Poisson regression for their AT model. Using time-dependent covariates with adjustment for case-mix, including demographic characteristics such

as age, race and gender and clinical characteristics including diabetes status, heart failure, peripheral vascular disease, myocardial infarction, malignancy, and late referral. A validated total co-morbidity score was used to classify levels of disease severity. Patients' modality was classified by the therapy they were receiving after 90 days. The uncorrected data showed the usual survival advantage for PD study but once full adjustments were performed there was no significant overall survival difference between the modalities (Fig. 3.2). Subgroup analyses were not performed due to sample size issues [25].

The Netherlands Cooperative Study on the Adequacy of Dialysis 2 (NECOSAD 2) was published in 2003 [32] and enrolled 1222 incident patients (61% HD and 39% PD) during the period from January 1997 to September 2002 [26]. The authors applied proportional and nonproportional Cox models for both ITT and AT models. Adjustment for case-mix was carried including baseline demographic (age and gender) and clinical characteristics such as primary renal disease, cardiovascular disease, Davies co-morbidity index, and Subjective Global Assessment of nutrition as well as baseline glomerular filtration rate, serum albumin, and hemoglobin measurements. As with the Canadian study, there was no overall difference between PD and HD patient survival during the first 2 years of follow-up. Beyond the second year, the Dutch study showed a significantly lower mortality in the HD cohort, however.

The CHOICE Study, published in 2005 by Jaar et al., enrolled 1041 incident U.S. patients (74% HD and 26% PD) from 81 dialysis centers in 19 states. Patients were enrolled during the period 1995–1998 with follow-up for 5–7 years. Compared to the previously described prospective cohort studies, the CHOICE Study was designed to capture an even wider variety of demographic and clinical patient variables and adjustment for case-mix included a wide variety of characteristics. Demographic factors included age, sex, education level, race, employment status, marital status, and geographic distance from the dialysis clinic. Clinical covariates included body mass index, primary renal disease, cardiovascular disease, glomerular filtration rate, index of co-existent disease, and late referral. Laboratory variables included serum levels of C-reactive protein, albumin, hemoglobin, creatinine, cholesterol, and calcium phosphate product. Both Cox proportional and nonproportional models were applied and showed that, overall, before adjustment for covariates, there was no difference between PD and HD survival. However, after adjustment for clinical and laboratory covariates, there was a significant survival advantage for HD that became very marked after the first year (Table 3.5).

One criticism of the CHOICE Study is that many of the laboratory parameters were not measured at baseline and were treated as continuous variables rather than analyzed as categories [26, 42]. Results of the CHOICE subgroup analysis showed HD as having a more significant survival advantage over PD for patients without diabetes and showed very little age interaction; all of which is widely dissimilar from the previously published registry based studies of U.S patients [13, 14]. These differences in outcomes have been postulated as being due to small subgroup sample size and potential bias from dialysis center selection in the CHOICE Study [26, 32, 42]. As patients in the CHOICE Study were recruited almost entirely from one dialysis provider (90%), less than half of whose centers provided both PD and HD, and given the low PD

Table 3.5 Relative risks of mortality in U.S. PD versus HD patients before and after adjustment and by vintage in Choice Study [26]

	Multivariate model RR	Propensity score model RR
All patients:		
Unadjusted	1.10 (0.80–1.51)	1.10 (0.80–1.51)
Adjusted:		
Demographics	1.25 (0.91–1.73)	1.33 (0.96–1.84)
Plus clinical	1.35 (0.97–1.87)	1.57 (1.12–2.18)
Plus laboratory	1.61 (1.13–2.30)	1.74 (1.23–2.46)
First year only:		
Unadjusted	0.75 (0.37–1.54)	0.75 (0.37–1.54)
Adjusted:		
Demographics	0.92 (0.45–1.89)	0.97 (0.47–2.00)

Plus laboratory	2.34 (1.19–4.59)	2.05 (1.07–3.92)

utilization rate in the United States, a rather contrived method of oversampling of PD patients was required and may have contributed to the discrepancy in the subgroup analysis results when compared to previously published studies.

There was also criticism of this study because of the enormous effect of adjustment for baseline laboratory findings that appeared to convert an advantage for PD into one for HD [34, 42]. This coupled with concerns about laboratory measurements made after initiation of dialysis has led to controversy about the results of this study [32].

Where to from Here?

How should all these data be interpreted? More importantly, should the results of these comparative studies be used to change practice patterns? It is possible that the differences in nephrologists' levels of PD training and expertise explain the between-country differences that have been reported in studies reviewed from Canada and Denmark; as compared to the United States [13–21, 39]. If this is the case, then perhaps comparing survival between PD and HD in countries where PD penetration has historically been low is potentially misleading. Caring for PD patients and managing complications requires training that may be lacking among physicians who have completed their nephrology training in the last decade in many parts of North America and Europe [38]. The concept that high PD penetration within a center, region, or country may impact on PD outcomes has been suggested in the past and has recently been further postulated [38]. Lo cites examples of locales with high PD penetration such as Mexico and Hong Kong [43]. Furthermore, where Mexico has experienced high PD penetration due to significant economic constraints [44], the publicly funded Hong Kong medical system has insisted on an economically driven "PD First" policy since the late 1980 s [36]. Survival comparisons between PD and HD patients in Hong Kong or Mexico would be equally difficult to assess due to the low HD rates in those countries.

What Conclusions Can Be Made Regarding Patient Survival in PD Compared with HD?

We have attempted to provide a review of study methodologies and various study designs that are meant to highlight features that should be considered when comparing studies on dialysis survival. Certainly the results reported by the most current prospective cohort studies should be taken into account with careful consideration given to the difference in study methodologies.

At this time there is no consistent evidence that PD or HD provide an overall survival advantage. Subgroup analyses would suggest that certain patient groups, namely older patients with diabetes or those with established cardiac disease, may have a survival advantage with HD, but it is neither large enough nor sufficiently convincing to override the individual patient-specific factors that drive modality selection in many centers. Furthermore, until the data is reproduced outside the United States, there will be concerns that it may reflect specific socioeconomic and other factors peculiar to the dialysis delivery model and the patient population in that country. Conversely, the survival advantage for PD that is seen in younger patients in many of these studies is impressive but not sufficient to mandate treating all such patients with PD, though clearly the modality is particular attractive and cost effective in this age group.

It would, however, be wise for PD researchers to pay attention to the possibility that adverse interactions between diabetes, cardiac disease, PD utilization, and survival may reflect real biological causation. The potential negative effects of glucose based PD solutions and their tendency to induce hyperglycemia and hyperlipidemia, and perhaps hyperinsulinemia and obesity, highlight the need for further research and development of effective non-glucose based dialysis solutions [45].

It is possible that, given the apparent nonfeasibility of carrying out a good quality randomized trial and given the inherent difficulties in comparing two very different modalities, we may never have a conclusive answer about overall comparative survival [24, 31, 32]. Some argue that the debate has become sterile and that the therapies are better seen as complementary and not competitive [40, 41]. There is a need to improve the practice of both and to address the particular complications of each. The survival debate has, however, been helpful in that it has assisted in our understanding of the two modalities and their potential strengths and weaknesses. It has also given unique insights into statistical analyses for comparing mortality in ESKD populations. Knowledge, however imperfect, is worth having as long as it is not overinterpreted.

These authors, at least, would argue that individual patient circumstances and center characteristics and, in particular, informed patient choice after predialysis education should have the maximum weight in modality selection processes. The data is simply not sufficiently strong to justify a blanket approach of, for example, putting all young patients on PD and all older diabetics or those with heart disease on HD.

Chapter 4
The Peritoneal Microcirculation in Peritoneal Dialysis

A.S. De Vriese, R. White, D.N. Granger, and N.H. Lameire

The peritoneal microcirculation is an intricate microvascular network through which physiological interactions occur between the systemic vasculature and the peritoneal cavity. In peritoneal dialysis these dynamic interactions are of paramount importance in maintaining effective dialysis. The peritoneal microcirculation participates in numerous physiological functions including solute transfer and exchange, regulation of fluid dynamics and ultrafiltration, delivery of nutrients and hormones, delivery of leukocytes to areas of inflammation, and distribution of drugs. Physiological and pathophysiological changes, as well as the process of peritoneal dialysis, may affect many of these microvascular functions. The emphasis of this chapter will be to review available information regarding the peritoneal microcirculation and to integrate this information into a general functional knowledge as it relates to peritoneal dialysis. The chapter will examine: 1) the functional anatomy and blood supply of the peritoneum, 2) components of the peritoneal microvascular network, 3) peritoneal microvascular hemodynamics and the effects of vasoactive agents on the microcirculation, and 4) inflammation in the peritoneal microcirculation with emphasis on leukocyte-endothelial interactions.

Overview of the Functional Anatomy and Blood Supply of the Peritoneum

Functional Anatomy of the Parietal and Visceral Peritoneum

The peritoneum is a large, intricately arranged serous membrane that lines the abdominal wall (parietal peritoneum) and visceral organs of the abdominal cavity (visceral peritoneum). The peritoneal cavity is the potential space between the parietal and visceral layers of peritoneum [1]. The primary purpose of the peritoneum is to provide a smooth surface over which the abdominal viscera may easily move [2]. Normally, the peritoneal cavity contains less than 100 mL of fluid but can accommodate a more than 20-fold increase without patient discomfort [3]. The peritoneal cavity is lined by a layer of mesothelial cells on a connective tissue base that is perfused with blood and lymphatic vessels. Specialized regions of peritoneum, the omenta and mesenteries, are double-layer folds of peritoneum that connect certain viscera to the posterior abdominal wall or to each other. For example, the greater omentum extends from the greater curvature of the stomach to attach to the transverse colon. Specific double-layered peritoneal folds attach solid viscera to the abdominal wall (e.g., the falciform ligament of the liver). The total surface area of the peritoneum in adults approximates the surface area of skin (1–2 m^2) [4]. However, the effective surface of the peritoneal membrane may be below 1 m^2, and can be further reduced as a result of adhesions or prior abdominal surgery [5, 6]. The visceral peritoneum accounts for the majority of the total peritoneal membrane surface area [7, 8]. About 60% of the peritoneal surface can be ascribed to the mesentery of the esophageal-rectal viscera, 15% covers the liver, and 15% is parietal [8]. Considering that most of the surface area is composed of visceral peritoneum, one might intuitively suspect that the contribution of the visceral peritoneum to total peritoneal membrane exchange would predominate over that contribution made by the parietal peritoneum. However, animal studies have suggested that the contribution of the visceral peritoneum to peritoneal exchange is less than would be predicted from the relative anatomical surface area. For example, eviscerated rats exhibit only slight reductions in peritoneal absorption rates for urea, creatinine, glucose, and inulin relative to control animals [9]. Studies in other evisceration animal models have shown similar findings with reductions in peritoneal mass transport of small solutes by only 10–30% [10–14]. In these eviscerated animal models, contact between the dialysate and the parietal peritoneal membrane may be improved, thus

DOI 10.1007/978-0-387-78939-2_4,

contributing to these findings. Other conditions may improve transport across the visceral peritoneum. Small solute mass transfer is significantly enhanced with vibration in the intact rat (i.e., with the visceral peritoneum intact), but only marginally improved in the eviscerated animal. With vibration, improved dialysate to visceral membrane contact is thought to occur. Based on these animal studies it has been proposed that the parietal peritoneum can significantly contribute to small solute transport, and that visceral peritoneal transport may be improved when contact is enhanced between visceral peritoneal surfaces and dialysis solutions [15]. The correlation of these animal findings to clinical peritoneal dialysis currently remains speculative, but these results suggest that the relative contribution of the visceral and parietal peritoneum to small solute mass transport may not necessarily correlate to anatomical surface area.

Blood Supply to the Peritoneum

The vascular and lymphatic systems supplying the peritoneal membrane and intraperitoneal organs constitute a complex and efficient system for fluid and solute delivery to the peritoneum. The arterial blood supply to the visceral peritoneum and intraperitoneal organs arises from the coeliac, superior mesenteric, and inferior mesenteric arteries. The arterial blood supply to the parietal peritoneum and underlying musculature arises from the circumflex, iliac, lumbar, intercostal, and epigastric arteries. The veins draining the visceral peritoneum and intraperitoneal organs empty into the portal vein, while the venous system of the parietal peritoneum empties into the systemic veins. A potentially important consequence of this venous vascular arrangement is that drugs and other solutes that are absorbed across the visceral peritoneum are subject to hepatic metabolism. Pharmacological studies have shown intraperitoneal administration of compounds such as atropine, caffeine, glucose, glycine, and progesterone and some intraperitoneally administered vasoactive drugs are subject to metabolism by the liver [16, 17]. Another important example is insulin, which may be absorbed through the portal circulation and a significant portion degraded through first-pass metabolism by the liver [18, 19]. Thus, the pharmacokinetic effects of hepatic first-pass metabolism may play an important role in the systemic availability of some intraperitoneally administered substances.

Summary

In summary, animal studies suggest that the contribution of the visceral and parietal peritoneal membrane to total solute transport may not necessary correlate to anatomical surface area. The importance of contact between peritoneal tissue and dialysis solutions was suggested both in the eviscerated animal model and in studies of the effect of vibration on solute transport in the intact animal model. The general vascular supply to the peritoneum was reviewed and the potential importance of the portal venous drainage was presented.

The Peritoneal Microvascular Network

Peritoneal Microvascular Architecture

The large vessels supplying blood to the visceral peritoneum function primarily as conduits to supply blood to the visceral organs. As the large vessels course through the mesentery they divide and reflect over the bowel surface forming capillary beds, which can presumably participate in transperitoneal solute and fluid exchange. Over 50 years ago, Chambers and Zweifach described the topography of the mesenteric microcirculation [20]. The typical capillary network consists of arterioles, terminal arterioles, precapillary sphincters, arteriovenous anastomoses, throughfare channels, capillaries, postcapillary venules, and venules (Fig. 4.1) [21]. Arterioles and throughfare channels modulate blood flow into the network, while precapillary sphincters regulate blood flow to single capillaries. Arteriovenous anastomoses can divert blood flow from arterioles directly into venules, thereby bypassing capillary networks. The flow through a capillary network can be extremely variable with individual capillary flow starting, stopping, and sometimes reversing direction [22, 23]. In baseline circumstances, only 25–50% of capillaries are perfused. Capillary recruitment increases perfused capillary density and increases surface area for potential exchange processes. Capillary recruitment may occur to meet metabolic demands, as a result of certain vasoactive agents or in response to exposure to peritoneal dialysate [24]. The architecture of the peritoneal microvasculature in animal models has been previously reviewed by Miller [25]. The visceral microvasculature may be visualized on the mesenteric surface and includes abundant arterial and venular arcades that may function to equalize flow during periods of bowel compression. The

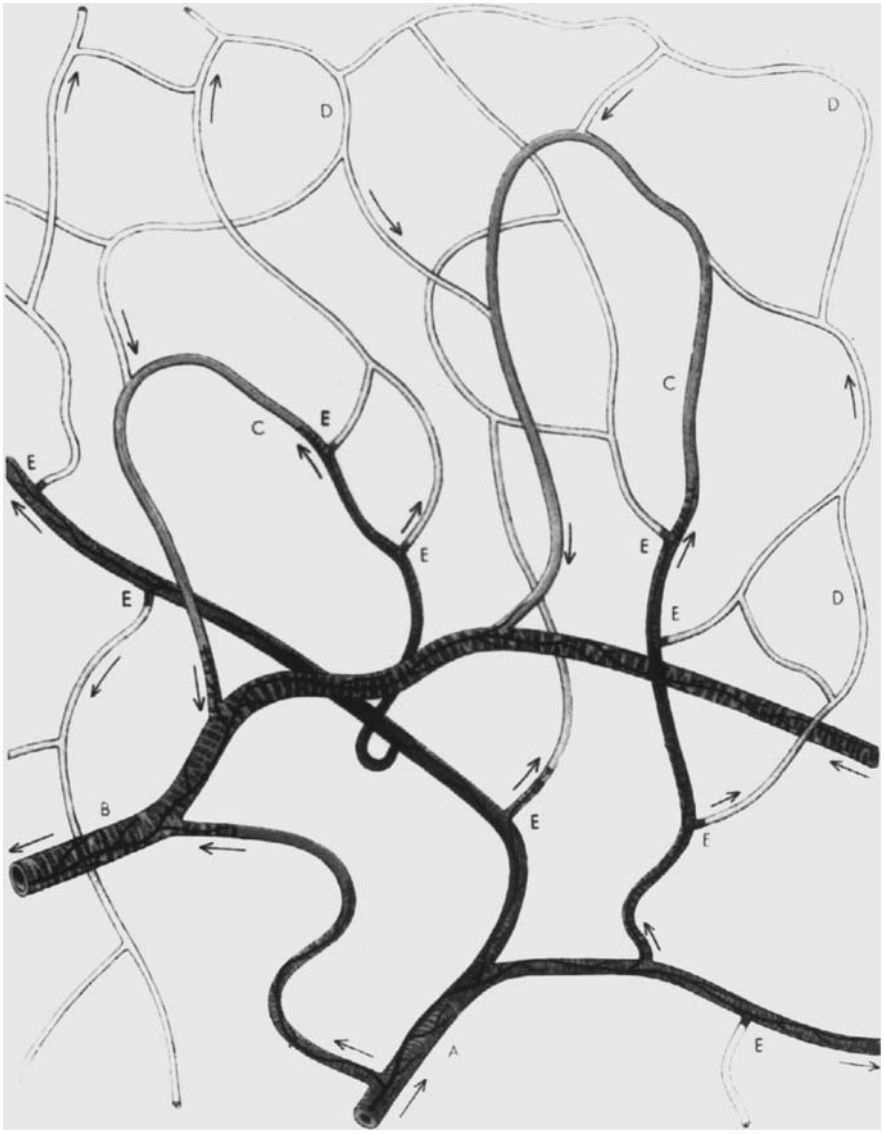

Fig. 4.1 Structural elements of a typical mesenteric microcirculatory bed. A = arteriole, B = venule, C = thoroughfare channel, D = capillary, E = capillary sphincter [21]

parietal microvasculature may be represented by the vascular supply to the cremaster muscle, since this muscle extends from the abdominal wall musculature. Features of the cremaster microcirculation include the absence of short artery to vein anastomoses and the formation of arteriolar and venular arcades from which capillaries may arise [25–27].

Arterioles

The arterioles are the major site of microvascular resistance and regulate flow to capillary beds. Arterioles are lined by endothelial cells resting on a basal lamina surrounded by a layer of smooth muscle cells. Terminal arterioles may participate in the exchange process as they have a discontinuous muscle layer and portions of these vessels are lined only by endothelium and basement membrane. However, the relative contribution to overall peritoneal transport is minimal since the surface area and permeability of these vessels are much less than in capillaries and postcapillary venules. The distal smooth muscle layer of an arteriole may extend to form a ring around the site of capillary origin. This area is termed a precapillary sphincter and regulates flow to single capillaries. Marked arteriolar vasoconstriction can completely close the vascular lumen, resulting in no flow to its capillary distribution [28]. Figure 4.2 illustrates the hemodynamic pressure profiles and demonstrates that the greatest slope for microvascular pressure change occurs in

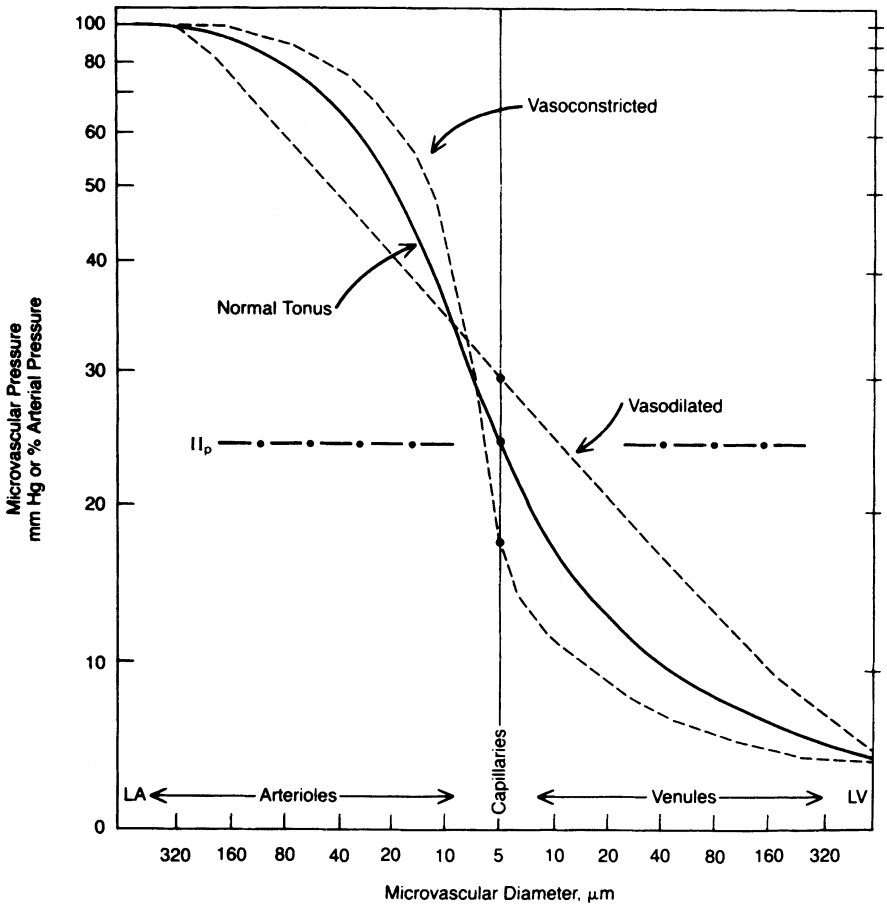

Fig. 4.2 Microvascular pressure profiles as related to microvascular diameter. The dotted lines represent changes in microvascular pressure that occur with vasoconstriction and vasodilation [29]

arterioles 8–40 μm in diameter [29]. This figure also illustrates the pressure changes associated with vasoconstriction and vasodilation and the typical microvessel size gradations for arterioles, capillaries, and venules.

Capillaries

In the peritoneal microvascular network capillaries are the principal sites for solute and fluid exchange [30, 31]. The wall of the capillary is composed of an endothelium and a basal lamina. Capillary size is approximately 5–8 μm, which is large enough to let red blood cells (average diameter 7.5 μm) through, usually one at a time and with some deformity [28]. The capillaries have no smooth muscle and do not vasoactively participate in blood flow regulation. There are three types of capillary endothelium present in the mesenteric area: 1) continuous endothelium as in the peritoneal vessels, 2) fenestrated endothelium as in the intestinal villi, and 3) discontinuous endothelium as found in the liver sinusoids [25]. The properties of peritoneal capillary transport will be reviewed in the following chapter.

Postcapillary Venules

The postcapillary venules participate in fluid and solute exchange, are an important site for microvascular leukocyte adhesion, and may demonstrate dramatic changes in permeability during inflammatory conditions. Small venules that are located just distal to the capillaries are often termed postcapillary venules. Postcapillary venules are generally 10–40 μm in diameter and are composed of endothelial cells resting on a basal lamina surrounded by pericytes with larger venules enclosed by muscular media [32].

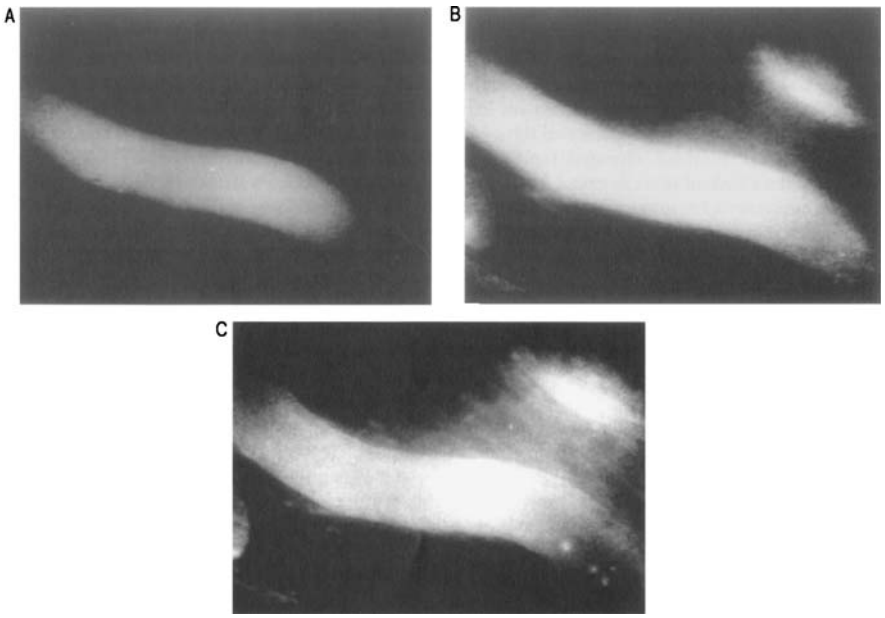

Fig. 4.3 Fluorescence photomicrograph of the mesenteric microcirculation demonstrating the effects of vascular endothelial growth factor (VEGF) on permeability in the rat mesentery. (**a**) No significant leakage of FITC-labeled albumin during basal conditions. (**b**) Superfusion of VEGF (660 pm) induces albumin leakage from the microcirculation after only 10 min of exposure. (**c**) Albumin leakage into the interstitium continues to progress after 20 min of exposure to VEGF. Photomicrograph courtesy of N. Yount, S. Ram, and R. White

Significant changes in microvascular permeability can occur in postcapillary venules. Numerous vasoactive agents, cytokines, and drugs may induce changes in permeability. Histamine, bradykinin, platelet-activating factor, vascular endothelial growth factor (VEGF), certain components of the complement cascade, and drugs such as nitroprusside are examples of agents that can affect mesenteric microvascular permeability [33–40]. For example, Fig. 4.3 demonstrates the effects of vascular permeability factor on albumin permeability in a mesenteric postcapillary venule.

Intravital microscopic studies have demonstrated that the attachment and migration of leukocytes from the vascular space to the extravascular space is localized primarily to postcapillary venules [41–45]. The mechanisms and determinants of intraperitoneal leukocyte migration will be discussed in detail later in this chapter.

Endothelium

The microvascular endothelium has a central regulatory role in microvascular physiology [46–48]. Endothelial-derived substances regulate microvascular hemodynamics, thrombogenesis, fibrinolysis, and leukocyte adhesion. Endothelial cells actively regulate basal vascular tone and vascular reactivity in physiological and pathological conditions, by responding to mechanical forces and neurohumoral mediators with the release of a variety of relaxing and contracting factors. The endothelium-derived relaxing factors include nitric oxide (NO), prostacyclin, and an, as yet elusive, endothelium-derived hyperpolarizing factor (EDHF) [49]. NO is a diffusible, labile gas with a short biological half-life (seconds) [46, 50]. NO is synthesized from L-arginine by a family of enzymes known as nitric oxide synthases (NOS), namely neuronal NOS (nNOS or NOS1), inducible NOS (iNOS or NOS2), and endothelial NOS (eNOS or NOS3). The eNOS is a constitutive, calcium–calmodulin dependent enzyme [50–52]. Once NO is produced in the endothelium it diffuses to the smooth muscle cells and produces smooth muscle relaxation via a cGMP-dependent mechanism [53]. All three NOS isoforms are present in the peritoneal membrane and can be upregulated in response to specific pathophysiologic circumstances [54]. NO production can be inhibited by several exogenous L-arginine analogues such as N^G-monomethyl-L-argine (L-NMMA), N^G-nitro-L-arginine methyl ester (L-NAME), and endogenous arginine analogues such as N^G, N^G-dimethylarginine (ADMA or asymmetrical dimethylarginine) [55–57]. Interestingly, ADMA and other guanidino compounds that inhibit NO production have been shown to accumulate in renal failure [56], although this cannot entirely explain the endothelial dysfunction observed in uremia [58]. Inhibition of NO synthesis produces mesenteric arteriolar vasoconstriction (Fig. 4.4) [59, 60]. This demonstrates that basal levels of NO are important in maintaining normal microvascular tone in the mesenteric microcirculation.

Although NO has generally been considered to be the principal mediator of endothelium-dependent relaxations, evidence is mounting that EDHF is a major determinant of vascular tone, especially in small resistance vessels, like the mesenteric arteries. These vessels control tissue perfusion and thus may be of larger physiological relevance than conductance arteries. The nature of EDHF is still not entirely elucidated [61]. Current evidence suggests that

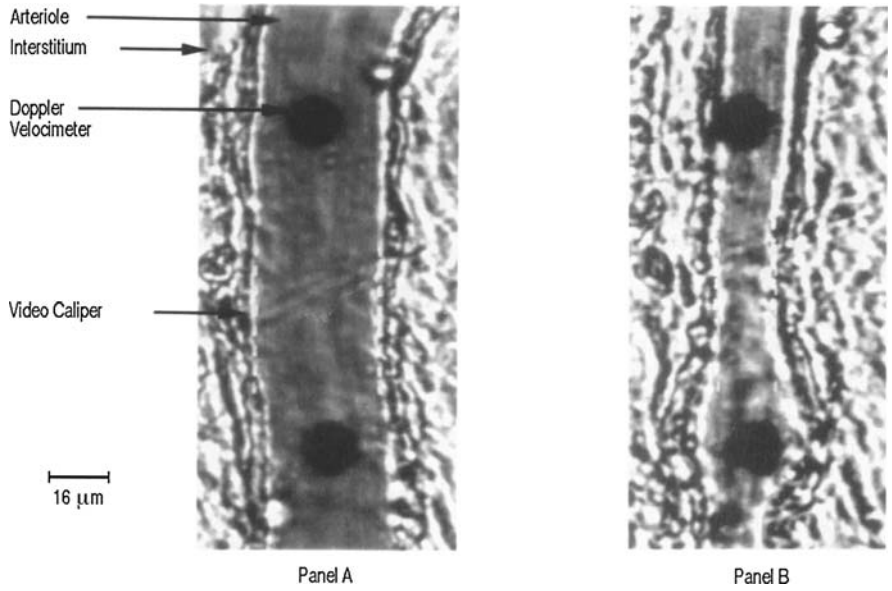

Fig. 4.4 Hemodynamic effect of a nitric oxide synthesis inhibitor (ADMA) on an arteriole in the mesenteric microcirculation in the rat. (**a**) The arteriole during basal conditions with superfusion of a buffer solution. (**b**) ADMA (100 μm) added to the buffer solution induces marked arteriolar vasoconstriction. This demonstrates that basal levels of NO are important in maintaining normal microvascular tone in the mesenteric microcirculation [60]

EDHF-mediated responses are initiated by activation of endothelial K^+ channels with resultant hyperpolarization of endothelial cells. This endothelial hyperpolarization spreads to the underlying smooth muscle layer through myoendothelial gap junctions, or the efflux of K^+ from the endothelial cells elicits hyperpolarization of the adjacent smooth muscle cells. Epoxyeicosatrienoic acids likely have a regulatory role in this pathway. The contribution of EDHF to relaxation is dependent on vessel size, being more prominent in smaller arteries than in larger ones. Although the effect of peritoneal dialysis on the EDHF-mediated responses has not been directly studied, both the uremic state [62] as well as exposure to high glucose concentrations [63] are known to affect EDHF-mediated relaxations. Disturbance of this pathway may thus contribute to altered vascular reactivity in the peritoneal circulation of patients undergoing peritoneal dialysis.

An important constricting factor produced by the endothelium is the potent vasoconstrictor endothelin. The endothelins (ET) are a family of amino acid peptides with diverse and overlapping biological activity. Three isoforms exist: ET-1, ET-2, ET-3 [62–66]. Two human ET receptors have been cloned: ET_A and ET_B. ET_A receptors bind ET-1 > ET-2 > ET-3, whereas ET_B receptors bind these three ET with approximate equal affinity [67–69]. ET-1 is the most potent vasoconstrictor produced by the endothelium and induces sustained, intense vasoconstriction. ET-1 has a short circulating half-life, but the effects may be sustained due to the slow dissociation of the bound peptide from its receptor [66]. In general, ET activates phospholipase C and increases the production of inositol trisphosphate, which mobilizes calcium from the endoplasmic reticulum. ET can also activate calcium channels that allow for the influx of calcium into the cytosol [70]. ET-1 produces vasoconstriction in both mesenteric arterioles and venules [71, 72]. Intravital microscopic observations of mesenteric arterioles have shown that ET-1 can completely arrest blood flow in the microcirculation. ET-1 in small concentrations attached to ET_B may produce mild vasodilation through the release of NO and prostacyclin from endothelial cells, thus forming a potential feedback mechanism [46, 73]. Levels of ET have been shown to be elevated in ESRD, and ET-1 is present in the peritoneal dialysis effluent of PD patients [74]. The relevance of some of these findings as it relates to peritoneal dialysis will be discussed in the next section.

NO and ET also have effects in modulating inflammatory processes. Inhibition of NO production is proinflammatory, as evidenced by an increase in the number of adherent leukocytes in postcapillary venules [75]. ET-1 is a proinflammatory cytokine and in cell culture, ET-1 stimulates neutrophil adhesion to endothelial cell monolayers [76]. ET-1 increases the in vitro endothelial expression of E-selectin [77]. In vivo observations in the mesenteric microcirculation have shown that ET-1 increases leukocyte rolling in postcapillary venules [78].

The endothelium produces both growth promoters and growth inhibitors. An intact endothelium protects the microvascular wall from processes such as intimal hyperplasia, which can occur when the endothelium is disrupted and smooth muscle growth factors are released. NO, heparin sulphates, and transforming growth factor $\beta_1$are inhibitors of vascular smooth muscle proliferation; while angiotensin II, epidermal growth factor, and platelet-derived growth factor contribute to smooth muscle proliferation [46]. ET-1 is known to exert significant proliferative activities on a variety of cell types leading to an accumulation of extracellular matrix. A prospective study in PD patients found that increasing the dwell volume from 1500 to 2500 mL per dwell induced an increase in peritoneal ET-1 synthesis [79]. This volume-induced ET-1 release may contribute to long-term structural alterations in the peritoneal membrane.

Junctional Adhesion Proteins

The tight junction forms an apical intercellular semi-permeable diffusion barrier between endothelial cells [80, 81]. A number of proteins have been described which participate in the formation of the tight junction. Zonula occludens-1 (ZO-1) was the first tight junction protein described and is a peripheral membrane protein located near the plasma membrane [80, 82]. Occludin is another important junctional protein and is transmembrane in location at membrane–membrane sites [83–86]. Occludin appears to be bound near the cytoplasmic membrane to ZO-1. A possible molecular model has ZO-1 bound to spectrin, which is bound to actin [82]. Regulation of occludin has been suggested as a possible mechanism for controlling paracellular permeability [87]. Occludin is more concentrated in arterial junctions than in venous junctions. Kevil and colleagues have shown that arterial endothelial cells express 18-fold more occludin protein than venous endothelial cells. These authors suggest that the arterial and venous endothelial barriers reflect the level of expression of different junctional molecules [88].

In addition to ZO-1 and occludin, many other junctional proteins have been identified. Another cell-to-cell junctional structure is the adherens junction. Adherens junctions are formed by the transmembrane cadherins bound intercellularly to catenins anchored to actin [89–92]. For example, VE-cadherin is a junctional protein localized to the borders between endothelial cells [93]. Kevil et al. have shown that VEGF increases permeability in endothelial monolayers through disorganization of endothelial junctional proteins. The increase in permeability has been related to the rearrangement of endothelial junctional proteins occludin and VE-cadherin [94]. The permeability-enhancing effect of VEGF may also involve the induction of endothelial fenestrations and the functional activation of vesicular-vacuolar organelles in the cytoplasm of endothelial cells. It has been proposed that the increase in microvascular permeability induced by VEGF is an essential step in angiogenesis, allowing the extravasation of blood-borne proteins and the formation of matrix to support the growth of the endothelial cells and the formation of tubes [95]. The relevance of this mechanism for peritoneal dialysis was demonstrated by the observation that VEGF mediates the development of hyperpermeability and angiogenesis in the peritoneal membrane induced by exposure to high glucose concentrations [96].

Basement Membrane

The basement membrane functions as a substratum that acts as a solid support to anchor cells and limits the domain of connective tissue, thus producing distinct cellular compartments [97]. With the exception of large molecules such as plasma proteins, the basement membrane appears to be freely permeable to most solutes [98–102]. This concept is supported by the fact that the restrictive properties of the intestinal capillaries to endogenous macro-molecules are similar to the capillaries found in the mesentery, skin, and skeletal muscle, despite the fact that numerous large fenestrations are present in the intestinal capillary endothelium [103]. It has also been shown that colloidal carbon penetrates the intercellular clefts of continuous capillaries after exposure to histamine, but the transport of the colloidal carbon into the interstitial space is impeded at the basement membrane [104, 105]. These observations imply that the basement membrane may constitute a component of the barrier in the blood to lymph transport of large macromolecules. In addition, the proteoglycans in the basement membrane and interstitial gel matrix create an electrostatic barrier that retards the movement of anionic solutes [106]. These findings suggest that, although the basement membrane is permeable to small solutes, it may provide a significant transport barrier for large macromolecules under conditions of endothelial contraction and/or injury.

Summary

The general architecture of the microvascular network and some important physiological processes occurring in arterioles, capillaries, and postcapillary venules have been reviewed. Arterioles are the major site of microvascular resistance and regulate blood flow to the capillaries. Capillaries are the principal location of solute and fluid exchange. Postcapillary venules are important sites for leukocyte adherence and may show marked changes in permeability under inflammatory conditions. The endothelium is active in the physiological regulation of numerous microvascular processes including microvascular hemodynamics, leukocyte adhesion, and production of growth factors and growth inhibitors. Endothelial adhesion molecules have been described and appear to have important roles in maintenance of tight junctions. The basement membrane appears to be freely permeable to small solutes, but restricts the transport of macromolecules.

Peritoneal Microvascular Hemodynamics

In this section we will first consider the regulation of mesenteric blood flow. Subsequently, the effect of peritoneal microvascular blood flow on solute clearance and ultrafiltration will be discussed. The effect of vasoactive agents on the peritoneal microcirculation will then be considered. Finally, the effect of peritoneal dialysis fluid (PDF) and certain agents with elevated concentrations in renal failure on the microcirculation will be examined.

Regulation of the Mesenteric Circulation (See Also Chapter 9)

The extrinsic control of the mesenteric circulation is mediated by the sympathethic and parasympathethic nervous system and by circulating vasoactive agents, including catecholamines, vasopressin, and angiotensin [107, 108]. There are also intrinsic vascular control mechanisms, that are evidenced by pressure-flow autoregulation, reactive hyperemia, vascular responses to acute venous hypertension, and functional hyperemia [109]. Although myogenic factors have long been considered to be solely responsible for the intrinsic ability of the mesentery to regulate its blood flow, more recent developments indicate that metabolic mechanisms may be of equal importance in this regard. The functional hyperemia after ingestion of a meal is mediated by hormones such as gastrin and cholecystokinin. The purine nucleoside adenosine is a powerful intestinal vasodilator and may be an important metabolic regulator of intestinal autoregulation, although the evidence is controversial [110].

The Impact of Effective Peritoneal Blood Flow on Clearance and Ultrafiltration

Approximately 25% of cardiac output is directed to the splanchnic vascular bed in normal, resting individuals [111]. Excluding the parietal peritoneum, the total abdominal splanchnic blood flow usually exceeds 1200 mL/min at rest [112]. Granger et al. have measured superior mesenteric and peritoneal blood flow during intraperitoneal administration of a commercial peritoneal dialysis fluid (PDF) in anesthetized cats. The PDF significantly increased blood flow to the mesentery, omentum, intestinal serosa, and parietal peritoneum [113]. When considering the overall effective capillary blood flow in the peritoneum, an important question arises. Is the effective blood flow adequate to deliver solutes and fluid such that solute clearance is not primarily blood flow limited?

Due to the heterogeneous nature of peritoneal tissue and its vasculature, it is difficult to precisely measure the effective blood flow in the peritoneal capillary bed. Indirect measures of effective peritoneal blood flow have been made using inert gas (H_2, Xe) washout techniques. Estimates of peritoneal blood flow range between 2.5 and 6.2 mL/min per kg body weight in rabbits to 7.5 mL/min per 100 g body weight in rats [114, 115]. Despite the difficulties in direct measurement of effective blood flow, Nolph et al. have presented indirect evidence that maximum clearance is not primarily blood flow limited [116]. This evidence relies on the interpretation of urea clearance data under conditions of decreased mesenteric blood flow as well as data derived from kinetic modeling. Maximum urea clearances obtained with rapid cycling and predicted clearances at infinite dialysis flow are in the range of 30–40 mL/min. If urea clearances were blood flow limited, a severe restriction in mesenteric blood flow would be expected to reduce urea clearance. However, the results of studies in dogs subjected to circulatory shock have shown that urea clearances remain at 74% of control values despite a 38% reduction in mean arterial pressure [117]. In rabbits, urea clearances are affected when blood flow is reduced to 20% of normal [114, 118]. These findings demonstrate that, despite marked reductions in mesenteric blood flow, only modest decreases in urea clearance occur, suggesting that urea clearance is not primarily blood flow limited. Estimates of effective capillary blood flow have been made using gas diffusion techniques and range between 68 and 82 mL/min. Peritoneal clearances of carbon dioxide are approximately two to three times the maximum urea clearance. Using the ratio of urea clearance to peritoneal blood flow, Aune predicted that a doubling in blood flow would produce less than a 10% increase in urea clearance [114]. However, results obtained using gas diffusion techniques should be viewed with caution since they are based on the assumption that peritoneal gas clearance is equal to effective blood flow. Further studies using intraperitoneal vasodilators and kinetic modeling have also suggested clearance is not blood flow limited [17, 106, 116, 119–123]. However, some authors have suggested that blood flow may be a limiting factor with rapid peritoneal exchanges such as with high flux automated peritoneal dialysis [124].

Kim and colleagues have performed experiments using diffusion chambers attached to the serosal side of the abdominal wall, stomach, caecum, and liver in conjunction with laser Doppler flowmetry to directly evaluate the effect of decreased blood flow on mass transfer of solutes [125, 126]. In these experiments local blood flow beneath a

diffusion chamber was monitored by Doppler flowmetry with simultaneous measurements of the disappearance of a tracer during conditions of baseline control blood flow, 30% of control, and zero blood flow. No significant difference in the rate of mass transfer for mannitol or urea was demonstrated between control blood flow and 30% of control in the abdominal wall. There was a significant reduction in rates of mass transfer with no blood flow. In similar experiments involving the stomach, caecum, and liver there was no difference in the urea mass transfer coefficient for the stomach and caecum when blood flow was reduced to 30% of control. There was a significant decrease in the urea mass transfer coefficient in the liver with reduction of flow to 30% of control. Significant reductions in mass transfer were again demonstrated with zero blood flow. These data demonstrate that reductions of blood flow by approximately 70% do not significantly reduce mass transfer in the parietal and visceral peritoneal areas tested, except in the liver. As noted previously, the relative contribution of a tissue to total transport must take into account the actual tissue surface area available for dialysis solution contact. Since the liver has only a relatively small effective exchange area available, it was concluded that total solute transport in peritoneal dialysis should not be greatly affected during conditions of decreased blood flow.

Rosengren and Rippe studied the effect of peritoneal blood flow on small solute transport in the rat [127]. Peritoneal blood flow reductions were achieved by bleeding the rats to 25% of their blood volume. The resultant reductions in blood pressure and peritoneal blood flow were associated with a significant decrease in the permeability-surface area product for ^{51}Cr-EDTA and glucose. The clearance of albumin fell largely in proportion to the estimated capillary hydrostatic pressure drop. It was concluded that the transperitoneal clearance of small solutes is blood flow limited when peritoneal perfusion is markedly reduced, but to a lower than expected extent, while albumin transport is not blood flow limited [127].

In 20 stable PD patients, effective peritoneal blood flow did not affect peritoneal transfer of small solutes in the first 25 min of the dwell, but appeared to affect transfer rates later in the dwell [128].

Current opinion thus prevails that under physiological conditions, peritoneal blood flow does not limit the transfer of solutes. However, the effective peritoneal blood flow available for transport is only a fraction of the total blood flow through the tissues surrounding the peritoneal cavity, because most of the capillaries are too far from the cavity to be active in the exchange process or they are contained in tissues not in contact with the solution in the cavity. In this respect, it was shown that the use of a surfactant (dioctyl sodium sulfosuccinate) increased the mass transfer rates of mannitol and protein by augmenting the contact area between the peritoneum and the dialysis solution [129].

To evaluate whether ultrafiltration may be limited by effective peritoneal blood flow, Grzegorzewska et al. studied the effects of ultrafiltration and effective peritoneal blood flow during peritoneal dialysis in the rat [130]. When maximum net ultrafiltration rate was obtained with hypertonic solutions, effective peritoneal blood flow was approximately five times greater than net ultrafiltration rate; and under isosmotic conditions effective peritoneal blood flow exceeded net ultrafiltration rate by 57 times. Since there is a great difference between effective peritoneal blood flow and net ultrafiltration rate, it is unlikely that normal peritoneal blood flow significantly limits ultrafiltration during peritoneal dialysis.

Using the same technique of diffusion chambers and laser Doppler flowmetry, the group of Flessner evaluated the effect of blood flow on the hypertonic water flux during periods of control, reduced (50–80%) or no blood flow [131]. With the exception of the liver, marked blood flow reductions had small but insignificant effects on osmotic water transport.

The Effects of Vasoactive Agents on the Peritoneal Microcirculation (See Also Chapter 9)

Numerous endogenous and exogenous vasoactive agents have been shown to modify blood flow in the peritoneal microcirculation. A wide variety of drugs, hormones, neurotransmitters, and mediators of inflammation alter mesenteric vascular resistance. In addition to altering blood flow, some of these agents can also simultaneously affect perfused capillary density and microvascular permeability. For example, bradykinin, glucagon, and histamine increase both blood flow and permeability [33–35]. In contrast, secretin and cholecystokinin infusions increase blood flow but do not alter microvascular permeability to macromolecules [132]. Despite the lack of effect of secretin and cholecystokinin on macromolecular permeability, these agents increase the capillary filtration coefficient. The latter observation suggests that changes in capillary surface area, secondary to capillary recruitment, primarily account for the ability of these agents to increase peritoneal clearances. Using intravital microscopy, the effect of a number of vasodilators on several components of the peritoneal circulation was evaluated [24]. Local application of acetylcholine (10^{-7} to 10^{-5} M), nitroglycerin (10^{-6} to 10^{-4} M), verapamil (10^{-6} to 10^{-4} M), and papaverine (10^{-6} to 10^{-4} M) resulted in

a vasodilation of the mesenteric arteries (diameter 250–350 μm). The diameter of the arterioles (15–25 μm) did not change, however, while the blood flow rate (calculated als $V_{RBC} \times \pi D^2/4$ with V_{RBC} indicating the red blood cell velocity and D indicating the luminal diameter) increased, indicating that the arterioles are passively conducting the rise in flow caused by the upstream vasodilation. The vasodilators also caused capillary recruitment, resulting in a rise of the perfused capillary length [24]. In this study, nitroglycerin was found to be the most powerful vasodilator [24].

Many vasoactive drugs and hormones are known to affect peritoneal clearance (Table 4.1). Nitroprusside and isoproterenol are the best studied agents known to augment clearances in peritoneal dialysis [17, 119, 121, 122, 133–135]. Nitroprusside increases the clearance of urea, creatinine, inulin, and protein in a dose-dependent fashion. Small solute clearance appears to be most affected at lower doses, while large solute clearances are significantly increased at higher doses [136]. The maximum effect of intraperitoneally administered nitroprusside appears to occur after three to five consecutive exchanges with the drug, and the effects of nitroprusside are reversed when the drug is removed from the dialysis solution. With nitroprusside, mass transfer coefficients increase proportionately more for inulin than for urea, suggesting that alterations in permeability occur with exposure to the drug [17]. Nitroprusside also enhances the leakage of fluorescein-tagged albumin across the mesenteric microvessels [25, 39].

Studies by Grzegorzewska et al. using gas diffusion techniques in patients receiving intermittent peritoneal dialysis showed that the intraperitoneal administration of nitroprusside produced no significant differences in the peritoneal transfer of CO_2 [137, 138]. Nitroprusside did enhance the removal of certain solutes such as urea and total protein. Thus, the effect of nitroprusside on solute clearance did not appear to be attributable to changes in effective peritoneal blood flow. Studies by Douma et al. in CAPD patients also demonstrated that the mass area transfer coefficient of CO_2 was not significantly different after the intraperitoneal administration of nitroprusside in a glucose dialysate [133]. Since nitroprusside appears to have no significant effects on effective peritoneal blood flow in the setting of peritoneal dialysis (based on gas diffusion of CO_2), the effects of nitroprusside on other parameters such as capillary permeability and perfused capillary density need to be defined in order to explain the increase in solute clearance.

In the same study of CAPD patients, Douma et al. demonstrated that nitroprusside increased the mass transfer area coefficient of low molecular weight solutes and serum proteins. Using kinetic modeling and concepts of the pore theory, they related the effects of nitroprusside to an increase in the radius of both large and small pores and an increase in the effective peritoneal surface area. An increase in the number of perfused capillaries would increase the total number of pores available for exchange but theoretically should not alter the distribution of the sizes of the pores. Nitroprusside had a greater relative increase in the clearance of larger molecular proteins, suggesting a greater relative effect on the large pore radius. In this study the dialysate to plasma concentration of cGMP was greater with the addition of nitroprusside, suggesting a local generation of NO produced by nitroprusside. There was no difference in the dialysate concentrations of PGE_2, 6-keto-$PGF_2\alpha$, or thromboxane B_2 with the addition of nitroprusside. These workers also demonstrated that the ultrafiltration rate was increased with nitroprusside during the initial phase of dwell but the effect on net ultrafiltration was not significantly different for nitroprusside and control after 4 h. This information suggests that the effect of nitroprusside in improving clearance in the setting of peritoneal dialysis is not due to arteriolar vasodilation but to changes in perfused capillary density and alterations in microvascular pore diameter.

Table 4.1 Drugs and hormones that modify peritoneal clearance

Agents that may increase clearance
Albumin, Aminoproprionate, Anthranilic acid, Arachidonic acid
Calcium channel blockers, Cetyl trimethyl NH_4Cl, Cholecystokinin, Cytochalasin D
Desferrioxamine, Dialysate alkalinization, Diazoxide, Dioctyl sodium sulphosuccinate, Dipyridamole, Dopamine
Edetate calcium disodium, Ethacrynic acid
Furosemide
Glucagon
Histamine, Hydralazine, Hypertonic glucose
Indomethacin, Insulin, Isoproterenol
Lipid in dialysate
Nitroprusside, N-myristyl alanine
Procaine hydrochloride, Prostaglandin A1, Prostaglandin E1, Prostaglandin E2, Phentolamine, Protamine, Puromycin
Salicylate, Secretin, Serotonin, Streptokinase
Tris hydroxymethyl aminomethane (THAM)
Agents that may decrease clearance
Calcium, Dopamine, Norepinephrine, Prostaglandin F2, Vasopressin

Isoproterenol administered intraperitoneally increases peritoneal transport. The route of administration is important in determining isoproterenol's effects on clearance. Intravenous isoproterenol increases superior mesenteric blood flow by 88%, but does not alter peritoneal clearances of creatinine and inulin. In contrast, intraperitoneally administered isoproterenol increases superior mesenteric blood flow and increases solute clearance [139]. In animal studies it has been suggested that the vasoactive effects of isoproterenol increase capillary surface area through the recruitment of capillaries. Isoproterenol increases the mass transfer area coefficients of small solutes, especially in the early phases of the dialysis dwell [140].

A possible and major disadvantage for clinical use of nitroprusside is the potential for systemic vasodilation. Some studies indicate the peripheral vasodilatory effects may be limited with appropriate intraperitoneal dosing [122]. In the study of CAPD patients by Douma et al. no marked blood pressure decreases were noted [133]. Intraperitoneal isoproterenol has been used in certain clinical situations [140]. Patients with vascular diseases such as scleroderma may experience decreased clearances during peritoneal dialysis. In a patient with scleroderma, addition of isoproterenol to the dialysis fluid appeared to improve clearance [140]. However, the clinical use of isoproterenol is hindered by its potential cardiac stimulatory actions [139].

The Effects of Peritoneal Dialysis Solutions on the Peritoneal Microcirculation

Peritoneal dialysis markedly affects the mesenteric microcirculation [24, 25, 60, 120, 141–145]. Topical application of a conventional PDF reversibly dilated mesenteric arteries by more than 20%. The extent of the PDF-induced vasodilation was similar to that of nitroglycerin 10^{-4} M, and no additive effects were observed when PDF and nitroglycerin were applied simultaneously [24]. In another study, no further vasodilation was observed after addition of nitroprusside 10^{-4} M, indicating that PDF induces a maximal vasodilation [144]. In contrast, the small arterioles in the peritoneal membrane did not appear to respond directly to the local application of PDF, because their luminal diameters remained unchanged. However, the flow in these arterioles nearly doubled, indicating that they are passively conducting the increased flow caused by the vasodilation of the mesenteric arteries. This PDF-induced increase in peritoneal blood flow resulted in capillary recruitment, increasing the number of perfused capillaries with more than 20% [24]. Conventional PDF have a high osmolality as a result of elevated glucose concentrations and contain lactate as the buffer system. The pH is approximately 5.5 to limit caramelization of glucose during heat-sterilization process with the formation of a variety of toxic glucose degradation products (GDPs). Even at this low pH, considerable formation of GDPs occurs. The vasodilatory effects of low pH, lactate, and hyperosmolarity are well recognized. However, adjustment of the pH of the PDF to 7.4 did not decrease the vasoactive effects [24, 120, 144], indicating that although low pH *per se* may cause vasodilation, it is not essential for the observed dialysate-induced hemodynamic effects. These observations are important because acidity is rapidly corrected after infusion of standard PDF in the abdominal cavity. Conventional PDF may thus maintain its vasodilatory potential during the entire dwell time.

Novel techniques to prepare PDF have been developed in order to decrease GDP content. A substantial reduction in GDP formation can be achieved by sterilizing glucose separately at a pH of approximately 3. The electrolytes and buffer are kept in another bag compartment at a pH of approximately 8. The contents of both chambers are mixed immediately before use, yielding a solution with neutral pH [146]. A similar double-chamber system has been applied to allow use of bicarbonate as the buffer system. Since bicarbonate and the divalent ions are kept in separate chambers and mixed immediately before use, the precipitation of calcium and magnesium carbonate is avoided [147]. Because glucose is also sterilized separately at a low pH, formation of GDPs is in addition markedly reduced [146]. Local application to the mesenteric microcirculation of a PDF with low GDP content and high lactate concentrations induced only a transient vasodilation and capillary recruitment despite ongoing exposure. Exposure of the peritoneal membrane to a PDF with low GDP content and use of bicarbonate as the buffer was found to be entirely neutral with respect to hemodynamic parameters. Resterilization of the PDF with low GDP content and bicarbonate as the buffer increased GDP levels without otherwise altering the composition of the solution. The resterilized solution caused similar increases in blood flow and capillary recruitment in the peritoneal microcirculation as the conventional solution [24]. Taken together, these results indicate that lactate is only in part responsible for the PDF-induced vasoreactivity, whereas GDPs exert major hemodynamic effects [24]. The results do not support a role for hyperosmolarity in PDF-induced vascular reactivity, because the bicarbonate solutions were hemodynamically inert, even though their osmolality is identical to that of conventional PDF. In addition, the neutral effect of the bicarbonate solutions demonstrates that high glucose concentrations *per se* do not have hemodynamic effects [24].

Superfusion of the peritoneal membrane with conventional PDF rapidly reverses the vasoconstrictive effects of NO synthesis inhibitors [60]. When L-NAME and PDF are simultaneously superfused, the arteriole remained significantly

vasodilated throughout a 1-h superfusion period. Thus, PDF remain vasoactive despite arteriolar exposure to NO synthesis inhibitors, suggesting that the vasoactive properties are largely NO-independent. In studies of CAPD patients using amino acid-based peritoneal dialysis solutions, amino acid solutions increased estimated peritoneal blood flow. Based on nitrate and cGMP mass transfer area coefficients, this effect was not attributable to NO [148]. The exact mechanism through which PDF are vasoactive remains imprecisely defined, but it does not appear to be attributable to NO.

Summary

Animal studies and other evidence suggest that peritoneal clearance is not blood flow limited as long as effective peritoneal blood flow is greater than 30% of normal (with the exception of the liver). Ultrafiltration does not appear to be significantly limited by blood flow under usual conditions. Numerous vasoactive agents can affect peritoneal clearance and one of the most studied vasoactive agents is nitroprusside. Conventional PDF are vasoactive and have pronounced vasodilatory effects on mesenteric arteries. They increase microcirculatory blood flow and cause capillary recruitment. PDF with a low GDP content and lactate as buffer induce only a transient vasodilation, while PDF with low GDP content and bicarbonate as the buffer do not cause hemodynamic effects. Lactate may thus be in part responsible for the PDF-induced increase in peritoneal blood flow, whereas GDPs exert major hemodynamic effects.

The Peritoneal Microcirculation in Inflammation

The microcirculation plays a critical role in inflammatory responses associated with peritoneal dialysis. An important aspect of this response is the interaction of leukocytes with the vascular endothelium during inflammation. In pathophysiological states such as peritonitis the intraperitoneal leukocyte cell count may rapidly increase from a few cells to thousands of cells per mm^3. This rapid rise in the number of peritoneal leukocytes is dependent on factors that govern adhesive interactions between leukocytes and the microvascular endothelium. This section will focus on leukocyte-endothelial interactions in the peritoneal microcirculation.

General Principles of Leukocyte–Endothelial Interactions

Leukocyte recruitment from the vascular to the extravascular compartment follows a multistep process, directed by adhesive interactions. Leukocyte adhesion is localized primarily to postcapillary venules [41–44]. In order for a leukocyte to establish an adhesive interaction with the endothelium it must first be displaced from the center stream to the vessel wall. This appears to be related to microvascular network topography and radial dispersive forces. As the blood vessel diameter increases from the capillary to the postcapillary venules, the more flexible erythrocytes begin to pass the leukocytes and deflect them towards the vessel wall [149]. Once displaced to the vessel wall, the leukocyte can begin to adhere. Adhesion begins as a rolling movement along the postcapillary endothelium. As the inflammatory process proceeds, the number of rolling neutrophils increases and the velocity of the rolling decreases. This exposes the leukocyte to chemotactic agents released from parenchymal cells and/or the endothelium. Leukocyte activation allows the establishment of firm (stationary) adhesive interactions. The firmly adherent leukocyte may then migrate across the endothelial barrier and enter the interstitium (Fig. 4.5) [150].

The adhesive interaction between the leukocyte and the endothelium is mediated by a complex, highly coordinated, dynamic interplay between adhesion glycoproteins expressed on the surface of both the leukocyte and the endothelium [151]. The selectin family of adhesion molecules and their carbohydrate-containing ligands mediate the leukocyte rolling. At flow conditions typical of postcapillary venules, selectins are capable of interacting with their ligands within a fraction of a second. The rates of bond formation and dissociation are very high, but the bonds have a high tensile strength [152]. These qualities give rise to the rolling phenomenon, which brings the leukocyte into transient but close contact with the endothelial cells. If the appropriate stimuli are present, the leukocyte undergoes juxtacrine activation and prepares for firm adhesion and transendothelial migration. The firm adherence and transendothelial migration are mediated by the interaction of integrins with Ig-like molecules.

The integrins are heterodimers composed of a common beta subunit (CD18) and a specific alpha subunit (CD11a, CD11b, or CD11c). The superimmunoglobulin family is represented by intercellular adhesion molecules known as ICAM. The selectins are represented by L-selectin, E-selectin, and P-selectin. The integrins and L-selectin are

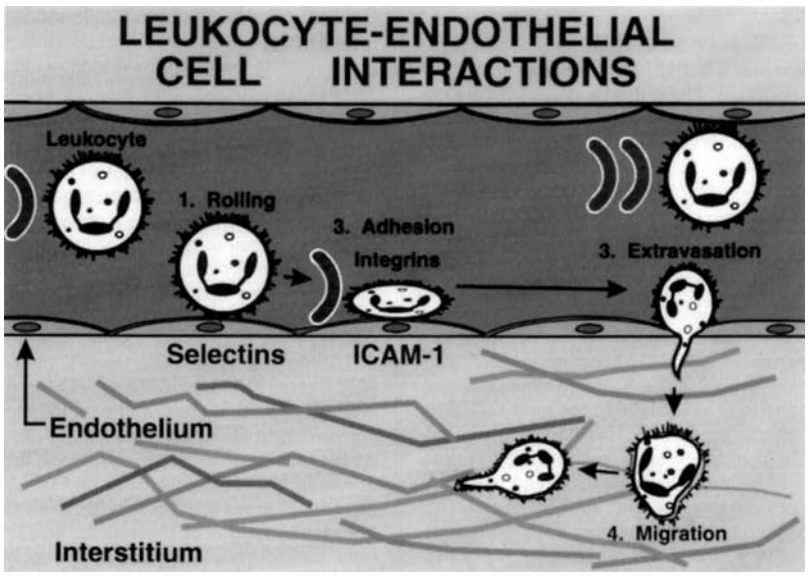

Fig. 4.5 The sequence of events involved in leukocyte adherence and migration to sites of inflammation requires coordination of the adhesive interaction between the leukocyte and vascular endothelium. (1) The initial leukocyte rolling appears to involve interaction between l-selectin on the neutrophil and E-selectin and P-selectin on the vascular endothelium. (2) This interaction allows for the up-regulation of the leukocyte integrin CD11b/CD18, which can bind to ICAM-1 and strengthen neutrophil adhesion. (3) The firmly adherent leukocyte may then extravasate by a process that is dependent on CD11a/CD18, CD11b/CD18, and ICAM-1. (4) The leukocyte may then migrate into the interstial tissue. expressed on the surface of neutrophils. ICAM-1 is present on endothelial cells and its expression may be increased by endotoxin and cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF). Cytokines can also activate endothelial cells to express E-selectin. P-selectin is present on platelets and vascular endothelial cells [153–158].

The sequence of events involved in neutrophil adherence and migration to sites of inflammation requires coordination of the adhesive interactions between the neutrophil and the vascular endothelium. The initial leukocyte rolling appears to involve interactions between L-selectin on the surface of leukocytes and E-selectin and P-selectin on the vascular endothelium with their carbohydrate-containing ligands. These interactions allow for the up-regulation of CD11b/CD18 which can bind to ICAM-1 and strengthen neutrophil adhesion (Fig. 4.6). L-selectin is then

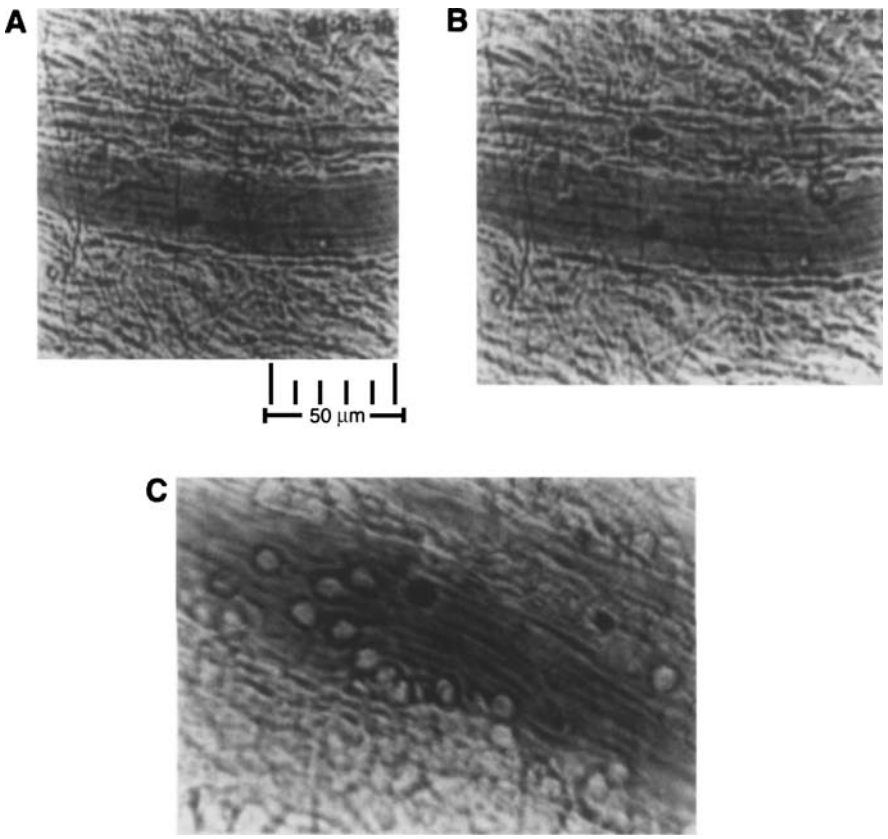

Fig. 4.6 (**a**) A mesenteric venule with a leukocyte (arrow) rolling along the length of the venule. (**b**) This micrograph was taken 2 s after the micrograph depicted in **A** to demonstrate that the leukocyte moved approximately 40 μm downstream in the venule. (**c**) A mesenteric venule during 2 ng/min platelet-activating factor (PAF) infusion. Note the numerous white blood cells adhering to the endothelial wall after PAF infusion [170]

down-regulated (shed) from the cell surface. The firmly adherent neutrophil may then migrate across the vessel wall by a process that is dependent on CD11a/CD18, CD11b/CD18, and ICAM-1.

Inflammatory Mediators and the Microcirculation

The physiological interaction between leukocytes and the endothelium may be influenced by several factors. Intravital videomicroscopic approaches have provided a wealth of information regarding the influence of intravascular hydrodynamic dispersal forces [41, 159, 160], leukocyte capillary plugging [161–163], electrostatic charge [164], and chemical mediators on leukocyte–endothelial cell interactions during inflammation. Table 4.2 lists several agents that affect leukocyte rolling and adherence in postcapillary venules.

As examples, platelet-activating factor (PAF), leukotriene B_4 (LTB_4), and nitric oxide synthesis inhibitors (such as L-NAME and ADMA) and superoxide have been shown to increase microvascular leukocyte adherence. The presence of adherent leukocytes and inflammatory agents may also promote changes in permeability. As an example, adherent leukocytes mediate PAF-induced vascular leakage. Pretreatment with monoclonal antibodies directed against the common beta subunit of the leukocyte integrin CD11/CD18 largely prevents the increased vascular protein leakage caused by infusion of PAF [165]. In the cat mesentery, local intra-arterial infusion of either LTB_4 or PAF promotes leukocyte adherence, but only PAF alters microvascular permeability. This indicates that leukocyte adhesion alone does not always result in increased microvascular permeability. When LTB_4 and PAF are infused simultaneously, LTB_4 causes a further increase in microvascular permeability than is observed with PAF alone. While PAF *per se* may increase microvascular permeability in the presence of adherent leukocytes, it may also serve as a "priming agent" that sensitizes neutrophils and/or the endothelium to other stimuli such as LTB_4 [166]. Reactive oxygen metabolites such as superoxide and hydrogen peroxide may be produced by neutrophils and endothelial cells [167–169]. Hydrogen peroxide appears to promote leukocyte adhesion to vascular endothelium by a PAF-mediated up-regulation or activation of CD11/CD18. Superoxide-induced increases in leukocyte adherence may be related to inactivation of nitric oxide by superoxide [170]. The inhibition of nitric oxide production by the vascular endothelium can produce an increase in microvascular protein efflux that is mediated in part by leukocyte-dependent mechanisms in the mesentery [171].

Thus, several agents promote leukocyte rolling and adherence in mesenteric postcapillary venules. Leukocyte adherence in the presence of an appropriate chemical stimulus may affect microvascular permeability. Since leukocyte adhesion has been associated with changes in permeability, the question arises as to whether leukocyte adhesion could modify endothelial junctional elements. Recent in vitro studies have shown that PMN adhesion to endothelial cells activated by tumor necrosis factor results in VE-cadherin/catenin disorganization [172]. This effect could be blocked by an anti-integrin beta 2 antibody. PMN adhesion also resulted in increased endothelial cell permeability. In vivo animal studies have shown that a monoclonal antibody against VE-cadherin increases vascular permeability and accelerates the entry of neutrophils into inflamed mouse peritoneum [173]. Thus, it appears that some agents which promote leukocyte adhesion may affect microvascular permeability through modulation of some junctional adhesion proteins.

The Effect of Peritoneal Dialysis Fluids (PDF) on Microvascular Leukocyte Adhesion

A large body of evidence indicates that conventional PDF cause a functional impairment of peritoneal host defense mechanisms [174]. The viability and production of inflammatory cytokines and chemoattractants by polymorphonuclear

Table 4.2 Substances or conditions that affect leukoctye adherence to postcapillary venules

A. Stimulants for leukocyte rolling
Superoxide, Histamine, Interleukin-1, Hydrogen peroxide, Indomethacin, Ischemia–reperfusion, Endothelin
Stimulants for adherence
C5a, PAF, Leukotriene B4, N-formylmethionyl-leucyl-phenylalanine, Hydrogen peroxide, Indomethacin, Nitric oxide synthesis inhibitors, Ischemia–reperfusion, Endotoxin, Superoxide
Substances which reduce leukocyte adherence
Adenosine, PGI_2, Iloprost (PGI_2 analogue), NO donors, 8-Bromo-cGMP (cGMP analogue), Superoxide dismutase, Catalase, Quinacrine (phosopholipase A_2 inhibitor), WEB2086 (PAF antagonist), Misoprostol (PGE_2 analogue), Colchicine, Methotrexate, Cromolyn (mast cell stabilizer), Salicylate

leukocytes, monocytes, and peritoneal macrophages is markedly affected by standard PDF. Phagocytosis, respiratory burst, and bacterial killing are lower when polymorphonuclear leukocytes, monocytes, and peritoneal macrophages are exposed to conventional PDF [174].

This section will focus on the effects of PDF on leukocyte recruitment in the peritoneal microcirculation. Intravital microscopy studies allow a direct visualization of the acute effects of PDF on leukocyte recruitment in mesenteric postcapillary venules [175–177]. Exposure of the rat peritoneal membrane to either LPS derived from *Escherichia coli* or a supernatant of a strain of coagulase-negative staphylococci previously isolated from a peritoneal dialysis patient with peritonitis resulted in an impressive increase in the number of rolling, adhering, and extravasated leukocytes in the postcapillary venules and a decrease in leukocyte rolling velocity [176]. The leukocyte response to these inflammatory stimuli was, however, dramatically suppressed by concomitant exposure to conventional PDF [176, 177] (Fig. 4.7). In contrast, superfusion with a pH-neutral, exclusively bicarbonate buffered PDF with low GDP content [176] and a pH-neutral bicarbonate/lactate-buffered PDF with low GDP content [177] had minimal suppressive effects. A lactate-buffered icodextrin solution partially blocked leukocyte-endothelial interactions and a lactate-buffered amino acid–based or amino acid/glycerol–based PDF abolished leukocyte recruitment in a similar manner as conventional PDF [177]. The differences between the responses to the various PDFs could not be attributed to variability of systemic blood pressure, circulating leukocyte numbers, or baseline levels of rolling, adhesion, extravasation, leukocyte rolling velocity, or venular shear rate, as these parameters did not vary between the groups. In addition, no correlation was found between the number of rolling leukocytes and venular wall shear rate at any time point, indicating that potential dialysate-induced variations in blood flow [24] were not responsible for the observed effects. The impairment of leukocyte recruitment by conventional PDF persisted after pH-adjustment to 7.4, indicating that, although low pH has well-documented inhibitory effects on various leukocyte effector functions in vitro [174], it does not appear to be essential for the observed inhibition in vivo. In order to identify the causative PDF-components in greater detail, additional experiments were performed. While superfusion with a pH-neutral solution containing high lactate concentrations and physiologic glucose levels caused a partial inhibition of leukocyte recruitment, a pH-neutral solution with both high lactate and high glucose concentrations abolished the leukocyte response similarly to conventional PDF [176], suggesting additive effects of lactate and hyperosmolarity on leukocyte kinetics.

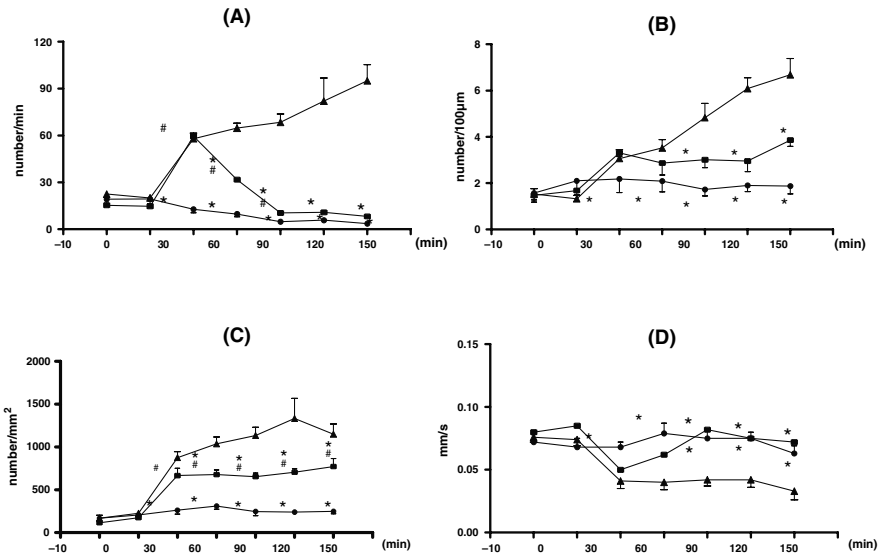

Fig. 4.7 The different aspects of leukocyte recruitment in peritoneal postcapillary venules after stimulation with LPS were evaluated with intravital microscopy, during superfusion with a pH-neutral buffer solution with physiological glucose and bicarbonate concentrations (EBSS) (triangles), a standard peritoneal dialysate fluid (PDF) (circles) and a pH-neutral bicabonate-buffered PDF with low glucose degradation product content (squares). (**a**) The number of rolling leukcytes rises progressively after an inflammatory stimulus, but not when the peritoneal membrane is superfused with a standard PDF. The suppressive effect of the pH-neutral bicarbonate-buffered PDF is less pronounced. *$p < 0.005$ versus EBSS, #$p < 0.01$ versus standard PDF. (**b**) The number of firmly adherent leukocytes in response to LPS increases after superfusion with EBSS, but not with standard PDF. During exposure to pH-neutral bicarbonate-buffered PDF, the response is intermediary. *$p < 0.05$ versus EBSS. (**c**) Extravasation of the leukocyte is the final step in leukocyte recruitment. The number of extravasated leukocytes rises sharply after LPS and reaches a plateau after 60 min. No recruitment occurs during standard PDF exposure, while a somewhat lower plateau is reached after pH-neutral bicarbonate-buffered PDF. *$p < 0.05$ versus EBSS, #$p < 0.005$ versus standard PDF. (**d**) Leukocyte rolling velocity decreases during EBSS, but not during standard PDF and only transiently during pH-neutral bicarbonate-buffered PDF. *$p < 0.05$ versus EBSS [176]

After resterilization, in order to increase GDP levels without otherwise altering the composition of the solution, the pH-neutral bicarbonate-buffered PDF suppressed leukocyte recruitment to a similar extent as the standard solution. These results thus support the inhibitory effects of GDPs on leukocyte recruitment, as suggested by in vitro experiments [174]. However, as the combination of lactate and hyperosmolarity already caused a maximal suppression of leukocyte recruitment, lowering the GDP content of a PDF alone may not be sufficient to improve host defense. The subordinate effect of GDPs on leukocyte recruitment is supported by observations of a lower influx of neutrophils in the peritoneal cavity of rats infected with *Staphylococcus aureus* after previous exposure to both a pH-neutral lactate-buffered PDF with low GDP content and a conventional PDF [178]. The pivotal role of lactate in the inhibition of leukocyte recruitment is further corroborated by the previously mentioned suppressive effects of the nonglucose lactate-buffered PDFs (icodextrin, amino acids, and amino-acid glycerol), that all have a low GDP content [177]. The low lactate concentrations in the combined bicarbonate/lactate-buffered PDF, however, do not appear to exert an adverse effect on leukocyte recruitment. These observations are in line with the finding that the migration distance of polymorphonuclear cells was not adversely affected unless lactate concentrations rose above 15 mmol/L [179].

The nonphysiologic composition of PDF disappears progressively during the dwell time. Osmolarity decreases due to glucose absorption and water ultra-filtration, although it never reaches physiologic values. Lactate concentration also diminishes rapidly during the dwell. Spent dialysate obtained from a patient after a 6-h dwell, however, affected leukocyte kinetics to a similar extent as fresh PDF [176], suggesting that osmolarity and lactate concentration remain sufficiently elevated to profoundly inhibit leukocyte recruitment. Alternatively, uremic toxins and reactive carbonyl compounds that accumulate in the dialysate during the dwell [180, 181] may affect peritoneal leukocyte behavior. Taken together, the results indicate that inhibition of leukocyte recruitment by conventional dialysate will persist throughout the entire PD cycle.

The underlying molecular mechanisms of the inhibition of leukocyte recruitment by PDF is unknown, but it likely involves effects on the adhesion molecules. Superfusion of the peritoneal membrane with L-NAME increased the number of firmly adherent leukocytes in the postcapillary venules. A standard PDF attenuated L-NAME-induced leukocyte adhesion, returning it to baseline conditions [182]. This suggests a possible effect on either the integrins or ICAM. In vitro studies have demonstrated that hyperosmolar solutions affect integrin expression. Kaupke and colleagues have demonstrated that incubation of blood with PDF resulted in depressed basal neutrophil expression of CD11b and CD18 and monocyte expression of CD14 [183]. In addition, the glucose-containing PDF decrease the LPS-induced upregulation of CD11b and CD18. PDF in which sodium chloride was substituted for glucose to obtain similar osmolalities as the glucose-based PDF also show a reduction in basal and LPS-stimulated expression of CD11b.

It is important to note that these in vitro and in vivo studies have been performed with acute exposure to PDF. Chronic exposure to conventional PDF resulted in neoangiogenesis and an increase in the baseline rolling of the leukocytes, while baseline leukocyte adhesion was unchanged [184]. These results possibly indicate changes in adhesion molecule expression in newly formed blood vessels in response to exposure to conventional PDF.

Summary

Several inflammatory mediators promote leukocyte rolling and adhesion in the mesenteric microcirculation. In the presence of some inflammatory agents, leukocyte adherence may affect microvascular permeability, possibly through modulation of junctional adhesion proteins. Animal models have demonstrated that PDF acutely affect leukocyte-endothelial interactions. Conventional PDF decrease leukocyte recruitment, most likely owing to a combination of high lactate concentrations, hyperosmolarity, and presence of GDPs. In contrast, bicarbonate-buffered PDF with low GDP content have only minimal effects on leukocyte kinetics.

Chapter 5
Functional Structure of the Peritoneum as a Dialyzing Membrane

L. Gotloib

Not everything that can be counted counts; and not everything that counts can be counted.

Albert Einstein

More than a century ago, Robinson [1], after summarizing more than two centuries of research, defined the diverse natural functions of the peritoneum as follows: a) to regulate fluid for nutrient and mechanical purposes: b) to facilitate motion; c) to minimize friction, and d) to conduct vessels and nerves to the viscera.

Several medical and scientific developments that occurred during the 20th century originated a new approach for the peritoneum being used as a dialysing membrane for long-term life support [2–6]. These same developments created the need for a deeper understanding of peritoneal structure and function.

The peritoneum is a serous membrane embryologically derived from mesenchyma and composed of thin layers of connective tissue covered by a sheet of mesothelium [7]. When the membrane is folded, forming the omentum and the mesentery, both luminal surfaces are covered by mesothelium.

The *anatomical* peritoneal surface area for the human adult is considered to range between 2.08 [8] and 1.72 m^2 [9], with a ratio of area/body weight of 0.284. The intestinal mesothelium, together with that of mesentery, makes up to 49% of the total mesothelial area [10]. For infants having a body weight of 2,700–2,900 g, the total peritoneal surface was found to oscillate between 0.106 [10] and 0.151 m^2 [8], with an area to body weight ratio that fluctuates between 0.383 [10] and 0.522. In infants the contribution of intestine and mesentery to the total surface area is 67.5% [10].

However, from the functional point of view, vis-à-vis peritoneal dialysis, it may well be that the peritoneal area of contact with the dialysis solutions were substantially lower than the anatomical one. This concept, postulated by Krediet et al., was defined as the effective surface area [11]. This hypothesis finds strong support in the elegant study performed by Chagnac et al. [12] showing that the peritoneal surface actively involved in the dialytic process, estimated in six CAPD patients, was 0.55∼0.04 m^2, about one third of the area measured in anatomical studies. Interestingly, other investigators reached similar conclusions in experiments performed in rats [13].

Peritoneal thickness is not uniform and varies according to the area examined. Measurements are quite problematic in parietal and diaphragmatic peritoneum due to the considerable amount of connective tissue, and at times fat, intervening between the peritoneum itself and the underlying tissue (Fig. 5.1). The submesothelial connective tissue layer of visceral peritoneum is firmly bound to the fibrous tissue of the viscus. Therefore, the mesentery, having mesothelial lining on both surfaces and including its trabecular connective framework, appears to be the most appropriate peritoneal portion for estimation of membrane thickness which, in the rabbit, ranges between 30 and 38 μm [14, 15] (Figs. 5.2 and 5.3).

Normal Mesothelium

Electron microscopic studies performed on mouse embryo disclosed that the mesothelium is derived from mesenchymal cells that become flattened, form their own basement membrane, and develop tight junctions as well as desmosomes [16] (Fig. 5.4, inset). Both pinocytotic vesicles and rough endoplasmic reticulum were present. Yolk sac of human embryos at the 5th–7th week of gestation also exhibit flattened mesothelial cells lying on a hyaline, homogeneous basement membrane [17, 18].

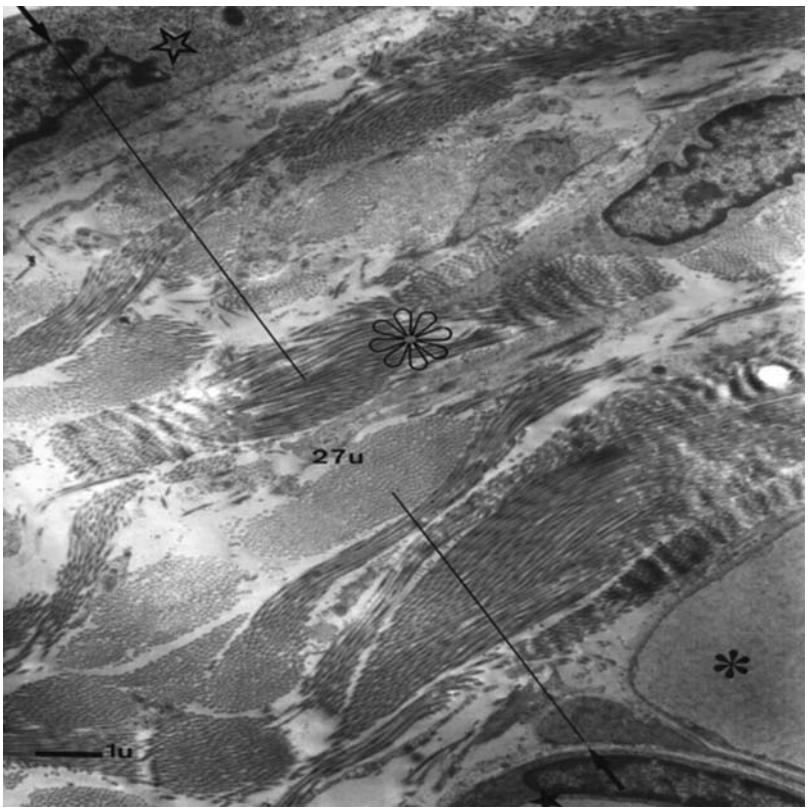

Fig. 5.1 Sample of diaphragmatic rabbit peritoneum. The distance (straight line) between the peritoneal space (upper arrow) and the lumen of the blood capillary (black star) is around 27 μm. The actual pathway through the collagen fibers (open asterisk) is longer (open star: mesothelial cell; black asterisk: fenestrated capillary (× 14,250))

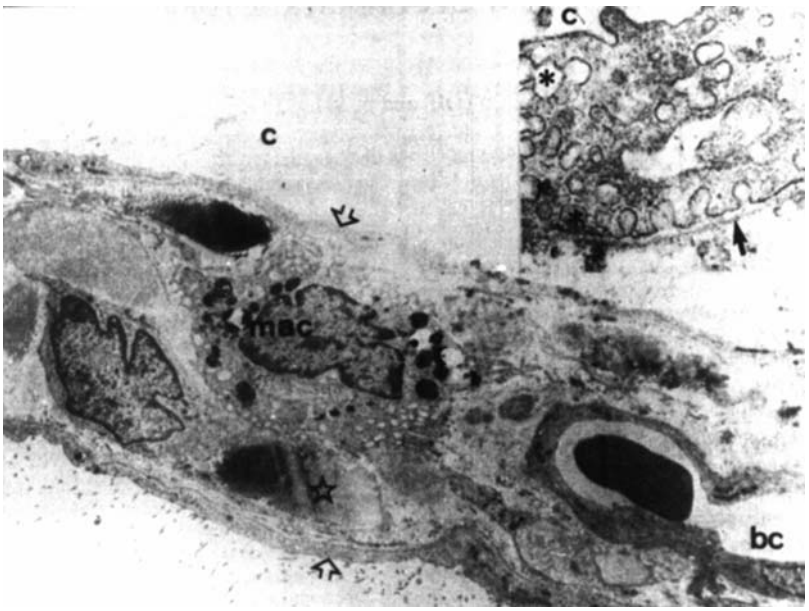

Fig. 5.2 Section of normal rabbit mesentery showing the mesothelial layer (open arrows) covering both aspects of the mesenteric surface area facing the abdominal cavity (c). The interstitium contains a continuous blood capillaty (bc), bundles of collagen (open star), as well as a macrophage (mac). Numerous microvilli can be seen at the lower mesothelial surface (original magnification × 4,750).

Upper right inset. Parietal peritoneum of normal mice. Note the presence of numerous pinocytotic vesicles (*) which, on the left side of the electron micrograph, form a chain between the luminal aspect of the mesothelial cell facing the abdominal cavity (c) and the abluminal one, lying on the continuous basement membrane (arrow) (× 41,500)

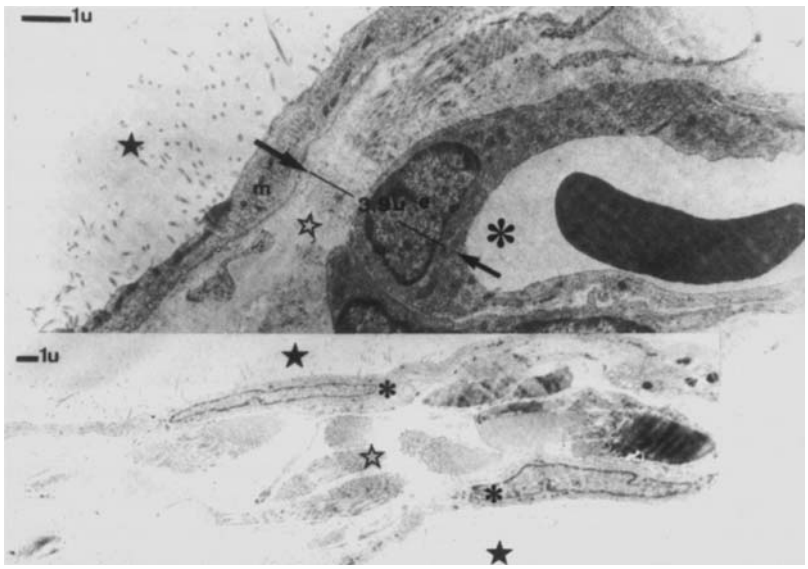

Fig. 5.3 The main photograph shows a sample of rabbit mesenteric peritoneum where the distance (straight line) between the peritoneal space (upper black star) and the microvascular lumen (*) is 3.9 µm (open star: interstitial connective tissue) (× 14,250).

Lower inset. Section of a 42.1 µm length avascular rabbit mesenteric peritoneum sample (black star: peritoneal space; asterisk: mesothelial cell; open star: interstitial connective tissue) (× 4,750)

The cell plasmalemma, when stained specifically, shows the typical trilaminar structure observed in all biological cell membranes [19]. The normal mesothelium occasionally shows macrophages implanted on the luminal peritoneal surface instead of mesothelial cells (Fig. 5.5).

The luminal aspect of the mesothelial cell plasmalemma has numerous cytoplasmic extensions: the microvilli (Figs. 5.2, 5.3, and 5.4), whose existence was originally reported by Kolossow [20] and many years later confirmed by electron microscopy on the serosa covering the rat oviduct [21, 22]. Even though microvilli are more frequently observed in visceral than in parietal peritoneum [23, 24], their distribution is variable and fluctuates from very numerous to completely absent [24, 25]. It should be taken into account, however, that microvilli are extremely sensitive to minor injury or even to dryness, and can therefore be lost from the cell surface if removal and handling of samples are not done with extremely careful techniques. On the other hand, loss of microvilli, as described in continuous ambulatory peritoneal dialysis (CAPD)patients [26] (Fig. 5.6), represent an early sign of impending apoptosis [27–29] that can be easily identified in mesothelial cell imprints (Fig. 5.7).

Light microscopy applied to the observation of resting mesothelium imprints [30] shows a continuous monolayer made up mostly of polygonal mononuclear cells (Fig. 5.8), showing, in mice visceral peritoneum, a density of about 300,000 cells/cm^2 [31]. The number of mesothelial cells per unit area seems higher on the visceral than on the parietal peritoneal surface. Of those cells, 1–2% are binucleated (Fig. 5.8, lower left inset), whereas cells showing three nuclei can be observed (Fig. 5.8).

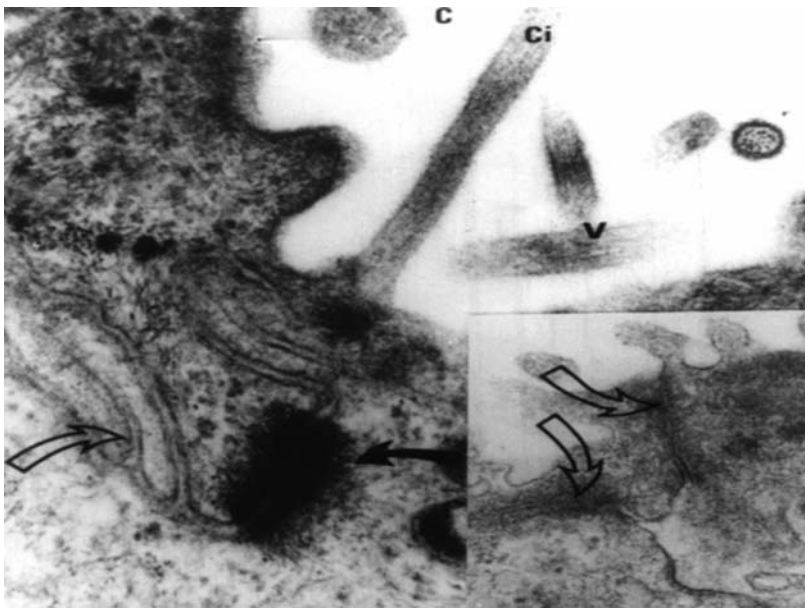

Fig. 5.4 Biopsy of parietal peritoneum taken from a chronic uremic patient on maintenance peritoneal dialysis. Note the presence of an oligocilium (Ci) showing the deviated axial microtubule (open arrow) and the attached basal body (black arrow). Their function is unknown (C: abdominal cavity; V: microvilli) (× 42,900).

Inset. (Lower right). Rabbit mesentery: the open arrows show tight junctions between adjoining mesothelial cells (× 62,500)

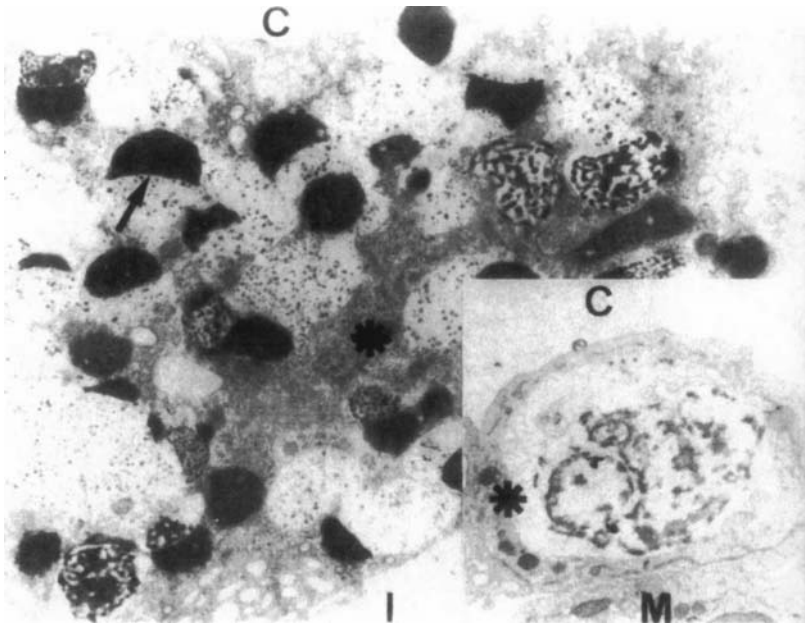

Fig. 5.5 Mesentery of normal rabbit. A macrophage (*) is covering a denuded area of peritoneum (C: abdominal cavity; black arrow: lysosome; I: interstitium). Original magnification × 27,500.

Inset. (Lower right). Mouse mesenteric mesothelium: a signet-ring macrophage (*) is covering a recently implanted mesothelial cell (M) (original magnification × 15,400)

Under normal circumstances the cell population of the monolayer is not stained by vital dyes such as Trypan Blue (Fig. 5.9). This is an indication of their viability. In perpendicular cuts observed under light microscopy, the resting normal mesothelium appears as a continuous layer formed by flattened cells that are apparently elongated, as a result of the angle of section (Fig. 5.10). The mesothelial sheet lies on a layer of connective interstitial tissue (Fig. 5.10), the thickness of which varies in the different portions of the peritoneum (Figs 5.1 and 5.3). The relevance of this point on peritoneal permeability will be discussed later.

Thickness of mesothelial cells in the rabbit ranges between 0.6 and 2 μm [14, 15] (Fig. 5.11).

The human omentum has not yet been studied in great depth. However, some ultrastructural investigations performed in mice and rats [22, 32] seem to indicate that there is little variation between species [33] and that, in mice, omental mesothelial cells can transiently increase their population of microvilli up to seven-fold, suggesting that their concentration in any given area could reflect functional adaptation rather than static structural variation [34].

The presence of pinocytotic vesicles in microvilli has been both reported [21, 23, 35] and denied [34].

Experimental studies done in mice and rats [35–37] using cationic tracers such as ruthenium red (MW 551 da) and cationized ferritin (MW 445 da) revealed the existence of anionic fixed charges on the luminal surface of the microvilli

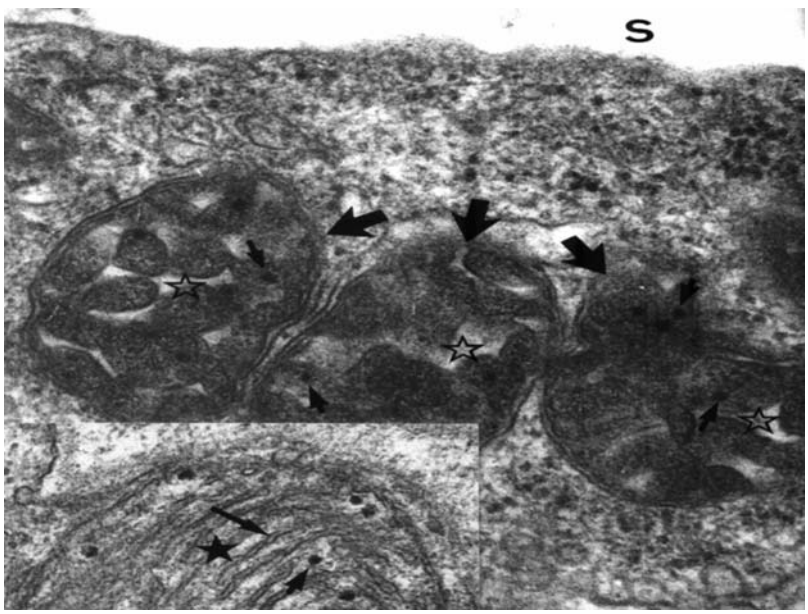

Fig. 5.6 Section of a mesothelial cell seen in a biopsy of parietal peritoneum taken from a patient on CAPD. Mitochondria (open stars) assumed a condensed configuration with increased density of the matrix, blurring of cristae as well as fusions and adhesions of the inner membrane (thick arrows). The matrical granules are still visible (short arrows). These signs of cell injury, in addition to the absence of microvilli, are early signs of impending apoptosis (S: peritoneal space) (× 54,600).

Inset. Intact mitochondrion (short star) showing normal cristae (long arrow) and matrical granules (short arrow) (× 64,550)

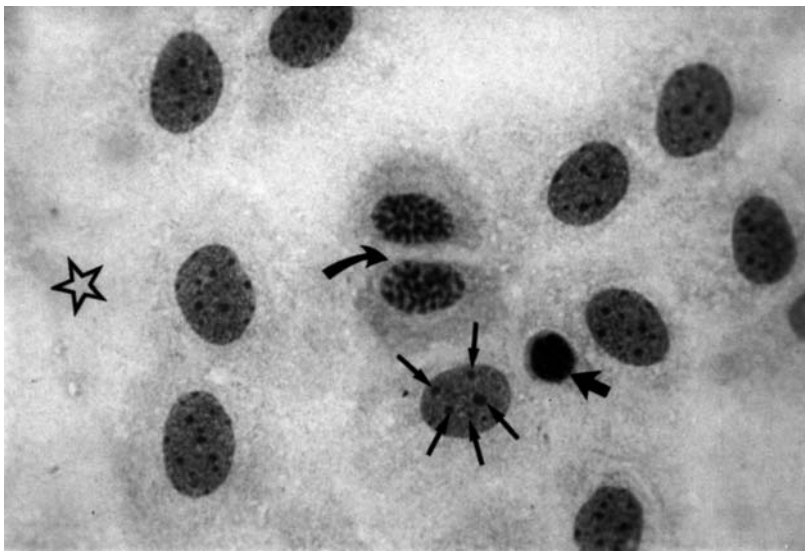

Fig. 5.7 Sample from a mouse injected for 30 consecutive days with 4.25% glucose-enriched dialysis solution. The material was taken 7 days after interruption of the exposure to the dialysis solution (7 days of recovery). This photograph shows the two most critical moments in the life cycle of a mesothelial cell: mitosis (curved arrow), and apoptosis (short thick arrow). Open star shows an area of peritoneum where the mesothelial monolayer is absent (desertic peritoneum). Note the substantially reduced density distribution of cells (small arrows: nucleoii) (hematoxylin-eosin; × 1,000)

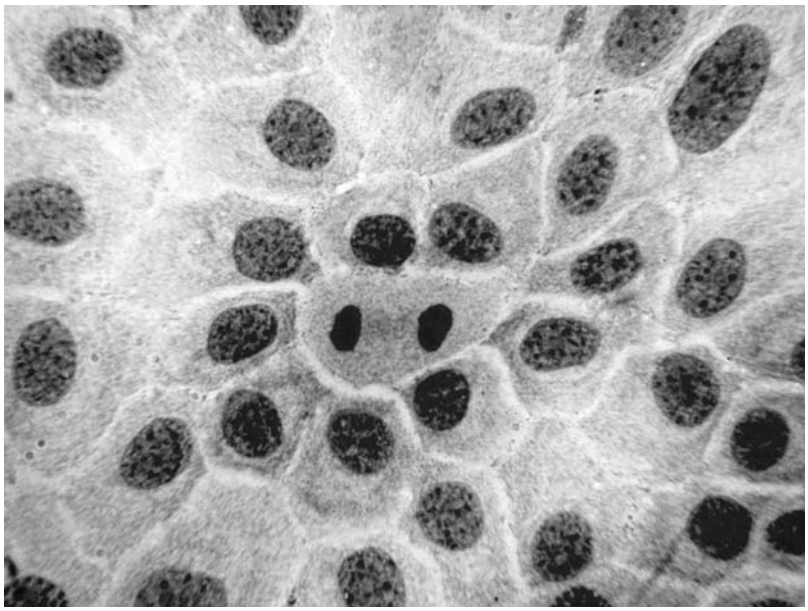

Fig. 5.8 Normal density distribution of mesothelial cells observed in intact, unexposed animals. Unstimulated mesothelium shows a quite low proportion of cells undergoing mitosis at any given time. (Center of microphotograph: cell in mitosis.) (× 1,000)

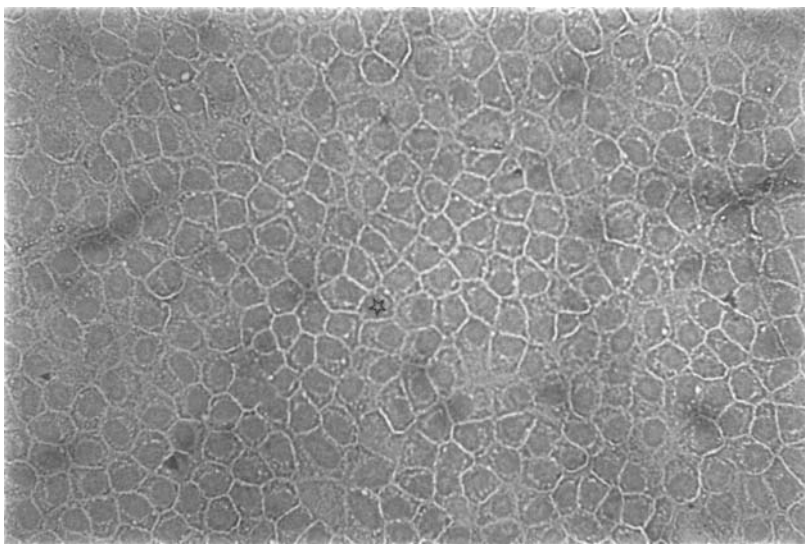

Fig. 5.9 Cell viability evaluated on visceral mesothelium by Trypan-blue exclusion in an intact unexposed mouse. The stain did not permeate the cell membrane (open star: mesothelial cell) (× 400)

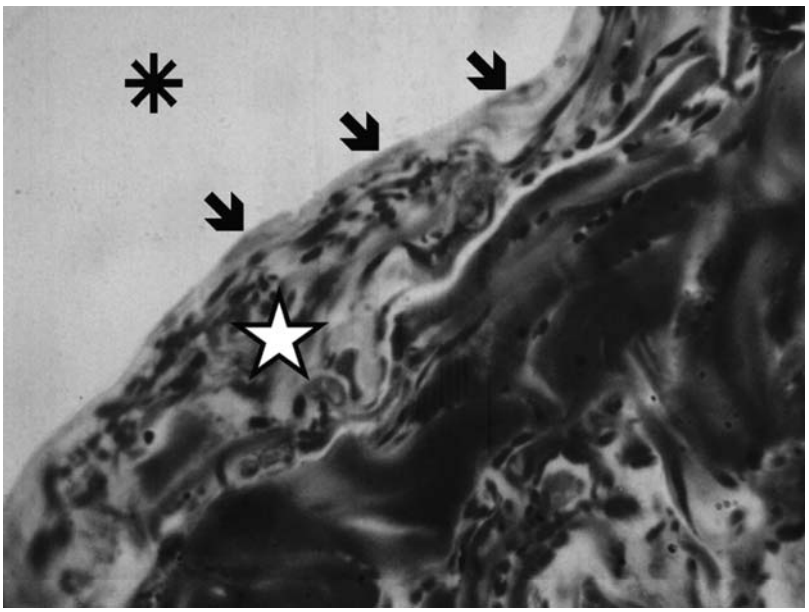

Fig. 5.10 Biopsy of parietal peritoneum taken from a uremic patient at the time of implanting the first dialysis catheter. Arrows point at nuclei of mesothelial cells. Open star was placed on the submesothelial interstitial tissue, the thickness of which ranges between 37 and 62 μm (*: peritoneal cavity) (toluidin blue; × 400)

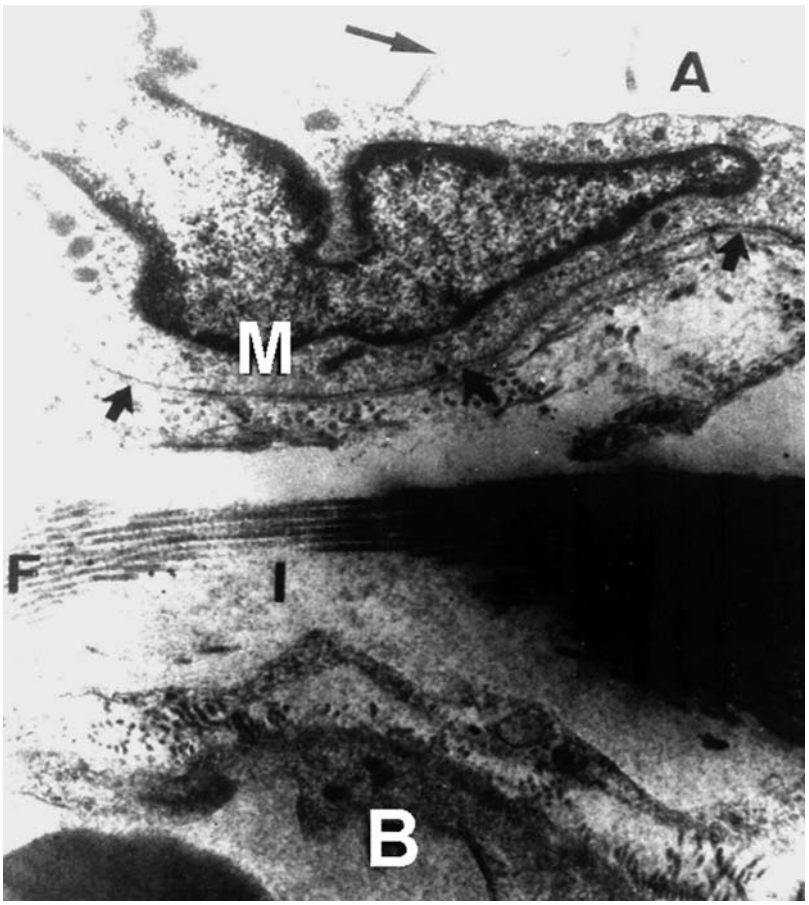

Fig. 5.11 Rabbit mesentery: normal resting mesothelial cell (M) lying on a continuous basement membrane (short arrows) (A: abdominal cavity; long arrow: microvilli; I: interstitium; F: collagen fibers; B: blood capillary; E: erythrocyte) (original magnification × 27,500)

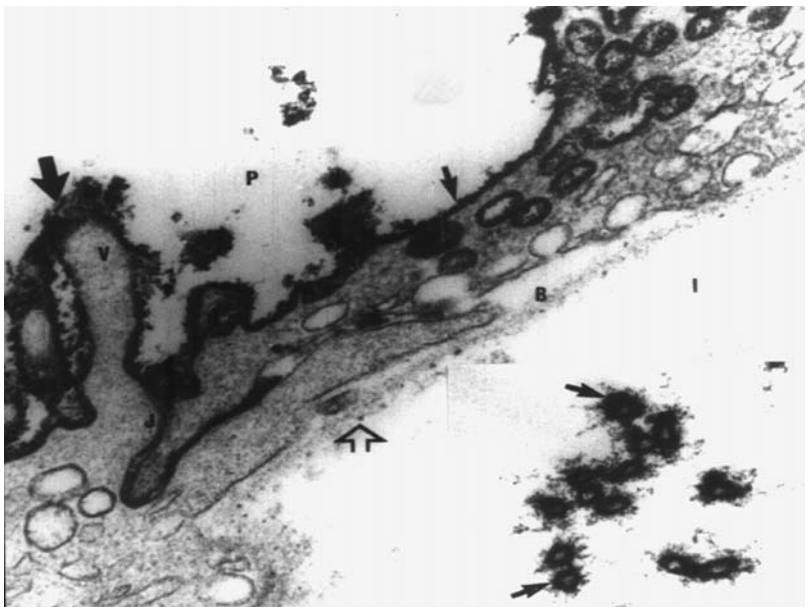

Fig. 5.12 Section of rat mesentery showing microvilli (V) with heavily ruthenium-red decorated glycocalyx (large arrow), also evident on the mesothelial cell plasmalemma (small arrow). The cationic dye also stains a long portion of the intercellular junction (J). The basement membrane (B) shows quite regularly distributed anionic sites (open arrow) (P: abdominal cavity; I: interstitium). Original magnification × 50,720.

Inset. Rat mesentery: transversal section of microvilli showing the fibrilar ruthenium red-stained glycocalyx (arrows) (× 50,720)

cytoplasmic membrane (Fig. 5.12, inset). This cell membrane coating, or glycocalyx, composed of fine fibers that are continuous with the membrane itself [38], furnishes the microvilli surface with electronegative charge, which most probably plays a significant role in the transperitoneal transfer of anionic macromolecules such as plasma proteins [36, 39], as well as in that of charged small molecules, as suggested by Curry and Michel [40] in their fiber matrix model of capillary permeability. This surface charge is substantially reduced in cells undergoing apoptosis [41]. The relevance of these charges upon peritoneal permeability will be discussed later.

Length of microvilli in rodents ranges between 0.42 and 2.7 μm, and their average diameter is 0.1 μm [14, 21, 23, 32]. We have observed a similar range in adult humans. However, mesothelial cells of human embryos (5th–7th week of gestation) showed microvilli up to 3.5 μm long [17].

It has been estimated that microvilli present in the striated border of intestinal epithelium increase the surface area of the intestine by a factor of 20 [42]. Consequently, it has been speculated that mesothelial microvilli could increase the actual peritoneal surface up to 40 m^2 [43].

Plasmalemma of mesothelial cells, like that of microvilli, shows electronegatively charged glycocalyx (Fig. 5.12) [35–37, 44].

Plasmalemmal vesicles, or caveolae, originally described by Lewis [45] in macrophages of rat omentum, are conspicuously present in mesothelial cells at both the basal and luminal borders, as well as in the paranuclear cytoplasm [21–23, 32, 46–48] (Fig. 5.2, inset). Their average diameter is approximately 0.717 μm [14]. At times, pinocytotic vesicles appear clustered together and communicating with each other (Fig. 5.2, inset). Occasionally they appear forming transcellular channels similar to those described in endothelial cells of blood capillaries [49, 50] (Fig. 5.13, inset), apparently communicating both aspects, luminal and abluminal, of the mesothelial cell. These channels can be formed by a chain of several vesicles (Fig. 5.13, inset) or just by two adjoining vesicles. Often pinocytotic vesicles appear to open through the plasma membrane into the luminal or abluminal aspect of the cell (Fig. 5.2, inset; Fig. 5.12), as well as into the intercellular space (Fig. 5.12), exhibiting a neck and a mouth whose respective average diameters are 0.176 and 0.028 μm [14]. With respect to the density distribution of these caveolae, it has been suggested that the parietal mesothelium is less well endowed than the visceral [47].

Palade [51] first proposed that a large part of the macromolecular transport across capillary walls could be attributed to exchange of pinocytotic vesicles between the internal and external surfaces of endothelial cells. This concept was repeatedly applied to the mesothelium. Several electron-dense tracers such as native ferritin [48], iron dextran [14, 32], and melanin [22] were found randomly distributed within pinocytotic vesicles of mesothelial cells after being injected intraperitoneally. Casley-Smith and Chin [47] calculated that the median transit time of vesicles through mesothelial cells ranges between 3 and 5 s, and that approximately 40% of the released vesicles reach the cytoplasmic membrane on the opposite side of the cell. It was even observed that metabolic inhibitors such as dinitrophenol, poisons (cyanide), or slow cooling to 0°C did not completely preclude the uptake of electrondense macromolecules by pinocytosis [48, 52]. This information, supporting Palade's prediction [51] that vesicles could be the structural

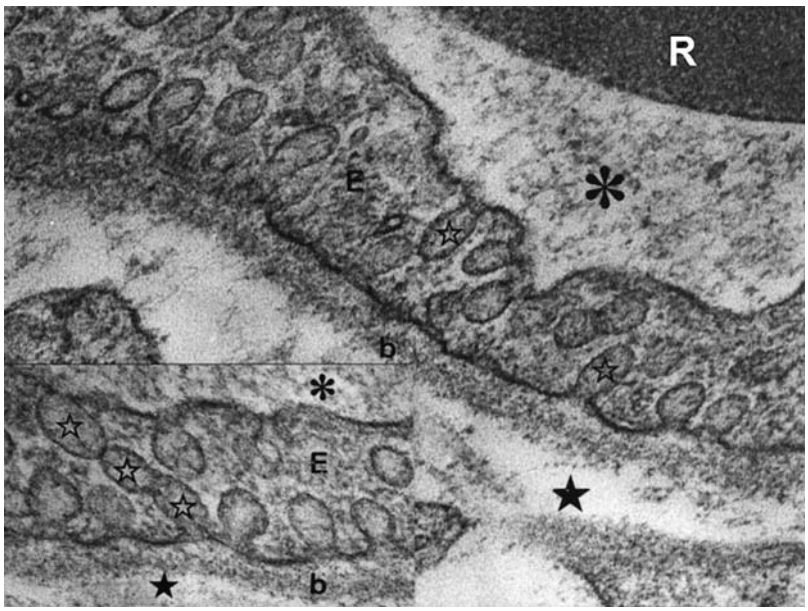

Fig. 5.13 Continuous blood capillary of rat mesenteric peritoneum. Plasmalemmal vesicles (open stars) are open to both aspects of the endothelial cell (E) (R: red blood cell; *: microvascular lumen; b: subendothelial basement membrane; black star: interstitial space) (× 87,000).

Inset. Another capillary from the same sample, showing a transcellular channel made up by a chain of three plasmalemmal vesicles (open stars), connecting both aspects of the endothelial cell (E) (*: microvascular lumen; b: subendothelial basement membrane; black star: subendothelial interstitial space) (× 87,000)

equivalent of the large pore [53], was challenged by stereological analysis of plasmalemmal vesicles. This study apparently showed that vesicles represent merely invaginations of the plasmalemma from both sides of the capillary wall in frog mesentery [54]. It was suggested that this organization of the vesicular system is incompatible with the concept that macromolecules could be transferred across cells by vesicular transport. The methodology followed in this study has been reviewed and criticized, and its conclusions have been refuted [55].

Furthermore, a huge body of scientifically based evidence indicates that endocytosis, transcytosis, as well as potocytosis (an endocytic pathway that utilizes phosphatylinositol anchored membrane proteins and plasmalemmal vesicles or caveolae to concentrate and internalize small molecules) are basic mechanisms used by cells to carry in, out, and through the cytoplasm a variety of substances [56]. The following part of our description applies to both mesothelium and endothelium.

Work done basically during the past decade shed new light on the intimal structure of pinocytotic vesicles. Even though their morphometric parameters are more or less homogeneous, differences in nature, function, and biochemical structure identified at least two kinds of vesicles showing distinctive characteristics.

Caveolae or plasmalemmal vesicles are membrane domains that represent a subcompartment of the plasma membrane [57], characteristic of all vascular endothelium [58]. In capillary endothelial cells, morphological studies indicate that caveolae are effectors of transcytosis of certain macromolecules across the microvascular endothelium: native as well as modified albumins [59–67], low-density lipoprotein (LDL) [68–71], protein hormones [72, 73], AGE [74], as well as orosomucoid [75], a 41 kDa glycoprotein that qualifies as a probe for the postulated large pore [76–78]. Furthermore, endocytosis and transcytosis of albumin–gold complexes have been observed in mice peritoneal mesothelium [79] (Fig. 5.14, inset; Fig. 5.15, inset).

Schnitzer and Oh have demonstrated that transendothelial transport of native albumin through caveolae in both experimental situations (in vivo as well as in the in vitro set-up) is dependent on the interactions of the probe with the endothelial cell surface protein albondin, a 60 kDa albumin binding protein formerly called gp60 [63]. Other binding proteins, gp30 and gp18, appear to mediate the attachment, endocytosis, and degradation of modified albumin. These vesicular carriers require key intracellular components that are sensitive to alkylation with N-ethylmaleimide. Indeed, this substance has been shown to substantially inhibit native albumin (MW: 67 kDa, $r = 36$ Å) and ferritin (MW $\sim$ 500 kDa, $r = 100$–110 Å) uptake, both transcytosed by caveolae [80]. Additional experiments have shown that transcytosis and capillary permeability of insulin and albumin are selectively inhibited by filipin, a complex of polyene antibiotics obtained from *Streptomyces filipenensis*, but does not affect endocytosis mediated by the clathrin-coated vesicles [81]. This concept that identifies two different vesicular pathways is completed with the recent discovery of caveolin, the major structural caveolar protein [82]. This substance is a 22 kDa integral protein that represents a subcompartment of the plasma membrane [57, 83]. Basically, it is a component of the coating covering the luminal aspect of caveolae [84] that, when specifically stained by immunocytochemical methods, serves as a useful marker to draw the diagnostic line between caveolae and other pinocytotic related structures, e.g., coated vesicles [85–87].

Coated pits and coated vesicles (Fig. 5.14, left and right insets) remain the most extensively characterized transport vesicles. They are involved in the intracellular transport of membrane proteins between a variety of membrane

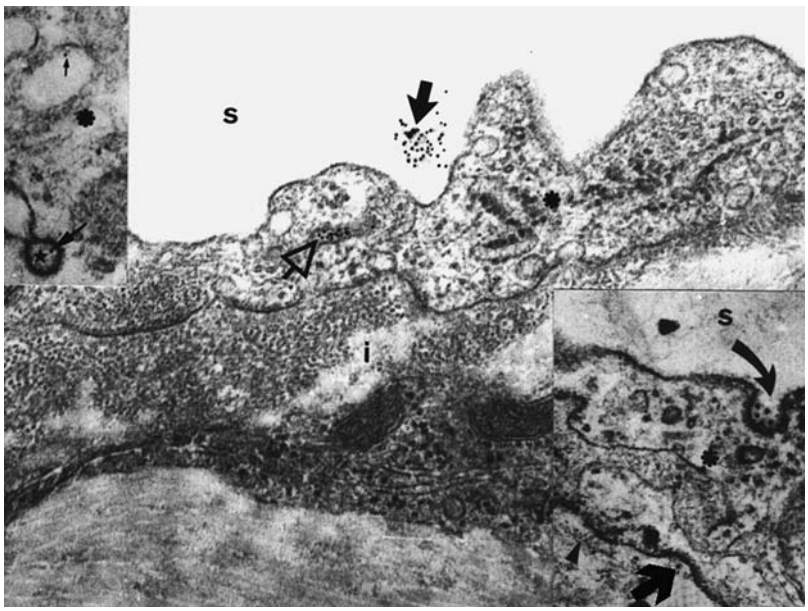

Fig. 5.14 Diaphragmatic peritoneum of a mouse taken 10 min after intra-arterial perfusion with gold-labeled albumin. Some particles (black arrow) can be seen in the peritoneal space (s). The mesothelial cell (*) shows a multivesicular body (open arrow) containing particles of the tracer (I: interstitial space) (× 41,500).

Upper left inset. Cytoplasmic compartment of a mesothelial cell (*) showing albu min–gold complexes decorating the membrane luminal aspect of a pynocytotic vesicle (small arrow), as well as that of coated vesicle (big arrow) (× 64,550).

Lower right inset. Particles of the tracer decorating the luminal glycocalyx of a coated pit (curved arrow) of a mesothelial cell (*), seen in the same sample. The tracer is also present in the abluminal aspect of the mesothelial cell (straight arrow), between the plasmalemma and the submesothelial basement membrane (arrowhead) (× 64,550)

components, mediate endocytosis of transmembrane receptors, and transport newly synthesized lysosomal hydrolases from the trans-Golgi network to lysosomes [88]. The luminal coat contains at least six polypeptides, in addition to the above-mentioned 180 kDa polypeptide clathrin [89, 90]. This type of vesicle is also involved in receptor-mediated endocytosis. Cell surface mediators operate endocytosis clusters into clathrin-coated pits, which pinch off to form vesicles that transport the receptors and their ligand [91]. The complex process of invagination, constriction and budding of clathrin-coated vesicles employs the coordinated actions of several proteins. The best characterized of them is the expanding family of dynamin guanosine triphosphate phosphatases (GTPase), essential for receptor-mediated endocytosis [92, 93]. This enzyme appears to be assembled around the necks of clathrin-coated pits, and assists in

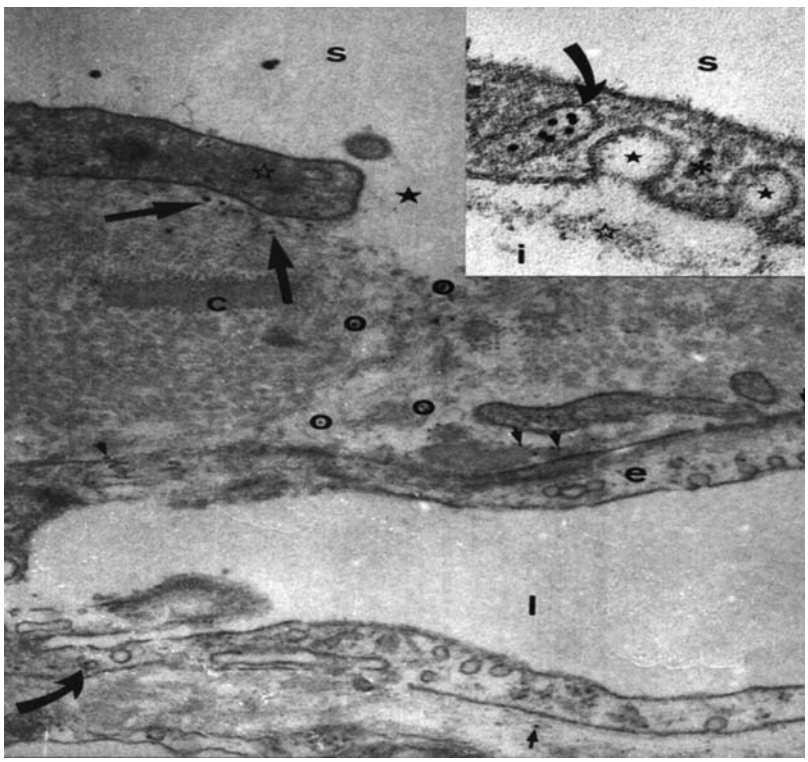

Fig. 5.15 Diaphragmatic peritoneum of a mouse, taken 10 min after intraperitoneal injection of albumin–gold complexes. The black star points at stomata communicating the peritoneal space(s), and the submesothelial connective tissue (c). Albu min–gold complexes (large straight arrow) are present immediately under the mesothelial cell (open star), between collagen fibers (open circles), as well as in the submesothelial interstitial space, near the lymphatic lacuna (short straight arrows). The curved arrow points at a particle of the tracer included in an endothelial pinocytotic vesicle (I: lymphatic lacuna; c: interstitial space) (× 30,740).

Inset. Mouse diaphragmatic mesothelium taken 10 min after intraperitoneal injection of albumin–gold complexes. Arrow indicates an endosome containing particles of the tracer (S: peritoneal space; *: mesothelial cell cytoplasm; black star: plasmalemmal vesicles; open star: submesothelial basement membrane; I: interstitial space) (× 64,550).

pinching vesicles from the plasma membrane [93]. Recently published information suggests that dynamins mediate both clathrin-dependent endocytosis and the internalization of caveolae in microvascular endothelial cells [94, 95].

Some 70 years ago [96], it was suggested that junctions between capillary endothelial cells should be considered the main pathway for exchanges across the microvascular wall. This concept was later extended to the peritoneal blood microvessels and mesothelium, and extensively analyzed within the frame of the two [77, 78], and lately, the three [97] pore size model of capillary and/or peritoneal permeability. (Assumed pores size: large pore: > 150 Å; small pore: up to 40–45 Å; ultra-small pore: 2–5 Å.) To date, physiological studies and mathematical models have failed to convincingly identify the morphological equivalents of the hypothetical cylindrical water-filled pores [76]. On the other hand, however, this short review of the topic testifies that, at least for protein traffic, the vesicular carried hypothesis has been largely proven and accepted in the last few years [80]. Basically, that caveolae and transcellular channels function as a continuous operating conveyor belt, fusing with each other [49, 50, 98, 99], and moving through the cell [98, 99]. The source of energy fuelling vesicular movement remains one of the many questions still open [98–104].

Furthermore, the demonstrated presence of glucose transporters in mesothelial cells [105] furnish further support regarding the active role of the monolayer in solute's transport from and to the peritoneal cavity. Specialized transporter proteins, which are the products of two closely related genes, UT-A (Sic 14a2) and UT-B (Sic 14a1), modulate the movement of urea across cell membranes. Up to date, five UT-A isoforms have been identified in most tissues [106]. It may be speculated that UT-A transporters are also present in the mesothelium. This hypothesis deserves to be explored.

Additionally, recently published evidence demonstrated not only the presence of aquaporin channels in mesothelial cells, but also that their expression can be modulated by both osmotic and non-osmotic stimulation [107]. The relevance of these channels for peritoneal permeability will be analyzed in the section dealing with peritoneal microvasculature. Their presence in mesothelial cells is one more indication giving support to Henle's prediction that the essential anatomy and physiology of the peritoneum are located in its "endothelia" [108].

Simionescu et al. [109] showed the existence of differentiated microdomains on the luminal surface of capillary endothelium where they found a distinct and preferential distribution of electronegative fixed charges, also called anionic sites. Cationic tracers, which did not bind to caveolae or to transcellular channels, decorated the luminal glycocalyx, coated pits, and coated vesicles [98, 103, 109]. Recent studies applying cationic tracers such as ruthenium red and cationized ferritin in rat and mouse peritoneum also showed a preferential distribution of negative charges at the level of the mesothelial cells luminal surface [36, 37, 44] (Figs. 5.12 and 5.16). Density of these surface plasmalemmal charges is substantially reduced in cells undergoing apoptosis [41].

Mesothelial cell boundaries are tortuous, with adjacent cells often tending to overlap (Fig. 5.4, inset; Fig. 5.12). Tight junctions close the luminal side of the intercellular boundaries [14, 21, 32] (Figs. 5.4 and 5.12). When studied in the horizontal plane by using the freeze-fracture technique, these junctional contact areas were defined as cell extensions and finger-like processes, overlapping into the adjacent cell body. Cell processes were wedge-shaped and numerous, and the cell periphery appeared serrated [110]. Desmosomes have also been observed near the cellular

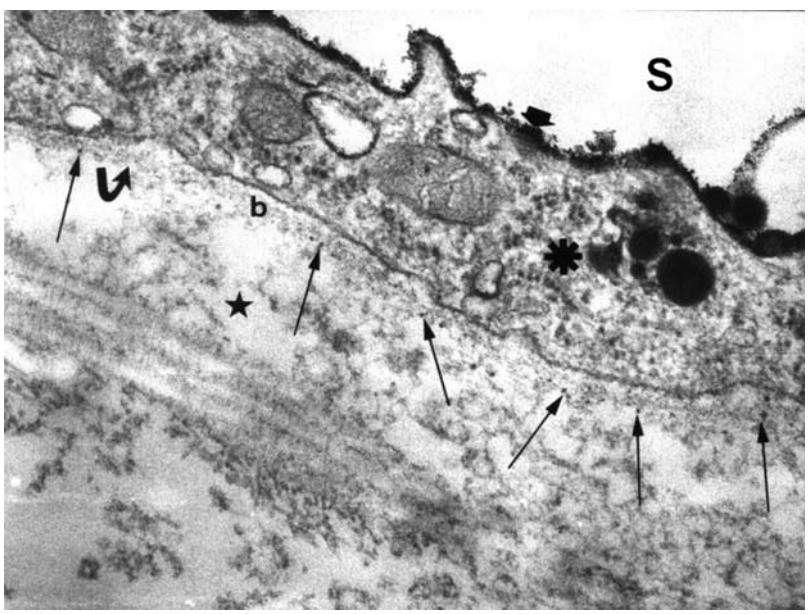

Fig. 5.16 Mesenteric mesothelial cell of a diabetic rat (*). The animal was perfused with ruthenium-red 6 months after induction of the disease, with streptozotocin (glucose blood levels were higher than 500 mg/dL; glycated hemoglobin: $16.38 \pm 0.57\%$). Glycocalyx covering the cavitary aspect of the mesothelial cell is heavily decorated by the cationic tracer (thick arrow). The submesothelial basement membrane (b) shows few dispersed anionic sites (long arrows), as well as areas where they are completely absent (curved arrow) (s: peritoneal cavity; black star: interstitial space) ($\times$ 41,500)

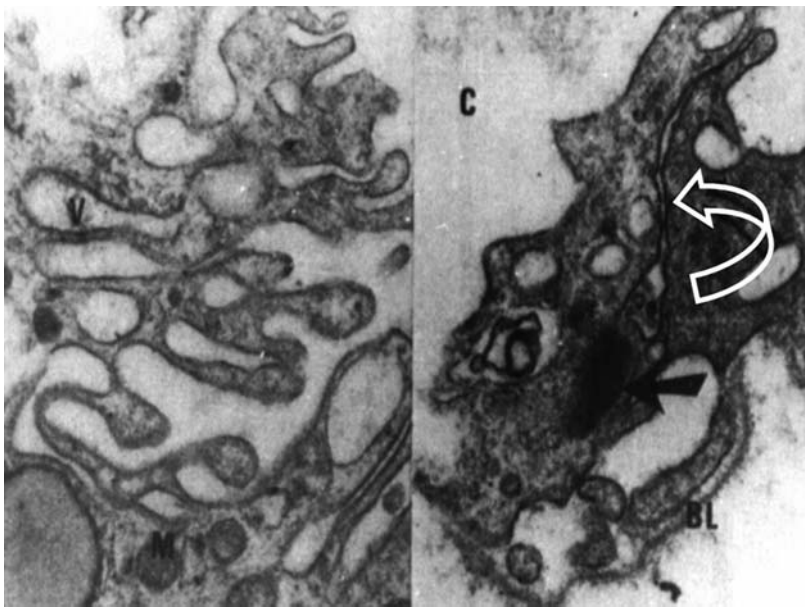

Fig. 5.17 Biopsy of parietal peritoneum taken from a 67-years-old chronic uremic patient, who was on IPD for a period of almost 2 years. A young mesothelial cell shows numerous vacuoles (V) giving a worm-like appearance, which is why this structure is called micropinocytosis vermiformis. The abluminal aspect of the mesothelial cell is lying on a hyaline basement membrane (open arrow) (C: abdominal cavity; M: mitochondrion) (× 26,000).

Right inset. Another area of the same biopsy. This electron micrograph shows the vacuolized cytoplasm of two adjacent mesothelial cells developing a new intercellular junction (open arrow). Note the presence of a typical desmosome (black arrow). The basement membrane (BL) is still discontinuous (original magnification × 30,740)

luminal front [14, 23, 25, 32] (Fig. 5.17) and so have gap junctions [25]. The abluminal portions of cell interfaces usually show an open intercellular infundibulum. Completely open intercellular interphases have not been observed in normal, resting mesothelium [14, 21, 32]. Even desquamated mesothelial cells showing severe degenerative changes can keep their junctional system almost intact (Fig. 5.18). These junctional morphological features are, however, different from those observed between mesothelial cells covering the diaphragmatic lymphatic lacunae, which are more cuboidal and prominent than mesothelial cells observed in other areas of the peritoneal surface.

The existence of stomata (open intermesothelial communications between the abdominal cavity and the submesothelial diaphragmatic lymphatics), predicted by William Hewson [1] 100 years before being discovered by Von Recklinghausen [111], have been the subject of a long and rich controversy along the years. Accepted by some [112–114] and denied by others [115–117], it was not until the advent of electron microscopy that their existence was demonstrated [44, 118, 119]. Scanning electron microscopy disclosed the patent intermesothelial junctions forming gaps whose average diameter ranged between 4 and 12 μm [118, 119] and circumscribed by cuboidal mesothelial cells. These gaps open into submesothelial lymphatics [44] and have not been observed in diaphragmatic mesothelium covering nonlacunar areas [119]. Additional studies have shown the passage of particles from the abdominal cavity into the submesothelial diaphragmatic lymphatics [114, 120]. These studies also confirm the results of experiments

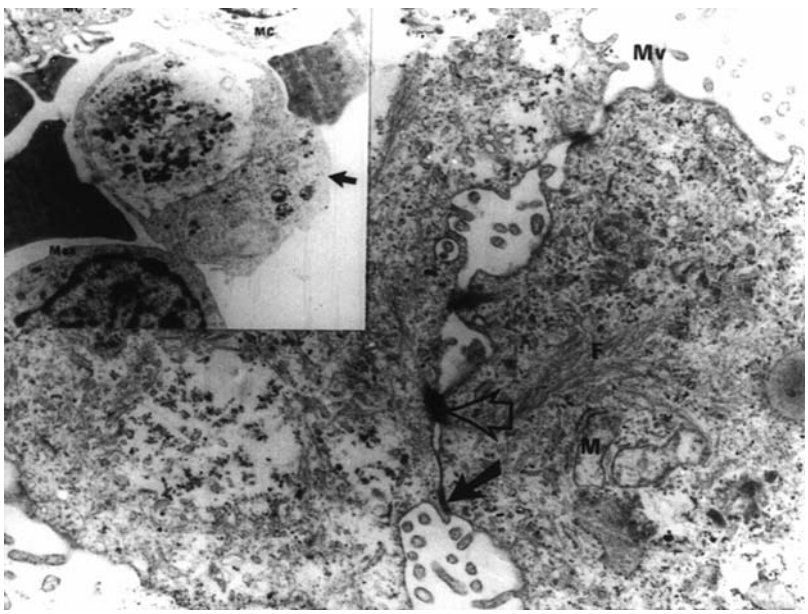

Fig. 5.18 Effluent dialysate obtained from a noninfected patient on peritoneal dialysis. Two desquamated mesothelial cells show severe degenerative changes: swollen mitochondria (M) with broken membranes, sheaves of filaments (F), and swollen cytoplasm. Part of the tight junction is still present (black arrow), as well as a desmosome (open arrow) (M: microvilli) (original magnification × 15,400).

Upper left inset. Effluent dialysate obtained from the same patient. Note the presence of a signet-ring macrophage (arrow), as well as part of two floating mesothelial cells (Mc) (mac: macrophage) (original magnification × 8,600)

performed by Allen [113], who demonstrated the passage of frog erythrocytes through stomata of the mouse diaphragmatic peritoneum, and their appearance within submesothelial lymphatics. This pathway paved the way for intraperitoneal blood transfusions that have been successfully performed in fetuses [121, 122], human adults [123], rats, mice, dogs, and lambs [124, 125]. On the other hand, intraperitoneal malignant cells [126] and bacteria [127] also leave the abdominal cavity on their way to the central venous circulation, through diaphragmatic stomata. The same pathway applies for absorption of albumin–gold complexes injected into the peritoneal cavity (Fig. 5.15) [79]. These structures can be found only between mesothelial cells overlying lacunae.

At the sites of stomata and their channels, mesothelial and lymphatic endothelial cells contain actin-like filaments [128] assumed to induce cell contraction, opening the stomatal pathway for the passage of macromolecules and cells. Cationized ferritin has been observed decorating the glycocalyx of mesothelial and lymphatic endothelial cells located along the stomata, as well as the coated pits and coated vesicles of both types of cells [44, 129]. It should be noted that the presence of stomata has been recently detected in mouse mesenteric mesothelium [130], in omental, ovaric, and pelvic peritoneum, as well as in that covering the anterior liver surface and the anterior abdominal wall [131, 132]. Therefore, it may be assumed that all these extradiaphragmatic openings contribute to the absorptive capacity of the entire peritoneal membrane. Albumin–gold complexes appear to be absorbed also from the peritoneal space through stomata [79] (Fig. 5.15), even though the capability of this pathway for the uptake of the probe did not seem to be much higher than that shown by nonstomatal mesothelial infundibular junctions that contained only 1% of the injected tracer.

Stomata have been ascribed the role of a preferential pathway for the output of fluids, cells, particles, and bacteria from the abdominal cavity [133]. However, the luminal surface of mesothelial cells (which limits the gaps), after staining with cationized ferritin, displayed dense labeling of their cytoplasmic plasmalemma as well as coated pits and coated vesicles. The same cationic tracer also decorated the lymphatic endothelial plasmalemma, which circumscribed the stomatal openings [44]. If this is so, the passage of solutes through stomata is most likely dependent not only on molecular weight, size, and shape, but also on electric charge [44].

Studies in rat and mouse perfused with ruthenium red revealed that intermesothelial cell junctions were, in general, stained just at the level of their infundibulum, even though the dye now and then decorated the junctional complex, staining approximately 50% of its length [37] (Fig. 5.12).

Nuclei are generally located in the central region of mesothelial cells, showing an elongated, oval, or reniform appearance with occasional irregularities in their outlines and sometimes protrusions and indentations (Fig. 5.11). The chromatin is fine, evenly distributed and forms a dense rim around the nuclear membrane (Fig. 5.11). In normal unexposed mesothelium, around 2% of cells are binucleated [31] (Fig. 5.8). Nucleoli have been reported both as present and absent [21, 32]. However, studies performed in imprints [31] showed that they are present and that their number ranges between 6 and 8 (Fig. 5.7). Rough endoplasmic reticulum and ribosomes are dispersed in the cytoplasm. Mitochondria and the Golgi complex are evident mainly in perinuclear areas (Fig. 5.6). Although seldom observed, isolated cilia may emerge from the luminal aspect of mesothelial cells, showing in their cytoplasmic part the axial microtubule as well as the attached basal body (Fig. 5.4). More frequently observed in splenic mesothelium [134], their functional significance is still unknown [135].

The submesothelial basement membrane, originally described by Todd and Bowman [136], and later reported as hyaline, homogeneous, one-layered, and continuous [112, 128], with an average thickness of approximately 40 nm for mouse and rabbit peritoneum [14, 22], normally appears lying under the mesothelial layer of visceral, parietal, and diaphragmatic peritoneum [137] (Figs. 5.11 and 5.17). As an exception, the functional significance of which is still unknown, the omental mesothelium of mice and humans lacks basement membrane [22, 138].

Submesothelial basement membrane of visceral, parietal, and diaphragmatic peritoneum of rat and mouse, perfused with the cationic tracer ruthenium red, consistently showed anionic charges periodically distributed along the lamina rara externa and interna, most of the time, forming double rows [36, 37] (Fig. 5.12).

The reported average diameter of ruthenium red–stained particles in the basement membrane was 2.7 nm, whereas the average distance measured between the one-row oriented basal lamina dye particles ranged between 65 and 90 nm, not far from the interval value of 60 nm observed using the same tracer in rats [139] and human kidney glomeruli [140].

The fact that these charges are, as stated above, distributed along both aspects of the basement membrane implies that the charge-free interval is actually smaller than the mean distance calculated for each membrane layer. The electric field of each particle of ruthenium is around 8–10 nm, and charge discrimination for negative tracers is effective for substances with a molecular radius around 1 nm, corresponding approximately to a globular molecule showing a molecular weight of 2 kDa [141]. In this sense it should be taken into account that the radius of macromolecular anionic albumin is 3.6 nm, whereas its molecular weight is 67 kDa.

It should be noted that the density distribution of these anionic fixed charges of the basement membrane almost disappears during the acute inflammatory reaction secondary to septic peritonitis [142] (Fig. 5.19), and is substantially reduced in rats, soon after 4 months of streptozotocin-induced, uncontrolled diabetes [143] (Fig. 5.16).

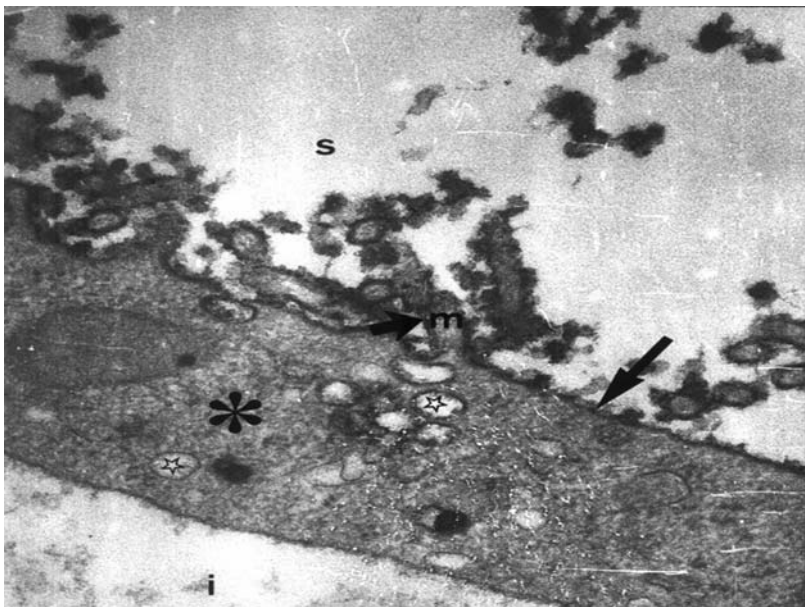

Fig. 5.19 Rat mesenteric mesothelium. The animal was perfused with ruthenium-red, 24 h after experimental induction of *E. coli* peritonitis. Plasmalemmal vesicles or caveolae (open stars) can be seen in the cytoplasm of the mesothelial cell (*). The submesothelial basement membrane is absent, as well as the normally present anionic sites. The luminal aspect of microvilli (m) and that of the cellular membrane are decorated by the cationic tracer (short and long arrows, respectively) (S: peritoneal space; I: edematous interstitial space) (× 41,500)

The relevance of the electronegative charge of the mesothelial monolayer upon the peritoneal permeability to anionic plasma proteins will be discussed in the section dealing with microvascular permeability.

Reduplicated submesothelial basement membrane has been observed in diabetic and nondiabetic chronic uremic patients treated by maintenance peritoneal dialysis [144, 145] (Fig. 5.20). It has been shown that perivascular basement membrane thickness increases with age [146, 147] as well as in the direction of head to foot [147, 148]. This same ultrastructural alteration has been observed in diabetics [147, 149]. It has been suggested that diabetes alone is not responsible for excessive accumulation of basement membrane associated with aging [150]. Therefore, it could be claimed that the reduplication of basement membrane observed in human mesothelium is a by-product of cell renewal regardless of the cause of cell death that triggers the process of repopulation [144, 151]. However, the fact that this phenomenon was also detected in the submesothelial basement membrane of diabetic rats suggests that a high glucose content in the extracellular fluid appears to be related to the mechanism(s) leading to these changes [143].

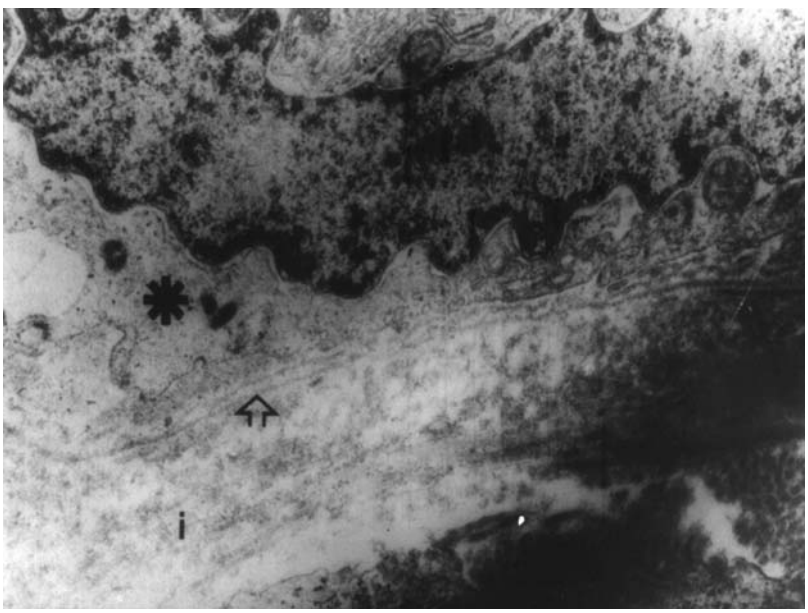

Fig. 5.20 Parietal peritoneum taken from a 67-year-old patient on IPD. The open arrow shows the reduplicated submesothelial basement membrane (*: mesothelial cell; i: submesothelial interstitium) (original magnification × 24,600)

Interstitium

Connective tissue, which originates from mesenchyma, is composed of cells and fibers embedded in an amorphous substance. The main connective tissue cell is the fibroblast and the main fiber is collagen [152].

The submesothelial connective tissue normally has a low cell population surrounded by high-molecular-weight intercellular material. Fibroblasts, mast cells in the proximity of blood microvessels (Fig. 5.21), occasional monocytes and macrophages (Fig. 5.2) are frequently observed.

Substantial amounts of quite compact bundles of collagen are usually interposed between the blood microvessels and the mesothelial layer (Figs. 5.1, 5.2, and 5.3). The collagen density distribution in the different regions of visceral peritoneum is quite variable [146].

The macromolecular common denomination of connective tissues is a broad molecular class of polyanions: the tissue polysaccharides. They form a gel-like structure with the collagen fibers [153], which, when stained with ruthenium red, shows the presence of anionic fixed charges [37].

Thickness of the interstitial layer is extremely variable in the different portions of the peritoneum. This heterogeneity can also be applied to the distances separating the submesothelial blood vessels from the peritoneal cavity, ranging between 1–2 μm to $\geq$ 30 μm (Fig. 5.1). It should be noted that restriction of molecular movement through the interstitial tissue and its progression from or to the microvasculature is affected not only by their molecular weight, shape, and electric charge, but also by the length of the pathway. According to Fick's law of diffusion, it is the difference in concentration per unit of distance (the concentration gradient) that determines the rate of movement of the solute. If we double the distance over which the same concentration difference occurred, the gradient and, therefore, the rate of transfer, would be cut in half. Therefore, the relevance of the interstitial compartment thickness in the transperitoneal transfer of solutes may well be critical [78, 154], and diffusion of solutes coming out from capillaries far from the abdominal cavity could be rendered useful only in long-dwell exchanges, like those performed in CAPD.

The question of the interstitium in terms of plasma to lymph traffic of macromolecules has been basically investigated in lung interstitial tissue [155], which, at physiological pH, has the properties of a negatively charged membrane [156]. Therefore, the polyanionic glycosaminoglycans (mainly hyaluronan) and glycoproteins located in the interstitial ground substance have the capability of influencing the interstitial distribution of volumes of plasma proteins coming out from the intravascular compartment, according to their molecular charge [157]. It has been suggested that these glycosaminoglycans restrict free diffusion through the interstitium [158] and can both reduce the interstitial distribution volume of anionic plasma proteins, and retard the plasma-lymph traffic of cationic macromolecules [155]. Anyway, the effect of protein charge on the interstitial hydraulic conductivity has been only partly clarified.

Fig. 5.21 Interstitial tissue of human parietal peritoneum. Bundles of collagen (c) and fibroblasts (f) are interposed between the blood microvessels (open stars) and the mesothelial cells (not included in the electron micrograph). Mast cells (*) are frequently observed near blood microvessels (original magnification × 42,900)

The extremely low and, at times, negative interstitial pressure (0 to –4 mm Hg) [159–161] represents, together with the capillary permselectivity and the lymphatic drainage, one of the three key factors modulating the plasma-to-lymph fluid traffic, therefore, preventing the formation of interstitial edema [162, 163]. Specifically, during peritoneal dialysis, studies by Flessner [164] have shown that transfer of small solutes through the tortuous interstitial pathways is primarily by diffusion, and that convection may contribute to overall transport in parietal tissue. As stated above, in normal conditions the interstitium has a hydrostatic pressure near 0 [159, 164]. During clinical peritoneal dialysis the intra-abdominal pressure ranges between 4 and 10 cm H_2O [165, 166], thus creating a pressure gradient that drives fluid as well as solutes out of the peritoneal cavity to the interstitium. Thus, fluid loss from the abdominal cavity to the periperitoneal interstitial space is directly proportional to intra-abdominal pressures higher than 2 cm H_2O [166].

Blood Microvessels

Capillaries of human and rodent parietal [167] and visceral peritoneum [43, 168] have been reported to be of the continuous type (Figs. 5.1, 5.3, 5.22–5.24), according to the classification of Majno [169]. However, the existence of fenestrated capillaries in human parietal and rabbit diaphragmatic peritoneum (Figs. 5.1 and 5.25), as well as in mouse mesentery [170–172] has been reported. The incidence of fenestrated capillaries in human parietal peritoneum (Fig. 5.22, inset) appears to be low (1.7% of the total number of capillaries) [172]. The reported density of fenestrated microvessels in mouse mesentery and rabbit diaphragmatic peritoneum ranged between 26 and 29% of the observed capillaries, whereas their presence in parietal peritoneum of nondialyzed uremic patients was only 1.7%. It should be noted, however, that the anterior abdominal wall of humans comprises less than 4% of the peritoneal surface area [10]. Diameter of fenestrae, which ranged between 60 and 90 nm, is well within the range of fenestrae observed in other capillary beds: 40–70 nm in renal peritubular capillaries [173], glomerular capillaries [169], and rabbit submandibular gland [174]. The reported density of fenestrae counted along the capillary circumference of mice mesenteric microvessels is 3.4 fenestrae/micron [175]. This value is quite close to that of 3 fenestrae/micron of capillary circumference observed in renal glomerular capillaries [169]. Density of fenestrae per square micron of endothelial surface is 45–60/μm^2 in renal peritubular capillaries [176] and 20/μm^2 in renal glomerular capillaries [169], whereas their frequency in mouse mesenteric capillaries is approximately 12/μm^2 [171].

The density distribution of submesothelial microvessels along the different portions of the peritoneum is variable. In the rabbit the mesentery appears to be the most vascularized peritoneal segment (contributing 71.1% of the total number of observed capillaries). The reported diaphragmatic and parietal contributions to the total microvascular bed examined were 17.9 and 10.9%, respectively [177].

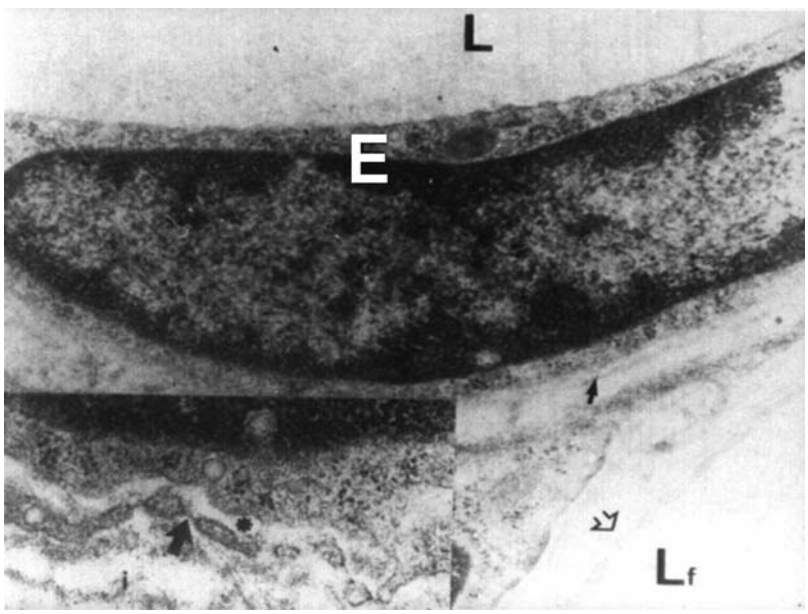

Fig. 5.22 Continuous capillary of a blood mesenteric rabbit capillary whose endothelial layer (E) is lying on the basement membrane (black arrow). (open arrow) (L: lumen of continuous capillary. (Original magnification × 47,400).

Lower left inset. Fenestrated capillary of human parietal peritoneum. The arrow points to a fenestral diaphragm (i: interstitium; *: lumen of fenestrated capillary) (original magnification × 42,900).

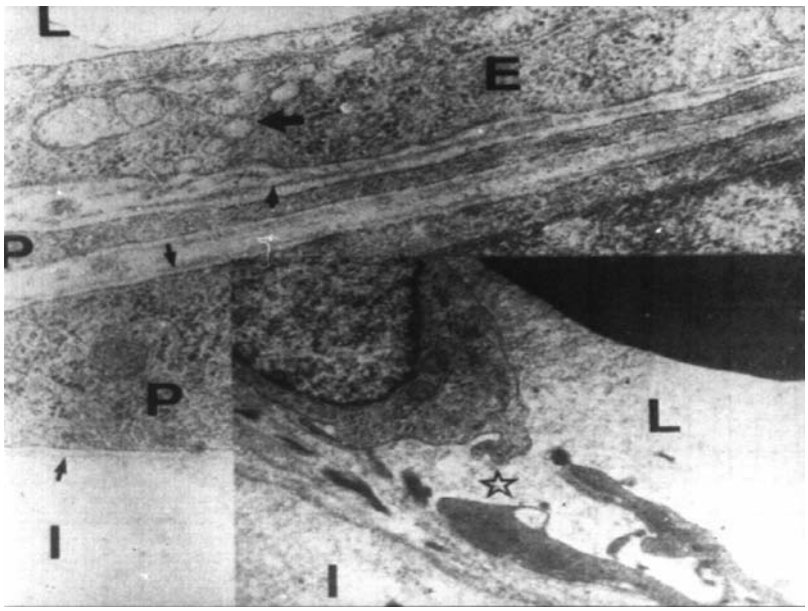

Fig. 5.23 Postcapillary venule of rabbit mesentery. The large arrow shows a transcellular channel (L: microvascular lumen; E: endothelial cell; short arrow: subendothelial basement membrane; P: pericyte; small arrows: subperithelial basement membrane; I: interstitium) (× 62,500).

Lower right inset. Human parietal peritoneum taken from a 21-year-old patient with *E. coli* peritonitis. The star shows an open interendothelial junction of a blood capillary. Note part of an erythrocyte in the upper right quadrant (L: capillary lumen; I: interstitium) (original magnification ×41,500)

In rabbit mesentery the main population of continuous blood microvessels is represented by:

1. True capillaries (without perithelial cells), the mean luminal diameter of which is 7.2 μm and whose mean wall thickness is 0.4 μm (Figs. 5.11, 5.22, 5.23, and 5.24).
2. Venous capillaries usually formed by the confluence of two or three capillaries. These show a thin endothelial layer, occasional peripheral perithelial cells, and have a mean luminal diameter of 9.2 μm.
3. Postcapillary venules whose luminal diameter ranges between 9.4 and 20.6 μm [43].

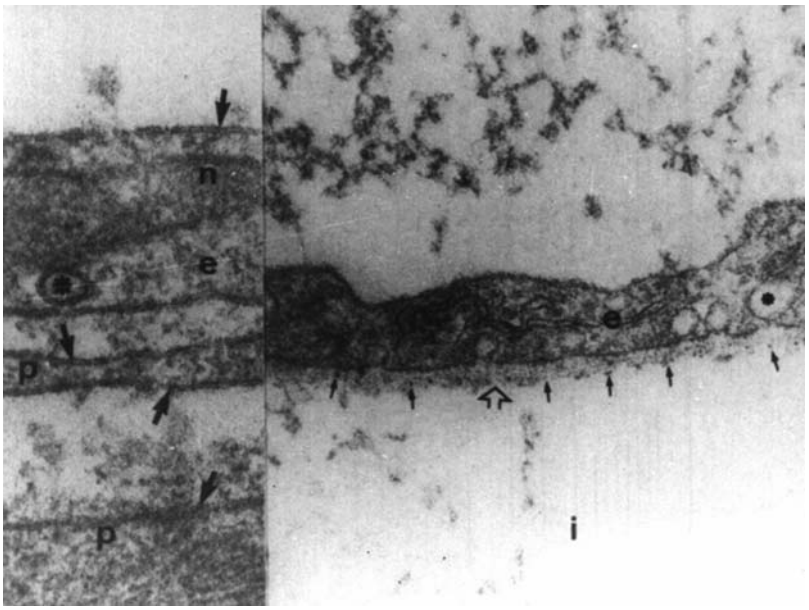

Fig. 5.24 The right part of the figure shows part of a blood capillary wall observed in a sample of diaphragmatic peritoneum obtained from a normal rat. The luminal aspect (upper cell border) of the endothelial cell (e) shows a fine reticular glycocalyx stained by ruthenium red which, on the other hand, does not decorate pynocytotic vesicles (*). The subendothelial basement membrane (open arrow) is continuous and shows quite regularly distributed ruthenium-red stained anionic sites (small arrows) along both the lamina rara externa and the lamina rara interna (original magnification × 50,720).

Inset. Left part of the figure. Part of a postcapillary venule observed in mesentery of rat, 5 days after induction of peritonitis. The trilaminar structure of the endothelial (e) and perithelial cell plasmalemma is clearly observed (arrows), as well as that of the limiting membrane of the pinocytotic vesicle (*). Glycocalyx, basement membrane and anionic sites are absent (n: nucleus of endothelial cell) (original magnification × 84,530)

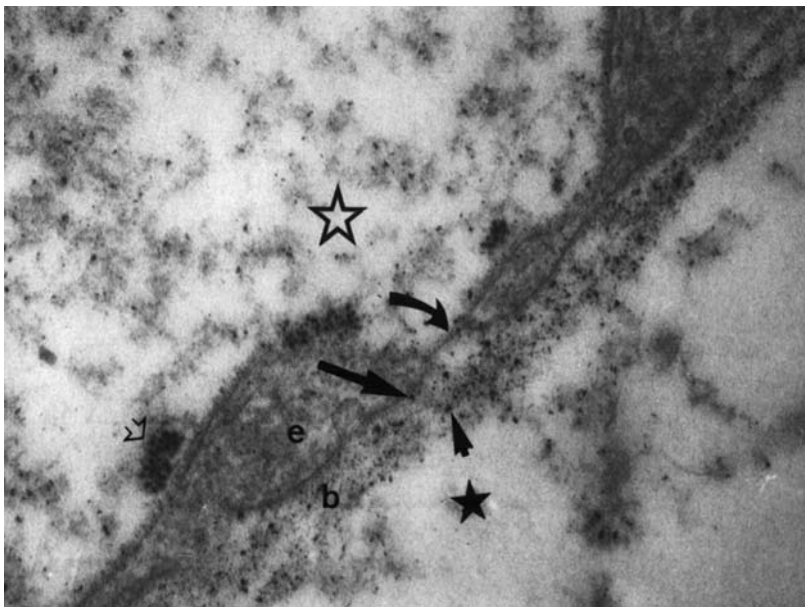

Fig. 5.25 Fenestrated capillary of mouse mesenteric peritoneum. The animal was perfused with cationized ferritin. Particles of the tracer decorate the luminal (long straight arrow) and the abluminal (short black arrow) aspects of the basement membrane (b) laying under the endothelial cells (e). A fenestral diaphragm is also decorated on its luminal aspect by particles of cationized ferritin (curved arrow). Clumps of the tracer appear located on the luminal endothelial cell plasmalemma (open arrow) (open star: microvascular lumen; black star: subendothelial interstitial space) (× 41,500)

With increasing luminal diameter there is a proportional increase in wall thickness due to the presence of more perithelial cells encircling the endothelial layer [178] (Fig. 5.23). The average ratio of luminal diameter to wall thickness is approximately 10/1 [178]. All aforementioned exchange vessels present at their luminal aspect a limiting area that separates the endothelial cell from the circulating blood and is formed by the plasmalemma with its trilaminar structure [19] (Fig. 5.24) and the glycocalyx (Fig. 5.24). The latter, originally described by Luft [38] in other vascular beds, has also been observed at the luminal aspect of peritoneal microvessels [39, 179] The presence of sialoconjugates, proteoglycans, and acidic glycoproteins organized as a fibrous network provides the plasmalemmal glycocalyx with electronegative charge [180] (Fig. 5.26).

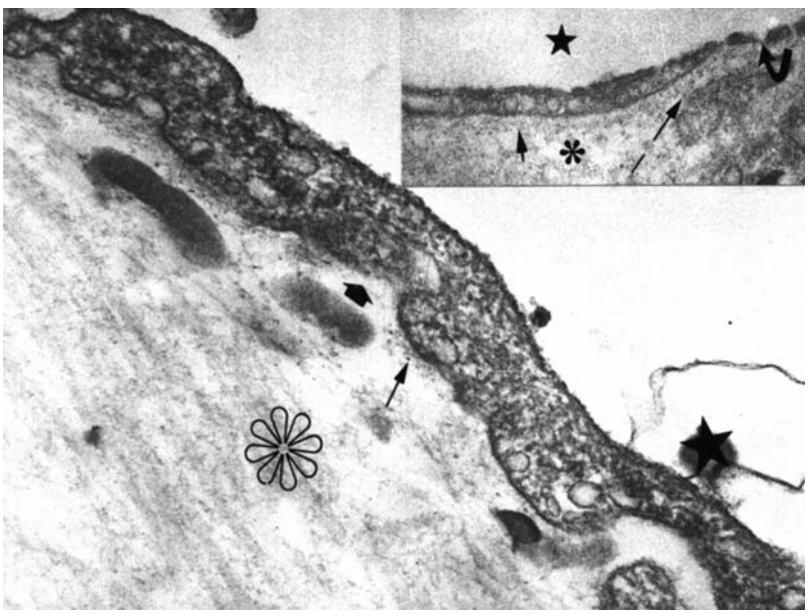

Fig. 5.26 Continuous capillary of rat mesentery. The sample of tissue was recovered 24 h after induction of abdominal sepsis. Distribution of subendothelial anionic sites is irregular; at times they are totally absent (thick arrow), whereas in other portions of the basement membrane they can be seen, but showing an extremely low density (small thin arrow). The luminal aspect of the endothelial cell shows a black rim decorated by ruthenium red, indicating the still-present negative charges of the endothelial glycocalyx (star: microvascular lumen; *: edematous interstitial tissue) (ruthenium red; × 41,500).

Inset. Mesenteric fenestrated capillary taken from the same animal. Occasional anionic sites (long arrow) can be seen along the basement membrane. Most of its length is free from ruthenium-red decorated negative charges (short arrow) (*: structureless interstitial space; star: capillary lumen; curved arrow: fenestra) (ruthenium-red; × 30,740)

There is evidence that anionic plasma proteins (albumin and IgG) are adsorbed to the glycocalyx of microvascular endothelial cells [181]. The fiber-matrix model of capillary permeability envisages the glycocalyx as a meshwork of glycoprotein fibers that, after adsorbing circulating proteins, would tighten its mesh, thereby rendering the underlying endothelium less accessible to water and other water-soluble molecules [40]. Furthermore, it has been shown that the adsorption of circulating anionic plasma proteins to the glycocalyx renders the underlying endothelium relatively impermeable to large, electron-dense, anionic tracers such as native ferritin (MW $\sim$ 450 kDa) [181].

The mean endothelial cell width of rabbit mesenteric capillaries is 0.4 μm, unless the cytoplasm bulges up to more than 1 μm at the site of the nucleus (compare Figs. 5.3 and 5.22 with Fig. 5.24). The cytoplasm includes the usual cell organelles: mitochondria, rough endoplasmic reticulum and free ribosomes [14, 169].

The mitochondrial content of vascular endothelial cells in frog mesentery decreases gradually from arterioles towards venous capillaries and subsequently increases toward venules [182].

The Golgi complex displays variable degrees of development in biopsies taken from different patients. This same variability was observed when comparing different peritoneal microvascular endothelial cells present in a single sample.

The cytoplasmic matrix of endothelial cells shows long filaments, parallel to the longitudinal cellular axis. Their diameter ranges between 20 and 100 Å [169], and at times they appear in bundles. These intermediate-size filaments seem to be a common component of the cytoplasmic matrix of vascular endothelial cells showing, however, a lower density distribution than that observed in other cell types [135].

Nuclei are generally oval, elongated (Fig. 5.22), or occasionally kidney-shaped with focal surface irregularities (Fig. 5.11). Their mean short-axis width in rabbit mesentery is 0.957 ± 0.417 μm [14].

Plasmalemmal vesicles, which can be found in most cell types, are particularly common in capillary endothelia [183], where they occupy approximately 7% of the cell volume [101] (Fig. 5.23). Their outer diameter is approximately 700 Å (it ranges between 500 and 900 Å) [14, 36, 50] and they have a round or oval shape surrounded by a three-layered membrane of 80 Å thickness (Fig. 5.24, inset).

According to their location in the cytoplasmic matrix, vesicles can be classified into three groups: a) vesicles attached to the plasmalemma limiting the blood front of the endothelial cell; b) free vesicles within the cytoplasmic matrix; and c) attached vesicles, but this time to the tissue front of the endothelial cell plasmalemma [50] (Fig. 5.23). The density population of plasmalemmal vesicles varies considerably from one vascular segment to another, even within the same microvascular territory [49, 50]. In the mouse diaphragm, arterioles show 200 vesicles/μm^2, true capillaries 900 μm^2, venular segments of capillaries 1,200 μm^2, and postcapillary venules 600 μm^2 [49].

Most vesicles that open to the extracellular medium have necks whose diameter can be as small as 100 Å [50]. Transendothelial channels formed by a chain of vesicles opening simultaneously on both fronts of the endothelium have been described in capillaries of mouse diaphragmatic muscle [49] as well as in postcapillary venules of rabbit and rat mesentery (Figs. 5.23 and 5.27) [14]. The relative frequency of transendothelial channels has been found to be higher in true capillaries than in arterioles and venules, with the highest density in the venular segment of capillaries [103]. Microvessels of frog mesentery showed a density distribution of three transendothelial channels for every

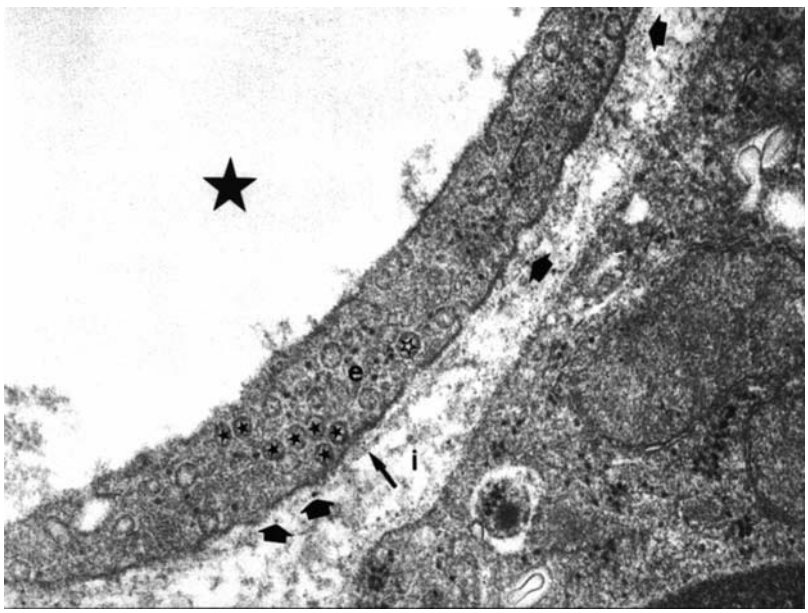

Fig. 5.27 Mesenteric capillary of a rat 6 months after induction of diabetes with streptozotocin (glucose blood levels were higher than 500 mg/dL; glycated hemoglobin $16.38 \pm 0.57\%$). The animal was perfused with ruthenium red. The basement membrane (long arrow), lying under the endothelial cell (e), shows few and occasional anionic sites (thick arrows) (large black star: capillary lumen; open star: pinocytotic vesicle; small black stars: transendothelial channel; i: interstitial space) ($\times$ 41,500)

400 vascular profiles examined [182]. Just as in observations made on mesothelial cells, plasmalemmal vesicles and transendothelial channels do not bind cationic electron-dense tracers that, on the other hand, decorate the luminal aspect of coated pits and coated vesicles [98, 109] in the peritoneal microvasculature [37].

The functional significance of plasmalemmal vesicles or caveolae, vesicles, transendothelial channels, coated pits, and coated vesicles has been discussed in the section on normal mesothelium.

As stated above, in fenestrated capillaries, endothelial cells are pierced by fenestrae closed by a diaphram [184] (Fig. 5.22, inset; Figs. 5.25 and 5.28). Fenestrae are not static structures. It has been shown that their prevalence can be increased under the effect of vitamin A metabolites [185], the influence of sexual hormones [168], thrombocytopenia [186], and by the acute inflammatory reaction [169]. In this sense a microvascular bed (capillaries and postcapillary venules), supplied with a continuous endothelium, can rapidly develop endothelial fenestrations under the influence of vascular endothelial growth factor (VEGF), a 34–42 kDa cytokine, released by different cell types (eosinophils, neutrophils, and others) during the acute inflammatory reaction [187–190]. This effect has been demonstrated in vivo [191, 192], after acute and chronic exposure of different microvascular beds.

High concentrations of negative fixed charges (heparin and heparan sulfate) have been found on the blood front of fenestral diaphragms in several microvascular beds [98, 109, 184, 193–196]. They are expected to discriminate against anionic macromolecules, essentially anionic plasma protein. Similarly, mesenteric fenestrated capillaries of mice perfused with the cationic tracer ferritin showed densely packed anionic fixed charges on the endothelial cell glycocalyx, on the luminal aspect of fenestral diaphragms, as well as along both sides of the subendothelial basement membrane [175] (Fig. 5.25).

What is the role of fenestrae and intercellular junctions in the still ill-defined mechanisms related to capillary permeability? For more than 25 years the fenestral pathway was ascribed a major role in the permeability capabilities of fenestrated capillaries [197]. Some investigators suggested that, while open fenestrae could represent the ultrastructural equivalent of the large pore [77], fenestrae, closed by diaphragms (Fig. 5.25), could also provide a diffusive pathway for water- and lipid-soluble substances [198]. However, fenestral openings of 60–90 nm diameter are too large to be considered the structural equivalent of the hypothetical large pores, the radii of which range between 11 and 35 nm [77, 199]. Furthermore, the density of these pores, estimated at one every 20 μm^2 [50], is substantially lower than the density of fenestrae per square micron observed in microvascular beds.

At least from a theoretical point of view, the presence of anionic fixed charges at the level of fenestral diaphragms, as well as in the subendothelial basement membrane (Fig. 5.25), is a strong argument against the transfenestral passage of macromolecular anionic proteins [139, 200]. Indeed, previously reported physiological studies have demonstrated the selectivity and restriction of the fenestrated microvascular wall to the passage of electronegatively charged

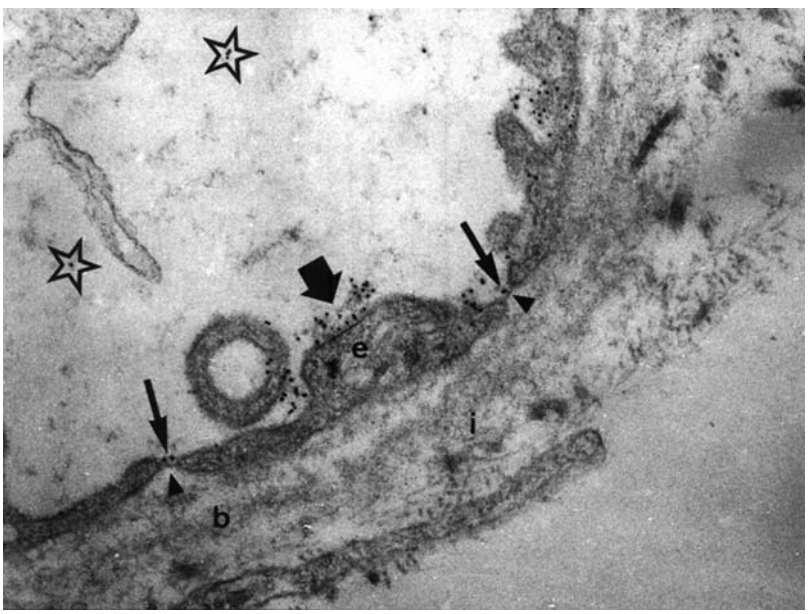

Fig. 5.28 Fenestrated capillary of mouse mesentery taken 30 min after intra-arterial perfusion of the tissue with albumin–gold complexes. Particles of the tracer can be seen in the microvascular lumen (open stars), on the glycocalyx of the endothelial plasmalemma (short thick arrow), as well as on the luminal aspect (long arrows) of fenestral diaphragms (arrowheads). The tracer did not reach the subendothelial interstitial space (i) (b: subendothelial basement membrane) (× 50,720)

macromolecules [201–203]. Moreover, the permeability of fenestrated capillaries to anionic macromolecules is not higher than that of capillaries of the continuous type [204]. In this context Fig. 5.28 offers a descriptive account of the problem, observed in our laboratory (Gotloib L, unpublished observations). Rat mesentery was perfused (in vivo) through the arterial tree with negatively charged albumin–gold complexes for a period of 30 min. As can be seen, substantial amounts of albumin–gold particles appear contacting the luminal aspect of the endothelial cell plasmalemma, as well as free into the capillary lumen. Particles of the tracer can be observed in close apposition to the luminal front of fenestral diaphragms. However, albumin–gold particles were not seen in the subendothelial space, even 30 min after perfusion. These observations support the hypothesis that fenestrae are not permeable to anionic plasma proteins. Consequently, it appears that fenestral openings are unrelated to the theoretically predicted large pore system [197, 200, 204, 205]. On the other hand, fenestrated endothelia have higher hydraulic conductivity, and are more permeable to small ions and molecules than continuous endothelia [206].

Capillary endothelial cells are linked to each other by tight junctions (zonula occludens), originally described by Farquhar and Palade [207–209] (Fig. 5.29). Communicating or gap junctions have been observed in arteriolar endothelium [208]. Postcapillary venules have loosely organized junctions with discontinuous ridges and grooves of which 25–30% appear to be open with a gap of 20–60 Å [50]. The presence of gap junctions has also been documented [14].

Cytoplasmic plasmalemma bordering both sides of junctions also shows anionic fixed charges [37]. Their functional significance in relation to the passage of charged molecules will be discussed later.

Research performed during the past 10–15 years revealed that interendothelial tight junctions appear as a set of long, parallel, linear fibrils that circumscribe the cell, with short fibrillar fragments interconnecting the main parallel array. The number of fibers correlates with junctional permeability: the more densely packed the fibrillar mesh, the lower the junctional permeability [210]. Therefore, the tight junction is not a simple fusion between the outer plasmalemmal leaflets of neighboring cells [211]; rather, it consists of protein molecules such as occludins and cadherins in tight junctions, desmoleins and desmocolins in desmosomes, and connexins in gap juctions [212, 213].

Occludin is an integral membrane protein, exclusively localized at tight junctions in both epithelial and endothelial cells [212], and is directly involved in sealing the cleft, creating the primary barrier to the diffusion of solutes through the paracellular pathway as well as regulating, according to the modulation of occludin expression, the permeability properties of different microvascular beds [214]. Occludin is bound on the endothelial cytoplasmic surface to ZO-1, a 220 kDa membrane-associated protein likely to have both structural and signaling roles [215, 216].

Vascular endothelial cadherin, in turn, is an endothelial-specific cadherin that regulates cell to cell junction organization in this cell type, and provides strength and cohesion to the junction [217]. Cadherins are also implicated

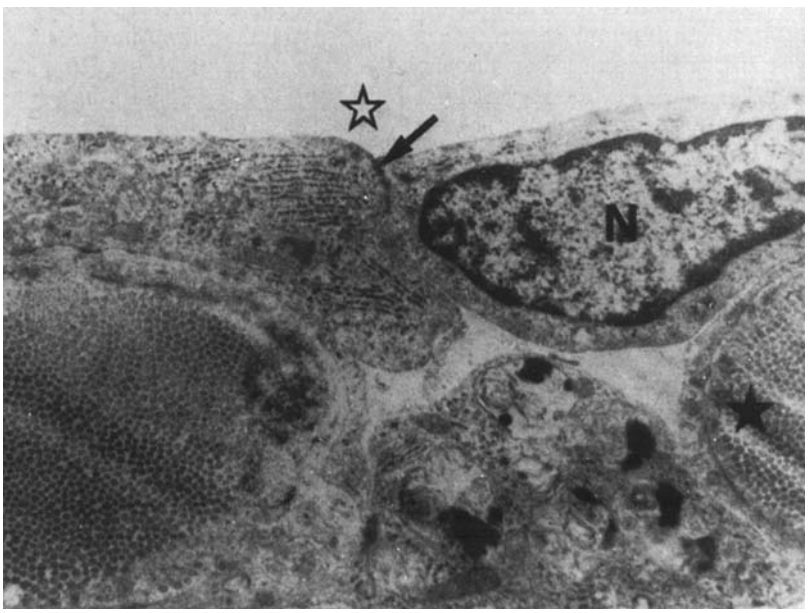

Fig. 5.29 Blood capillary of rabbit mesentery. The black arrow points at a tight junction formed by two adjoining endothelial cells. A macrophage can be observed lying under the endothelial cells interposed between two bundles of collagen (black stars) (open star: capillary lumen; N: nucleus of endothelial cell) (original magnification × 85,000)

in junctional permeability, basically under the effect of inflammatory mediators such as tumor necrosis factor and histamine, which have been shown to induce a redistribution of these adhesion molecules to nonjunctional regions and junctional disassembly [218, 219].

The role of tight junctions in the permeability capabilities of the microvasculature, during the situation of normal physiology, has been a topic for intensive research and controversy through the years. Whereas some groups considered the intercellular cleft as the main pathway for water, as well as for small and large solutes and electrolytes [220, 221], other groups developed the concept that tight junctions create a regulated paracellular barrier to the movement of water, solutes, and immune cells between the microvascular compartment and the interstitial space, enabling the endothelial monolayer to create compositionally different fluid compartments [210, 222–224]. Recently published information indicates that the presence of tight junctions does not imply a foolproof seal of the intercellular cleft. Instead, this structure contains discrete ion-selective pathways through the extracellular portion of the junction, regulated, at least in part, by the activity of the cytoskeleton [210, 225]. As stated above, the transmembrane protein occludin is an excellent candidate for the sealing protein. Understanding the mechanisms involved in junction permeability will require both a more detailed molecular characterization of tight junction proteins and the regulation by the endothelial cells of their attachment to the perijunctional cytoskeleton [222]. As stated by Renkin [204] in 1977, identification of the tight junction with the diffusional pathway for macromolecular plasma proteins, in a situation of normal physiology, still remains questionable. Their role in capillary permeability is still debated.

As for blood cells, recent investigations showed that neutrophils preferentially migrate by crossing at tricellular corners, rather than passing through tight junctions that lie between two adjacent endothelial cells [226].

The basement membrane of true capillaries is normally a thin sheet at the interface between the abluminal aspect of the endothelial cell and the connective tissue (Figs. 5.13 and 5.22). In postcapillary venules it is interposed between the endothelial and the periendothelial cell (Fig. 5.23). Generally uniform for a given structure, its thickness varies among the different parts of the body. True capillaries of normal rabbit mesentery have a mean basal membrane thickness of 0.234 ± 0.095 μm [14]. As described for the submesothelial basement membrane, that of human capillaries also exhibits a significantly increasing thickness in the direction of head to foot [147]. It has been suggested that these regional variations are secondary to differences in venous hydrostatic pressure effective on the capillary bed [147]. Diabetic and nondiabetic patients on long-term peritoneal dialysis, showing reduplicated submesothelial basement membrane, had similar alterations on the capillary basement membrane of parietal peritoneum [144]. These changes were also observed in postcapillary venules and small arterioles of parietal peritoneum taken from diabetic uremics on CAPD (Figs. 5.30 and 5.31), as well as in skin capillaries (Fig. 5.32). Additionally, reduplication of mesenteric subendothelial capillary basement membrane has been recently reported in streptozotocin-induced diabetic rats, as early as after 4 months of uncontrolled hyperglycemia [144], whereas thickening was seen in the same animals 6 months after induction of the disease. These structural alterations of diabetic basement membranes seem to be derived from a substantial increased presence of collagen IV [149, 227–231] which, according to in vitro studies, appears to derive from extended exposure of cells to high concentrations of glucose [232, 233].

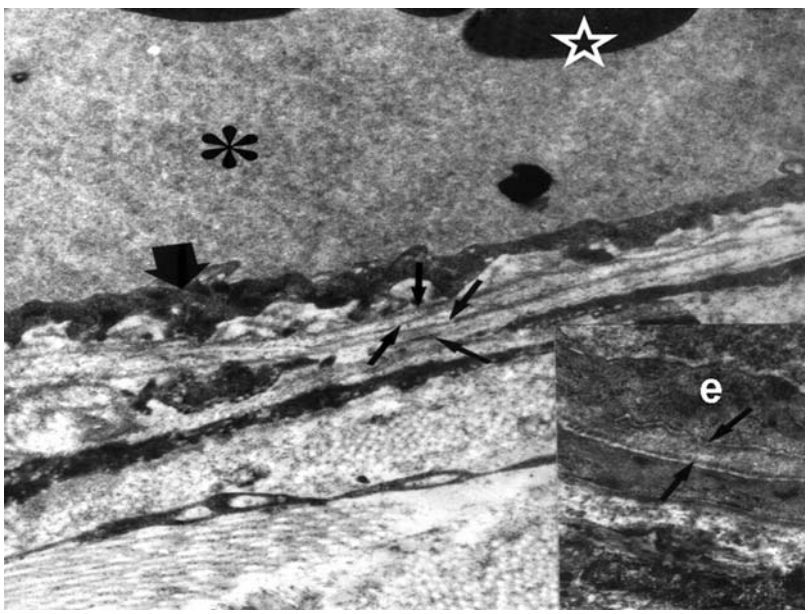

Fig. 5.30 Subendothelial reduplicated basement membrane (small arrows) observed in a small venule of parietal peritoneum taken from a diabetic patient on CAPD (open star: red blood cells; *: vascular lumen; thick arrow: endothelial cell) (× 15,400).

Inset. One arteriole from the same biopsy shows splitting of the subendothelial basement membrane (arrows) (e: endothelial cell) (× 12,600)

Fig. 5.31 Blood capillary of parietal peritoneum taken from a 69-year-old uraemic patient on IPD for almost 3 years. The endothelial cell (e) is lying on a reduplicated basement membrane (arrow) (i: interstitium) (× 24,600)

In rats, both thickening and layering of microvascular basement membrane can also develop as a consequence of aging [151, 234], but not before completing the first year of life [234].

So far, it may be speculated that reduplication or layering of submesothelial and peritoneal microvascular basement membranes in nondiabetics on CAPD could result from their continuous and long exposure to high glucose concentrations.

Subendothelial basement membranes of both continuous and fenestrated capillaries (Figs. 5.24 and 5.25), have regularly distributed anionic fixed charges along both aspects of the membrane [39, 175]. Their density distribution in continuous capillaries ranges between 31 and 34 μm of basement membrane [39, 143]. These values, shown in the section devoted to the mesothelial basement membrane, are not far from those detected in other microvascular basement membranes.

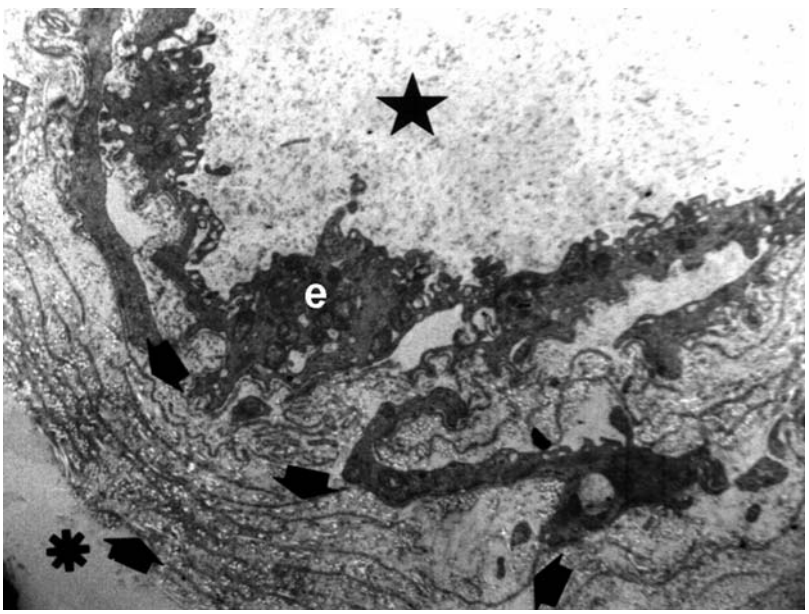

Fig. 5.32 Blood capillary observed in a skin biopsy taken from the same diabetic chronic uraemic patient, whose parietal peritoneum was shown in Fig. 5.31. Arrows point at the multiple layers of basement membrane (star: microvascular lumen; e: endothelial cell; *: interstitial space) (× 5,850)

The chemical composition of the fixed electronegative charges linked to the subendothelial basement membrane has been explored in several microvascular beds. Studies have shown that their main structural components are glycosaminoglycans such as heparan sulfate and chondroitin sulfate [109, 235–237]. This is at variance with the biochemical and histochemical observations made on the glycocalyx cell surface charges, the main component of which is sialic acid and sialo conjugate. This pattern has been detected in microvascular endothelium [238–242], pleural, pericardial, and peritoneal mesothelial cells [243], as well as in macrophages [244], erythrocytes [245], and platelets [246].

What is the functional significance of these electronegative charges? A strong body of literature supports the concept that the permselectivity of capillary walls to anionic macromolecules is basically dependent on molecular charge, besides size and shape [139, 141, 167, 205, 236, 247–253]. Investigations performed in in vivo, whole organ studies [155], in isolated perfused frog capillaries [254], and in isolated rat hindquarters [248] have demonstrated their presence evaluating permeability of different endogenous proteins in a variety of microvascular beds. Indeed, similar results were observed in patients on CAPD comparing dialysate to plasma concentrations of amino acids, having almost the same molecular weight but quite different charge [255], as well as in rat peritoneum, using charged dextrans [256]. The fact that endogenous proteins of graded size are heterogeneous with respect to their molecular charge [257] lead to some conflicting results [258]. The key to this problem was found investigating clinical and experimental situations, where the permselectivity was substantially reduced or neutralized, enabling the observer to evaluate changes in permeability, derived from the absence of the normally present fixed electronegative charges. In the clinical set-up, type I diabetes [259], congenital [260, 261], and acquired nephrotic syndrome [262, 263] have been shown to expose the association of depleted glomerular negative charges and loss of the permselectivity of the capillary wall, leading to massive proteinuria. Experimental interventions performed in laboratory animals confirmed, in turn, the aforementioned findings. Enzymatic removal of sulfated (heparan sulfate) or nonsulfated (hyaluronic acid) glycosaminoglycans from the glomerular basement membrane resulted in a substantially increased permeability to bovine serum albumin [264]. Rats with streptozotocin-induced diabetic nephropathy showed reduced glycosaminoglycan contents in the glomerular basement membrane [265], decreased presence of their heparan sulfate-associated anionic sites [266], as well as significantly increased proteinuria [143]. Further observations made in the streptozotocin diabetic rat have shown a substantial reduction in the submesothelial and capillary subendothelial density distribution of anionic fixed charges (from 31 ± 2 to 12 ± 2 ruthenium red-decorated anionic sites/μm of basement membrane) and, at the same time, a significant increase of albumin losses in the peritoneal dialysis effluent, indicating a marked decrease of the permselective capabilities of the charged components of the peritoneal membrane (Fig. 5.16) [143]. Similar observations were made in intact rats after neutralization of the peritoneal negative charges with protamine sulfate [267].

The acute inflammatory reaction is the most spectacular experimental set-up to demonstrate the permeability changes derived from an acute reduction of the microvascular negative charge. This situation has been classically defined by the development of acute low hydrostatic pressure, high capillary permeability, and albumin-rich interstitial edema [163, 268]. In this sense the generalized acute inflammatory reaction derived from abdominal sepsis promotes a major erosion of the density distribution of the anionic fixed charges in several microvascular beds, diaphragmatic and mesenteric peritoneum (showing values as low as six anionic sites/micron of basement membrane) [269], myocardium [270], skeletal muscle, pancreas, renal peritubular capillaries [271], as well as in the submesothelial basement membrane of rat diaphragmatic and mesenteric peritoneum [142] (Figs. 5.19 and 5.26). Additional studies in the same experimental model of abdominal sepsis in rats demonstrated abnormally increased albumin content in mesenteric, diaphragmatic, and pancreatic interstitial fluid [272]. This drastic loss of the permselectivity of the capillary wall derives from a massive liberation and reduced inactivation of a host of mediators of inflammation triggered by acute inflammation [273–275], including tumor necrosis factor alpha, interleukins, platelet-activating factor, leukotrienes, thromboxane A2, activators of the complement cascade, kinins, transforming growth factor B, vascular endothelial growth factor, as well as many others already known, or still waiting to be identified [185, 276–279].

The role of intercellular junctions in macromolecular leakage during acute inflammation is still controversial. Some groups pointed to the endothelial tight junction as the main pathway for extravasation of macromolecular plasma protein. It was postulated that inflammatory mediators such as histamine, serotonin, bradykinin and leukotriene E4 induced junctional openings (Fig. 5.23, inset), by means of endothelial cells contraction [280–283] or by a loss of occludin and cadherin from the junctional complex [284, 285]. Unpublished observations from our laboratory (Gotloib L.) made in intact rats, as well as in rats with *E. coli* peritonitis, by means of intra-arterial injection of albumin–gold complexes, showed that most particles of the tracer cross the endothelial barrier transcellularly, via plasmalemmal vesicles. In both experimental situations, intact and infected rats, the tracer was not seen beyond the junctional infundibulum (Figs. 5.33 and 5.34); just the opposite: the tracer was present in plasmalemmal vesicles (Fig. 5.34, inset), and reached the subendothelial space in areas far from intercellular junctions (Figs. 5.33 and 5.34). This concept of transcellular transport of albumin through the capillary wall, also during acute inflammation, is

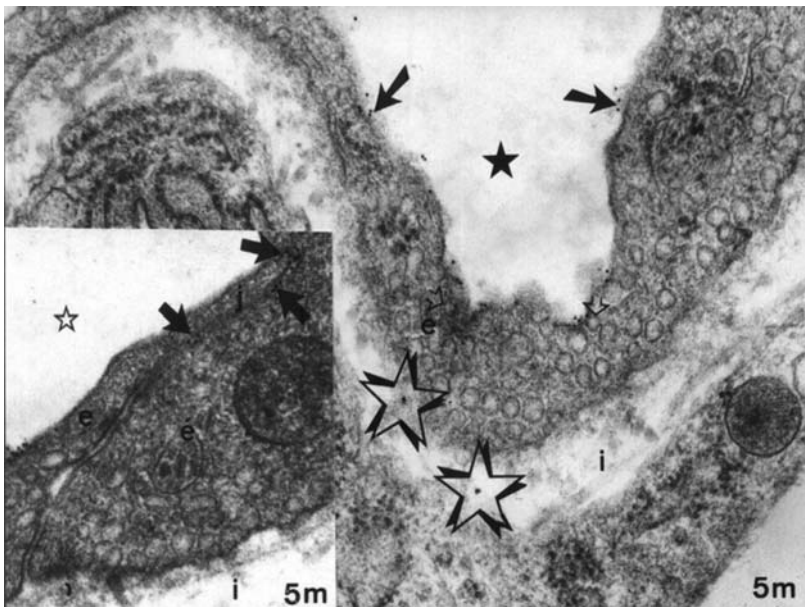

Fig. 5.33 Blood continuous capillary of mouse diaphragmatic peritoneum. The material was taken 5 min after intra-arterial perfusion of the tissue with albumin–gold. Particles of the tracer decorate the luminal aspect (black arrows) of the endothelial cell, as well as that of pynocytotic vesicles (open arrows). Note the presence of albumin–gold complexes (open stars) in the subendothelial interstitial space (i), in an area free of intercellular junctions (× 41,500).

Inset. Another aspect of the same sample shows particles of the tracer (arrows) in the luminal side of the intercellular junction, whereas the interstitial space (i) is devoid of albumin–gold complexes (open star: microvascular lumen; b: subendothelial basement membrane; e and é: adjacent endothelial cells) (× 41,500)

supported by recently published evidence postulating a significant role for plasmalemmal vesicles and even for fenestrations induced by vascular endothelial growth factor [286–288].

Water transport across endothelium of continuous capillaries was classically thought to occur almost completely via the paracellular pathway through intercellular junctions. Transcellular transport was considered to be nil.

However, the relevance of the transcellular pathway also for water has recently been brought to the forefront by the immunohistochemical identification of aquaporin-1 channels in peritoneal microvascular endothelium [289, 290], as well as in rat peritoneal mesothelium [107]. Expression of this transmembrane water channel protein in the endothelial cell surface of continuous capillaries appeared to be basically localized in plasmalemmal vesicles, and its concentration is quantitatively comparable to that seen in erythrocyte plasma membrane [291]. The presence of aquaporin-1 in microvascular endothelium provides a molecular explanation for the water permeability of some capillary beds [292], as well as a low-energy cost pathway [293] for almost 70% of the transmembrane transport of water [289]. Furthermore, this evidence confirms the predicted concept that, also during peritoneal dialysis, not less than 50% of the transperitoneal water flow occurs through postulated ultra-small transcellular pores [97] that appear to be metabolically driven pathways rather than just holes located in the microvascular wall.

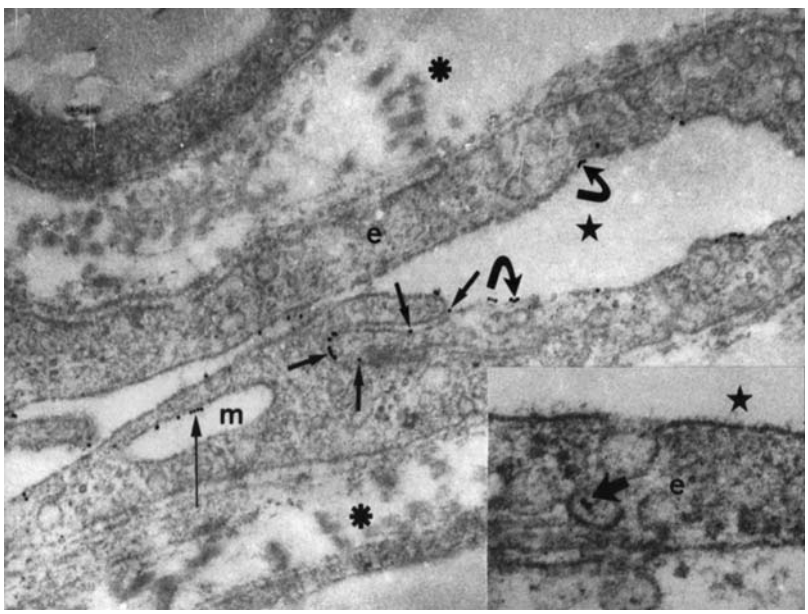

Fig. 5.34 Mesenteric capillary of a rat with experimentally induced *E. coli* peritonitis. Intraarterial perfusion with albumin–gold was performed 24 h after provoking the disease. Particles of the tracer can be seen adsorbed to the luminal aspect of the endothelial cell membrane (curved arrows), as well as within the infundibulum of the interendothelial cell junction (short arrows). Some particles of the tracer (long thin arrow) are also present in a cytoplasmic multivesicular body (m) (*: interstitial space; e: endothelial cell; black star: capillary lumen) (× 41,500).

Inset: Another aspect of the sample taken from the same animal. Albumin–gold complexes are also present in a pinocytotic vesicle (arrow) (star: capillary lumen; e: endothelial cell) (× 84,530)

Summarizing the information obtained from ultrastructural and physiological studies, it can be stated that the microvascular endothelial cell should be considered a highly active structure, serving not only as a permeability barrier and an effective thromboresistant surface, but also as the location of important synthetic and other metabolic activities [182, 209].

Continuous capillaries are more permeable to larger molecules than are fenestrated capillaries [199]. Coated pits and coated vesicles are involved in receptor-mediated endocytosis, whereas the uncharged pinocytotic vesicles and transcellular channels are involved in the transfer of proteins and fluid-phase pinocytosis. The transcellular pathway plays a relevant role in the transmembrane transport of water and macromolecular plasma proteins. Additionally, all the resistances described by Predescu et al. [75] along the pathway leading from the microvascular lumen to the abdominal cavity, are negatively charged [37, 39].

Lymphatics

The lymphatic system serves to drain, from the interstitial compartment, a range of materials such as water, proteins, colloid materials and cells [294], all elements included in the interstitial fluid. Under normal conditions fluid crosses the microvascular endothelial membrane at a rate whose magnitude depends on the Starling forces acting at each aspect of the capillary membrane, as well as on the permeability properties of the endothelial microvascular monolayer. The local autoregulation of interstitial volume is provided by automatic adjustment of the transcapillary Starling forces and lymphatic drainage [161]. Therefore, an alteration in the aforementioned forces results in interstitial accumulation of fluid that will eventually be removed by the lymphatic flow that, in situations of high capillary permeability edema occurring during acute inflammation, can increase by a factor of ten [295]. In the abdominal cavity, lymphatics have a relevant role in the prevention of ascites [296].

Work during the last 20 years has revealed relevant evidence characterizing lymphatic structure and organization. The first stage of lymph collection occurs through a system of interstitial nonendothelial channels, or low-resistance pathways known as pre-initial lymphatics [297, 298], which have been seen in the cat and the rabbit mesentery [299].

This most peripheral part of the lymph vessel system is a completely open net of tissue channels which drain, at least in the cat mesentery, mainly along the paravascular area of the venous microvasculature, into a network of 0.5 mm long, irregularly shaped endothelial tubes, approximately 20–30 μm width [300]. By the time these tubes are completely filled they can reach a maximal diameter of up to 75 μm [301]. A single endothelial layer (Fig. 5.35, inset) forms these endothelial tubes defined as initial lymphatics or lymphatic capillaries [299, 301, 302].

The subendothelial area is most of the time devoid from basement membrane, as well as from a smooth muscle layer present in larger lymphatic collectors [303]. The sporadically observed patches of basement membrane have, as in blood capillaries, anionic fixed charges that can be decorated by cationic tracers [304]. Due to the absence of muscular layer, lymphatic capillaries lack the capability for spontaneous contractility [305]. However, the fact that lymphatic

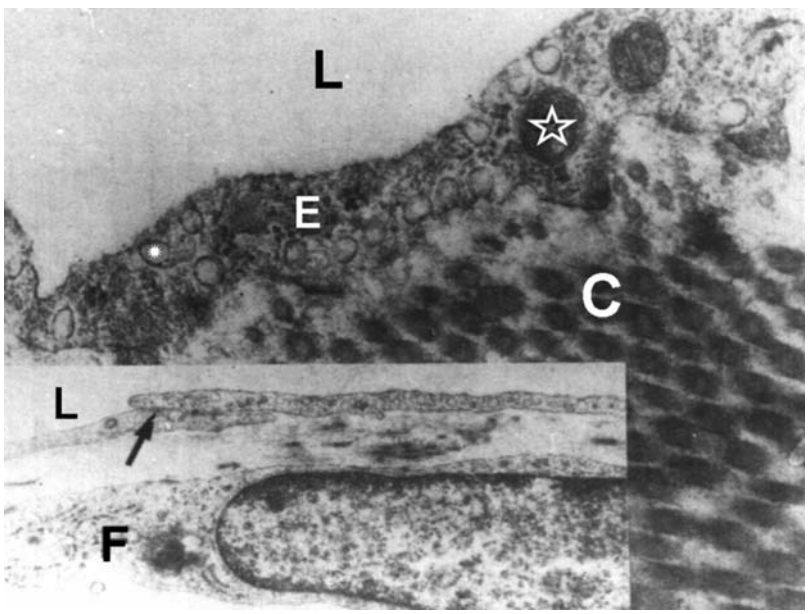

Fig. 5.35 Partial view of a lymphatic lacuna observed in a sample of rabbit diaphragmatic peritoneum. The thin endothelial cell (E) shows numerous pinocytotic vesicles (*) and occasional mitochondria (star). Note the absence of subendothelial basement membrane (L: lacunar lumen; C: collagen fibres) (original magnification × 85,000).

Lower left inset. Lymphatic capillary of rabbit diaphragmatic peritoneum. Two adjoining endothelial cells, forming a tight junction (arrow), appear lying on the interstitial tissue. Basement membrane, as well as anchoring filaments, are not observed (L: capillary lumen; F: fibroblasts) (original magnification × 62,500)

endothelial cells contain an abundant supply of fine actin-like filaments, 40–60 Å in diameter, arranged in bundles parallel to the long axis of the cell, led some investigators to postulate that these filaments could function as a contractile element of the lymphatic capillary wall [306, 307].

Anchoring filaments, having histochemical and ultrastructural characteristics similar to those observed in elastin-associated microfibrils, form a uniform population of fibrous elements, leading to the development of structural and functional continuity between the abluminal aspect of the lymphatic capillary endothelial cell and the elastic network of the adjacent connective tissue [308]. The main role of these anchoring filaments is the prevention of capillary collapse, when the interstitial pressure gains strength as a consequence of expanded fluid content of the interstitial compartment [309]. This simple element enables the lymphatic system to launch a mechanism of fluid drainage that accounts for 25% of the safety factors that can prevent formation of interstitial edema [308]. In this context it has been proposed that initial lymphatics directly sense and regulate the interstitial fluid volume [310].

The total surface area of pre-initial and initial lymphatics seems to be smaller than the total exchange area of blood microvessels [198]. Other studies on cat and rabbit mesentery showed the additional presence of flat, blind saccular structures up to 40 μm wide, with a wall made up of a simple layer of thin endothelial cells, devoid of basement membrane [198, 300].

Lymphatic endothelial cells are flat and elongated, showing an average thickness of 0.3 μm in non-nuclear areas [46, 306]. The luminal aspect of lymphatic endothelium, when exposed to cationic tracers such as cationized ferritin or ruthenium red, shows a high density of anionic fixed charges that, at times, can also be detected labeling the luminal aspect of the intercellular cleft (Fig. 5.36) [307, 44]. These charges prevent the adhesion of electronegatively charged blood cells to the endothelial luminal surface and may play a significant role in the movement of charged solutes from the interstitial compartment to the capillary lumen [44]. Furthermore, the absence of subendothelial and negatively charged basement membrane (Fig. 5.36) points at the asymmetry of the lymphatic capillary wall that is at variance with the electric symmetry characteristic of blood capillaries.

Nuclei of endothelial cells are flattened and, on electron microscopy, appear elongated. Their irregular outline shows a thin peripheral rim of dense chromatin. Plasmalemmal vesicles [46, 311] and transendothelial channels, similar to those described for blood microvessels, are commonly observed [307]. Plasmalemmal vesicles have been shown to participate in the transcellular movement of albumin–gold complexes, from the submesothelial interstitial space to the lumen of capillary lymphatics [79] (Fig. 5.37). Furthermore, the endocytotic pathway has been shown up by the presence of the same tracer into cytoplasmic endosomes (Fig. 5.38).

Several types of interendothelial junctions have been described. Approximately 2% of the whole junctional system consists of open junctions, showing gaps up to 100 nm width, that can, at times, be as wide as 1,000 nm [307, 312]. These openings serve as a way in for macromolecular solutes such as gold-labeled albumin (Fig. 5.38) or cationized ferritin (Fig. 5.39). At times two adjoining endothelial cells overlap each other, forming a kind of valvular junction that can be easily opened by an eventual increase of interstitial pressure (Fig. 5.36, inset). Junctional infundibuli show anionic fixed charges similar to those observed in the luminal endothelial glycocalyx (Fig. 5.36). Around 10% of junctions are

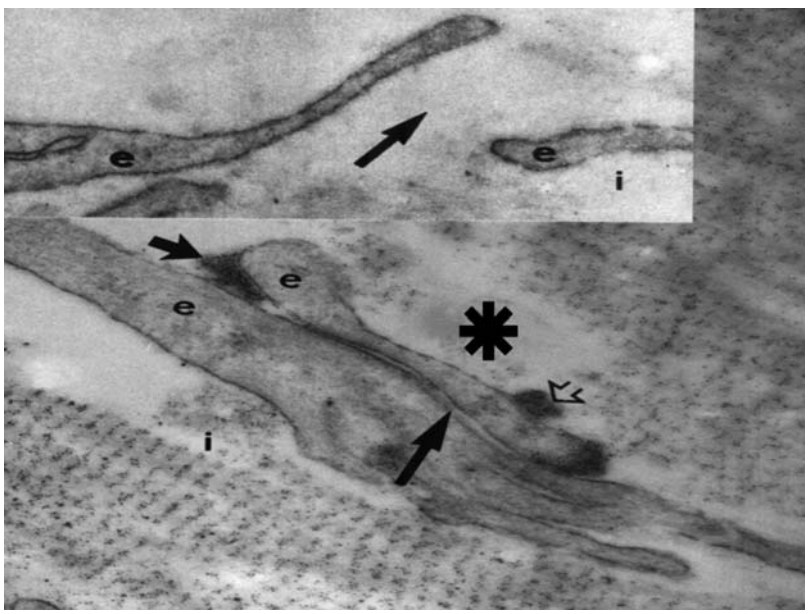

Fig. 5.36 Mesenteric lymphatic capillary of a mouse perfused with cationized ferritin. The long arrow points at the intercellular junction formed by two adjacent endothelial cells (e). The short black arrow indicates the presence of the electropositive tracer on the luminal aspect of the intercellular junction, whereas the open arrow shows particles of ferritin decorating the endothelial luminal plasmalemma. Note the absence of subendothelial basement membrane (*: microvascular lumen. i: subendothelial interstitial space) (× 41,500).

Inset. Mesenteric lymphatic capillary of an intact mouse. The arrow points at an open intercellular cleft formed by two adjacent endothelial cells (e). The junction serves as a valvular structure sensitive to the hydrostatic gradient between the interstitial space (i) and the microvascular lumen (open star) (× 41,500)

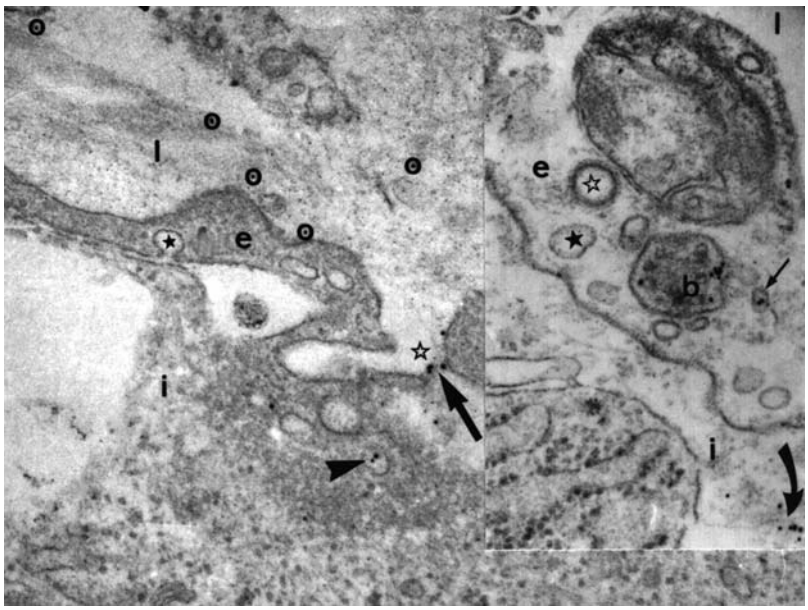

Fig. 5.37 Diaphragmatic submesothelial lymphatic capillary taken from a mouse 10 min after intraperitoneal injection of albumin–gold complexes.

Left inset. Albumin–gold complexes (long arrow) can be observed in their pathway through an open interendothelial cell junction (open star). More particles of the tracer are seen (open circles) within the luminal space (I) of the microvessel. Arrowhead points at albumin–gold included into a pinocytotic vesicle (i: subendothelial interstitial space; black star: plasmalemmal vesicle) (× 41,500).

Right inset. Lymphatic capillary endothelial cell (e). Albumin–gold complexes appear in an endosome (b) as well as in a pinocytotic vesicle (straight arrow). Curved arrow points at albumin–gold complexes present in the interstitium (i). Notice the absence of subendothelial basement membrane (black star: plasmalemmal vesicle; open star: coated vesicle) (× 64,450).

zonula adherens, whereas the rest are tight junctions [301, 313]. It has been proposed that, in addition to the organized prelymphatic system [314], a small percentage of open junctions (1–6%) can account for a substantial proportion of the lymphatic pathway for fluid as well as small and large molecule drainage [301].

The diaphragmatic lymphatic capillary net is organized as a plexus along the submesothelial surface [315], which drains, through an intercommunicating microvascular system, into a plexus on the pleural side of the diaphragm [133]. The distribution of the whole diaphragmatic network is irregular, and varies in different species.

A prominent feature of diaphragmatic lymphatics is the presence of flattened, elongated cisternae or lacunae, approximately 0.3–0.6 cm length, with a long axis that is parallel to the long axis of the muscle fibres [315–317] (Fig. 5.40). The monolayer endothelial lining of the lymphatic lacunae is thin and shows no tight junctions. Adjacent cells usually overlap, forming valve-like processes, leaving an open interface that can be as wide as 12 μm. The cytoplasm of endothelial cells, basement membrane, and anchoring filaments of lymphatic lacunae are similar to those structures described for lymphatic capillaries. While anionic sites have not been observed, the glycocalyx of cisternal endothelium, when exposed to ferritin, is heavily decorated by the cationized tracer, which also appears along the open intercellular clefts [44, 318].

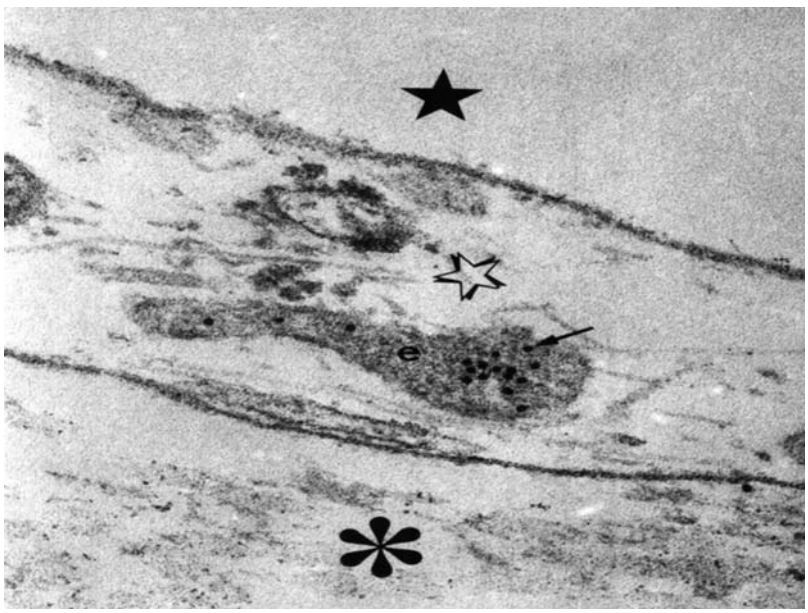

Fig. 5.38 Diaphragmatic lymphatic capillary of a rat. The sample was taken 15 min after starting intraarterial perfusion with albumin–gold complexes. Endosome (e) present in the cytoplasm of the endothelial cell (open star) shows particles of the tracer. This may well represent the endocytotic pathway for degradation of the complex. Note the absence of subendothelial basement membrane (black star: microvascular lumen; *: interstitial tissue) (× 87,000)

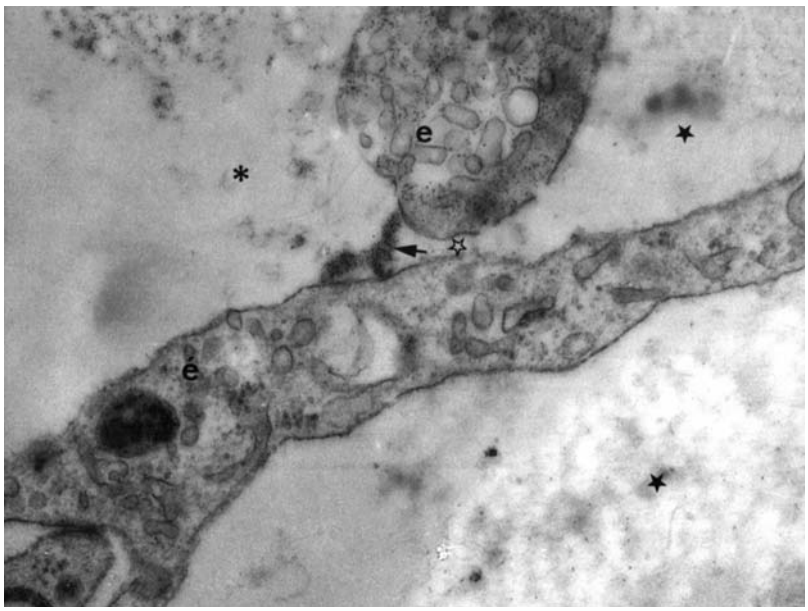

Fig. 5.39 Mesenteric lymphatic capillary obtained from a mouse intraperitoneally injected with cationized ferritin. Particles of the tracer (arrow) can be seen entering the microvascular lumen (*) through the open interendothelial cell junction (open star). Again, note the absence of subendothelial basement membrane and anionic sites (e and é: lymphatic endothelial cells; black stars: interstitial space) (× 41,500)

Diaphragmatic lymphatic lacunae, regularly connected by transverse anastomosis [114], and capillaries from the whole peritoneal lymphatic network, including the rich omental plexus [319], drain into a system of precollector, small-caliber lymph vessels that have a poorly developed smooth muscle layer underlying the endothelium. These vessels, which have semilunar valves [1, 320], drain, in turn, into the larger collecting vessels, whose diameter ranges between 40 and 200 μm [321]. The luminal aspect of the endothelial layer shows a sequence of valvular segments, with a semilunar bicuspidal valve at the distal end of each [133, 321]. The smooth muscle layer underlying the subendothelial basement membrane shows a spiral arrangement around the endothelial tube that becomes more pronounced towards the downstream end of the intervalvular segment [305, 322, 323]. Distances between adjacent valves range between 0.1 and 0.6 mm [323]. Thereby, the anatomical and functional unit (lymphangion) is established, consisting of one valve and the following intervalvular segment, which measures 2–3 mm in length [324]. This collecting segment, limited by two one-way valves and an intrinsic smooth muscle layer, compresses the lymphatic lumen driving the intravascular fluid centrally into the next compartment, making up an escalated system of drainage that has, in the proximal part of each lymphangion, a valve that prevents retrograde flow [305]. The presence of valves also enables this part of the system to reach differential intraluminal pressures around 1–2 cm of water [325].

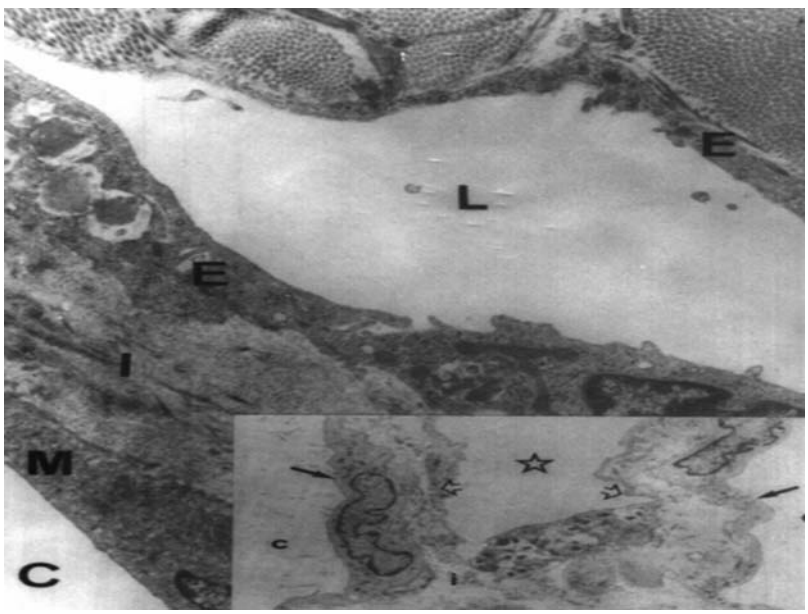

Fig. 5.40 Lymphatic lacuna of rabbit diaphragmatic peritoneum. The wide lacunar lumen (L) is surrounded by the lymphatic endothelium (E). Connective tissue (I) is interposed between the lacuna and the mesothelial cell layer (M) (C: abdominal cavity) (original magnification × 17,750).

Lower right inset. Lymphatic lacuna of rabbit mesentery. The open star shows the lacunar lumen surrounded by a thin endothelial layer (open arrows). Mesothelial cells (black arrows) are covering both aspects of the mesenteric peritoneal surface (i: interstitium. C: abdominal cavity) (original magnification × 4,750)

Capillary lymph that flows from the interstitium slowly moves downstream (average velocity for particles with diameter up to 5 μm = 1 μm/min) [303], drains into large collecting channels (40–200 μm diameter), and proceeds in the direction of the central venous circulation, propelled by peristaltic and rhythmic contractions of consecutive lymphangions [292, 303, 321, 326], with frequencies ranging between 4 and 12 contractions/minute [321, 326]. Within each lymphangion, hydrostatic pressure increases to a threshold of approximately 12 cm of water, after which the proximal valve is closed, and the downstream valve is opened. The cycle is repeated in the following segment. Contractility of lymphangions is modulated by a pacemaker site of spontaneous activity, apparently located, at least in bovine mesenteric lymphatics, in the vessel wall near the inlet valve of the unit. Activity propagates at a speed of 4 mm/s, and the ejection fraction was evaluated at 45–65% [327].

Contractions are generated by myogenic stimuli (hydrostatic pressure of 5–7 cm water) [327], and influenced by activation of α- and β-adrenoreceptors [328–330], histamine, leukotriene C4 and D4, platelet-activating factor [331, 332], PGF2 alpha, PGA2, PGB2 [333], bradykinin [334], and vasoactive intestinal peptide [335]. It should be noted that all the aforementioned vasoactive substances are mediators of inflammation present in high concentrations in blood and tissues during the localized or the generalized acute defense reaction [276].

Lymph flows from collectors to the thoracic duct and the right lymph duct, and finally drains into the subclavian veins. Lymphangions join larger collecting lymphatic vessels, forming a dichotomous tree that drains entire tissue regions. This arrangement has been described in the diaphragm as well as in mesentery [305, 325, 336].

Innervation of lymph vessels has been studied in the dog and cat mesentery, by means of silver stains [320]. It was shown that large lymphatic collectors have myelinated nerves that remain on the adventitial area, and nonmyelinated nerve fibers that penetrate into the region of valve attachment and are considered to be the motor supply to the smooth muscle. Bovine mesenteric lymphatics show adrenergic nerve fibers in the media, as well as in the adventitia. Human mesenteric lymph collector neurotransmitters are both adrenergic and cholinergic, the former being prevalent. Lymphatic capillaries are devoid of innervation [337].

Since Starling [338, 339], it has been accepted that, besides the removal of excess interstitial tissue, the lymphatic system has the special function of absorbing protein. Normally, blood capillaries leak protein, which will not re-enter the blood vessels unless delivered by the lymphatic system [340]. It is generally accepted that the rate of lymph formation is equal to the net capillary efflux under normal physiological conditions, in order for the interstitial fluid volume to remain constant [310]. However, the mechanisms involved in the formation of lymph, at the level of the most peripheral part of the lymphatic system, are still controversial. According to Allen and Vogt [341], who formulated the hydraulic theory, lymph formation is the end-result of hydraulic forces acting across initial lymphatics. Assuming that the interstitial hydrostatic pressure is zero, or even negative [159, 342], any rise will also increase the initial lymphatic flow, and edema will eventually develop if and when the lymphatic drainage capabilities are exceeded [343–345]. This concept of increased hydrostatic pressure as the main factor in the process of lymph formation was extrapolated to the lymphatic absorption from the peritoneal cavity [346, 347]. In this context it was postulated that, during peritoneal dialysis, the intra-abdominal pressures [348, 349] modulated lymphatic drainage from the abdominal cavity well within the range of values observed in dialyzed patients [166, 350]. This concept has been substantially challenged by a series of elegant studies performed by Flessner et al. [166, 351], who showed that a significant proportion of the intra-abdominal fluid is lost to the abdominal wall, the rate of which is also dependent on the intra-abdominal pressure. This fluid, after being incorporated to the tissues surrounding the abdominal cavity, will be drained through the lymphatic circulation [352]. The eventual influence of the intrathoracic negative pressure upon the lymphatic downstream circulation [353] may well be an additional component of the hydrostatic forces involved in lymph progression to the venous-blood compartment.

The osmotic theory of lymph formation [354] postulates the existence of a protein-concentrating mechanism at the level of the initial lymphatics, the main result of which would be that only 10–40% of the fluid initially entering within the lymphatic network would flow downstream, back to the blood compartment, and the remaining fluid would be filtered out from the lymphatics as a protein-free solution. This process would eventually cause a high protein concentration, and an oncotic gradient between the contents of the initial lymphatics and the surrounding interstitial fluid. Other investigators have proposed a vesicular theory of lymph formation, which holds that plasmalemmal vesicles provide the major route for transendothelial transport of protein, thereby creating the oncotic gradient needed for further fluid flow between adjacent cells or through transendothelial channels [355, 356]. This hypothesis is supported by recent studies that have shown active transendothelial transport of albumin in plasmalemmal vesicles [60, 357]. Figure 5.37 shows gold-labeled albumin transported by plasmalemmal vesicles of a mouse diaphragmatic lymphatic capillary.

On the other hand, it has been suggested that the postulated mechanisms may not necessarily be exclusive in the sense that some or all could function simultaneously. However, the relative influence of each one could vary in different areas of the initial lymphatic network [358].

The relevance of peritoneal lymphatics, as well as their impact upon ultrafiltration during peritoneal dialysis, is addressed in Chapter 6. Omental milky spots have, relatively recently, attracted the attention of investigators working in

the field of peritoneal dialysis. First described by Von Recklinghausen in pleura of rabbits [359], and later on in humans [360], these structures are part of the peritoneal lymphatic system [361]. Been described as submesothelial lymphoid structures essential for the maturation of resident peritoneal macrophages, they are actively involved in peritoneal defense reactions under a diversity of inflammatory conditions [362]. Macroscopically, milky spots appear as small (up to 1 mm diameter), white bodies, most commonly detected in perivascular areas of the greater omentum. Their structure, as seen under light microscopy, has been thoroughly reviewed by Di Paolo et al. [362, 363] in rats, rabbits as well as in patients on long-term peritoneal dialysis. In all the abovementioned species, they are located in the submesothelial tissue, showing blood capillaries surrounded by lymphocytes and macrophages and, at times, even lymphatic microvessels that can be identified within the frame of the same structure. The cell population of milky spots is made up by 400–600 cells, including macrophages (45–70%), lymphocytes (14–29%), and a low number of plasma cells (around 6%). Occasionally, megakariocytes and adipocytes can also be detected. Work done in experimental animals showed that number and size of milky spots, as well as their cell population, substantially increase after introduction of a peritoneal catheter, at the time of infection and inflammation, or after repeated exposure of the peritoneum to dialysis solutions containing 1.5 or 4.25% glucose [363]. Observations made in patients depicted changes not far from those seen in experimental animals, since both, size and cellularity of milky spots increased with the time-span of maintenance term peritoneal dialysis [363].

Peritoneal Innervation

The first report announcing the presence of nerves in the peritoneal interstitium was made by Haller in 1751 [364] and confirmed during the 19th century by Ranvier and Robin who, using osmic acid and silver nitrate, described nerve trunks, branches, and nerve endings accompanying arteries and veins. Robinson [1] described the peritoneum as being richly supplied with myelinated and nonmyelinated nerves (Fig. 5.41).

In rat mesentery, networks of adrenergic axons innervate the principal and small arteries and arterioles. Precapillary arterioles, collecting venules and small veins are not innervated, and are most likely under the influence of humoral vasoactive substances [365]. Lymphatic innervation was described in the previous section.

In 1741, Vater observed that the submesothelial connective tissue of cat mesentery contained oval corpuscles with a diameter of approximately 1–2 mm. In 1830, Paccini rediscovered and gave a systemic description of this corpuscle, known as the Vater–Paccini corpuscle [1]; it takes the form of a nonmyelinated nerve ending, which, in transverse section, appears as a sliced onion. In humans it has been observed in the peritoneum of mesentery and visceral ligaments, functioning as the main receptor for perception of pressure.

Fig. 5.41 Parietal peritoneum taken from a 67-year-old chronic uraemic patient on IPD, showing a transversal section of an unmyelinated nerve (star) (× 12,600).

Cytology of the Peritoneal Fluid

The peritoneal fluid of laboratory animals has classically been a favored site for experiments dealing with the inflammatory response [366], as well as for those designed to analyse the biological reaction to infection [367].

More than 50 years ago, Josey and Webb realized that fluid shifts into and out of the peritoneal cavity could change the concentration of cells without affecting their absolute number [368–371]. The methodological answer to this question was given by Seeley and colleagues, who weighed peritoneal fluid and measured the cellular concentrations, and so were able to estimate the absolute number of cells [372]. Padawer and Gordon [370], after analyzing the cellular elements present in peritoneal fluid of eight different normal mammals, concluded that the most frequently observed cells were eosinophils, mast cells and mononuclears (including lymphocytic and macrophagic elements). Total cell numbers, as well as percentages of the different cells, varied greatly among the species examined. Neutrophils were never observed in normal animals. Total absolute counts were higher for females than for males, as well as for older animals compared with younger ones. In the individual animal, under normal conditions, the number of cells present within the abdominal cavity was constant [370].

Observation of peritoneal fluid obtained from healthy women showed that macrophages and mesothelial cells contributed more than 70% of the whole cell population, whereas lymphocytes and polymorphonuclears contributed to a lesser extent (18 and 7%, respectively) [373]. Other investigators observed that at the midphase of the menstrual cycle, macrophages, which comprised 82–98% of the peritoneal cells, showed morphological as well as biochemical heterogeneity and were seen to be involved in phagocytosis of erythrocytes [374] (Fig. 5.42). However, other studies showed up to four different types of cytological patterns in peritoneal fluid of women during the course of the menstrual cycle, in all of which mesothelial cells contributed substantially to the total cell counts. The paramenstrual type was in most cases hemorrhagic and highly cellular [375]. Ciliocytophtoria, anucleated remnants of ciliated mesothelial cells, can be occasionally observed in effluent dialysate, basically in young women. Inability to identify

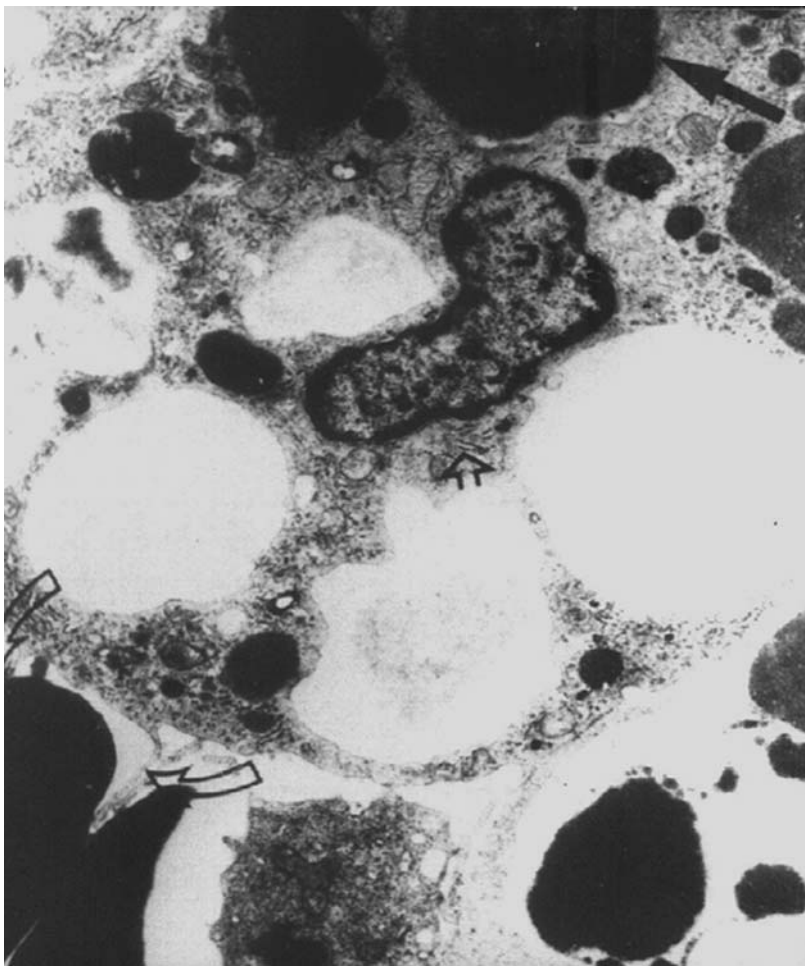

Fig. 5.42 Peritoneal effluent obtained from a chronic uraemic patient on peritoneal dialysis. The macrophages depicted in the figure show phagolysosomes digesting erythrocytes (black arrow). Note the presence of rough endoplasmic reticulum (short open arrow) near the nucleus (n). The former normally appears in macrophages when the cells are involved in phagocytic activity. The curved open arrows are pointing to cell processes engulfing red blood cells (× 8,600)

these structures can mislead the laboratory team as well as the physician to search for parasitic or fungal contamination [376].

The apparently puzzling effect of intraperitoneal saline inducing substantial influx of neutrophils into the abdominal cavity, which was observed long ago [367], was not confirmed when the experiments were carried out using sterile techniques. Bacterial lipopolysaccharides proved to be very effective in producing intraperitoneal exudate rich in cells [371]. This phenomenon was inhibited by prior intraperitoneal injection of cortisone [377].

In humans, sterile inflammatory effusions are characterized by a rich cellular content including neutrophils, lymphocytes, macrophages, mesothelial cells, eosinophils, and basophils, usually in that order of frequency [378]. The presence of macrophages, mesothelial cells, lymphocytes, eosinophils, and even plasma cells has been confirmed by electron microscope studies [379–381].

Peritoneal eosinophilia (eosinophils >10–50%) has been experimentally induced by intraperitoneal injection of iodine, chalk, nucleic acids, pilocarpine, hemoglobin or red blood cells, egg albumin, gold salts, mineral and vegetable oils, hydatidic fluid, and saline [378, 382]. On the other hand, intraperitoneal injection of bacteria and/or bacterial endotoxins induces a massive migration of neutrophils and monocytes into the peritoneal cavity [370, 383, 384].

The information presented above suggests that the cell content of effluent peritoneal dialysate is likely to be modified by so many factors that a concise description of a standardized cytological pattern becomes extremely difficult. There are, however, a few aspects of peritoneal effluent dialysate that have been defined: a) Patients on CAPD have total cell counts up to 50 cells/mL [383]. (b) The population of resident peritoneal cells observed in patients on long-term peritoneal dialysis is basically made up by macrophages (around 50% of the population), and lower

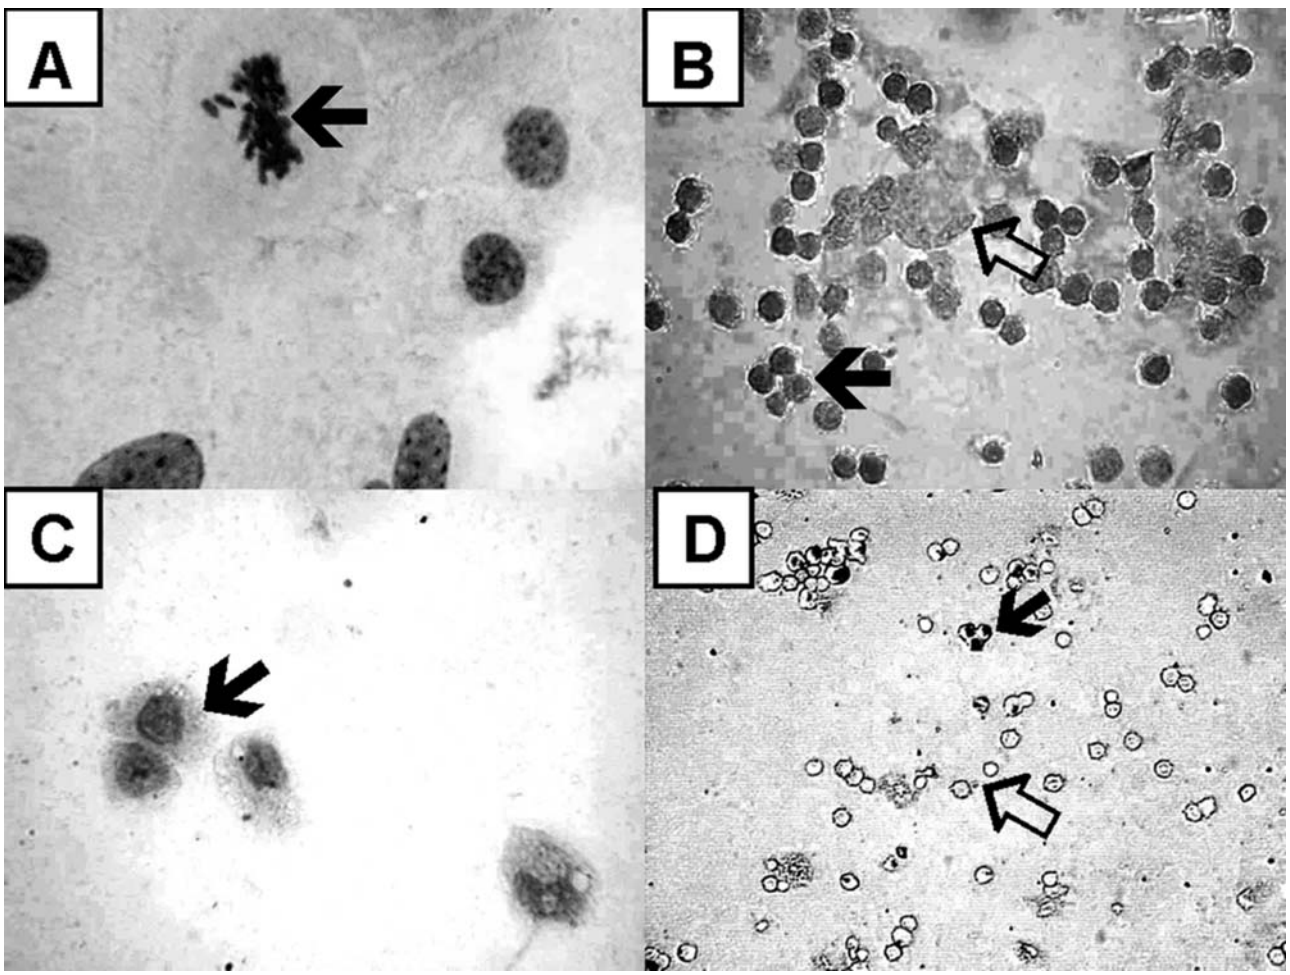

Fig. 5.43 Samples of the first dialysate effluent recovered from a new chronic uremic patient starting renal replacement therapy by means of PD. **(A)** Wandering mesothelial cell undergoing mitosis. prevalence of lymphocytes, mast cells, and mesothelial cells [385–388]. (c) During infection there is a substantial increase in total cell number [389], as well as in the proportion of neutrophils [385–388]. (d) Fluid eosinophilia is a basic component of the still ill-defined eosinophilic peritonitis [390–392].

Besides, the unphysiological situation of PD derives in substantial micro environmental changes that significantly affect the life cycle of the exposed and still attached monolayer. As a result, the population of cells recovered from dialysate effluent from a new patient is considerably different from that of patients on long-term PD. As shown in Fig. 5.43, cells detected in the first effluent of a new patient show remarkable mitotic activity (Figs 5.43a and 5.43b), a quite modest proportion of non viable cells (Fig. 5.43c) as well as a low prevalence of cells demonstrating positive expression to beta galactosidase, denoting the low prevalence of cells undergoing terminal replicative senescence (Fig. 5.43d). On the other hand, mesothelial cells isolated from effluent of patients on long-term PD (Fig. 5.44) show a quite different phenotype: they appear mostly as nonviable (Fig. 5.44a), the mitotic activity is nil (Fig. 5.44b), the vast majority are positively stained by beta galactosidase (Figs 5.44c and 5.45d), whereas a high proportion are undergoing apoptosis (Fig. 5.46). As it will be discussed later, this senescent phenotype of mesothelium was also detected in the monolayer of experimental animals exposed to high glucose concentration dialysis fluids. So, it may be hypothesized that careful and sequential observation of mesothelial cells recovered from patients' effluent, using the aforementioned staining technique, may well give quite representative information regarding the regenerative capabilities of the mesothelial monolayer still dressing the cavitary aspect of the peritoneal membrane of patients undergoing long-term PD.

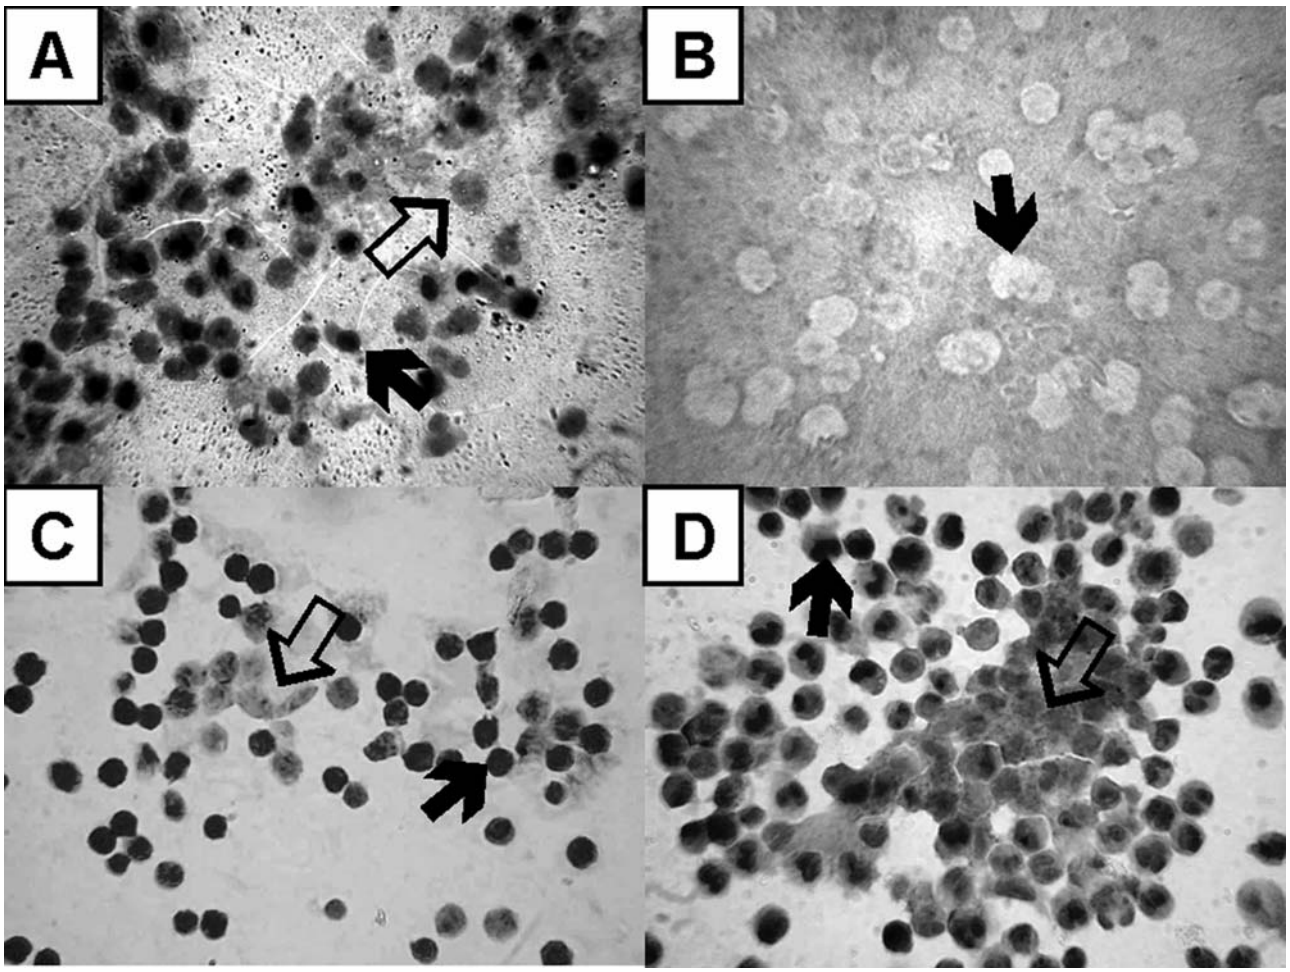

Fig. 5.44 Samples of fluid taken from effluent of a patient treated by means of CAPD for a period of seven months. **(A)** Most cells appear as nonviable, as indicated by positive staining with Trypan Blue (black arrow). (Open arrow: nonstained viable cells). (Trypan Blue; × 400). **(B)** There are no cells expressing PCNA positive immunostaining (black arrow), indicating that the mitotic activity is nil. (PCNA immunostaining; × 1,000). **(C)** Most cells show β-galactosidase expression (black arrow), pointing at the fact that they have reached a situation of terminal replicative senescence. (Open arrow: unstained cells). (β-Galactosidase expression at pH 6; × 400). **(D)** A substantial proportion of cells show P53 activity (black arrow), indicating that they are undergoing apoptosis. (Open arrow: unstained cells). (P53 immunostaining; × 400)

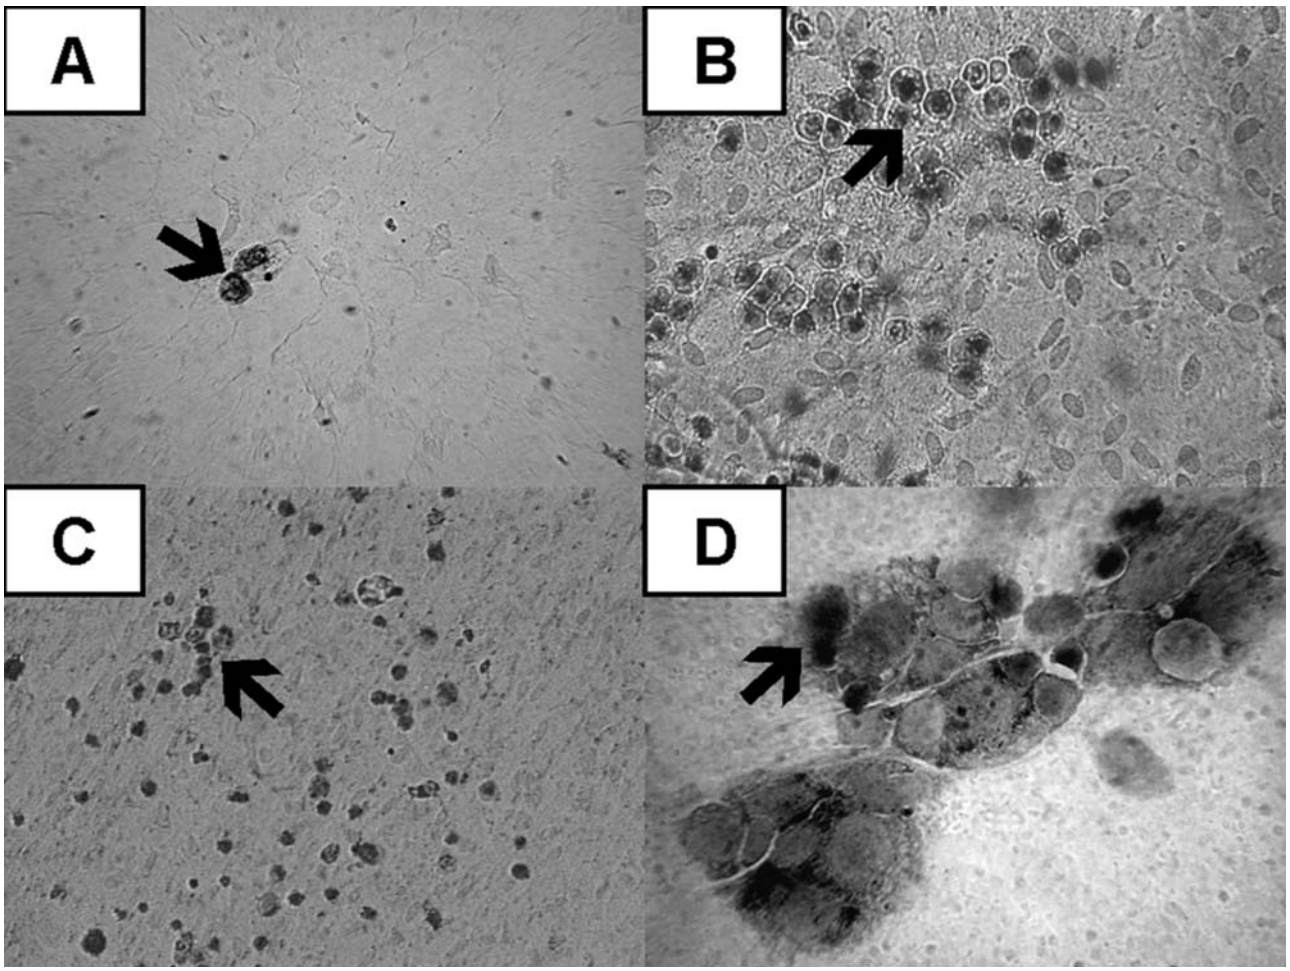

Fig. 5.45 (A) Sample of intact, unexposed mice mesothelium. Notice the low proportion of cells expressing β-galactosidase (arrow). (β-Galactosidase staining at pH 6; × 400). **(B)** Imprint recovered from a mouse after 30 days exposure to one daily intraperitoneal injection of 4.25% glucose, lactated dialysis solution. Arrow calls attention to the high prevalence of senescent cells, as indicated by positive staining to β-galactosidase. (β-Galactosidase staining at pH 6; × 400). **(C)** This imprint was recovered from a rat treated during 30 days with one daily intraperitoneal injection of 7.5% icodextrin. The prevalence of senescent cells is substantially higher than that detected in intact, unexposed animals. (β-Galactosidase staining at pH 6; × 160). **(D)** Mesothelial cells recovered from dialysate effluent of a patient on long term (7 months) peritoneal dialysis. Most cells express β-galactosidase activity. (β-Galactosidase staining at pH 6; × 1,000)

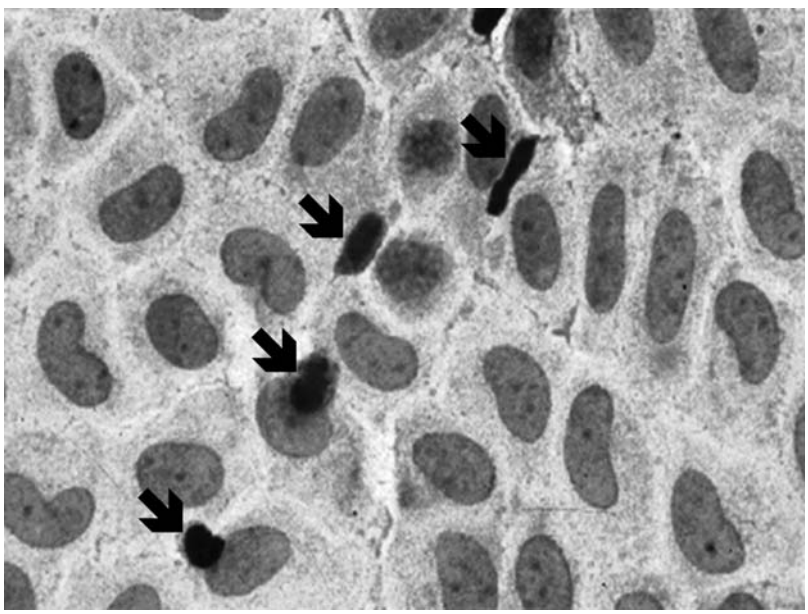

Fig. 5.46 Sample of a mesothelial imprint exfoliated from a rat after a 30 days exposure (one daily intraperitoneal injection) of 7.5% icodextrin dialysis solution. Notice the increased prevalenve of cells undergoing apoptosis (black arrow). (Hematoxylin-eosin; × 1,000)

Ultrastructure of Peritoneal Fluid Cells

Free-floating mesothelial cells are round or oval in shape and show a central, round nucleus (Fig. 5.47). Occasionally, binucleated mesothelial cells can be observed (Fig. 5.48). Nuclear chromatin is quite evenly distributed (Fig. 5.49, inset) and a small nucleolus may be observed. Numerous slender and sometimes branching microvilli emerge from the cytoplasmic membrane [379, 381, 393–395]. Branching microvilli, similar to those observed in human embryos [14], can be quite crowded in some cells, whereas in others they are scarce [381] (Fig. 5.49, inset). The glycocalyx covering the luminal aspect of the plasmalemma is endowed with electronegative fixed charges as shown in preparations exposed to the cationic tracer ruthenium red. Mitochondria, numerous cisternae of rough endoplasmic reticulum, and free ribosomes are mainly located in the outer part of the cytoplasm, and so are pinocytotic vesicles [379, 395]. The presence of intermediate-size filaments, perinuclear or irregularly scattered along the cytoplasm, has been documented in young free-floating mesothelial cells

Fig. 5.47 Effluent dialysate obtained from a non-infected uraemic patient, showing a floating mesothelial cell (star), as well as one macrophage. (*) (× 6,900)

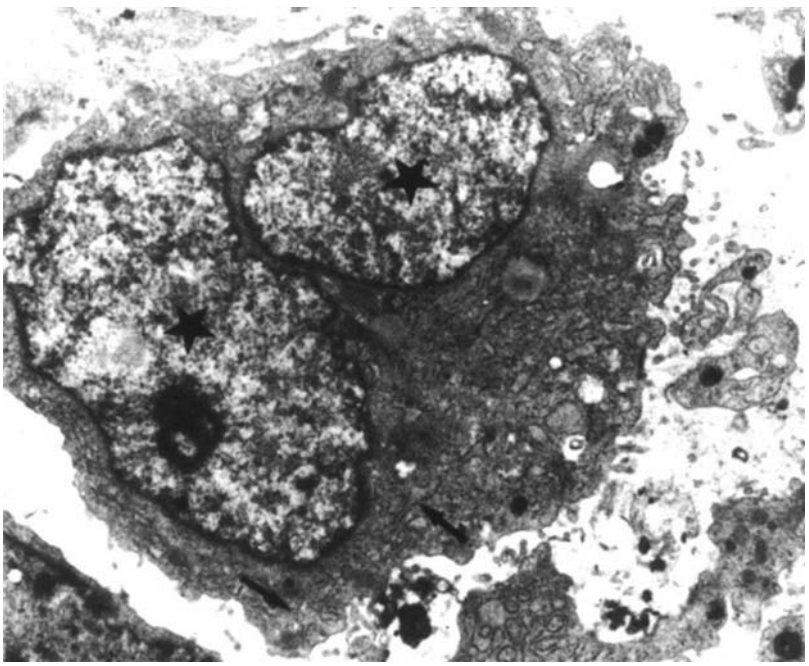

Fig. 5.48 Binucleated mesothelial cell observed in effluent fluid from a patient on CAPD. Note the abundance of rough endoplasmic reticulum (arrows) (stars: nuclei of mesothelial cell) (× 8,600)

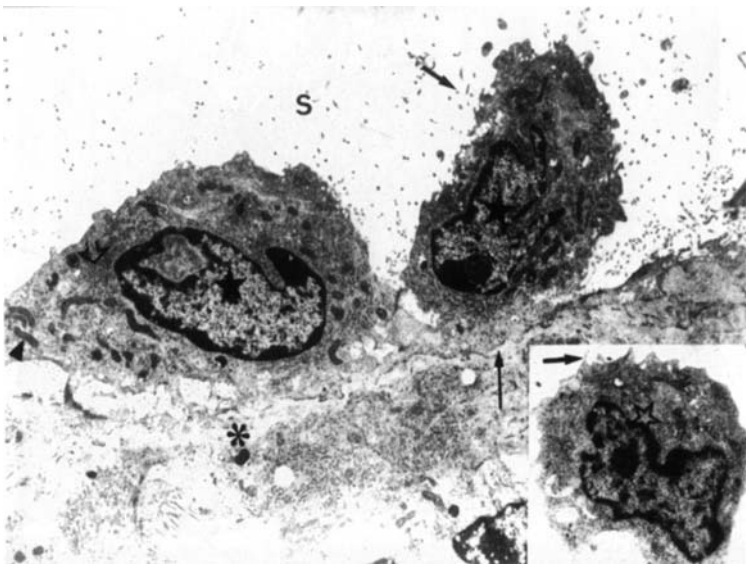

Fig. 5.49 Sample taken from the parietal peritoneum of a patient on CAPD. Two recently implanted young and active mesothelial cells (black stars), showing numerous mitochondria (arrowhead), rough endoplasmic reticulum (open arrow) and microvilli (short arrow). The cell on the right is forming its own basement membrane (long arrow) (*: submesothelial connective tissue; S: peritoneal space) (× 6,900).

Inset. Free-floating mesothelial cell (open star), seen in effluent dialysate of a CAPD patient (arrow: microvilli) (× 5,600)

[378, 380], as well as in those recently implanted on the peritoneal surface. These free-floating mesothelial cells should be distinguished from desquamated, degenerating mesothelial cells wandering in the peritoneal fluid (Fig. 5.48) [396].

Macrophages, which can be observed in large numbers, usually show an irregular and, at times, kidney-shaped nucleus with distorted masses of chromatin concentrated along the nuclear membrane (Figs. 5.42 and 5.47). The cytoplasmic outline of macrophages is irregular, with thin processes of variable length which, at times, engulf degenerated cells (Fig. 5.42) or take the form of signet-ring macrophages (Fig. 5.5, inset). Mitochondria, a small Golgi complex and phagolysosomes are more evident when the cell is involved in phagocytic activity (Fig. 5.42).

The ultrastructural aspect of inflammatory cells that eventually appear in the peritoneal fluid is similar to that classically described for other tissues.

The Origin of the New Mesothelial Cells

It has been experimentally shown that small and large mesothelial wounds heal at the same rate within 7–10 days after injury [397]. The basal, normally observed mitotic rate of mesothelial cells, as measured in the rat by ^{3}H-thymidine incorporation, ranges between 1 and 2% day (Fig. 5.50). This concept is supported by the fact that the steady state of the cell population is clearly defined by the following parameters: the proportion of cells passing through the G1 checkpoint, indicated by PCNA expression (proliferative cell nuclear antigen) that is also around 1–2%, as well as prevalence of non viable (Trypan Blue stained) senescent (positively stained with beta galactosidase at pH 6) (Fig. 5.45) and apoptotic mesothelial cells (Figs 5.46 and 5.51) that are within the same range [398, 399]. This rate of renewal is significantly increased during peritonitis, reaching maximal values of up to 19% between 1 and 3 days after injury, and returning to the basal activity on the 4th or 5th day [400]. It should be noted, however, that proliferations of fibroblasts, as well as mesothelial cell regeneration, are substantially inhibited in experimental uremic animals [400–402].

The origin of the new mesothelial cells repopulating denuded areas of injury is still controversial. Four different hypotheses have been proposed:

1. The repopulating cells originate from the bone marrow [102]. Other experimental studies showed, however, that whole-body irradiation sufficient to depress peripheral white blood cell count as well as cell replacement by the bone marrow did not prevent mesothelial healing [403]. Therefore, the existence of a circulating mesothelial precursor originating from the bone marrow seems unlikely.
2. Free-floating cells of the serosal cavity settle on the injured areas and gradually differentiate into new mesothelial cells [283, 404–406], (Fig. 5.49). Research done in order to settle this proposal, exposed evidence indicating that, after injury, free floating mesothelial cells, exfoliated from noninjured areas or from omental milky spots (12), settle on the injured areas, being instrumental to the healing of the monolayer [399, 407, 408]. Even though some investigators have not accepted this hypothesis [401, 406, 409], this approach finds support in other studies demonstrating the feasibility of mesothelial cells transplantation in humans, rabbits and rats as reported by several investigators [410, 411], as well as by our group (Fig. 5.52a).

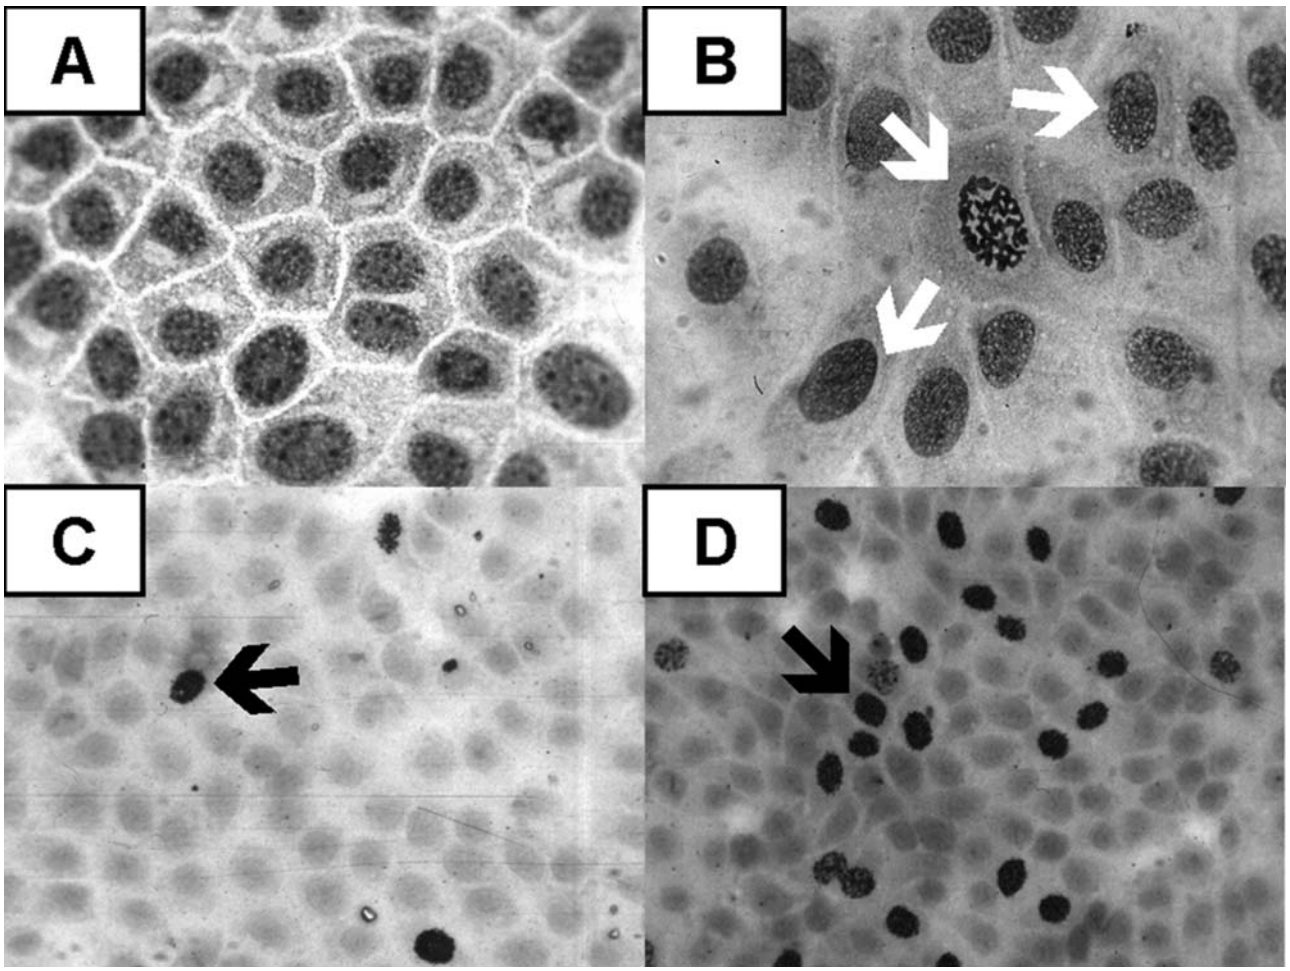

Fig. 5.50 **(A)** Intact unexposed mesothelium. Notice the normal density distribution of the cell population. (Hematoxylin-eosin; × 1,000). **(B)** Sample of the monolayer recovered from a mouse after a 2 h exposure to a 4.25% glucose, lactated dialysis solution. Notice the increased prevalence of cells undergoing mitosis (white arrows). Compare with precedent microphotograph. (Hematoxylin-eosin. × 1,000). **(C)** Again, intact unexposed mesothelium showing a few cells in S phase, incorporating tritriated thymidin (black arrows). (Autoradiography with tritriated thymidin and hematoxylin-eosin; × 400). **(D)** Imprint taken from a mouse after a 2 h exposure to the same high glucose concentration dialysis solution used in Inset B. Many cells are incorporating thymidin (black arrows), testifying for a remarkable acceleration of the cell cycle. In addition, this micro photograph, indicates that counts of cells in mitosis underestimate the mitotic activity, if compared with the information obtained by evaluation of cells incorporating thymidin. (Autoradiography with tritriated thymidin and hematoxylin-eosin; × 400)

3. Other studies [393, 401, 412] suggested the sequence of a two-stage process; during the first 24 h, macrophages forming the first line of defense [413] and coming from the peritoneal fluid, repopulate the wound surface (Fig. 5.5, inset). Later, during the second stage, new mesothelial cells, arising from metaplasia of mesenchymal precursors located in the interstitial tissue well below the site of injury, migrate to the surface and differentiate into mature mesothelial cells (Fig. 5.53). This hypothesis has not been universally accepted [25, 283, 399, 404, 414]. It has also been suggested that the early implanted macrophages are gradually transformed into mesothelial cells [414]. However, Raftery [415], after labeling peritoneal macrophages with polystyrene spheres, presented strong evidence against the hypothesis that peritoneal macrophages could be transformed into mesothelial cells.

   On the other hand, elongated, fish-like mesothelial cell precursors coming up from the submesothelial connective tissue were also observed under the damaged areas. The nuclear and cytoplasmic aspects of these cells were identical to that shown by new mesothelial cells already implanted on the peritoneal surface (Fig. 5.52b).
4. Mature mesothelial cells from adjacent areas migrate and proliferate to repopulate a depopulated area [407, 416]. This approach is supported by in vitro studies [417, 418] showing early migration and increased bromodeoxyuridine (BrdU) incorporation 24 h after injury, the latter showing values ranging between 20 and 26% of the observed cells. It should be noticed that these figures, representing the proportion of cells in S phase, imply an underestimation

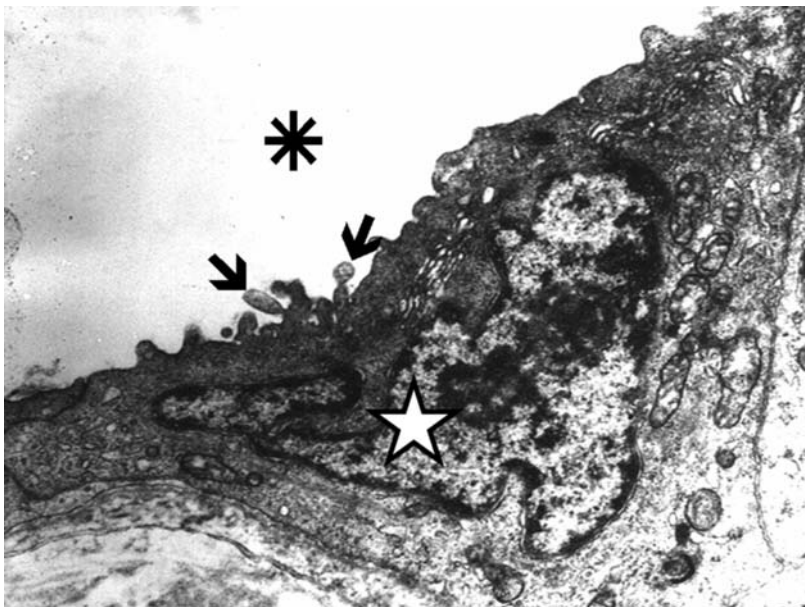

Fig. 5.51 Sample of parietal peritoneum taken from a patient undergoing peritoneal dialysis during a period of 16 months. Arrows point at areas of blebbing in the plasma membrane. Notice the absence of microvilli. Both elements define the situation of a cell at a relatively early stage of apoptosis. (Asterisk: peritoneal space; white arrow: nucleous of mesothelial cell; × 41,500).

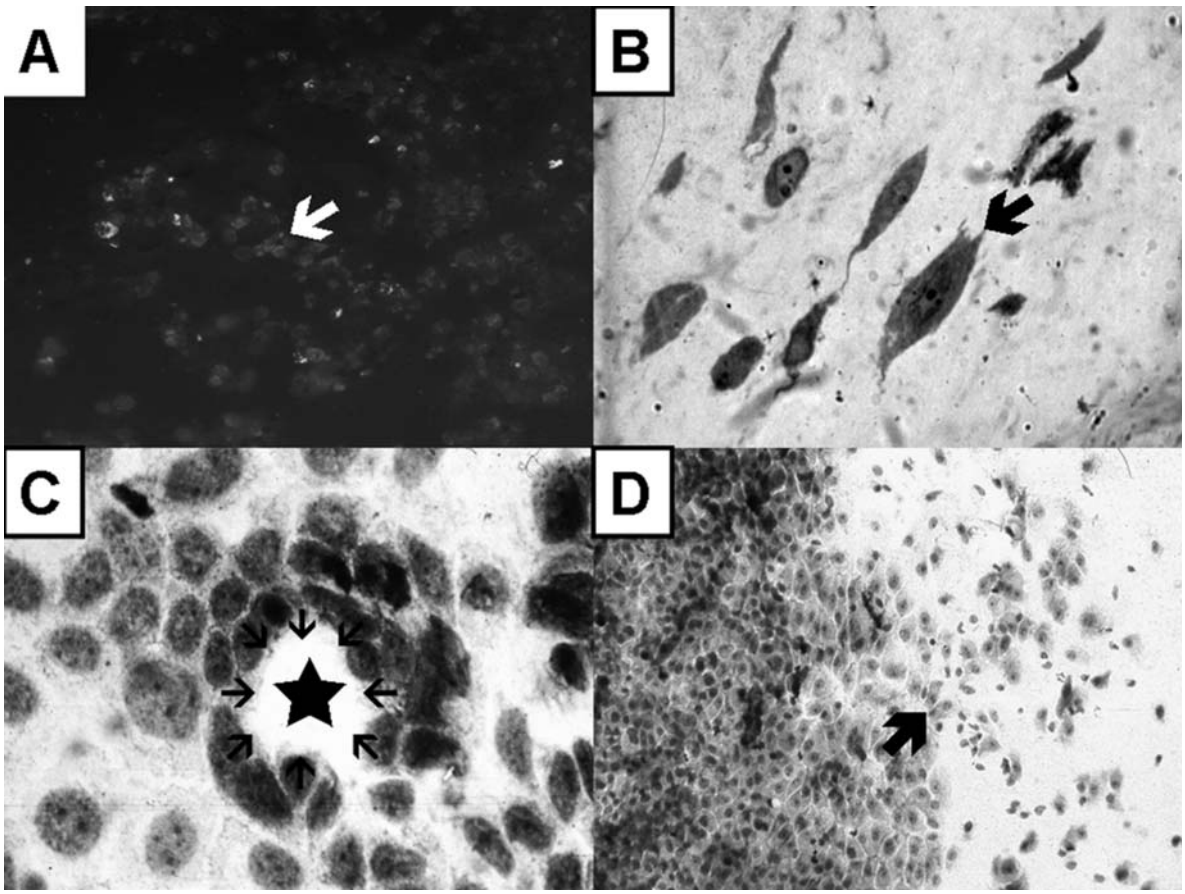

Fig. 5.52 (a) Imprint taken from a rat 24 h after autologous transplantation of mesothelial cells. White arrow points at cells already engrafted on the peritoneal surface. (PKH 26; × 400). **(b)** Peritoneal biopsy taken from a patient on peritoneal dialysis. Microphotograph shows elongated, fish like mesothelial cells migrating towards the cavitary aspect of the peritoneal membrane (arrow). (Toluidine blue; × 1,000). **(c)** Sample of the monolayer recovered 5 days after experimental, localized exfoliation of the mesothelial dressing. Young mesothelial cells that circumscribe an area of depopulated mesothelium (star), appear as moving centripetally in order to fill the gap in the monolayer. (Hematoxylin-eosin; × 1,000). **(d)** This imprint was taken from a rat 5 days after the experimental exfoliation. New mesothelial (arrow) redress the denude area through replication and centripetal migration. (Hematoxylin-eosin; × 160)

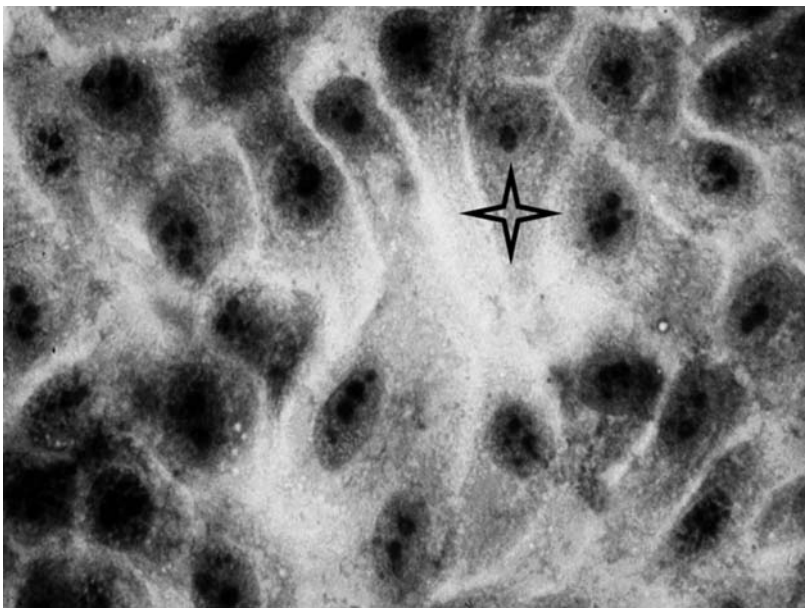

Fig. 5.53 Sample of mesothelium taken from a control animal, 10 days after the experimental exfoliation. Most of the peritoneal cavitary surface area has been repopulated. Yet, some elongated, fish like cells (four pointed star) are present, indicating that the regenerative process is still going on. (Hematoxylin-eosin. × 1,000)

of the actual number of cells undergoing mitosis. Indeed, the proportion of cells that passed the G1 checkpoint and supposed to reach S phase after some 10 h may well be similar, or even higher, than that observed during incorporation of BrdU. In addition, in vivo studies have been performed evaluating sequentially the dynamics of mesothelial repopulation, after a local mechanical exfoliation creating a doughnut-like area of undressed peritoneal surface [419]. This study demonstrated that repopulation also takes place by replication and centripetal migration of mature mesothelial cells located in in the monolayer bordering the injured area. (Figs 5.52c and 5.52d, Figs 5.53 and 5.54). Here again, the prevalence of cells undergoing mitosis is several times higher than that observed in intact, unexposed mesothelium.

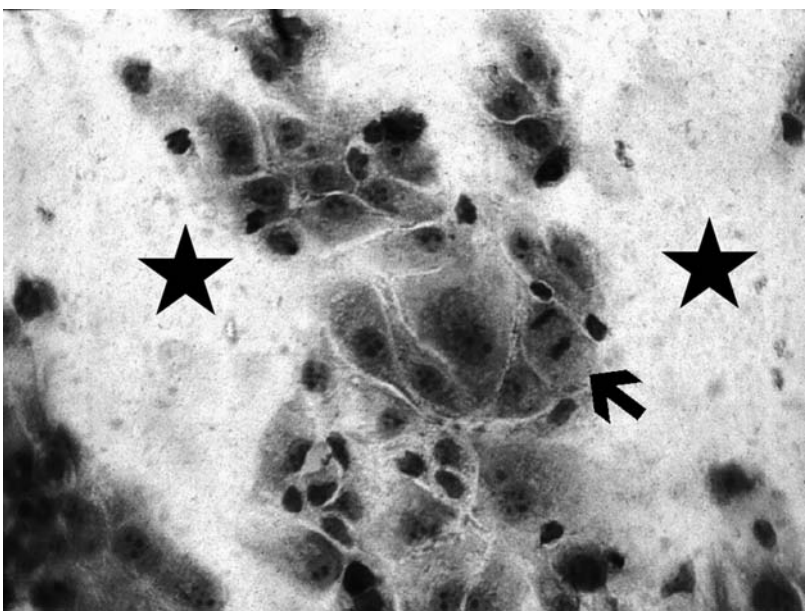

Fig. 5.54 Specimen obtained from a rat 2 days after experimental, localized, exfoliation of the monolayer. Mesothelial cells appear migrating, building up a bridge in order to repopulate undressed domains of the peritoneal cavitary surface of the liver (stars). Some cells are undergoing mitosis (arrow). (Hematoxylin-eosin; × 400)

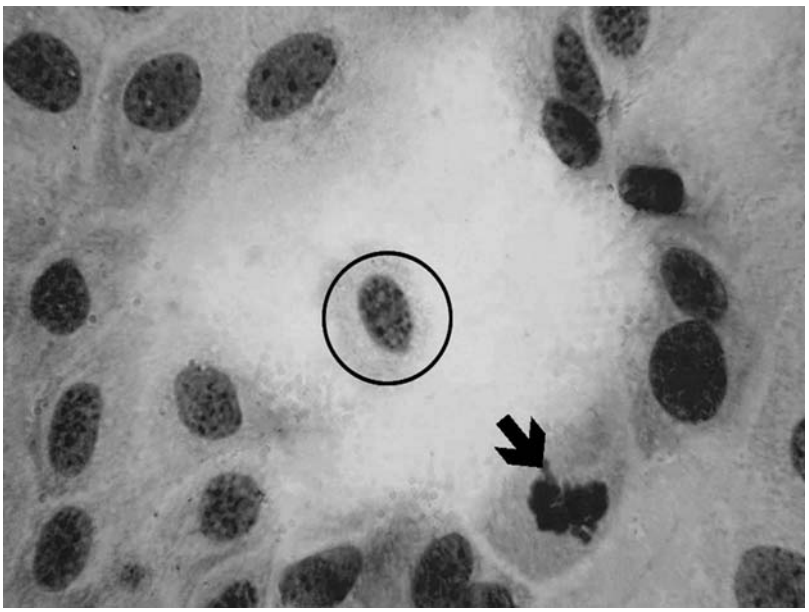

Fig. 5.55 Another sample of the monolayer recovered from a rat 5 days after the experimental exfoliation. One mesothelial cell is located in the middle of a depopulated area. (black circle), surrounded by young cells, one of them undergoing midosis (arrow). This image illustrates about the complexity of identifying the origin of new, repopulating cells. This specific cell could have reached the peritoneal surface migrating from the bordering area or from the submesothelial tisuue, or just be a free-floating mesothelial cell, recently implanted on the cavitary aspect of the peritoneum. (Hematoxylin-eosin; × 1,000)

All this evidence suggests that, most likely, mesothelial cell regeneration takes place through three different processes occurring simultaneously: implantation of young wandering mesothelial cells, migration of mesothelial cell precursors coming from the underlying connective tissue, and mitosis and migration of mature mesothelial cells bordering the injured area. The individual contribution of each mechanism cannot still be evaluated, as suggested by the presence of isolated new mesothelial cells repopulating denuded areas of the peritoneal surface (Fig. 5.55). These cells could eventually derive from by any of the already mentioned pathways of regeneration. According to studies done using the doughnut model of mesothelial regeneration, complete repopulation of the monolayer occurs after a recovery period of 15 days (Fig. 5.56).

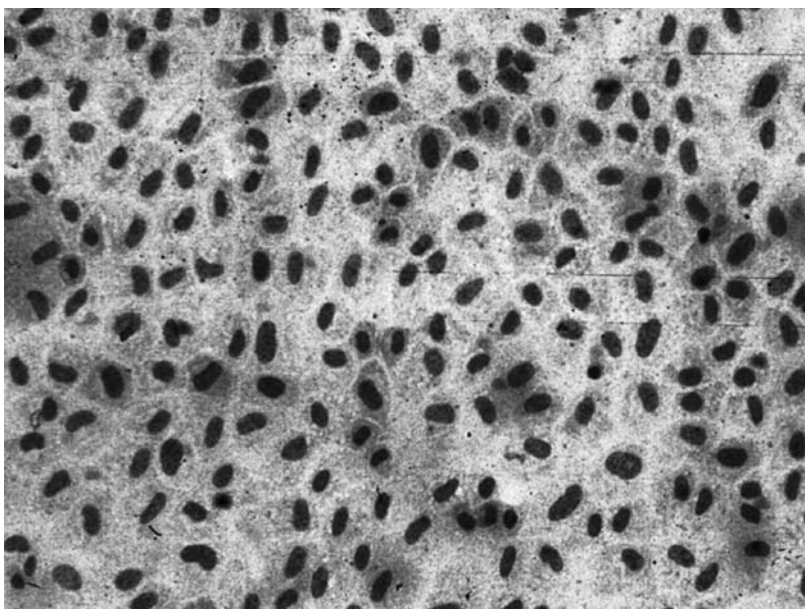

Fig. 5.56 Imprint recovered from a control rat, 15 days after performing a localized, doughnut shaped exfoliation of the monolayer dressing the anterior liver surface. The injured area appears completely repopulated. (Hematoxylin-eosin; × 400)

The Price of a Failing Regeneration

The normal density population of mesothelial cells dressing the cavitary aspect of the peritoneum is around 300,000/cm^2 in mice and rats [31, 420].

This number remains basically unchanged in the intact, unexposed animal, showing a minimal and non significant variability between samples of the same animal, as well as between those obtained from different mice or rats. This situation of no numerical change results from a continuous replacement of dying cells by means of cell replication. This mechanism has also been detected in peritoneal biopsies taken from human patients on long-term peritoneal dialysis [421], suggesting that the therapeutic procedure induced a situation of continuous mesothelial injury, coupled to an also continuous process of regeneration. This working hypothesis found support in the original observation of Di Paolo et al. [26] regarding the absence of mesothelial microvilli in peritoneal biopsies taken from patients on CAPD, later on identified as a sign of impending apoptosis [422] (Fig. 5.51).

A tight regulation of the rates of cell growth and cell death is critical for maintaining a normally populated monolayer. In this sense, a decreased rate of mesothelial cells growth, an increased proportion of dying cells, or both could eventually lead to a depopulated monolayer that, in turn, would result in repair by means of connective tissue [399, 423, 424], the thickness of which can be as high as 100 μ.

So far, during the situation of steady state, new mesothelial cells continuously replace the dying ones [425]. This steady state is broken when: a) the magnitude of cell injury overwhelms the regenerating capabilities of the monolayer; b) the cell cycle of the mesothelial cells is blocked or departs from its normal course; and c) both developments occurring simultaneously. When the balance between regeneration and injury is broken, proliferative mechanisms are required to relieve the structural alterations represented by a depopulated monolayer. This process of repopulation and regeneration is dependent on the presence of a resilient cell population that has retained the potential for proliferation and differentiation. Failure of this mechanism leads to repair by means of connective tissue, which, in turn, becomes the first step toward peritoneal fibrosis and sclerosis [425] (Fig. 5.57). At this point it is pertinent to remind that submesothelial peritoneal sclerosis is an extremely frequent complication of long term peritoneal dialysis. It has been detected in about one half of dialyzed patients during the first year on peritoneal dialysis [426], whereas its prevalence reaches an 80% level after only 2 years on the aforementioned technique of renal replacement therapy [427, 428]. Actually, a variable degree of diffuse peritoneal fibrosis has been documented in all patients who have been on long-term peritoneal dialysis [429]. And, in turn, this development paves the way to membrane failure [430], a situation in which, at least from the point of view of its dialytic capabilities, the peritoneum is no more peritoneum.

Mesothelial cells are extremely vulnerable to minor injury. Mild drying or wetting of rat cecal peritoneum for 5 min induced mesothelial cell degeneration and detachment, and severe interstitial edema [393, 394]. This fragility of the monolayer is somehow compensated by the remarkable regenerative capabilities mentioned before. Evidence of this property is brought to light by the almost complete repopulation of the mesothelium 15 days after its massive exfoliation resulting from exposure to a 0.125 mg% Trypsin solution during a period of 10 min [431] (Fig. 5.58). This enzyme is commonly used in order to harvest mesothelial cells from human omentum or from experimental animals [432].

However, as stated in the title of this section, exfoliation always demands a price. Meticulous observation of peritoneal biopsies showed, in the same animals, small domains were depopulation was repaired by connective tissue, launching at the local level the mechanisms involved in peritoneal sclerosis (Fig. 5.58). Recently published investigations have shown that new fibroblastic cells can develop from native mesothelial cells by a mechanism of epithelial-to-mesenchymal transition, launched by injury resulting from the use of poorly biocompatible dialysis solutions [433]. So far, these findings coincide with previously reported observations [420, 425] postulating that the mesothelial cell plays a key role in the preservation of the peritoneum as an effective dialysis membrane, as well as in its structural break down and final functional failure. In addition, it has been postulated that submesothelial myofibroblasts, actively involved in the reaction to the persistent tissue injury derived from exposure to PD solutions, take part in the inflammatory response leading to extracellular matrix accumulation and angiogenesis. Probably, these cells may also arise from mesothelial cells through epithelial to mesenchymal transition [433].

Peritoneal sclerosis goes along with a marked increase in the density of microvessels of neoformation. This phenomenon of neoangiogenesis has been detected in peritoneal biopsies of patients in long term peritoneal dialysis [433–436], as well as in rats after experimental induction of the fibrous reaction [431]. Those studies showed that the thicker the peritoneal tissue, the higher the number of vessels/surface area unit.

Besides, analysis of the microvascular alterations seen in humans on long-term peritoneal dialysis led Williams et al. [436] to systemize and define four sequential degrees of pathology, that go from presence of subendothelial hyaline material with thickness lower than 7 μm (degree 1); same changes but with thickness over 7 μm (degree 2); additional

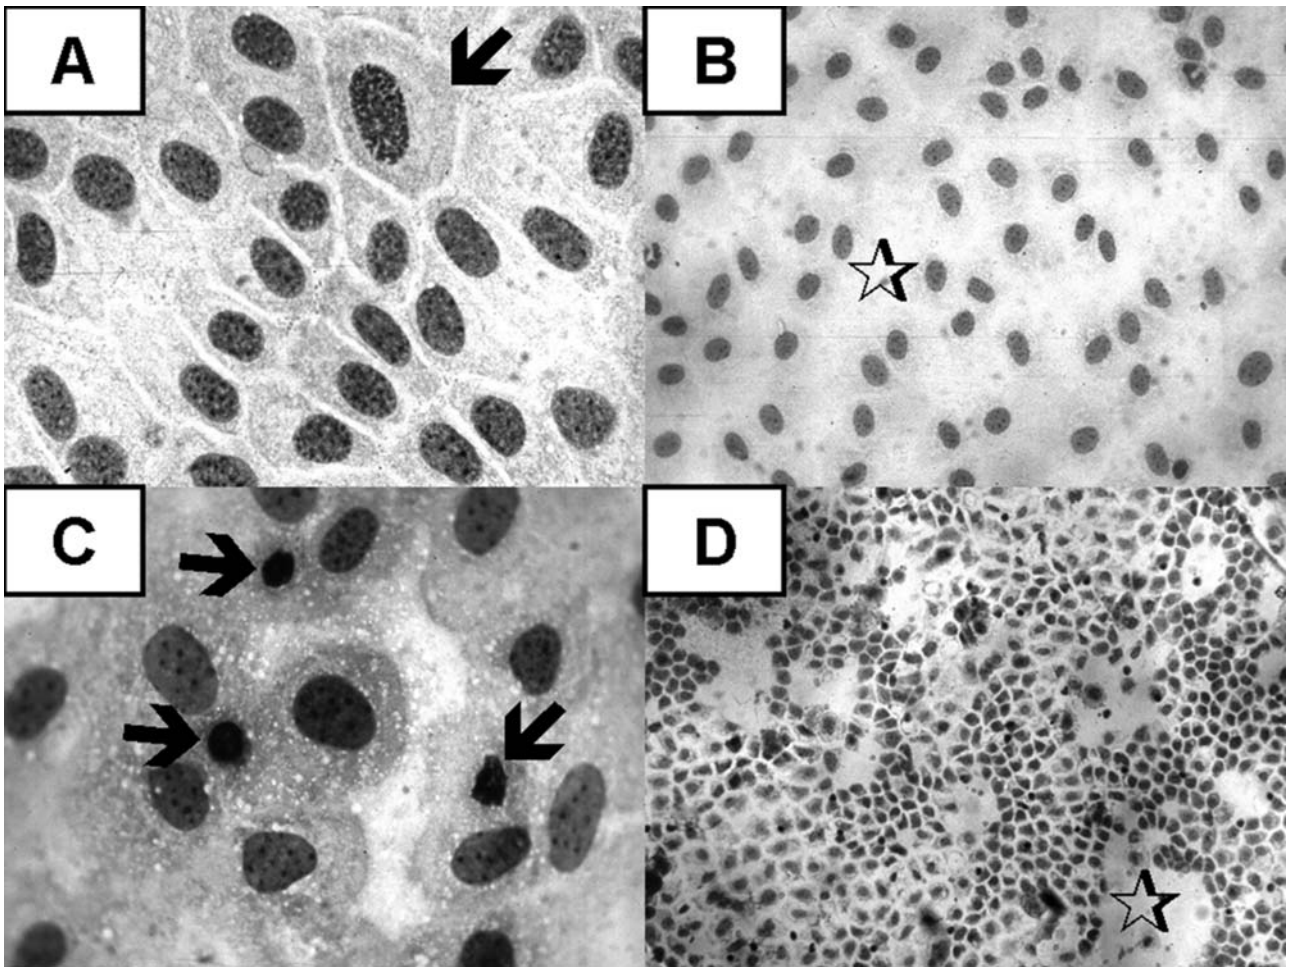

Fig. 5.57 **(a)** Mesothelial sample exfoliated from an intact, unexposed mouse. Arrow points at one cell in methaphase, (Hematoxylin-eosin; × 1,000). **(b)** Imprint obtained from a rat after being treated with one daily intraperitoneal injection of a 4.25% glucose, lactated dialysis solution. Open star denotes one of the many undressed domains of the liver surface. (Hematoxylin-eosin; × 400). **(c)** Same sample of Inset B at larger magnification. Notice the presence of unusual number of phagocytized apoptotic bodies (arrows). (Hematoxylin-eosin; ×1,000). **(d)** Specimen recovered from a rat treated during 30 days with one daily injection of 7.5% icodextrin dialysis fluid. Open star calls attention to the presence of large domains of undressed peritoneal liver surface. (Hematoxylin-eosin; × 160)

luminal distortion or narrowing (degree 3); and luminal obliteration (degree 4). It is interesting to remark that in this same study [436], 87% of patients treated with PD for periods of 6 years, exhibited clear signs of microvasculopathy, and that in 66% of them, changes reached degree 4. Therefore, two thirds of microvessels appeared closed. From this information it may be deduced that, in the long range, development of neovascularization does not automatically imply increase of blood flow. Indeed, having such a high proportion of occluded microvessels, not few areas of the peritoneal tissue become, with time, underperfused. This point should be taken into consideration in order to analyze the pathophysiology of permeability changes commonly detected in cases of membrane failure. This, in addition to the increased thickness of the peritoneal membrane that, per se, will substantially affect the transit time of solute's molecules between the still permeable capillaries and the peritoneal cavity.

All osmotic agents present in commercially available solutions for peritoneal dialysis share, regarding the long-term exposed monolayer, at least three basic effects: a substantial reduction of the cell population density of around 50%, a mitotic index near zero, and a significantly increased prevalence of nonviable cells [423].

This information suggested that the monolayer became depopulated under the influence of dialysis solutions (Figs. 5.59 and 5.60). But, going from bad to worse, the regenerative capabilities of the mesothelial cells still dressing the cavitary surface of the peritoneum appeared substantially reduced. In addition, the mechanisms leading to regeneration are substantially restrained, at least in experimental grounds, by the continuous exposure to the commonly used osmotic agents. This concept finds support in experimental observations done in rats using the "Doughnut" model of mesothelial regeneration in the rat [419]. After a ring of the monolayer was exfoliated, animals were exposed to either

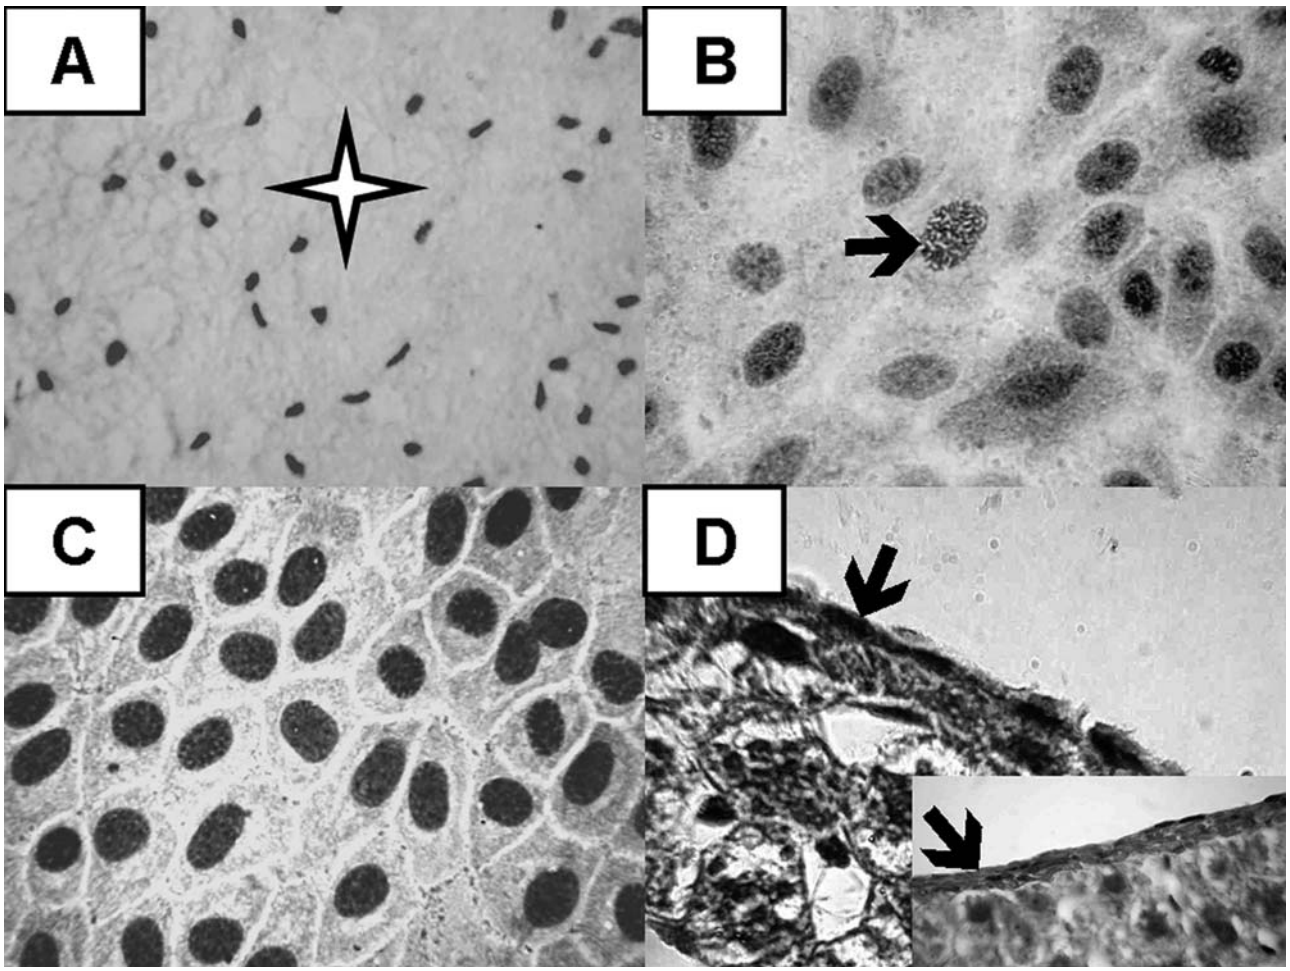

Fig. 5.58 **(a)** This sample was taken from a mouse after a 15-min exposure to 0.125% Trypsin solution. Notice the substantially decreased density of the cell population and the consequent presence of large depopulated areas (four-pointed star). (Hematoxylin-eosin; × 160). **(b)** Imprint exfoliated from a mouse 2 days after the 15-min exposure to the 0.125% Trypsin solution. Increased density as well as mitosis (arrow), point at the undergoing process of repopulation. (Hematoxylin-eosin; × 400). **(c)** Repopulated, normal monolayer seen after a recovery period of 30 days after the experimental intervention. (Hematoxylin-eosin; × 400). **(d)** Liver biopsy taken at the end of the 15-day recovery period. A normal monolayer is dressing the cavitary aspect of the liver surface (arrow). (Hematoxylin-eosin; × 400).

Inset. Other sector of the same biopsy showing that in spite of the repopulation, occasional areas of repair by means of fibrous tissue can be detected (arrow). (Hematoxilin–eosin; × 160)

4.25% glucose or 7.5 icodextrin dialysis solution for a period of 30 consecutive days. Macroscopic observation of the abdominal cavity at the end of the observation period showed that most animals developed scarring and fibrous adhesions at the level of the injured areas. Imprints and biopsies taken from the affected domains confirmed that not only repopulation failed, but that the missing mesothelial dressing was replaced by a thick layer of fibrous tissue, containing numerous microvessels of neoformation (Fig. 5.61). Consequently, these observations support the contention that both osmotic agents, 4.25% glucose and 7.5 icodextrin, substantially restrain the normal process of mesothelial repopulation expected to take place during and after the experimental exfoliation. This development launched the repair mechanisms leading to peritoneal sclerosis.

Several studies have shown evidence indicating that different cell types exposed to hydrogen peroxide display a reduced rate of proliferation, premature senescence, and, consequently, higher prevalence of apoptosis [437]. Within this context, additional experiments exposed to view the existence of a dose-related effect. Indeed, low levels of oxidants potentiate growth signals and enhance proliferation as long as the specific cell type can initiate new rounds of mitosis (Fig. 5.50), whereas higher concentrations of oxidants can block cell proliferation, which, in turn, derives in premature senescence and the consequent activation of the mechanisms leading to apoptotic cell death [438] (Figs. 5.45 and 5.46).

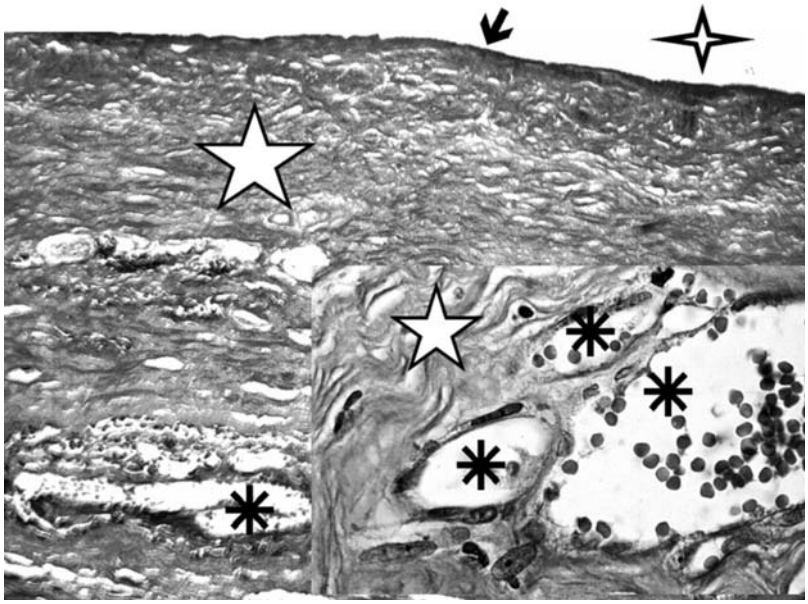

Fig. 5.59 Biopsy of parietal peritoneum taken from a patient with total membrane failure developed after being treated with CAPD for a period of 44 months. Notice the absence of mesothelial dressing (Arrow) on the peritoneal surface facing the abdominal cavity (four-pointed star). A thick layer of fibrous tissue (white star) replaced the missing monolayer. These images define the the situation of peritoneal sclerosis. (Asterisk: venule of neoformation). (Masson × 160).

Inset: Other section of the same biopsy showing a group of microvessels (asterisks) indicating the magnitude of neovascularization. (White star: fibrous tissue). (Masson × 400)

Higher degrees of oxidative injury lead to cell death by nonphysiological, necrotic pathways that, in turn, put in motion the local inflammatory reaction derived from extravasation of the cytoplasmic contents into the interstitial tissue [439] (Fig. 5.62). Both glucose-enriched solutions and icodextrin have the intrinsic capabilities of inducing different degrees of oxidative stress upon the exposed mesothelium. Glucose acts through products derived from its nonenzymatic degradation [440] and the irreversible formation of AGE products [441] by glucose autoxidation [442] and/or by oxidative mitochondrial DNA damage [443]. Icodextrin, in turn, induces substantial lipid peroxidation of mesothelial cell's membrane almost immediately after being infused into the abdominal cavity [444, 445].

This injury derives, at least in part, from the intra-abdominal formation of carbonyl compounds during the dwell time [446]. This phenomenon of carbonyl compounds liberation during the dwell time has been shown by the same group of investigators, using amino acid–based dialysis solutions.

Development of oxidative injury is facilitated by the demonstrated capability of mesothelial cells in culture to generate hydrogen peroxide [447]. This interpretation of the above-mentioned chain of events has been substantiated by a recent study, showing that acute and severe in vivo oxidative stress applied to the mesothelial monolayer results in

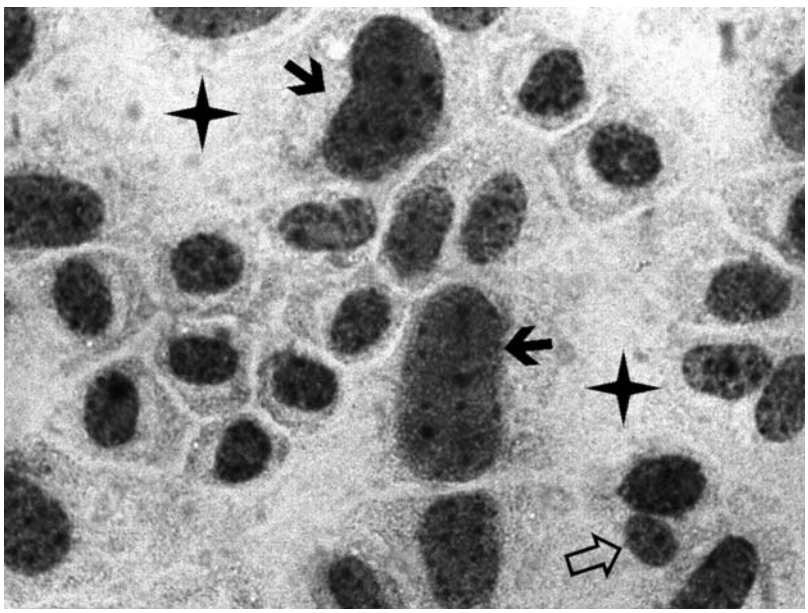

Fig. 5.60 Imprint of the mesothelial monolayer recovered from a mouse after being injected once a day, during 30 consecutive days with a 1.1% Aminoacids solution for peritoneal dialysis. Density of the mesothelium looks reduced as shown by the presence of depopulated areas (four-pointed stars). Black arrows indicate large, senescent cells. (Open arrow: Binucleated mesothelial cell with one micronucleus, the presence of which is suggestive of DNA damage). (Hematoxylin -eosin; × 1,000).

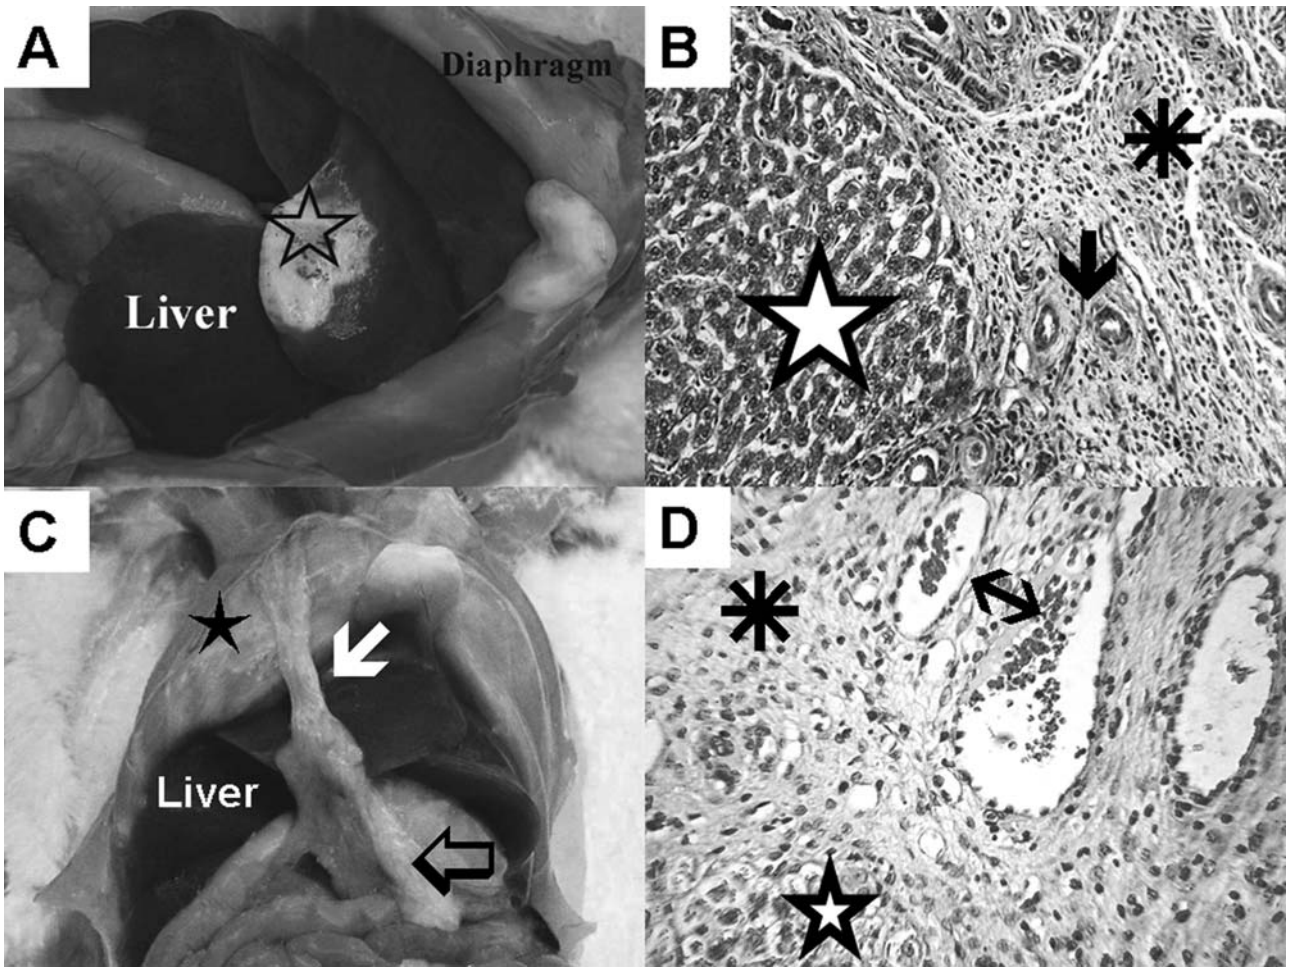

Fig. 5.61 **(A)** Photograph taken 15 days after focal exfoliation of an 8-mm diameter, doughnut-shaped area of mesothelium. The intervention was performed on the anterior liver surface of a rat that, after the procedure, was treated with one daily intraperitoneal injection of a 4.25% glucose, lactated dialysis solution. A failing repopulation derived in fibrous scarring of the exfoliated area (open star). **(B)** Sample of the liver taken from the same rat showing a thick layer of fibrous tissue (asterisk) that replaced the absent mesothelial dressing. (White star: liver tissue; black arrow: microvessels of neoformation). (Hematoxylin-eosin; × 160). **(C)** Open abdominal cavity of a rat that, after creation of a doughnut-like local exfoliation on the anterior liver surface, received one daily intraperitoneal injection of 7.5% icodextrin dialysis fluid, during 15 consecutive days. Notice the fibrous adhesion (white arrow) between an intestinal loop (open arrow), the experimentally injured liver surface and the diaphragm (black star). **(D)** This specimen belongs to the same rat of Inset C. A dense layer of fibrous tissue (asterisk) appears covering the subjacent liver tissue (five-pointed star). Double arrow points at two venules of neoformation. (Hematoxylin-eosin; × 160)

extensive fibrosis, adhesions, and permeability changes similar to those observed in clinical ultrafiltration failure [448] (Fig. 5.63).

Peritoneal sclerosis has been induced in rodents by in vivo exposing the membrane to a variety of experimental interventions: asbestos [449], 0.1% chlorexidine [450], iron dextran [451], glucose degradation products [452], AGE deposits derived from uremia per se [453], sodium hypochlorite [454], lipopolysaccharide [455], low pH of around 3.8 [456], pure water combining low pH and hypo-osmolarity [457], silica [458], and zymosan [459].

It should be noticed at this point of the analysis that, with a few exceptions (pure water, chloroxidine, and low pH), the other substances quoted as used to experimentally induce peritoneal sclerosis operate setting out different degrees of oxidative stress [460–471]. So far, after evaluating the aforementioned offered evidence, it may be concluded that addition of antioxidant agents to the currently used peritoneal dialysis solutions seems to be a quite rational and wanted development [472, 473].

We cannot complete this review without mentioning the enigmatic problem of sclerosing encapsulating peritonitis (SEP), currently also named encapsulating peritoneal sclerosis (EPS). This fearful syndrome leads to a situation in

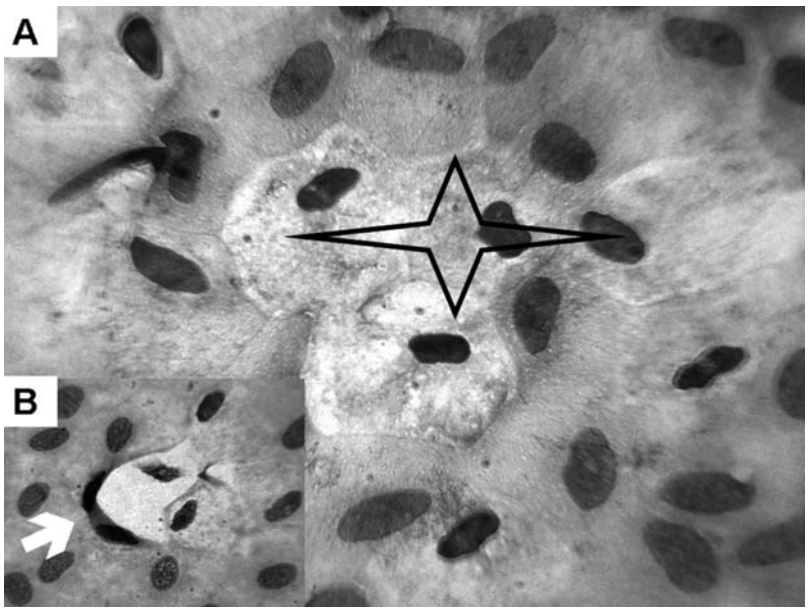

Fig. 5.62 **(A)** Imprint recovered from a rat 10 min after acute oxidative injury. Group of mesothelial cells undergoing picnotic changes (4 points star). (Hematoxylin-eosin; × 1,000). **(B)** Other aspect of the same specimen showing picnotic mesothelial cells exfoliating from the peritoneum dressing the anterior liver surface. (Hematoxylin-eosin; × 160)

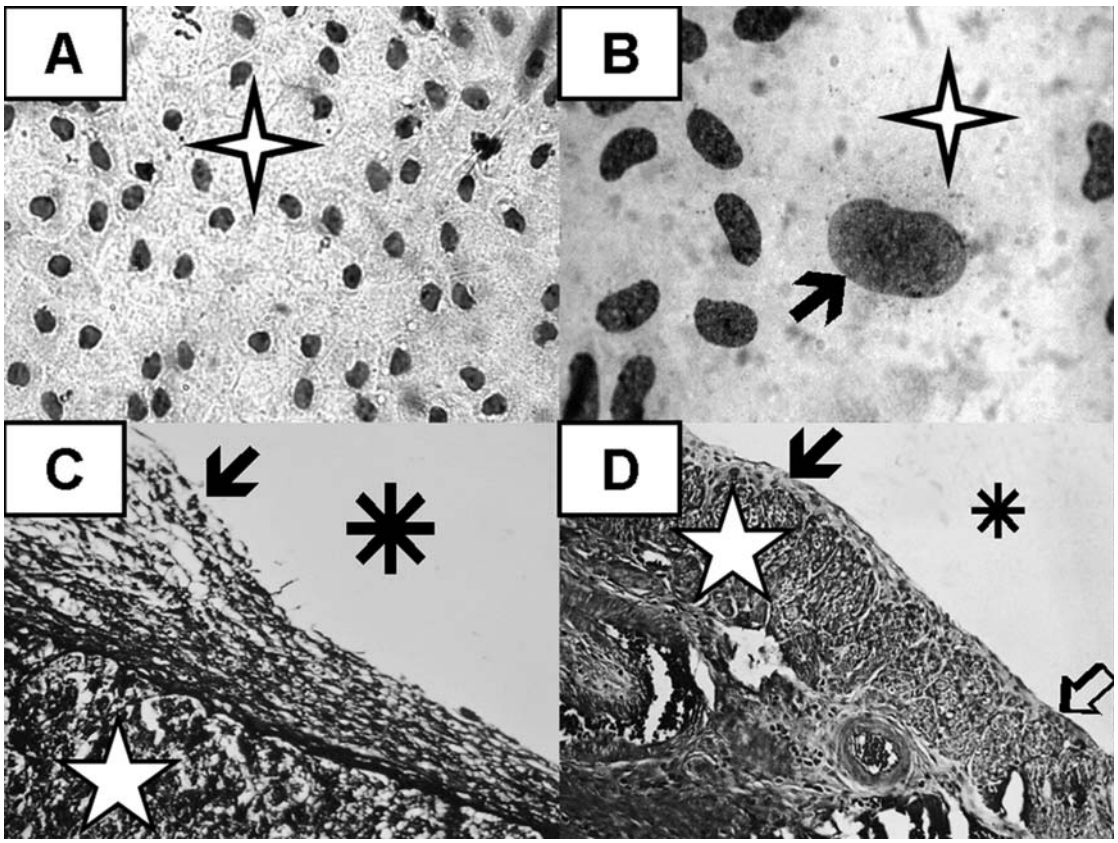

Fig. 5.63 **(A)** Imprint taken from the liver surface 10 min after experimental exfoliation by means of 5 mM/L deoxycholate solution. It is evident that most of the peritoneal surface is devoid of the normally seen mesothelial dressing (open star). (Hematoxylin-eosin; × 160). **(B)** After a recovery period of 15 days, mesothelial cells are still absent in large domains of the peritoneal surface (open star), suggesting that fibrous repair took place, instead of regeneration of the monolayer. Arrow points at a large senescent mesothelial cell. **(c)** Sample of a liver biopsy obtained from a rat, 15 days after the experimental intervention using deoxycholate. A thick layer (arrow) of fibrous tissue replaced the missing mesothelial monolayer. (Asterisk: peritoneal cavity; white star: liver tissue). (Hematoxylin-eosin; × 400). **(d)** Section of small intestine recovered from the same rat mentioned in Inset C. Some areas of the intestinal wall are covered by a wide coat of fibrous tissue (black arrow), whereas neighboring domains show a normal mesothelial dressing (open arrow). (Asterisk: peritoneal cavity; five-pointed white star: intestinal wall). (Hematoxylin-eosin; × 160)

which a thickened, fibrous sheet of tissue envelops the small intestine [474–477], liver, and stomach, as well as pelvic organs. This complication covers a wide range of morphological alterations starting from peritoneal opacification, passing through the tanned peritoneum syndrome, and finally reaching replacement of the serosal layer by fibrous tissue. Fibrous bands may be present compromising mesentery, gallbladder, spleen, liver, and stomach, as well as pelvic organs and even the cavitary aspect of the peritoneal tissue. The most affected areas configure, at times, a mass of fibrous tissue packaging abdominal viscera, conforming the cocoon that usually includes loops of small intestine as well as pockets of encapsulated ascites. Light microscopy reveals serosal fibrosis and total absence of the mesothelial monolayer, replaced by a thick layer of connective fibrous tissue, the thickness of which can reach 4 cm [478, 479] (Fig. 5.64). Neovascularization is also seen, even though these blood vessels show major structural alterations: sclerosis of the whole vascular wall, at times occlusion of the lumen, and even hyaline changes of the blocked microvessels (Fig. 5.65). Peritoneal calcifications and formation of bone and even bone marrow have been detected. All this may be combined with wide areas of inflammatory infiltrates [480, 481].

Changes detected in patients with SEP/EPS appear far away from those described in the commonly observed peritoneal sclerosis. Besides, its prevalence in patients on peritoneal dialysis is, fortunately, extremely low, whereas the impact of each condition is absolutely different. SEP/EPS carries a quite poor prognosis, with a mortality rate ranging between 26 and 93% [480], whereas simple peritoneal sclerosis basically leads patients to switch to other ways of renal replacement therapy, usually hemodialysis. These differences support the concept postulated by Di Paolo and Garosi [478, 479], who concluded that both conditions represent different nosological entities. In patients on peritoneal dialysis, the origin of this complication is still ill-defined. Many possible factors have been invoked (acetate, hyperosmolarity, recurrent peritonitis, glucose, antiseptics, intraperitoneal antibiotics, bacterial endotoxins), even though there is no available evidence clearly demonstrating specific relevance for any of them [474, 482]. Besides, at least one case has been reported on a chronic uremic patient having renal replacement therapy by means of only hemodialysis [483].

It should be noticed that sclerosing peritonitis has been reported in not few clinical situations unrelated to both, chronic uremia and peritoneal dialysis as: idiopathic [484, 485], associated with the use of some β-blockers such as practolol [486], propranolol [487], or timolol [488], as well as to metoprolol [489], oxprenolol [490], and intraperitoneally administered antibiotics such as tetracycline [491]. Besides, the literature mentions cases of sclerosing peritonitis associated to intra-abdominal tumors like gastric carcinoma, carcinoma of pancreas, familial polyposis of colon, renal carcinoma, lymphoma, ovarian teratoma or thecoma, and even in patients affected by liver cirrhosis as well as after liver transplantation [492–502]. So far, our understanding of SEP/EPS is still blurred as a result of the complexity of the problem, and namely, by its multiple ethiopathogenesis.

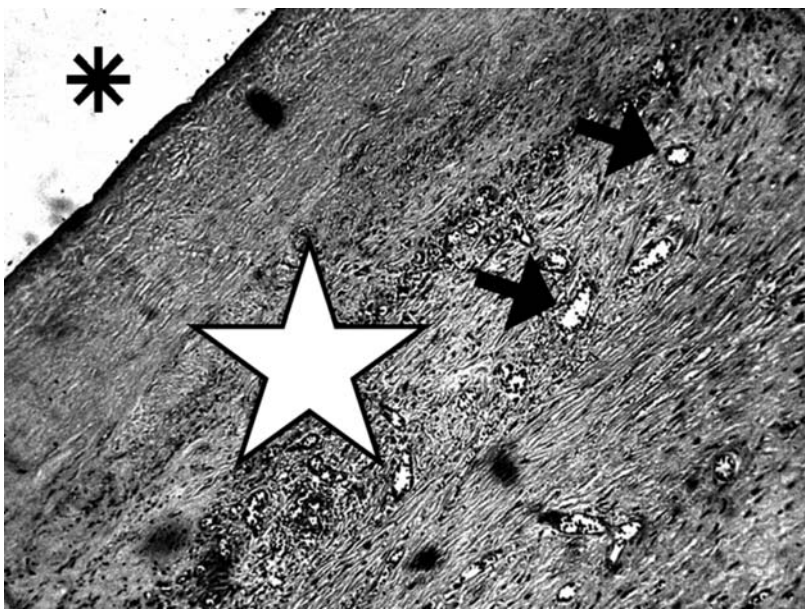

Fig. 5.64 Biopsy of parietal peritoneum recovered from a patient with sclerosing peritonitis. A thick layer of around 2,500 microns (white star) is covering the peritoneal surface. (Asterisk: peritoneal space; arrows: blood vessels of neoformation). (Hematoxylin-eosin; × 100)

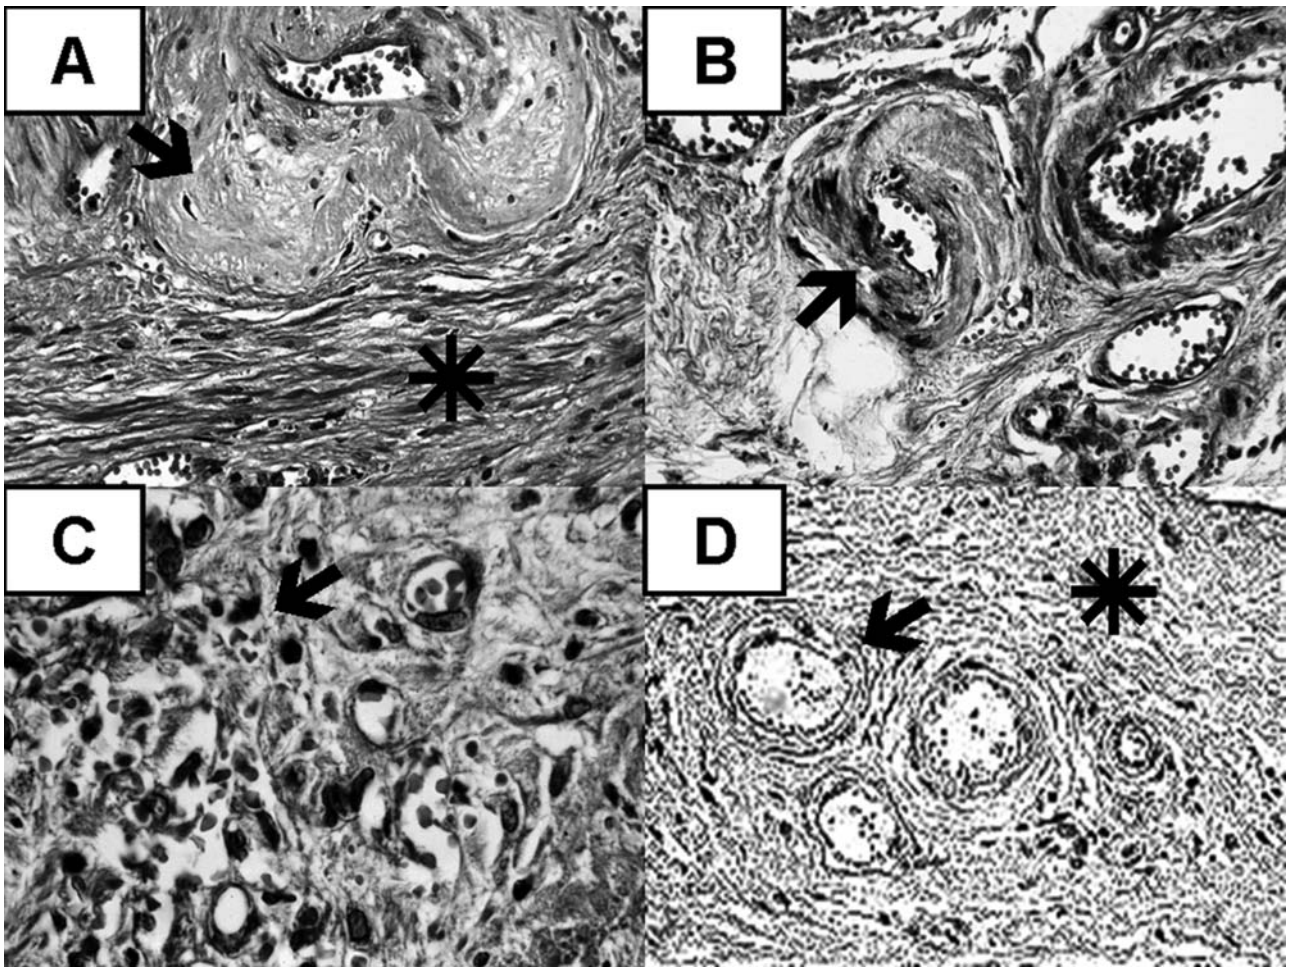

Fig. 5.65 **(A)** Dense hyaline deposits (arrow) located in the thickened wall of an almost obstructed blood vessel of neoformation, embedded in a mass of fibrous tissue (asterisk). (Masson; × 160). **(B)** Microvessels of neoformation showing thickened sclerotic wall (arrow). (Masson; × 160). **(C)** Mononuclear cells (black arrow) infiltrating the fibrous tissue surrounding blood vessels of neoformation (open arrow). (Masson; × 400). **(D)** Perivascular fibrosis in blood vessels (arrow) embedded into a densely packed interstitial mass of fibrous tissue. (Hematoxylin-eosin; × 400)

The Potential Use of the Mesothelium as a Source of Mesenchymal Stem Cells

As stated in the previous paragraphs, the existence of pluripotent mesenchymal cells as precursors of the mesothelium has been already proposed. Even though a mesothelial stem cell has not yet been definitely identified, the existence of pluripotent mesenchymal cells in the mesothelial monolayer as well as in the submesothelial connective tissue, has been repeatedly considered in the literature [401], opening the way in order to consider their use, as an actual option, in regenerating therapies [503].

Some observations performed in human pathology as well as in animal experimentally induced tissue reactions lend strong support to this contention. As a living proof, it may be mentioned that differentiation towards cartilage and bone has been described in a primary tumour of pleura, suggesting that mesothelial cells are pluripotent. In this sense, being mesenchyma, they may well retain the potential to differentiate along embryonic developmental lines, including cartilage and bone [504, 505].

Besides, cartilaginous differentiation of the peritoneum not associated with intra-abdominal malignancy has been already detected [506], whereas bone and cartilaginous formation has been reported in both, human patients and experimentally induced mesothelioma [507, 508]. Bone formation was also seen in four cases of sclerosing peritonitis observed in patients treated by means of peritoneal dialysis, whereas in two of them, islands of bone marrow were also detected [481].

Interestingly, glomerular-like structures in fibrous tissue of biopsies of visceral peritoneum have been detected in biopsies taken from rats with experimentally induced peritoneal sclerosis [505] (Fig. 5.66). This information emphasizes the capability of the mesothelium to differentiate in other cell lines in response to injury [504].

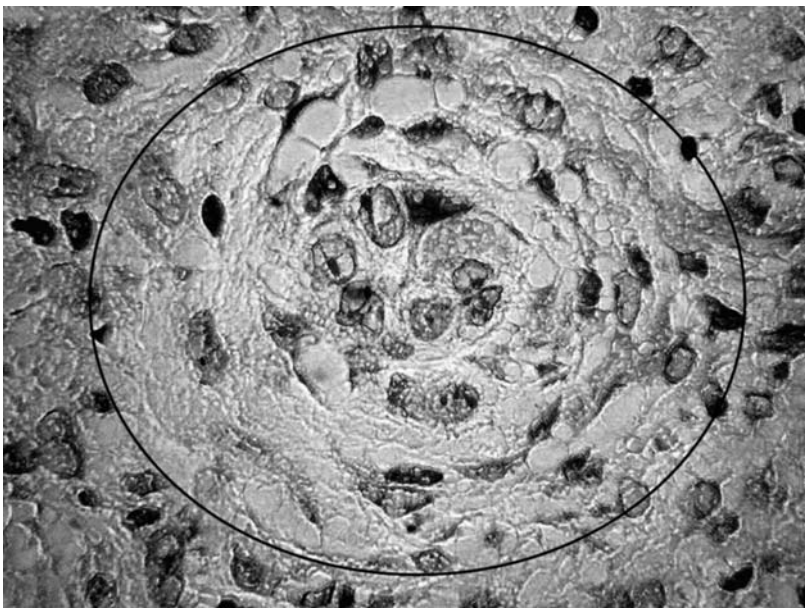

Fig. 5.66 Glomerular-like structure detected in fibrous tissue covering the cavitary aspect of the liver. The specimen was taken from a rat with experimentally induced peritoneal sclerosis. (Hematoxylin-eosin; × 400).

Additional research identified mesenchymal cells in the adult human synovial membrane. These cells showed the capability to differentiate in chondrocytes and osteocytes [509, 510]. Synovium, also of mesenchymal origin, is considered one more type of serous membrane like peritoneum, pericardium and pleura [511]. Therefore, this common embryological origin opens the possibility of eventual therapeutic interventions in the course of joint diseases that could be performed using peritoneal mesothelial cells [505].

Recent published evidence exposed to view the fact that, when placed under the appropriate biophysical and/or biochemical conditions mesothelial cells demonstrate a remarkable degree of plasticity. This property supports the concept, that mesothelial cell progenitors are endowed with the capability to switch between different cell types, according to the conditions of their microenvironment [504]. Within this context, it is illustrating to remind the observed myofibroblastic conversion of human adult mesothelial cells in culture, under the influence of transforming growth factor (TGF)-β-1 [512, 513].

The relationship between blood cells and mesothelium represents one more exciting aspect of this topic. As mentioned before, a proposed mechanism of mesothelial healing postulated that progenitor cells, originally located in the bone marrow, migrate and convert into mesothelial cells [380]. Although additional research concluded that this hypothesis looks unlikely [403], a link between both cell lines seems to be possible. A quite strong point is that hemangioblasts, a proposed progenitor of the endothelial and hematopoietic cell lineages, derive from the embryonic splanchnic mesothelium. This structure, in turn, has been proposed as the embryonic source of the endothelium-lined vascular system, pointing at a specialization of the phylogenetically older celomic cavities. Within this context, the origin of the hematopoietic cells might be related to differentiation of celomocytes derived from the celomic epithelium. So far, endothelial and blood cells appear to derive from a common mesothelial-derived progenitor [514].

In addition, morphological and immunohistochemical evidence for a translocation of cells from the celomic mesothelium to the ventral wall has been observed during development of the quail embryos. Consequently, the concurrence of translocation of mesothelial cells and the appearance of aortic smooth muscle cell progenitors point at a link between the former and the latter cells lineages [515].

This ontogenetic relationship between mesothelium, blood, and blood vessels is substantiated by two excellent studies performed applying the tools of tissue bioengineering. Donna et al. [516] presented evidence demonstrating that cultured adult human mesothelial cells have the capabilities to generate hematopoietic cells, similar to those of the bone marrow. This conversion was confirmed by morphological analysis as well as by cell immunoreactivity toward specific antibodies directed to antigens of the hematopoietic cell lines, at various stages of differentiation. The experiment was performed culturing mesothelial cells in collagen sponges. This is one more suggestion of the remarkable plasticity of the mesothelium, as well as of the relevance of the microenvironment hosting the cultured cells. Regarding blood vessels, a key study is that reported by Campbell et al. [517], who succeeded in creating an artificial blood conduct by inserting a Silastic tubing into the peritoneal cavity of rats. Two weeks after the surgical intervention, a new laparotomy showed that the implanted

silicon rubber tubing was covered by several layers of fibroblasts, collagen matrix, and a single layer of mesothelium. This new "blood vessel" was everted and successfully grafted by end-to-end anastomosis, in arteries of the same animal in which it was grown. These observations have been confirmed by Moldovan and Haveman [518], as well as by our group [505].

So far, it seems evident that peritoneal mesothelial cells are endowed with a degree of plasticity that shapes their capability of generating other cell lines, if placed in the appropriate micro-environment. Investigative steps will have to define the best conditions that will eventually lead to the use of mesothelium in stem cell therapy as well as in tissue engineering, taking also in account that harvesting of large numbers of cells from patients having an unexposed monolayer, may well be unlimited.

Final Remarks

It was not the purpose of the author merely to deliver a cold and tedious description of anatomical structures. On the contrary, the goal has been to offer the reader a comprehensive and balanced analytical approach of structure and function covering, at least in part, their interactions. It is evident that the function of the peritoneum as a dialysis membrane cannot be evaluated only within the frame of passive diffusion through water-filled, cylindrical pores [204] and/or mathematical models [519], based on assumptions that, at times, lose sight of the formidable barrier of the living cell membrane as well as the structural organization of the tissues.

Research during the last two decades provided enough evidence to characterize the peritoneum not as an inert dialyzing sheet, but as a living and reusable membrane for dialysis [271], as predicted more than 25 years ago [520].

It becomes evident that the mesothelial monolayer continuously exposed to dialysis solutions in vivo is structurally and functionally different, at least from the histochemical point of view, from that observed in unexposed–intact cells, or in those growing in the in vitro set-up of culture and later exposed to experimental incubation [521]. Therefore, I have the feeling that a good deal of creative thinking is required to integrate data obtained during 50 years of physiological studies and mathematical models, with the realities of tissue structure and cell biology.

Introduction of peritoneal dialysis as a therapeutic tool to fight chronic uremia shaped a kind of chain reaction that went well beyond the expectations of the early years. Actually, observations made in clinical settings showed the way to a new window open to the fascinating world of cell biology. Within this specific field, there are still more questions than answers.

It is the author's hope that this chapter will serve to stimulate the imagination of young scientists as a catalytic element for further research.

Chapter 6
The Physiology of Peritoneal Solute, Water, and Lymphatic Transport

R.T. Krediet

The Surface Area of the Peritoneum

Few studies have been published on the magnitude of the surface area of the peritoneum. Wegener mentioned a surface area of 1.72 m^2 in one adult woman [1] and Putiloff a value of 2.07 m^2 in one adult male [2]. More recent autopsy studies reported lower values [3–5]; the average peritoneal surface area in adults ranged from 1.0 m^2 [3] to 1.3 m^2 [5]. Using CT scanning in continuous ambulatory peritoneal dialysis (CAPD) patients a value of 0.55 m^2 has been found [6]. Some studies reported relationships between peritoneal surface area and body weight and/or body surface area, while others did not. The ratio between peritoneal surface area and body weight in adults is about half of that found in newborn infants [3]. A difference between adults and infants is barely present when peritoneal surface area is related to body surface area [3]. The peritoneal/body surface area averaged 0.6–0.8 in adults and 0.5–0.6 in infants. About 60% of the peritoneum consists of visceral peritoneum, 10% of which covers the liver, 30% of mesenterium and omentum, and 10% is parietal peritoneum [3–5]. The latter includes the diaphragmatic peritoneum, which comprises 3–8% of the total peritoneal surface area. Species differences are present, especially with regard to the contribution of diaphragmatic peritoneum, which is larger in humans than in rodents [5]. The contribution of the various parts of the peritoneum to solute transport during peritoneal dialysis may vary. Evisceration was found to cause a marked reduction in the transport of creatinine in rabbits [7] but not in rats [8, 9]. Effective peritoneal dialysis has been described in a neonate with extensive resection of the small intestine [10]. It has been hypothesized that the peritoneum covering the liver might be especially important in solute transport during peritoneal dialysis because of the close proximity with the liver sinusoids, but this could not be confirmed in experimental studies in rats [11, 12]. The diaphragmatic part of the peritoneum is especially involved in the absorption of solutes and fluid from the peritoneal cavity into the lymphatic system [13]. Observations in rats have shown that the peritoneal surface area increases with the age of the animals, with a proportional increase in dialysate/plasma (D/P) ratios of urea and creatinine [14].

The proportion of the peritoneum that is involved in transport during peritoneal dialysis is not known. The above-mentioned evisceration experiments suggest that the relative contribution of the parietal peritoneum may be more important than that of the visceral peritoneum. Although similar diffusion rates were found during experiments in rats undergoing peritoneal dialysis using a diffusion chamber, placed at various parts of the peritoneum, it appeared that only 25–30% of the visceral peritoneum was in contact with the dialysis solution [11]. Furthermore, it has been shown in cats that commercial dialysis solutions increase blood flow to the mesentery, omentum, intestinal serosa, and parietal peritoneum without altering total splanchnic blood flow [15]. This study, using microspheres, points to hyperemia of these tissues, thereby increasing the peritoneal capillary surface area.

It appears from the above data that the surface area of the peritoneal membrane involved in peritoneal dialysis is not a static property but should be defined in a functional way. The functional surface area of the peritoneal membrane cannot be measured directly, but the functional cross-sectional exchange pore area divided by the effective diffusion path length can be estimated. This parameter takes not only the capillary surface area into account, but also the distance to the dialysate/mesothelial contact. Using kinetic modeling, values of 117–250 m have been reported [16–19]. When the surface area of the peritoneum that is involved in transport is 0.6 m^2 and the unrestricted area over diffusion distance is set at 190 m, it can be calculated that the length from the capillary wall to the peritoneal cavity would be 3 mm in case of unrestricted diffusion in water. As the peritoneum is much thinner, this means that the resistance to diffusion of interstitial tissue must greatly exceed that of water. This will be discussed further in the following section.

Pathways and Barriers

Solutes passing from the blood in the peritoneal capillaries to the dialysate-filled peritoneal cavity have to pass at least three structures that can offer resistance: the capillary wall, the interstitial tissue, and the mesothelial cell layer (Fig. 6.1). Stagnant fluid layers at the mesothelial site have also been proposed as sites of resistance [20]. However, it has been calculated by Flessner that these are only a minor barrier to solute transport compared to the interstitial tissue [21]. The mesenterium is an important layer in the prevention of friction between abdominal organs, and is also involved in host defense. It is, however, not a main barrier to peritoneal transport of solutes and water. In vitro studies on the diffusion properties of an isolated avascular part of mesentery, thus representing transport in a diffusion chamber across two layers of mesothelium divided by interstitial tissue, have shown that the diffusion of particles with a molecular weight up to 500 kDa was similar to the expected values on the basis of their molecular weights [22, 23]. A pore radius of 0.7 μm could be calculated [22]. In vivo studies have shown that, although permeability coefficients were lower than in vitro [24], intraperitoneally administered macromolecules could easily pass the mesothelial layer [25, 26]. The mesothelium of the parietal peritoneum was also no osmotic barrier [27].

The interstitial tissue in general consists of bundles of collagen within a mucopolysaccharide hydrogel. It has been described as a two-phase system, in which a colloid-rich, water-poor phase is in equilibrium with a water-rich, colloid-poor phase [28]. The mucopolysaccharides of the colloid-rich phase are mainly composed of glycosaminoglycans, either hyaluronan or proteoglycans fixed to their core proteins. The free fluid phase is interspaced between areas of the colloid-rich phase. It is assumed that water transports throughout the interstitial space, while small solutes are partly excluded from the colloid phase and protein transport is restricted to the tortuous, water-rich phase. The thickness of the peritoneum is variable depending on its localization. In the mesentery the average thickness from mesothelium to mesothelium is 30 μm, with exceptions up to 110 μm [29]. The parietal peritoneum is loosely attached to the abdominal wall and easily stripped. Its thickness is estimated to be 2 mm [30]. The visceral peritoneum is more dense and firmly attached to the underlying tissues [30]. Examining cross-sections of the gut reveals that the thickness of the serosa varies from 30 to 250 μm [31]. Assuming a contribution of the visceral peritoneum to solute transport of 30% [11], an average thickness of the peritoneal interstitium of 500 μm can be calculated. This corresponds to the findings of Flessner et al. in which the steepest concentration gradient of EDTA in various parts of the peritoneal interstitium was found 400–600 μm from the serosa [32]. This is a factor 6 less than the 3 mm calculated on the basis of the unrestricted area over diffusion distance. This difference is likely to represent the restriction of the interstitial tissue to diffusion, compared with diffusion in water. The question arises whether this interstitial restriction is size-selective, i.e., the proportional restriction of solutes with various molecular weights is more pronounced than can be expected on the basis of free diffusion of these solutes only. The in vitro studies using an isolated mesentery suggested no size selectivity [22, 23], but the in vivo study on an isolated rat mesentery provided evidence that the apparent diffusion coefficients of various neutral dextran fractions were progressively lower than those in water [33]. No size selectivity was found for low molecular weight solutes.

The capillary wall is probably the most important restriction barrier. Solute transport occurs size selectively and is generally considered to take place through a system of pores [34, 35]. Although the vascular wall is likely to be

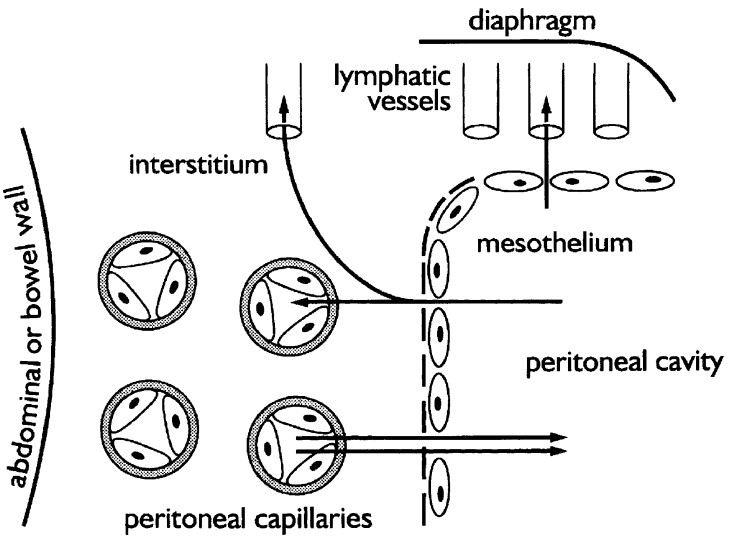

Fig. 6.1 A schematic representation of the peritoneal membrane. Diffusion and transcapillary ultrafiltration occur in two directions. Transcapillary ultrafiltration from the peritoneal capillaries to the peritoneal cavity occurs through small interendothelial pores and transcellularly through water channels. Lymphatic absorption from the peritoneal cavity is partly directly into the subdiaphragmatic lymphatics and partly into the lymphatics that drain the mesothelium

heteroporous, the capillary wall can be considered to function mainly as an isoporous membrane in combination with a small amount of very large pores, as has been described for the glomerulus [36]. This combination is known as the two-pore theory of capillary transport [37–39]. This theory assumes the presence of small pores with radii of 40–50 Å that are involved in the transport of low molecular weight solutes. Interendothelial clefts with radii of 40 Å have been considered the anatomical equivalents of the small pores [40, 41], but this is still an assumption. Transport through plasmalemmal vesicles, that would form channels, has also been suggested in electron microscopy studies [42]. It is not known to what extent the endothelial glycocalyx is involved in solute transport during peritoneal dialysis.

The two-pore model also consists of a small number of large pores with various radii, that are expressed as the average large-pore radius. The number of large pores is likely to be less than 0.1% of the total pore count and their average radius exceeds 150 Å. These pores are involved in the transport of macromolecules, such as serum proteins. The morphological equivalent of the large pores has not been established. Electron microscopic studies also suggested transport of macromolecules through plasmalemma vesicles [43]. Such a transport route would, however, require active metabolic processes and hence energy. Cooling experiments reduced the transcapillary passage of albumin only to the extent that cooling reduced passive transcapillary filtration, but not to the extent that would be expected due to decreased cell metabolism [44]. A light short-term fixation of vascular endothelial cells had no effect on their permeability to albumin [45]. Also the administration of transcytosis inhibitors did not reduce the peritoneal transport of albumin and LDL [46]. It follows from these experiments that the transcapillary transport of macromolecules is not an active process, but occurs by passive filtration and/or diffusion. Other possible morphological equivalents of the large-pore system are transcellular channels, vesicular-vacuolar organelles, or interendothelial gaps. It has been shown that the interendothelial vesicles that can be seen with electron microscopy are actual invaginations from either side of the cell membrane [47] with the possibility of a connection, thereby forming a channel. This theory has more recently been extended by the description of vesicular-vacuolar organelles (VVO) that would account for the increased vascular permeability of tumor vessels [48, 49]. VVO are grape-like clusters of vesicles and vacuoles present in the cytoplasm of endothelial cells lining venules and small veins. The individual vesicles and vacuoles are interconnected with each other and with the endothelial cell plasma membranes by means of fenestrae that may be open or closed by diaphragms. The function of these VVO is up-regulated by vascular endothelial growth factor [50].

Other candidates for the large pores are the postulated presence of very rare interendothelial clefts in which the adherence discontinuity is three to four times wider than in the ordinary clefts [38], or venular interendothelial gaps with radii of 500–5,000 Å, that can be provoked by the administration of histamine [51]. Such gaps could also be induced by other locally produced vasodilating substances. All this evidence indicates that the large-pore radius is not a constant value, but that it can be subject to variations. In other words, the capillary wall is a heteroporous membrane that can be described by the combination of a large set of small pores with uniform radii and an additional small set of large pores with different radii. The radius calculated for the large pores is therefore an average value.

The two-pore model with a predominance of small pores of uniform size does not explain the discrepancy between sieving coefficients and osmotic reflection coefficients that is found in peritoneal dialysis. The sieving coefficient (S) describes the magnitude of convective solute transport (solute transport coupled to the transport of water; solvent drag), while the reflection coefficient (σ) of a solute to a membrane determines its osmotic effectiveness. Both can range between 0 and 1 for a semipermeable membrane. For a homoporous membrane the relationship between the two is: $S = (1 - \sigma)$. Various studies on convective transport of low-molecular-weight solutes have reported sieving coefficients (calculated as solute clearance/net volume flow) of 0.6–0.7 [52–56]. However, estimates of the reflection coefficient of glucose yield values ranging between 0.02 and 0.05 [57–61]. This apparent discrepancy has been explained by assuming the presence of water-conductive ultrasmall pores in the plasma-lemma of endothelial cells with radii of 3–5 Å allowing the transport of water, but not of solutes (free water transport) [17, 62, 63]. This so-called three-pore model also explains why glucose is an effective osmotic agent during peritoneal dialysis despite its small size (radius 2–3 Å). According to this model about one-half of transcapillary ultrafiltration would occur through these ultrasmall pores, whereas the other half passes through the small interendothelial pores. Estimations in CAPD patients showed that transcellular water transport contributed about 40% to ultrafiltration, but with marked interindividual differences [64, 65].

At the time of the above computer simulations, a 28-kDa protein was discovered, present in the plasma membrane of red blood cells and *Xenopus* oocytes, that appeared to be involved in channel-mediated water transport [66]. This protein, originally named CHIP 28, and now aquaporin-1, was subsequently found to be the water channel in the proximal tubular cells of the kidney [67]; it is present both in the apical and basolateral membrane of these cells [68]. Water can be transported through it when an osmotic gradient is present. Aquaporin-1 is also present in various nonfenestrated epithelia [69]. It could be detected in endothelial cells of peritoneal capillaries and venules, both at mRNA and at protein levels [70, 71]. Peritoneal tissues also contain aquaporin-3 and -4, but their expression is much less pronounced [72]. Besides in endothelial cells, aquaporin-1 has also been shown in mesothelial cells of peritoneal biopsies [73]. Cultured mesothelial cells express aquaporin-1 and their expression is up-regulated by glucose [74].

A similar effect was found for aquaporin-3 [75]. Endothelial aquaporin-1 is likely to be the major water channel that constitutes the ultrasmall pore system. This is based on studies inhibiting aquaporin-1 function by the administration of mercury compounds [76]. Intraperitoneal administration of mercury chloride reduced free water transport, both in rats [77] and in rabbits [78]. Even more convincing are the results obtained in aquaporin-1 knock out mice. These animals showed a reduced peritoneal osmotic water permeability [79] and an absence of free water transport as judged from the sieving of sodium [80]. Heterozygotes had some reduction in sodium sieving.

Mechanisms of Solute Transport

Diffusion and convection are the mechanisms involved in the transport of solutes during peritoneal dialysis. Diffusion through a membrane takes place when a concentration gradient is present. According to Fick's first law of diffusion, the rate of transfer of a solute is determined by the diffusive permeability of the peritoneum to that solute (the ratio between the free diffusion coefficient of that solute and the diffusion distance), the surface area available for its transport, and the concentration gradient:

$$J_s = \frac{D_f}{\Delta x} \cdot A\Delta C \tag{6.1}$$

in which J_s is the rate of solute transfer, D_f is the free diffusion coefficient, Δx is the diffusion distance, A is the surface area, and ΔC is the concentration gradient. $D_f A/\Delta x$ is called the permeability surface area product or the mass transfer area coefficient (MTAC). During peritoneal dialysis, ΔC is the concentration difference between the plasma concentration of a solute (P) and its dialysate concentration (D):

$$J_S = \mathrm{MTAC}(P - D) \tag{6.2}$$

Convective transport or solute drag occurs in conjunction with the transport of water, and thus during ultrafiltration. It is determined by the water flux (J_v), the mean solute concentration ($\bar{C}$) in the membrane, and the solute reflection coefficient (σ):

$$J_s = J_v \bar{C}(1 - \sigma) \tag{6.3}$$

For reasons of simplicity $\bar{C}$ is often approached as:

$$\bar{C} = \frac{(P + D)}{2} \tag{6.4}$$

Staverman's reflection coefficient σ is the fraction of the maximal osmotic pressure a solute can exert across a semi-permeable membrane. It equals 1.0 for an ideal semi-permeable membrane and 0 when the membrane offers no resistance to the transport of a solute. With an isoporous membrane $\sigma = 1 - S$ in which S is the sieving coefficient. S is the ratio between the concentration of a solute in the filtrate divided by its concentration in plasma when no diffusion occurs. The explanation for the discrepancy between S and σ values has been discussed in the section on pathways and barriers.

Size-Selectivity

Diffusion of solutes across the peritoneal membrane is a size-selective process. It means that small molecules diffuse at a faster rate than large molecules due to differences in their free diffusion coefficients. The question whether the peritoneal membrane is a size-selective barrier in itself can be analyzed by relating transport by diffusion of various solutes to their molecular weights. When a particle is an ideal sphere the relationship between its radius (r) and molecular weight (MW) is given by:

$$\mathrm{MW} = \frac{4}{3}\pi r^3 \tag{6.5}$$

The relationship between the free diffusion coefficient (D_f) of a solute and its radius is given in the Einstein-Stokes equation:

$$D_f = \frac{RT}{6\pi\eta r N} \tag{6.6}$$

in which R is Bolzmann's gas constant, T is the absolute temperature, η is the viscosity of the solvent, and N is Avogadro's number. This implies that, in the case of an ideal sphere, the free diffusion coefficient of a solute is related to the cubic root of its molecular weight:

$$D_f = a\mathrm{MW}^{-0.33} \tag{6.7}$$

in which a is a constant.

It is evident from the above that relationships between solute transport and molecular weight should be expressed as power functions:

$$y = ax^b \tag{6.8}$$

or

$$\ln y = b \ln x + \ln a \tag{6.9}$$

This implies that the power (b) is the slope of the correlation line that is obtained when x and y are plotted on a double-logarithmic scale. Most solutes are not ideal spheres. When the free diffusion coefficients in water of urea, glucose, and inulin were plotted against their molecular weights on a double-logarithmic scale, the slope of the correlation line was −0.46 [81, 82]. This implies that values up to −0.46 are consistent with free diffusion across the peritoneal membrane. In that case only the surface area determines the maximal transport capacity. Values exceeding −0.46 imply size-selectively restricted diffusion. This means that the membrane itself (the pore size or the interstitium) offers an additional size-selective barrier to the transport of solutes. For the clearances of low-molecular-weight solutes up to β_2-microglobulin (MW 11.8 kDa), a value of −0.44 was found during intermittent peritoneal dialysis [83]. During CAPD we found a value of −0.50 (Fig. 6.2).

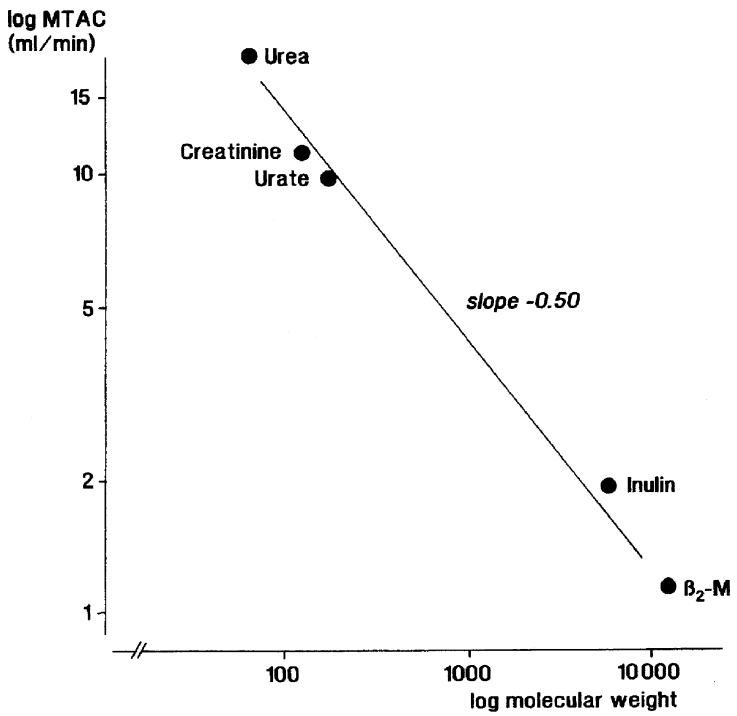

Fig. 6.2 The power relationships of MTAC of low- and middle-molecular-weight solutes with their molecular weights. Mean values are given. Based on data from [92, 98]. See text for explanation

These data give no indication for an important size-selective restriction barrier for low molecular weight solutes during peritoneal dialysis, but are more in favor of a transport process, similar to free diffusion in water, but in a colloid/water interstitial ground substance as vehicle for diffusion, instead of water. It follows from Eq. 6 that this will influence the magnitude of the diffusion rates, but the effects will be similar for all low-molecular-weight solutes. The functional or effective peritoneal surface area is mainly determined by the number of perfused peritoneal capillaries (the number of pores) in combination with interstitial resistances. No evidence is available that exogenous factors such as the hydration status of the interstitium would markedly influence MTAC of low-molecular-weight solutes. This contrasts with the observation that under basal circumstances only 25% of the peritoneal capillaries are perfused, and that this may be changed by exogenous stimuli (see section on regulation of peritoneal transport) [84]. In addition, it has been shown that splanchnic blood volume, not the flow rate, is an important determinant of peritoneal solute transport capacity [85]. It can therefore be concluded that the peritoneal vascular surface area is the main determinant of the MTAC of low-molecular-weight solutes. Consequently, the MTAC of such a solute, for example, creatinine, can be used as a functional measurement of the vascular peritoneal surface area. Changes in the MTAC of creatinine in individual patients are likely to reflect changes in their vascular peritoneal surface area.

Another approach to describe the size-selectivity of the peritoneal membrane is to relate MTAC of various solutes to their free diffusion coefficients in water, instead of to their molecular weights. This is based on the notion that the molecular weight of a solute is not the only determinant of its diffusion velocity. The density and the shape of a molecule can also have an effect. This is evident for nonprotein macromolecules, such as dextrans. Based on the equation: radius = 3.05 $MW^{-0.47}$ [86], as derived from the data of Granath and Kvist [87], it can be calculated that the dextran fraction with a diffusion radius identical to that of β_2-microglobulin (MW 820 kDa) has a molecular weight of only 4.6 kDa. For α_2-macroglobulin (MW 820 kDa) the molecular weight of the corresponding dextran fraction is 176 kDa [88]. Since diffusion is the most important mechanism for the transport of low-molecular-weight solutes, and restricted diffusion may be the most important mechanism for the transport of macromolecules, the establishment of power relationships between the MTAC of solutes and their free diffusion coefficients in water, is a more rational approach than the use of the molecular weights. A power relationship was found for peritoneal clearances (C) of proteins and their free diffusion coefficients in water (D_w) [89], according to the equation:

$$C = aD_w^{rc} \tag{6.10}$$

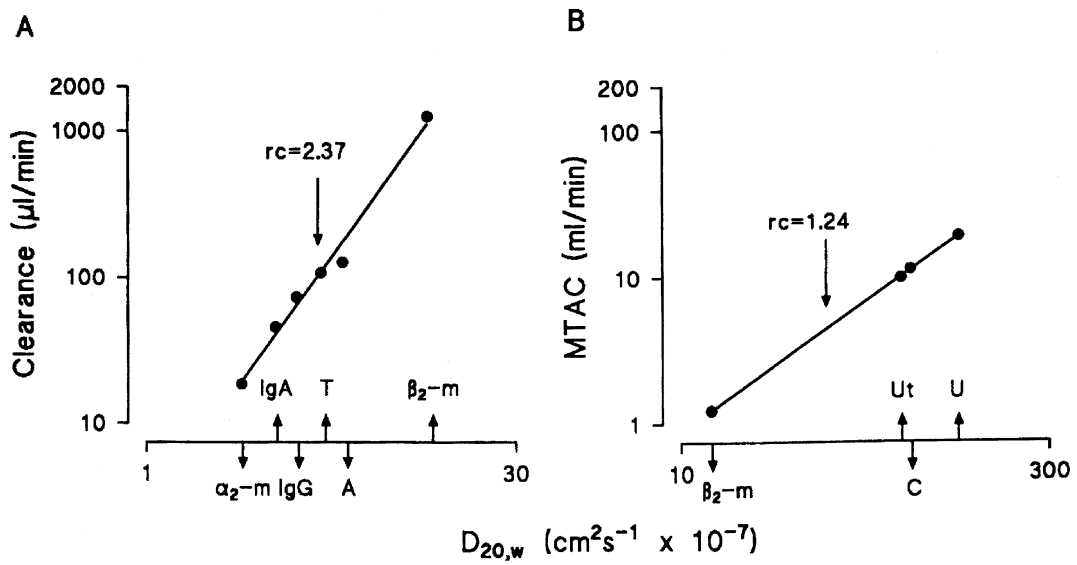

Fig. 6.3 The power relationship between MTAC of urea (U), creatinine (C), urate (Ut) and β_2-microglobulin (β_2-m) and their free diffusion coefficient in water ($D_{20,w}$) is given in panel (**a**) and the power relationship between the protein clearances of β_2-microglobulin, albumin (A), transferrin (T), IgG and α_2-macroglobulin (α_2-m) and their free diffusion coefficients in water is given in panel (**b**) All values are plotted on a double logarithmic scale. The slope of the regression line represents the restriction coefficient. A restriction coefficient of 1.0 means that a linear relationship is present between clearances of solutes and their free diffusion coefficients in water. For the low molecular weight solutes a slope of 1.24 ± 0.03 and for the proteins a slope of 2.37 ± 0.04 were found. Published with permission from [92] and from Blackwell Scientific Publications

Table 6.1 Relationship between parameters of solute transport and permeability characteristics of the peritoneal membrane

	Functional or vascular surface area	Size-selectivity or intrinsic permeability
MTAC or D/P ratio of low molecular weight solutes	+	–
Selectivity index or restriction coefficient to macromolecules	–	+

in which the slope (rc) was called the peritoneal restriction coefficient. The restriction coefficient represents the size-selective permeability of the peritoneal membrane: high values mean a low permeability. The application of the restriction coefficient in individual patients was validated both for proteins [90] and for dextran fractions [91].

A restriction coefficient that equals 1.0 means a linear relationship between MTAC and free diffusion coefficients, and no hindrance by the size-selective restriction barrier. In this situation differences in free diffusion coefficients of solutes are the only determinants of the differences in their clearances, and so the functional (vascular) peritoneal surface area is the only membrane characteristic that determines the differences in solute transport. In a study in 10 CAPD patients, a mean value for the restriction coefficient of 1.24 was found for low molecular weight solutes and of 2.37 for serum proteins (Fig. 6.3) [92]. These figures have been confirmed in a larger group of patients [93]. This is consistent with a mainly size-unrestricted diffusion process for low molecular weight solutes and a size-selectively restricted transport for macromolecules. In Table 6.1 a summary is given of the relationship between the parameters of solute transport and the permeability characteristics of the peritoneal membrane. The functional surface area can be characterized by the MTAC of creatinine. The size-selective permeability can be characterized by the calculation of the restriction coefficient. The functional surface area can be considered as a reflection of the number of pores, whereas the restriction coefficient mainly represents the size of the large pores and possible size-selective interstitial resistances.

Electric Charge

Glycosaminoglycans exhibit a negative electric charge. This is especially important in the glomerular basement membrane where the strongly negative charged glycosaminoglycan side-chains of heparan sulfate proteoglycan are involved in the charge-selective glomerular permeability [94]. Using ruthenium red staining, fixed negative charges have also been demonstrated in peritoneal tissue of rats not exposed to peritoneal dialysis [95], but with a much lower density than in the glomerular basement membrane. They were especially found on the basal lamina of the capillary endothelial cells and also along interstitial collagen fibers. It is, however, not established whether, and how, they influence solute transport during peritoneal dialysis. Intraperitoneal administration of protamine sulfate to rabbits led to increased concentrations of total protein in the effluent, that could be prevented by simultaneous administration of heparin [96]. This was interpreted as an effect of neutralization of anionic sites by protamine. Such an effect would particularly favor the transport of the negatively charged albumin molecules. A direct toxic effect on mesothelial cells leading to release of tissue proteins, however, could not be excluded [97]. No evidence for charge selectivity was found in a study comparing the transport of the negatively charged serum albumin with a dextran fraction of a similar diffusion radius in CAPD patients [98]. An opposite finding was reported in a study in rabbits that compared the transport of intravenously administered neutral and charged dextrans [99]. The positively charged dextrans were especially hindered in their transperitoneal transport. This could be explained by the assumption that the colloid-rich phase of the peritoneal interstitium behaves as a cation exchange column, facilitating the transport of negatively charged solutes through the tissue and retarding that of cationic macromolecules. Such effects are likely to disappear during steady-state conditions, as present for serum proteins during CAPD. In that situation the concentrations of serum proteins in the interstitium are probably in equilibrium with their plasma concentrations. Therefore, comparisons were made between the transport of proteins with (near)-identical sizes, but different charges. IgG subclasses range in isoelectric points between less than 6 and 8.7. Their clearances in CAPD patients were not different [100]. Comparisons between the peritoneal clearances of albumin and transferrin, β_2-microglobulin and lysozyme also gave no indication for a charge-selective barrier [101]. Only the clearances of lactate dehydrogenase (LDH) subclasses suggested charge selectivity. Observations during peritonitis showed that an alternative explanation is more likely. Fixed negative charges disappear during peritonitis [102], However, during peritonitis in CAPD patients signs of increased charge selectivity for LDH were found [101]. This could be explained by release of LDH by the cells present in the peritoneal effluent.

Taken together, most evidence points to an absence of charge selectivity of the peritoneum in the transport of macromolecules. This may be explained by the lower density of fixed negative charges in the peritoneum compared to the glomerular basement membrane. Another possibility might be the occurrence of loss of negative charges caused by the continuous exposure of peritoneal tissues to high glucose concentrations during peritoneal dialysis. Such loss has been shown to occur in the glomerular basement membrane in patients with diabetic nephropathy [103, 104]. Also a glucose-induced loss of endothelial glycocalyx might lead to loss of negative charge [105]. It is not known whether this phenomenon can also be observed in long-term peritoneal dialysis, or whether it has impact on peritoneal protein transport.

Peritoneal Blood Flow

The number of perfused peritoneal capillaries is dependent on peritoneal blood flow and blood volume [85]. Based on the anatomical situation, splanchnic blood flow is probably much more important than flow in the abdominal wall. Splanchnic blood flow averages 1,200 mL/min in normal adults [106]. Its distribution over the various splanchnic organs is markedly influenced by the instillation of dialysate. Experiments in rats, using microspheres, showed marked increases in the blood flow to the mesentery, omentum, intestinal serosa, and parietal peritoneum [15]. There was no effect on total splanchnic blood flow. Using the peritoneal clearance of hydrogen gas in rabbits [107], a value of 4.2 mL/min per kg body weight was found. Similar values could be calculated during peritoneal dialysis in rats with the microsphere technique [15]. Using the peritoneal clearance of carbon dioxide in rats an average value of 4.9 mL/min per kg was found after the instillation of an isotonic solution and of 8.1 mL/min per kg with a hypertonic dialysis fluid [108].

The relationship between peritoneal blood flow and solute transport in animals is only marginal. A reduction of blood flow in dogs by hemorrhagic hypotension caused only a 10–25% decrease in peritoneal urea clearance [109, 110]. More recent similar experiments in rats showed that a bleeding-induced reduction of peritoneal blood flow to 41% of the initial value decreased the MTAC of EDTA to 76% and that of glucose to 87% [111]. Instillation of sodium chromate in rabbits induces hepatic venous stasis leading to a decreased blood flow, but increased solute transport [85], indicating that peritoneal blood volume is more important than peritoneal blood flow. Intravenous isoproterenol in dogs increased peritoneal blood flow but had no effect on solute clearances [112]. Intraperitoneal isoproterenol resulted almost in a doubling of mesenteric blood flow, but this was accompanied by an increase in clearances of small solutes of only 20–30% [112]. More recent in vivo studies using a diffusion chamber in rats combined with laser Doppler flowmetry showed that a 70% reduction of blood flow did not alter the transfer rate of urea and mannitol across the abdominal wall [113] or hollow viscera [114]. Similar findings were done for osmotic water transport [115]. However, when blood flow was halted, the transport rates were reduced significantly. Only a reduction of the local blood flow to the liver induced significant decreases in solute transfer in this model [114], but the hepatic peritoneum makes up only a small portion of the effective exchange area. These studies imply that only a minimal blood flow is necessary for solute transport.

Estimation of peritoneal blood flow in peritoneal dialysis patients revealed lower values than in animals when expressed per kg body weight; it has been assumed to average 60–100 mL/min [116]. Studies in a limited number of intermittent peritoneal dialysis patients, using the peritoneal mass transfer area coefficient of carbon dioxide, yielded values ranging between 68 and 82 mL/min [117], or of about 150 mL/min [118]. Using the same technique in stable CAPD patients, values ranging from 20 to 151 mL/min were found in three studies using 1.36% glucose [119–121]. The median value averaged 66 mL/min. A much lower value of 25 mL/min has been estimated in one study [122, 123]. This was based on the relationship between the hydrostatic pressure and the plasma protein concentration obtained with a hollow-fiber hemofilter, and extrapolated to the situation in peritoneal dialysis. These authors also reported a linear relationship between blood flow and small solute clearances or ultrafiltration in an in vitro perfusion model of small vascular loops of isolated human peritoneal tissue [124, 125]. The "nearest capillary" hypothesis has been developed by the same group [126]. In this hypothesis it is assumed that the capillaries positioned closest to the mesothelium will be dilated and have low blood flow, while the most distal ones have the highest blood flow, but less effective diffusion due to interstitial resistances. The resulting "effective" peritoneal blood flow would be a limiting factor for solute clearances. It is difficult to predict to what extent the above models and hypotheses are important in clinical peritoneal dialysis.

In agreement with the data obtained in animals, the effects of peritoneal blood flow on solute transport in peritoneal dialysis patients are probably limited. This is supported by the following studies. (1) Effective peritoneal dialysis is possible in patients with intractable heart failure following an acute myocardial infarction [127], a condition in which decreased splanchnic blood flow can be expected. (2) CAPD with a 1.1% amino acid solution increased peritoneal

blood flow 55% compared to 1.36% glucose, but the increase in the MTAC of urea and creatinine averaged only 15% [119]. (3) Intraperitoneally administered nitroprusside had no effect on peritoneal blood flow [120, 128], but caused a marked increase in the MTAC of small solutes and macromolecules. These data make it likely that, similar to the situation in animals, peritoneal blood volume is more important than peritoneal blood flow in the transfer of solutes during peritoneal dialysis. Peritoneal blood volume can be increased by nitroprusside-induced vasodilation and by an increased venous pressure. This increased venous pressure is probably the explanation for the fact that effective peritoneal dialysis has been described in patients with severe congestive heart failure [129–133] and in patients with liver cirrhosis [134, 135].

Regulation of Surface Area and Permeability

In the previous section it has been shown that peritoneal blood flow is unlikely to be the main factor in the regulation of the peritoneal vascular surface area and permeability. Therefore endogenous substances with vasoactive properties may be involved. Plasma levels of catecholamines, vasopressin, aldosterone and plasma renin activity are elevated in CAPD patients [136–138]. This does not necessarily imply increased sympathetic activity, but could also be the result of a decreased clearance [137]. Dialysate levels of catecholamines have been measured in one study [136]. The dialysate/plasma ratio was 0.69 for epinephrine and 1.17 for norepinephrine, suggesting local production in the peritoneal cavity. A correlation was found between the dialysate levels of norepinephrine and the effective peritoneal surface area, represented by the mass transfer area coefficient of creatinine. Because this finding is the opposite of the effects of intraperitoneally administered norepinephrine, as will be discussed below, it may be that the large effective surface area causes the release of norepinephrine.

Prostaglandins and cytokines are likely to be produced locally in the peritoneal cavity during peritoneal dialysis. This has been shown for the prostaglandins 6-keto-PGF1α, prostaglandin E2 (PGE2), PGF2α, thromboxane B2 (TXB2), and 13,14-dihydro-15-keto-PGF2α [139–141]. The concentrations of the vasodilating prostaglandins exceeded that of the vasoconstricting ones. Drained peritoneal effluent also contains the cytokines tumor necrosis factor (TNF)α [142, 143], interleukin-1 (IL-1) [144, 145], IL-6 [146–148], and IL-8 [148]. The presence of TNFα in the dialysate of uninfected CAPD patients is probably caused by diffusion from the circulation [142, 143], while the other cytokines mentioned above are produced locally within the peritoneal cavity. A relationship has been reported between very high dialysate IL-6 levels in stable CAPD patients and a low peritoneal restriction coefficient, representing a high intrinsic permeability to macromolecules [147]. In that study, no relationship was found with the vascular peritoneal surface area. Marked elevations of prostaglandins and cytokines in dialysate are present during peritonitis [139–141, 146, 148, 149]. In addition, local production of TNFα also occurs during the acute phase of the inflammation [149]. It appeared that the increase in intrinsic permeability to macromolecules was especially correlated with dialysate PGE2 concentrations [149]. Intraperitoneal administration of indomethacin during peritonitis inhibited the increase of prostaglandins. This was accompanied by a reduction of the dialysate protein loss in one study [141], but this effect could not be confirmed in a longitudinal study during peritonitis [150]. Only a small effect on the peritoneal restriction coefficient for macromolecules was found [150]. Intraperitoneal indomethacin had no effect on peritoneal permeability characteristics in stable, uninfected peritoneal dialysis patients [151]. Relationships between cytokines in peritoneal effluent and permeability have been reviewed recently [152, 153].

Nitric oxide is the final common pathway for various vasodilating processes. Endothelial nitric oxide synthase (eNOS) is present in all types of peritoneal endothelia [71]. Nitric oxide is very rapidly converted into nitrite and nitrate. Dialysate concentrations of these metabolites have therefore been used to study possible involvement of nitric oxide in the regulation of peritoneal permeability. In contrast to nitrite in plasma, which is converted to nitrate, nitrite in fresh and spent peritoneal dialysis fluids is stable [121], but its concentration is much lower than that of nitrate. Comparing MTAC of nitrate with those of other solutes made it likely that dialysate nitrate concentrations in stable uninfected CAPD patients were dependent only on diffusion from nitrate from the circulation to the dialysate-filled peritoneal cavity [154]. Increased expression and activity of NOS, both endothelial and inducible, is present in a rat model of acute peritonitis [155]. Elevated dialysate nitrate concentrations have been found in some studies during the acute phase of peritonitis [154], but not in all [121]. Relationships between effluent nitrate levels and peritoneal permeability characteristics have not been established.

Possible effects of solutes, generally considered to be involved in the regulation of the permeability characteristics of the peritoneum, have been analyzed by studying transport kinetics during peritoneal dialysis after their intraperitoneal or intravenous administration. These include: 1) the dialysate itself; 2) hormones, such as catecholamines, gastrointestinal hormones and vasopressin; and 3) histamine and prostaglandins.

The administration of hypertonic and acid dialysate in the rat causes arteriolar vasodilation in the cremaster muscle preceded by an initial vasoconstriction [156–158], and also vasodilation of cecum arterioles [159]. This effect was more pronounced for acetate-buffered than for lactate-buffered dialysate, and also more pronounced for glucose 1.5% than for glucose 0.5%-containing dialysate. A more recent study using intravital microscopy confirmed that a conventional PD solution caused marked arteriolar vasodilation [160]. This effect was independent of the pH, but largely caused by the presence of glucose degradation products and to a lesser extent by the lactate buffer. The application of an iso-osmotic bicarbonate-buffered solution, which was not vasoactive in the rat cremaster muscle model, to patients treated with intermittent peritoneal dialysis, had no effect on the functional peritoneal surface area when compared with commercial dialysate [161]; however, it led to an increase in the total protein concentration of the dialysate. In further studies it appeared that this effect could not be explained solely by the osmolarity or pH of the dialysis fluid [162]. A more recent study using a single 4-h exchange with a hypo-osmotic bicarbonate-buffered solution confirmed the above findings for the clearances of individual plasma proteins [163]. However, clinical trials with bicarbonate-buffered glucose-containing solutions did not report alterations in the transport of low-molecular-weight solutes or dialysate protein loss [164–168].

Intravenously administered amino acids cause renal vasodilation [169, 170]. This effect is mediated by nitric oxide [171]. Therefore, effects on the permeability characteristics of the peritoneal membrane during CAPD could in theory be expected. However, the results of different studies on the use of amino acids are equivocal. In some studies, reviewed in [172], no effect was found on peritoneal transport [173–175], while others reported increased peritoneal protein loss [176–178]. This was accompanied by increased dialysate concentrations of PGE2. A study using a bicarbonate-buffered amino acid solution reported no effect on MTAC of low-molecular-weight solutes, increased peritoneal D/P ratios for serum proteins and increased dialysate concentrations of prostaglandins, IL-6, IL-8, and TNFα [167]. An effect on MTAC of low-molecular weight-solutes, reflecting the vascular surface area, was found in two studies [119, 179]. No increased protein clearances were present in these studies. Neither was an indication detectable for involvement of nitric oxide or prostaglandins likely [119]. It is possible that differences in the composition of the dialysis solutions can explain the divergent effects on peritoneal permeability characteristics.

Increasing the glucose concentration of the dialysis solution from 1.36 to 3.86% has no effects on the indices of the vascular peritoneal surface area or the intrinsic size-selective permeability [92]. Only the clearance of β_2-microglobulin is greater, with 3.86% glucose due to higher convective transport across the small pores [92]. The use of the glucose polymer icodextrin also increased β_2-microglobulin clearance [64, 180–182], but its administration has no effects on other peritoneal permeability characteristics [64, 180].

Intravenous administration of norepinephrine in rabbits leads to a decrease in vascular surface area as judged from the clearances of urea and creatinine [183]. In contrast, intravenous glucagon increases the clearances of urea and creatinine [184, 185]. As glucagon, a peptide with a molecular weight of 3484 Da, was not effective after intraperitoneal administration, these findings support a direct effect on the peritoneal microvasculature. The effects of glucagon have also been confirmed in dogs [112]. Vasopressin, administered either intraperitoneally [186] or intravenously [187], leads to a fall in solute kinetics consistent with a decreased effective peritoneal surface area. Topical application of histamine causes arteriolar vasodilation with leakage of proteins both in skeletal muscles and in the mesenterial vasculature [51, 188]. This would suggest an action both on the vascular peritoneal surface area and on the permeability to macromolecules. Intraperitoneal administration of histamine in rats caused a 10–20% increase in the clearance of urea [189]. This effect was not confirmed in rabbits in another study, but a marked increase was reported for the protein loss in the dialysate [190]. The histamine-induced protein loss could be blocked by a combination of H_1 and H_2 receptor antagonists. These antagonists were not effective when given alone or during desoxycholate-induced chemical peritonitis.

The possible role of prostaglandins on the functional peritoneal surface area has been studied by intravenous and intraperitoneal administration of vasodilating and vasoconstricting prostaglandins in rabbits [191–193]. In general, the effects were most pronounced after intraperitoneal administration. Arachidonic acid and the vasodilating prostaglandins led to an increase in the vascular peritoneal surface area, while the vasoconstricting PGF2α decreased the clearances of urea and creatinine. The oral administration of cyclo-oxygenase inhibitors had only a marginal effect. Combining these data with those obtained on effects of indomethacin in humans suggests that prostaglandins are not important in the regulation of peritoneal surface area and permeability during uninfected CAPD with glucose-based solutions.

Intraperitoneal administration of the direct nitric oxide donor nitroprusside in intermittent peritoneal dialysis patients causes an increase in clearances and MTAC of low-molecular-weight solutes and also in peritoneal protein loss [194, 195]. This effect markedly exceeded that of other vasodilators such as isoproterenol and diazoxide [194]. Nitroprusside, in combination with different buffer anions and varying pH, augmented peritoneal clearances in all solutions to a similar extent [196]. These effects of nitroprusside are also present during CAPD [120, 197]. In addition,

a decrease was found in the restriction coefficient to macromolecules [120]. Exposure of animal peritoneal tissues to nitroprusside caused opening of previously unperfused capillaries and increased the capillary pore area [195, 198]. These human and animal data all point to an effect of intraperitoneal nitroprusside on the peritoneal vascular surface area and the size-selective permeability to macromolecules. Involvement of nitric oxide in these processes was confirmed by an increase in the D/P ratio of the NO second messenger cGMP [120] and in the induction of an increased peritoneal albumin clearance after intraperitoneal administration of the nitric oxide substrate L-arginine in high dosages [198]. Administration of the NO inhibitor L-NMMA in this model had no effect on solute transport. These data suggest that nitric oxide is probably not involved in the regulation of peritoneal permeability during stable CAPD. The effects of nitroprusside should be regarded as a pharmacological phenomenon.

The peritoneal surface area and permeability are not only influenced by vasoactive substances, but physical phenomena might also affect them, such as position and intra-abdominal pressure. Most studies reported lower solute transport rates in the upright position than during recumbency [199–201], but another study did not report an effect of position [202]. Increasing the intraperitoneal pressure by the application of external pressure also decreased MTAC of low-molecular-weight solutes and clearances of serum proteins [203].

It can be concluded that many factors may be involved in the regulation of peritoneal surface area and permeability. Some of these factors have been identified but much uncertainty is present on the effects of many others.

Models and Parameters of Solute Transport

Because of the very complex structure of the various barriers to the peritoneal transport of solutes and fluid, the so-called distributed models are probably the most complete ones to describe peritoneal exchange [32, 204, 205]. They are, however, very complicated and based on a large number of assumptions. A much simpler approach is to consider the peritoneal tissues involved in the exchange of solutes and fluids as a single membrane that separates two well-mixed pools: the blood compartment and the peritoneal cavity compartment. In this membrane concept the peritoneal dialysis system is compared with an artificial membrane having cylindrical, fluid-filled pores, similar to the situation for transcapillary transport.

With these so-called "lumped" models the MTAC is determined. This parameter is the theoretical maximal clearance by diffusion at time zero, i.e., before solute transport has started. The MTAC can be calculated using very complicated models, but more simple equations can also be used. In general a distinction can be made between complicated numerical models and more simple analytical models (reviewed in [206]). The numerical models include those of Popovich and Pyle [207–209], Randerson and Farrell [210], Smeby et al. [211], and Waniewski et al. [212]. The analytical models generally start with the same mass balance equation, in which the accumulation of solutes in the peritoneal fluid in time is given by: $\mathrm{d}(VD)/\mathrm{d}t$, in which V is the dialysis volume and t is time. As this is the result of diffusion and convection, the mass balance equation using Eqs. 6.2–6.4 is:

$$\frac{\mathrm{d}}{\mathrm{d}t}(VD) = \mathrm{MTAC}(P - D) + 0.5J_{\mathrm{v}}(P + D)(1 - \sigma) \tag{6.11}$$

The most simple approach to solve this differential equation is to neglect the contribution of convective transport and to assume that the appearance rate of solutes in dialysate follows first-order kinetics. This is the basis of the Henderson and Nolph equation [213].

$$\mathrm{MTAC} = \frac{V_t}{t}\ln\left[\frac{P - D_0}{P - D_t}\right] \tag{6.12}$$

In this equation V_t is usually the drained dialysate volume. This method that can be considered a rough estimation has been used in a study on effects of various instilled volumes on the MTAC [214]. The Henderson and Nolph equation is especially useful during a period of isovolemia, as described by Lindholm et al. [215]. Correction for convective transport leads to the following equation:

$$\mathrm{MTAC} = \frac{V_t}{t}\ln\left[\frac{V_0^{1-f}(P - D_0)}{V_t^{1-f}(P - D_t)}\right] \tag{6.13}$$

in which f is a weighing factor between diffusion and convection, dependent on the transcapillary ultrafiltration, the sieving coefficient and the mass transfer area coefficient. When convection is relatively high compared to diffusion, f approaches zero. When diffusion is the principal transport mode, f rises to a limiting factor of 0.5. Garred et al. [216] developed a simple model based on multiple dialysate samplings, and assuming $f = 0$ and $S = 1$:

$$\text{MTAC} = \frac{V}{t} \ln \left[\frac{V_0(P - D_0)}{V_t(P - D_t)} \right] \tag{6.14}$$

This model could also be used taking samples only before instillation and after drainage, and taking the drained volume for V [217]. Waniewski et al. [218] pointed out that f values of 0.33 for a large degree of convective transport and of 0.5 for negligible convection are more justified. In addition, plasma concentrations of small solutes should be corrected for aqueous solute concentrations, either by a correction factor of 1.05 or using the total protein concentration in plasma [219]. However, in a comparison between the effect of 1.36% dialysate glucose and 3.86% glucose on the calculation of MTAC values for urea, creatinine, and urate, the difference was marginal between $f = 0$, 0.33, or 0.5 [92]. In all three models no significant difference was found for the MTAC of creatinine between the 1.36% glucose study (little convection) and the 3.86% glucose study (more convection). This indicates that all simplified models that correct for convective transport give MTAC values that represent diffusion, and that they are not influenced by convection to a clinically relevant degree. It should be appreciated that all simplified models use the intraperitoneal volume, instead of the volume that would have been present in the absence of lymphatic absorption, and also do not correct for solute loss due to uptake in the lymphatic system. However, the two factors are likely to compensate each other more or less.

The MTAC is usually calculated on solute concentrations obtained during 4–6 h exchanges. However, a number of studies have shown that MTACs are somewhat higher during the initial phase of a dwell, compared to the subsequent hours [16, 60, 92, 220, 221]. The explanation for this phenomenon is not clear, but it may be an aspecific reaction to the instillation of fresh dialysis fluids. It is one of the reasons that assessment of the MTAC by using solute clearances obtained during short dwell, as used in the mini peritoneal equilibration test, will overestimate MTACs [222]. Another problem with the use of short clearance periods is the relatively large contribution of time of inflow and drainage compared to the dialysis time, making it difficult to establish the precise dwell time. The contribution of convective transport will also be relatively large, leading to an inflated estimate of the MTAC.

Dialysate/plasma (D/P) ratios after a 4-h dwell and 24-h clearances are most often used in clinical practice. The time course of the D/P ratio of urea, creatinine and urate for a 1.36% glucose dialysis solution are shown in Fig. 6.4. It appears from this graph that D/P urea almost approaches 1.0. Consequently, the peritoneal clearance of this solute will mainly be determined by the drained dialysate volume. Therefore, the 24-h peritoneal clearance of low-molecular-weight solutes does not reflect their MTAC, but provides an overall estimation of the removal of urea (expressed as Kt/V_{urea}) and of creatinine. They can therefore be used as estimates of the adequacy of peritoneal dialysis with regard

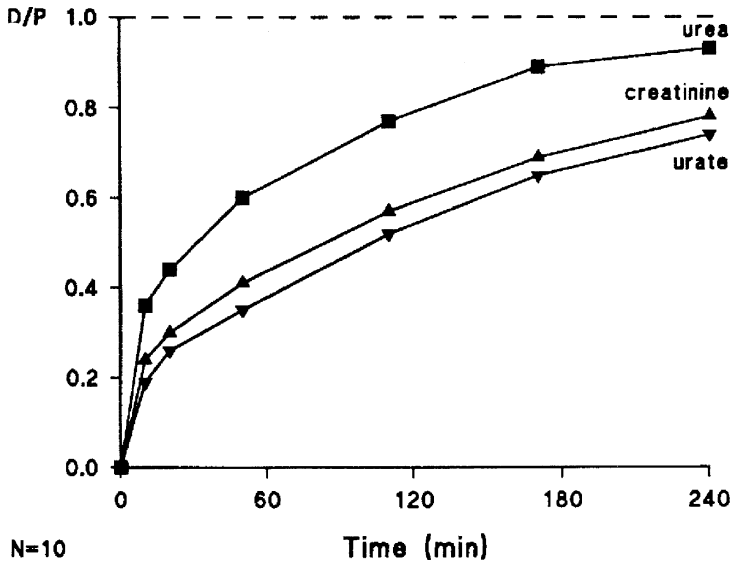

Fig. 6.4 The time-course of dialysate/plasma (D/P) ratios of urea (MW 60 Da), creatinine (MW113 Da), and urate (MW 168 Da). Mean values of 10 stable CAPD patients are given. Reprinted with permission from the Boerhaave Committee for postgraduate medical education of the faculty of medicine, Leiden University, The Netherlands

to solute removal. This is further discussed in Chapter 16. Good relationships are present between D/P ratios and MTAC [223, 224], but deviations from linearity are especially present in patients with very low and very high MTAC values [224]. D/P ratios overestimated the MTAC in the low ranges, whereas in the high ranges the MTAC values were underestimated. Both D/P ratios and MTAC have a high reproducibility in individual patients. This has been found for D/P ratios within a period of 3 months [225], but changes may occur in the long term [225, 226]. Using the simplified Garred model for the calculation of MTAC the intraindividual coefficient of variation averaged 7% [200].

Transport of Low-Molecular-Weight Solutes

Diffusion is quantitatively the most important transport mechanism for low-molecular-weight solutes, such as urea, creatinine, and uric acid. This is especially the case when the osmolality of the dialysate is low. Figure 6.5 shows the D/P ratios of urea and creatinine using 2.5% glucose-based dialysis solutions in the population of 86 patients studied by Twardowski et al. [227]. Normal values for the MTAC of urea, creatinine, and uric acid as obtained in a cross-sectional study using 1.36% glucose dialysate in 86 adult patients [224] are given in Table 6.2. Essentially similar values were found when a 3.86% glucose solution was used [228, 229]. Some relationship was present between MTAC creatinine and body surface area, but the variation is rather large. This suggests some relationship between peritoneal surface area and body surface area, but also underlines the fact that many other factors may influence peritoneal solute transport, such as the vascular peritoneal surface area. Nevertheless, MTAC are preferably expressed per 1.73 m^2 body surface area. A more detailed description of peritoneal function measurement is given in Chapter 15.

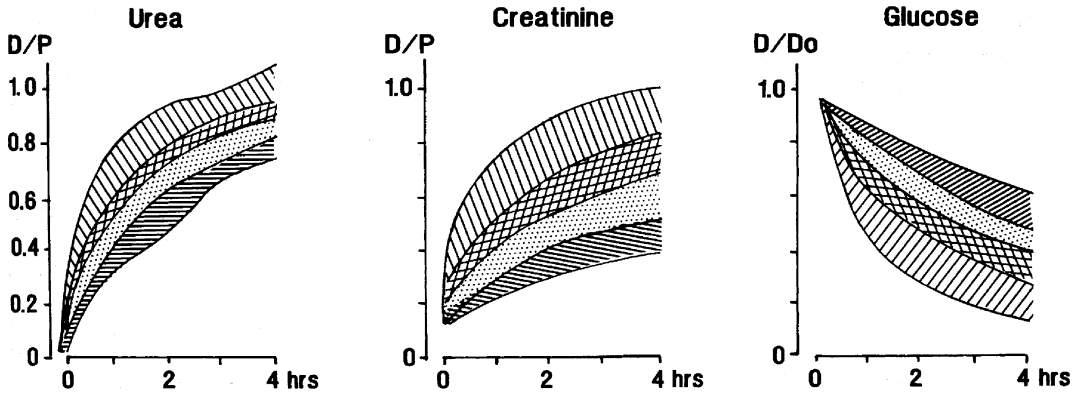

Fig. 6.5 The results of 103 peritoneal equilibration tests using glucose 2.5% dialysate. The upper zones of D/P ratios of urea and creatinine represent high transporters (> mean + SD), the adjacent zones high average transporters (between mean and mean + SD), the following zone (between mean and mean – SD) the low average transporters, and the lowest zone (< mean – SD) represents the low transporters. The same symbols, but in a mirror view, indicate the same transport categories for D/Do glucose. Redrawn from [228], with permission from the author and from Pergamon Press

Table 6.2 Normal values for the MTACs of low-molecular-weight solutes and clearances (Cl) of serum proteins (data from Ref. [226])

Parameter	Mean of normal distribution	95% Confidence interval
Simplified Garred model		
$MTAC_{urea}$ (mL/min per 1.73 m^2)	160	10.7–21.2
$MTAC_{creatinine}$ (mL/min per 1.73 m^2)	9.4	5.5–13.4
$MTAC_{urate}$ (mL/min per 1.73 m^2)	7.9	3.9–11.8
Waniewski model		
$MTAC_{urea}$ (mL/min per 1.73 m^2)	17.5	11.5–23.5
$MTAC_{creatinine}$ (mL/min per 1.73 m^2)	10.2	5.7–14.7
$MTAC_{urate}$ (mL/min per 1.73 m^2)	8.6	4.1–13.0
$Cl_{\beta 2m}$(μL/min/1.73 m^2)	853	400–1310
Cl_{alb} (μL/min/1.73 m^2)	89	34–144
Cl_{IgG} (μL/min/1.73 m^2)	45	15–76
$Cl_{\alpha 2m}$ (μL/min/1.73 m^2)	13	3–23

β_2m: beta-2-microglobulin; alb: albumin; α_2 m: alpha-2-macroglobulin

Transport of Electrolytes

The dialysate concentration of sodium decreases during the initial phase of a dialysis dwell using hypertonic solutions, followed by a gradual rise [55, 221, 230–233]. The minimum value is usually reached after 1 h. It is likely that this apparent sieving of sodium is caused by transcellular water transport through ultrasmall pores or, alternatively, temporal binding of Na^+ in the interstitial tissue. The time-course of the D/P ratio of Na^+ is shown in Fig. 6.6. Water transport rates are high during the initial phase of a hypertonic exchange; therefore, the decrease in dialysate Na^+ is a dilutional phenomenon [234]. This implies that during short dwells using hypertonic dialysate much more water than sodium is removed from the extracellular volume. This can lead to hypernatremia [235]. The gradual rise during the subsequent hours is probably caused by diffusion of sodium from the circulation. The effect of sodium diffusion on the D/P ratio of Na^+ is most marked in patients who also have high MTACs of other uncharged low molecular weight solutes [233].

The MTAC of sodium is difficult to calculate due to the small differences in dialysate and plasma concentrations. Using 3.86% dialysate glucose, an average value of 4 mL/min has been reported during a period of isovolemia [219, 231]. Using dialysate with a sodium concentration of 102–105 mmol/L, average values of 7–8 mL/min have been found [60, 236]. Corrections for Gibbs-Donnan equilibrium were applied in these calculations. The MTAC of chloride was 9 mL/min [60]. Both for Na^+ (MW 23 Da) and Cl^- (MW 35.5 Da), the MTAC values were considerably below those of urea (MW 60 Da), creatinine (MW 113 Da), and urate (MW 168 Da). As a consequence, these electrolytes are transported at a lower rate than expected on the basis of their molecular weight. The molecular radii of anhydrated sodium (0.98 Å) and chloride (1.81 Å) are also smaller than those estimated during peritoneal dialysis, based on computer simulations (2.3 Å for sodium and chloride) [17]. It is conceivable that interactions of these ions with H_2O molecules, leading to a water shell, may cause transport characteristics that suggest a higher molecular weight. In the study by Imholz et al., the calculated radius of sodium during peritoneal dialysis was 2.68 Å and that of chloride 2.42 Å [60]. The lower MTAC of sodium than that of chloride is in accordance with the lower permeability coefficient of sodium compared to that of chloride, present for transport across synthetic lipid bilayer membranes in vitro [231].

The Na^+ concentration that is most currently used in dialysis fluids is close to or slightly lower than the plasma Na^+ concentration, that is, Na^+ transport is accomplished almost in the so-called isocratic condition. Therefore, the diffusive transport component plays a minor role in peritoneal Na^+ transport, except in patients, where a high Na^+ gradient is present and that have a large vascular surface area. In general, however, convection, including ultrafiltration-induced Na^+ transport and transport by peritoneal absorption, dominates Na^+ transport [233]. Similar mechanisms apply for the transport of calcium [233, 237].

The finding that sodium diffuses as a larger molecule during peritoneal dialysis has focused attention on the potential use of ultra-low sodium dialysis solutions to improve net ultrafiltration, especially as Nakayama et al. reported favorable results of such a solution in overhydrated CAPD patients [238]. In two studies comparing dialysate with a normal sodium concentration with a dialysate containing an ultra low sodium concentration and that was made isosmotic by addition of more glucose, a slightly better net ultrafiltration was found with the low-sodium dialysate:

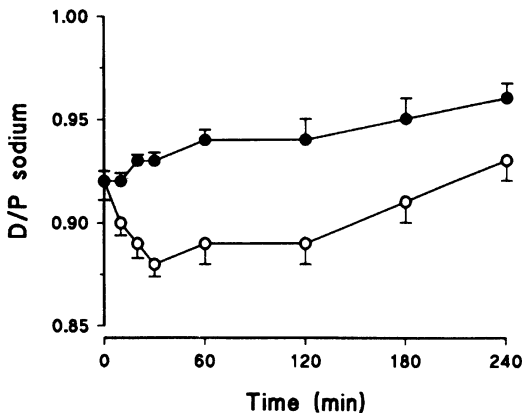

Fig. 6.6 The D/P sodium ratios in a group of 10 CAPD patients with normal net ultrafiltration (based on data from [92]). Mean and SEM values obtained with 1.36% glucose are presented as closed dots and those obtained with 3.86% glucose-based dialysate are presented as open dots. Published with permission of Multimed Inc

about 100 mL during a 6-h dwell [60, 239]. This difference could be explained by the calculated reflection coefficient of glucose (0.0326), that was slightly higher than the reflection coefficient of sodium (0.0297).

The clearance of potassium by diffusion during intermittent peritoneal dialysis averages about 17 mL/min [240]. Average MTAC values between 12 and 16 mL/min have been reported in CAPD patients [60, 219, 231], in between those of urea and creatinine. During the first hour of a dwell the value is 24 mL/min [60]. The most probable explanation for these high values is release of potassium from the cells that line the peritoneal cavity. This may be promoted by the initial low pH and/or by the hyperosmolality of the instilled dialysate. It is also supported by the finding of sieving coefficients of potassium exceeding 1.0 [180, 218]. It can be concluded that charged electrolytes are transported at lower rates than expected on the basis of their molecular weights, irrespective of the charge being positive or negative. For potassium release from intracellular sources during the initial phase of a dialysis dwell is likely to occur.

The standard peritoneal dialysis solutions contain 1.75 mmol/L Ca^{2+} and 0.75 mmol/L Mg^{2+}. The normal ionized concentrations of these electrolytes in plasma are 1.25 mmol/L for Ca^{2+} and 0.55 mmol/L for Mg^{2+}. Consequently, peritoneal dialysis will lead to mass transfer from the dialysate to the circulation by diffusion, especially when dialysis solutions inducing little convective transport are used. A positive mass transfer for Ca^{2+} of 0.96 mmol/4 h exchange and for Mg^{2+} of 0.21 mmol/4 h exchange has been found in stable CAPD patients using 1.36% glucose-based dialysate [241]. The balance will approach zero when 3.86% glucose is used because of convective transport from blood to dialysate, counterbalancing the diffusion [233, 241].

The MTAC of bicarbonate (MW 61 Da) has been reported to average 18 mL/min in intermittent peritoneal dialysis [242]. This may be an overestimation because of the short dwell time employed. From a more recent study using 24 h collections, an average value of 9.5 mL/min can be calculated [243]. The bicarbonate loss with the dialysate is slightly greater than the lactate gain using 35 mmol/L lactate [241], but a dialysis alkali yield of 31 mmol/day has been found in CAPD patients using 40 mmol/L lactate [243]. The total mass transfer of bicarbonate from the circulation to the dialysate is determined by the plasma bicarbonate concentration and the ultrafiltration rate [244, 245]. Bicarbonate loss is especially increased during high ultrafiltration rates due to additional convective transport.

Transport of Macromolecules

Macromolecules, such as serum proteins, are transported from the circulation to the peritoneal cavity at a much lower rate than low-molecular-weight solutes. Therefore, their dialysate concentrations are low and do not reach equilibrium with serum. Consequently, their clearances can be used as an approximation of MTAC. Normal values for the clearances of β_2-microglobulin (MW 11.8 kDa), albumin (MW 69 kDa), IgG (MW 150 kDa), and α_2-macroglobulin (MW 820 kDa) are given in Table 6.2. The transport of macromolecules is size-selective, both for proteins and uncharged dextran molecules [88, 246]. Similar to low-molecular-weight solutes, the relationship between clearances and molecular weights can be described as a power relationship [246, 247]. The slope of the regression line between molecular weights and clearances is however much steeper (−0.69) than that between molecular weights and free diffusion coefficients (−0.36) [246]. This indicates that the transperitoneal transport of macromolecules is hindered by a size-selective restriction barrier within the peritoneal membrane. Unlike the transport of low-molecular-weight solutes, that is mainly dependent on the functional surface area of the peritoneum, the transport of macromolecules is determined both by surface area and intrinsic size-selective permeability.

It is still controversial whether the main transport mechanism of macromolecules during peritoneal dialysis is by convection [248, 249] or by restricted diffusion [51, 98, 250, 251]. In vitro studies using endothelial monolayers on polycarbonate filters suggest that macromolecular transport in this system is caused by both diffusion and convection [252]. Restricted diffusion was especially present with highly confluent monolayers on filters with pores of about 400 Å, a situation probably similar to that in peritoneal dialysis. Convection requires fluid transport. This can occur by hydrostatic forces and by osmotic forces. An effect of osmotically induced convection has been demonstrated only for the low-molecular-weight protein β_2-microglobulin, but not for larger proteins such as albumin, transferrin, IgG, and α_2-macroglobulin, which are transported through the large pores [92]. A mathematical approach has been used in an attempt to demonstrate that proteins larger than 50 Å reach the peritoneal cavity exclusively by hydrostatic convection through the large pore system [62]. However, this can occur only when the pressure in the peritoneal blood vessels exceeds that in the interstitial tissue. The intraperitoneal pressure during CAPD averages 8 mmHg during recumbency [199]. This value is lower than that in the arterioles, but similar to that in the venules. This implies that the localization

of the large pores determines whether hydrostatic convection across them is likely to occur. Increasing the intraperitoneal pressure by 10 mmHg with the application of external compression decreased the clearances of proteins [203]. This effect was most pronounced for proteins with the highest molecular weights, suggesting an effect on the size of the pores. The measured data could be explained by convection through large pores with a radius of about 180 Å, but also by diffusion through large pores with an average radius of 1,000 Å. The large venular inter-endothelial gaps with radii from 500 to 5,000 Å, which can be found after the application of vasoactive substances, such as histamine [51], suggest that the latter value is not unrealistic.

It can be concluded that the peritoneal transport of albumin and larger proteins presumably occurs through the large pore system, and is size-selectively restricted. The mechanism involved may be restricted diffusion, or hydrostatic-induced convection, or a combination of the two, as has already been suggested by Renkin [37]. The localization and size of the large pore system determine which mechanism prevails.

Transport from the Peritoneal Cavity

Low-Molecular-Weight Solutes

The disappearance rate of intraperitoneally administered low molecular weight solutes from the dialysate is dependent on their molecular weights [82, 253]. This suggests a mainly diffusive process. As a consequence the absorption of lactate during a 4-h dialysis dwell was found to average 82% of the instilled quantity (data from [82]). For glucose a mean value of 66% has been reported, irrespective of the glucose concentration used in the dialysate [254]. This could range between 51 and 80% in individual patients. When the disappearance of glucose is expressed as the ratio between the dialysate concentration after a 4-h dwell and the initial dialysate concentration (D/D_0), as is usually done during PET tests, values ranging from 0.12 to 0.60 can be found [227]. Other low-molecular-weight solutes that can be used as osmotic agents during peritoneal dialysis, such as glycerol and amino acids, are also absorbed according to their molecular weights. The absorption of glycerol (MW 92 Da) averages 71% after a 4-h dwell [255] and 84% after a 6-h dwell [256], and that of amino acids (mean MW 145 Da) 73–90% [175, 257]. The absorption of these solutes by diffusion occurs mainly in the portal circulation [258].

Babb et al. were the first to study bidirectional solute transport [259]. This was done by comparing mass transfer area coefficients of radiolabeled sucrose and vitamin B_{12} in the same patients after intravenous and intraperitoneal administration. Higher MTAC values were found after intraperitoneal administration. Similar results have been reported for the clearances of the non-protein-bound antibiotics fosfomycin [260] and cefamandole [261], as well as for inulin [262, 263]. A difference between MTAC values after intravenous and intraperitoneal administration of the same order of magnitude is present when transport rates of endogenous creatinine and albumin are compared to those of intraperitoneally administered solutes with an almost identical molecular weight [253, 264]. These data are summarized in Table 6.3. When we assume that the peritoneal restriction barrier is symmetric in its hindrance to diffusion, i.e., there is bidirectional equivalency to diffusive mass transfer, then a molecular-weight-independent, convective transport out of the peritoneal cavity of 1–2 mL/min should be present for solutes that are administered intraperitoneally. Although such a bidirectional equivalency to diffusion has not been proven definitely, it is supported by the fact that the absolute difference between intravenous and intraperitoneal administration is always of the same order of magnitude, irrespective of the size of the solutes. However, the relative difference (compared to the MTAC after intravenous administration) ranges from 16% for low molecular weight solutes such as creatinine, to more than

Table 6.3 Comparison of bidirectional transport of solutes with similar molecular weights. Transport rates are expressed as mass transfer area coefficients (MTAC). Only paired data are used

Solute (IV/IP)	Molecular weight (dalton)	IV administration (mL/min)	IP administration (mL/min)	Absolute difference (mL/min)	Relative difference (%)
MTAC creatinine/ 5-flucytosine [257]	113/129	16.10	19.20	3.10	19
MTAC sucrose [263]	360	5.48	7.56	2.08	38
MTAC vitamin B_{12} [263]	1,355	3.30	4.85	1.55	47
MTAC inulin [266]	5,500	1.83	3.17	1.35	74
CI albumin/ hemoglobin [268]	69,000/68,000	0.12	1.53	1.43	1192

1,000% for albumin. When diffusion would not occur equally in both directions, but would always be systematically higher for intraperitoneally administrated solutes, a constant relative difference would have been expected. Furthermore, Leypoldt et al. compared the bidirectional transport of creatinine in rabbits using a kinetic model that included convective solute transport out of the peritoneal cavity, and found identical MTAC values [265]. This confirms the presence of a size-independent transport out of the peritoneal cavity from 1 to 2 mL/min.

The higher solute transport rates after intraperitoneal administration due to convection imply that MTAC calculations do not represent diffusion only, when they are calculated with simplified models that do not take into account convective transport out of the peritoneal cavity. This convective leak is probably caused by the lymphatic drainage from the peritoneal cavity, and by transmesothelial transport to the peritoneal interstitial tissue induced by abdominal pressure. The contribution of convection to diffusive transport is relatively small for low-molecular-weight solutes, but becomes increasingly more important the higher the molecular weight of a solute. The convection/diffusion ratio is about 0.1 for glucose, 1.0 for inulin [262], but 10 for intraperitoneally administered autologous hemoglobin [264], making the disappearance rate of macromolecules relatively independent of molecular size (see below).

It can be concluded that the absorption of intraperitoneally administered molecules is partly size-selective (diffusion) and partly non-size-selective (convection). The relative contribution of convection increases the higher the molecular weight of the solute. Size-selectivity is therefore most pronounced for solutes with a molecular weight of less than 500.

Effects of Bidirectional Anion Transport on Acid-Base Status

Lactate used in peritoneal dialysis fluids usually consists of a racemic mixture of L- and D-lactate. One study reported a greater absorption of L-lactate than of D-lactate in chronic peritoneal dialysis patients [266], similar to the stereospecificity of the blood-brain barrier [267]. However, in more recent studies similar peritoneal absorption rates were found for L- and D-lactate [268]. Absorbed L-lactate is converted by L-lactate dehydrogenase to pyruvate and then metabolized to bicarbonate. Lactate dehydrogenase is stereospecific and does not convert D-lactate. Accumulation of D-lactate could in theory cause metabolic acidosis. Such a D-lactate acidosis has been described in patients after extensive bowel surgery with bacterial overgrowth [269, 270]. In this situation the abnormal gut flora produced very large amounts of D-lactate. D-lactate can be metabolized in mammals, although slowly, probably by the enzyme D-2-hydroxy acid dehydrogenase [269]. Yet the capacity of the liver to metabolize D-lactate is probably sufficient for intravenous or intraperitoneally administered lactate solutions. Infusion of L- and D-lactate in the portal circulation of dogs showed hepatic extraction rates that were not different for both isomers [271]. Also, metabolic acidosis due to accumulation of D-lactate has not been found in peritoneal dialysis patients [242, 268, 271]. Impairment of lactate metabolism probably occurs only in patients with poor hepatic function [272].

Net base balance in patients treated with peritoneal dialysis is mainly dependent on the difference between the dialysate base gain (the difference between the mass transfer of bicarbonate and lactate) and the production of metabolic acids. As the latter is related to the breakdown of proteins, a relationship with the protein equivalent of nitrogen appearance (PNA) can be expected. Gotch et al. showed that the PNA multiplied by 0.77 corresponds well to the production of metabolic acids in stable patients [273]. Indeed, a negative relationship has been found between blood bicarbonate concentration and the estimated metabolic acid production [244]. The lactate mass transfer from the peritoneal cavity will be greatest during the beginning of a dwell, when the dialysate lactate concentration is highest. As a consequence, increasing the dialysis dose by performing more exchanges will increase the alkali gain. This explains the metabolic alkalosis that has been described in patients treated with high-dose CAPD [274]. The potential of bicarbonate-containing dialysis solutions in correcting acid-base disorders of CAPD patients is not essentially different from that of lactate-based fluids [245]. The net bicarbonate gain appeared to correlate with the ultrafiltration rate, the plasma bicarbonate level, and the dialysate bicarbonate concentration [275]. Similar to lactate-based solutions, the ultrafiltration rate was the predominant parameter. A dialysis solution with a combination of bicarbonate and lactate as buffer also showed good control of acid–base status [166, 168].

The use of acetate as a buffer has now been abandoned because of its association with the development of peritoneal sclerosis [276–278]. Comparison of acetate- with lactate-based dialysis solutions showed that the rise in pH after instillation was more rapid with lactate [279]. Using acetate, 18 min were required to reach a dialysate pH of 7, while this was only 7 min for lactate. The most probable explanation is the higher buffer capacity of acetate ($pK_A = 4.76$) compared to lactate ($pK_A = 3.86$) at pH = 5.6. This difference in pK_A is the reason for the much higher content of titrable acid in acetate than in lactate-buffered dialysis fluid [279].

Macromolecules

Particles, such as blood cells and bacteria, that are introduced into the peritoneal cavity, are absorbed in the diaphragmatic lymphatics (reviewed in [13]). It is therefore not surprising that a proportion of intraperitoneally administered macromolecules, during peritoneal dialysis, also disappears from the peritoneal cavity. Gjessing used dextran 70, 60 g/L as a dialysis solution in peritoneal dialysis patients treated with 30-min dwells. The recovery of dextran 70 in the dialysate averaged 92% after the dwell, while the plasma concentration increased to 1 g/L after 8 h dialysis and even to 4 g/L after 24 h [280]. Recoveries of intraperitoneally administered macromolecules of 70–90% after 4–7 h dwells in patients have been reported for radioiodine-tagged serum albumin [275, 281–285], for unlabeled human albumin [286], for dextran 70, 10 g/L [287] and 1 g/L [288], and for autologous hemoglobin [263, 284]. In only one study has a recovery of autologous hemoglobin in excess of 95% been reported [289]. A high recovery of one batch of unlabeled human albumin was found in another study [290]. This was shown to be caused by a high transport of endogenous albumin, because this particular batch contained a high concentration of prekallikrein activator that caused an inflammatory reaction.

The disappearance rate of intraperitoneally administered macromolecules is independent of molecular size, both in animals [25, 291, 292] and in CAPD patients [293]. Furthermore, it is linear in time [288–294]. In one study it was influenced by the osmolarity of the dialysis solution [284], but other studies could not confirm this [92, 294]. The disappearance rate is increased after the instillation of large dialysate volumes [82], and after the application of external pressure [202, 295]. It is likely that a proportion of the intraperitoneally administered macromolecules is taken up directly into the subdiaphragmatic lymphatic vessels, as has been shown in experiments using india ink [296]. Transmesothelial uptake, especially in the anterior abdominal wall, has been shown in rats using radiolabeled fibrinogen [297] and radiolabeled albumin [26]. Uptake of radiolabeled albumin in peritoneal tissues is also likely to be present in peritoneal dialysis patients [281]. The macromolecules transported to the interstitial tissue are probably taken up slowly in the lymphatic system, as continuous intraperitoneal administration of dextran 70 in CAPD patients had no effect on the magnitude of its disappearance rate from the peritoneal cavity [288].

In summary, the above data from the literature point to the presence of a non-size-selective mechanism for the disappearance of macromolecules from the peritoneal cavity. They are partly taken up directly by the subdiaphragmatic lymphatic vessels and partly in the peritoneal interstitium. Subsequent uptake into the lymphatics that drain the interstitial tissues is likely to occur.

Fluid Transport

Transcapillary Ultrafiltration

Fluid transport during peritoneal dialysis consists of water transport from the peritoneal capillaries into the peritoneal cavity by transcapillary ultrafiltration and by fluid loss out of the peritoneal cavity. The latter consists of transcapillary back-filtration and by fluid uptake into the lymphatic system. As a consequence, the changes in the in situ intraperitoneal volume are determined by the magnitude of the transcapillary ultrafiltration and lymphatic absorption. The water removal from the body at the end of a dwell period, defined as net ultrafiltration, is therefore the difference between the cumulative transcapillary ultrafiltration and fluid uptake into the lymphatic system.

The transport of water across the capillary wall occurs through the small pore system and through aquaporin-1, localized in endothelial cells of peritoneal capillaries and venules (see section on pathways and barriers). The small pores are mainly involved in transport by hydrostatic and colloid osmotic forces, transport through the ultrasmall pores is dependent on the osmotic gradient across the endothelial cells. Using the three-pore model it has been assumed that, during CAPD, 40% of the filtered fluid volume passes through transcellular water channels [62]. Using the relationship between the peritoneal removal of sodium and water during the first hour of a dialysis dwell with a 3.86%/4.25% glucose dialysis solution [222], a similar value for free water transport could be calculated in stable PD patients, but with a very large variation among the patients [65, 298].

According to Starling's law, the transcapillary ultrafiltration rate in peritoneal dialysis is determined by the ultrafiltration coefficient of the peritoneal membrane and the driving forces between the peritoneal capillaries and the abdominal cavity. These forces are exerted by hydrostatic, crystalloid osmotic, and colloid osmotic pressure gradients. The dependency of the transcapillary ultrafiltration rate (TCUFR) can be described by the following equation:

$$\text{TCUFR} = \text{UFC}(\Delta P - \Delta\Pi + \sigma\Delta O) \tag{6.15}$$

in which UFC is the peritoneal ultrafiltration coefficient, ΔP is the hydrostatic pressure gradient, $\Delta\Pi$ is the colloid osmotic pressure gradient, σ the reflection coefficient and ΔO the crystalloid osmolality gradient. The ultrafiltration coefficient of the peritoneum is the product of the hydraulic permeability and surface area. Little is known about determinants of the hydraulic permeability, which is most likely dependent on the combination of intracapillary pressure, and the number and size of the pores. The state of the interstitial tissue, possibly containing sites of fibrosis, may also be one of the determinants. In computer simulations of peritoneal transport, values of 0.04 and 0.08 mL/min per mmHg have been calculated for the ultrafiltration coefficient [63].

The hydrostatic pressure in the peritoneal capillaries is assumed to be 17 mmHg [299]. The intraperitoneal pressure during CAPD has been reported to average 2 mmHg [300] and 8 mmHg [200, 203] in the supine position, depending on the choice of reference point. It exceeds 20 mmHg while walking [300], and is dependent on the instilled dialysate volume [301]. This implies that the hydrostatic pressure gradient is determined mainly by the intraperitoneal pressure. The colloid osmotic pressure in the peritoneal capillaries probably averages 26 mmHg [299]. In CAPD patients who have a mean serum albumin concentration of 34 g/L [302], a value of 21 mmHg can be calculated [64]. The contribution of the dialysate to the colloid osmotic pressure gradient can be neglected because of its low protein content. The crystalloid pressure gradient is mainly determined by glucose. The effectiveness of this osmotic agent depends on the resistance the membrane exerts on its transport. This is expressed as the osmotic reflection coefficient (see section on pathways and barriers); it can range from 1 (no passage, ideal semipermeable membrane) to 0 (passage not hindered, no osmotic effect). In case of a reflection coefficient of 1, every mosmol exerts an osmotic pressure of 19.3 mmHg according to van't Hoff's law. The reflection coefficient for glucose during CAPD is very low, probably between 0.02 and 0.05 [57–61]. It must be appreciated, however, that these are mean values. The reflection coefficient for glucose across the ultrasmall pores will be 1.0, and will approach zero across the large pores. This might explain why glucose is an effective osmotic agent despite its small size.

The hyperosmolality of commercial dialysis fluid when compared to uremic plasma is about 45 mosmol/kg H_2O for the lowest glucose concentration (1.36%) and 180 mosmol/kg H_2O for the highest glucose concentration (3.86%). The osmotic pressure exerted by these solutions across the peritoneal membrane can therefore be estimated as 45×0.03 (reflection coefficient) $\times$ $19.3 = 23$ mmHg (lowest glucose concentration), and similarly 104 mmHg (highest glucose concentration). The various pressure gradients are summarized in Table 6.4. The values for the crystalloid osmotic pressure gradients are the maximum values, as present during the initial phase of a dialysis dwell. They will decrease in time due to absorption of glucose from the dialysate. This glucose absorption averages 61% of the instilled quantity during a 4-h dwell [224] and 75% after 6 h [231]. The absolute, but not the relative, absorption is influenced by the glucose concentration used [254]. As a consequence the transcapillary ultrafiltration rate has its maximum value at the start of dialysis and decreases during the dwell. The figures given in Table 6.4 imply that dialysate with a low glucose concentration will induce only a small amount of osmosis-induced transcapillary ultrafiltration. The maximal transcapillary ultrafiltration rate with 1.36% glucose during the initial phase of a dwell averages 2.7 [119] to 4.3 mL/min [63]. With 3.86% glucose-based dialysate, the initial transcapillary ultrafiltration during 4-h dwells averages 12–16 mL/min [63, 92, 232, 303]. Mean values for transcapillary ultrafiltration during 4-h dwells average 1.0–1.2 mL/min for 1.36% glucose [92, 119, 224] and 3.4 mL/min for 3.86% glucose [92]. The osmotic conductance to glucose determines its effectiveness as an osmotic agent. Mathematically, it can be expressed as the product of the ultrafiltration coefficient and the reflection coefficient. On average a value of 4.5 μL/min/mmHg can be calculated [304].

Dextrins are glucose polymers that can also be applied as osmotic agents during peritoneal dialysis. Icodextrin is a disperse mixture of dextrins with an average molecular weight of 16.8 kDa that is currently used in clinical practice

Table 6.4 Pressure gradients across the peritoneal membrane during the initial phase of a peritoneal dialysis exchange

	Pressure in peritoneal capillaries	Pressure in dialysate-filled peritoneal cavity	Pressure gradient
Hydrostatic pressure (mmHg)	17	8 recumbent	9
Colloid osmotic pressure (mmHg)	21	0.1	–21
Osmolality (mosmol/kg H_2O)	305	347 (glucose 1.36%)	
		486 (glucose 3.86%)	
Maximal crystalloid osmotic pressure gradient (mmHg)		(glucose 1.36%)	24
		(glucose 3.86%)	105

The reflection coefficient of low molecular weight solutes is set at 0.03

[305]. Due to its high molecular weight, icodextrin is likely to induce colloid osmosis [306]. This implies that macromolecules are able to induce transcapillary ultrafiltration even in an isotonic or hypotonic solution. The process of colloid osmosis is based upon the principle that fluid flow across a membrane that is permeable to small solutes, occurs in the direction of relative excess of impermeable large solutes, rather than along a concentration gradient. Consequently, dialysis solutions containing macromolecules to remove fluid from the body will induce water transport through the small pore system. When such a solution is not hypertonic, no water transport will be induced through the ultra-small water channels. The pressure gradients across the peritoneal membrane that can be expected using a 7.5% icodextrin-based dialysis solution are shown in Table 6.5. It follows from this table that the maximum pressure gradient across the peritoneal membrane is 42 mmHg, which is higher than the 12 mmHg exerted by 1.36%/1.5% glucose, but markedly less than the 93 mmHg exerted by 3.86%/4.25% glucose. However, because of its lower absorption than glucose, the gradient will remain present for a much longer time. It must, however, be realized that icodextrin is a polydisperse solution with a wide range of molecular weights, which might influence the overall values [307]. Using 7.5% icodextrin a UFC of 0.05 mL/min per mmHg can be calculated. This value can be employed to estimate the back-filtration of dialysis fluid into the capillaries by the colloid osmotic pressure gradient: back-filtration rate = 0.05 (9–21) = 0.6 mL/min. In a previous study using a dialysis solution without an osmotic agent, the overall back-filtration rate was 0.9 mL/min during a 4-h dwell [163]. It was highest during the start of the dwell (2.6 mL/min), because the solution was hypotonic to uremic plasma, and averaged 0.4 mL/min during the last 2 h. A value of about 1 mL/min can be calculated on data from a study using intraperitoneal 0.9% NaCl [281].

The absorption of icodextrin averaged 19% during an 8-h exchange [308]. Therefore, the transcapillary ultrafiltration rate induced by it is almost stable during an exchange [64, 309] and averages 1.4–2.3 mL/min [64, 309]. This could explain why icodextrin-based dialysis solutions are especially effective during dwells of 8–12 h [310].

Lymphatic Absorption

Direct measurement of the lymphatic flow from the peritoneal cavity is impossible in humans; therefore, indirect methods have been used. They include the disappearance rate (clearance) of intraperitoneally administered macromolecules from the peritoneal cavity, and their appearance rate in the circulation. Using the disappearance rate it is assumed that the administered macromolecule is removed from the peritoneal cavity by absorption into the lymphatic system. Human albumin [286], radioiodinated serum albumin (RISA) [221, 231, 285], autologous hemoglobin [232, 264, 284, 289], and dextran 70 [287] have all been used. This approach is justified because the disappearance rate of these solutes is constant in time [288, 294] and independent of molecular size [293] (see also the section on transport from the peritoneal cavity). Using these tracers average values of 1.0–1.5 mL/min have been found in CAPD patients [221, 224, 231, 264, 285–287,]. Local accumulation of intraperitoneal RISA has been found in the anterior abdominal wall of rats [26], most likely caused by transmesothelial transport. It is probable that macromolecules in the peritoneal interstitial tissue will eventually be taken up into the lymphatic system, as has been made plausible in mice [311]. This is supported by the observation that saturation of the peritoneal interstitium in CAPD patients by continuous administration of dextran 70 did not alter the appearance rate of this macromolecule [288]. Measurement of appearance rates requires the use of radiolabeled traces like RISA, because the plasma concentrations of the other markers, after a single intraperitoneal administration are too low. Comparing both methods using RISA, it appeared that the appearance rate in the circulation was only about 20% of the disappearance rate [281, 282]. Furthermore, the appearance rate shows remarkably little variability [312]. Half of the difference between the disappearance and appearance rates can be explained by the fact that only 40–50% of the total albumin mass is intravascular [313]. It can therefore be concluded

Table 6.5 Pressure gradients across the peritoneal membrane during the initial phase of a peritoneal dialysis exchange using 7.5% icodextrin

	Pressure in peritoneal capillaries	Pressure in dialysate-filled. Peritoneal cavity	Pressure gradient
Hydrostatic pressure (mmHg)	17	8 recumbent	9
Colloid osmotic pressure (mmHg)	21	66	45
Osmolality (mosmol/kg H_20)	305	285	
Maximal crystalloid osmotic pressure gradient (mmHg)			(285–305) × 0.03 × 19.3 = −12

It is assumed that the molecular weight of icodextrin is 16,800 and the reflection coefficient is 0.767. The reflection coefficient of low molecular weight solutes is set at 0.03

that the disappearance rate overestimates the true flow through the lymphatics, while the appearance rate underestimates it. The differences between the two methods has been assumed to represent transmesothelial clearance [312].

Direct measurement of lymphatic flow from the peritoneal cavity has been studied by the group of Johnston, both in anesthetized and conscious sheep [314–317]. In these animals the right lymphatic duct could not be cannulated. Anesthesia appeared to have a pronounced effect on the flow in the cannulated lymphatics, probably because of reduced movements of the diaphragm. The mean lymph flow in conscious sheep ranged from 1 to 1.5 mL/h per kg body weight, depending on estimations for flow in the right lymphatic duct. Comparisons of these measured flow rates with disappearance and appearance rates of RISA in sheep are difficult, because the disappearance rate of RISA was very high and the RISA appearance rate was 60% of the disappearance rate, i.e., a much smaller difference than in human CAPD patients. The amount of RISA administered intraperitoneally, recovered in the blood and in the drained lymphatic vessels, was always equal to the amount lost from the peritoneal cavity during a 6-h dwell. This is not supportive of marked accumulation of RISA in the anterior abdominal wall. The flow from the caudal mediastinal lymph node can be raised 200% in the awake sheep model by intraperitoneal administration of fluid [318]. In analogy, the disappearance rate of intraperitoneally administered autologous hemoglobin is higher in CAPD patients after the administration of a 3-L dialysate volume than with a volume of 2 L [82]. Increasing the intraperitoneal pressure in rats that underwent peritoneal dialysis also increased the RISA disappearance rate [295]. However, it had no effect on its appearance rate in the systemic circulation. Combining this observation with those in awake sheep and CAPD patients suggests that the disappearance rate of macromolecules can be used relatively easy in clinical practice for the analysis of fluid kinetics in CAPD patients.

It has been suggested that fluid transport associated with the disappearance of macromolecules should not be called lymphatic flow or lymphatic absorption, but simply fluid loss [319]. This is a simplification, because reabsorption of fluid into the capillaries by the colloid osmotic pressure gradient is not associated with the transport of macromolecules, as has been shown in studies using normal saline [281], or hypotonic dialysate without an osmotic agent [163]. The amount of saline absorbed during a 7-h dwell was 24% in the former study, but the amount of RISA that had disappeared was only 17%. In the latter study the dialysate concentration of intraperitoneally administered dextran 70 increased 10% during a 4-h dwell, most likely because of transcapillary back-filtration of water, caused by the colloid osmotic pressure gradient. This underlines that fluid loss from the peritoneal cavity is coupled mainly to the disappearance of macromolecules (lymphatic absorption), but is also partly uncoupled (back-filtration by colloid osmosis). Based on these data it can be concluded that the disappearance rate of intraperitoneally administered macromolecules cannot be used alone as a measurement of lymph flow through the subdiaphragmatic lymphatics, but also cannot be used as an overall indicator of fluid loss from the peritoneal cavity, irrespective of the mechanism involved. It is plausible that the disappearance rate can be used as a functional approach for the calculation of the effective lymphatic absorption from the peritoneal cavity during CAPD. Consequently, all pathways of lymphatic drainage from the peritoneal cavity, both subdiaphragmatic and interstitial, are included in the definition of the effective lymphatic absorption rate. The term *effective* is analogous to the effective renal plasma flow, where a clearance is used to estimate flow. The pros and cons of the concept of the effective lymphatic absorption rate have been subject of a recently published "controversy in peritoneal dialysis" [320, 321].

Intraperitoneal pressure is likely to be one of the determinants of the effective lymphatic absorption. Intraperitoneal administration of saline in rats causes an increase in the number of patent subdiaphragmatic stomata, not present when the intraperitoneal pressure was kept constant [322]. A relationship has also been found between intraperitoneal pressure in CAPD patients and the disappearance rate of intraperitoneally administered dextran 70 [323]. Increasing the intraperitoneal pressure 10 mmHg, by external compression, leads to a marked increase in the effective lymphatic absorption rate [203], and consequently a lower net ultrafiltration. Net ultrafiltration is also somewhat (16%) lower in the upright position compared to recumbency [200], caused by the combination of a small increase in the dextran disappearance rate and a slight decrease in the transcapillary ultrafiltration rate. The effects of higher intraperitoneal pressure in the upright position are probably counterbalanced by the effect of gravity leading to a decreased contact between the dialysate and the subdiaphragmatic lymphatics. The coefficients of intraindividual variation of the parameters of fluid transport average 17% [200]. The time course of transcapillary ultrafiltration, effective lymphatic absorption, and net ultrafiltration (the difference between the two) is shown in Fig. 6.7 for 1.36%/1.5% glucose, 3.86%/4.25% glucose, and 7.5% icodextrin. The transcapillary ultrafiltration rate on glucose-based solutions is negatively related to the MTAC creatinine (representing a large vascular surface area), but the relationship is positive when an icodextrin-based solution is used, as shown in Fig. 6.8. These relationships can be explained by the different properties of the two osmotic agents. The presence of a large vascular surface area allows high water transport rates, as many pores are available for transport. This explains the effects of icodextrin. For glucose-based solutions, however, the positive effects on water transport are counteracted by high glucose absorption rates, leading to a rapid disappearance of the osmotic gradient.

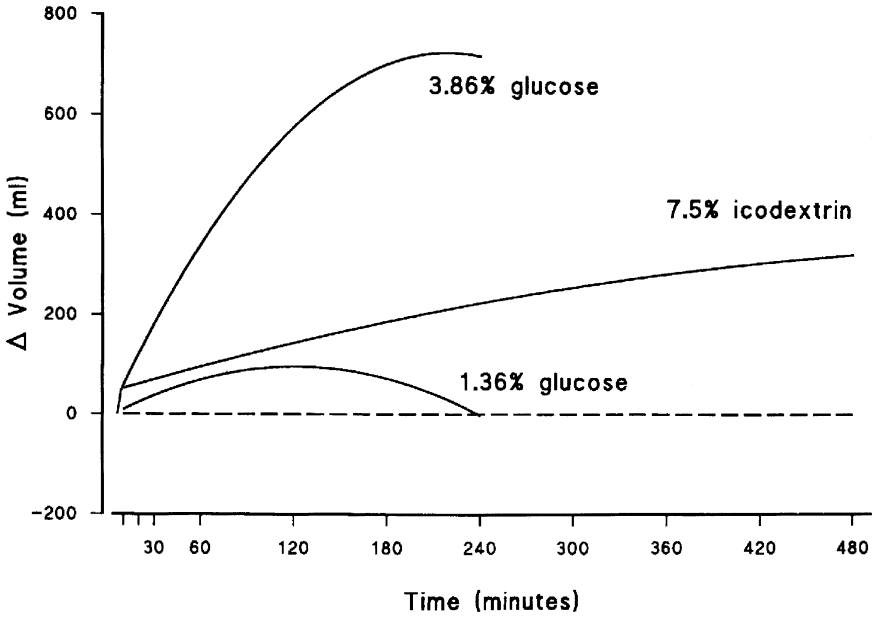

Fig. 6.7 The time-course of the intraperitoneal volume during a 4-h exchange with 1.36% glucose, a 4 h exchange with 3.86% glucose and an 8-h exchange with 7.5% icodextrin-based dialysis solution. Median values are given. Based on [64, 119, 314]

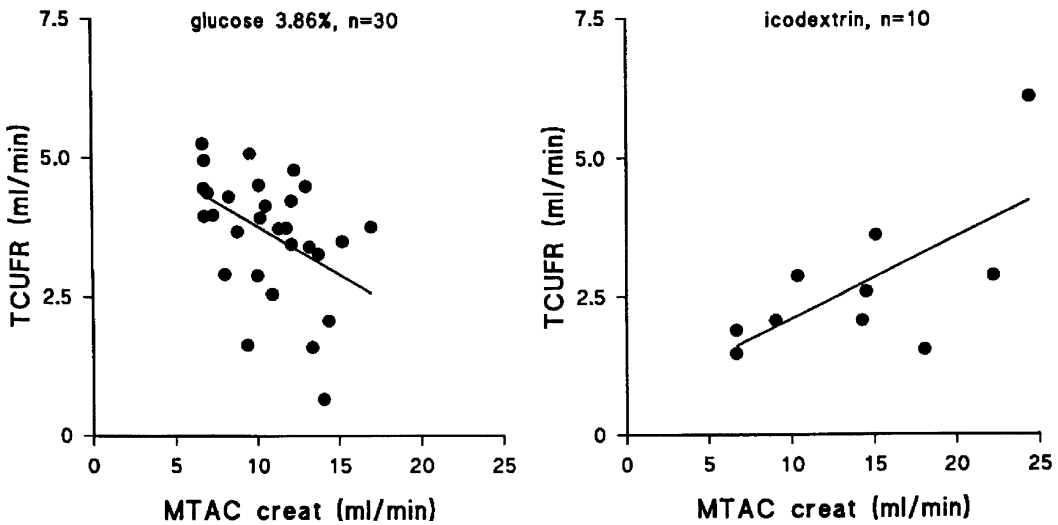

Fig. 6.8 The different relationships between the MTAC creatinine, representing the vascular peritoneal surface area and the transcapillary ultrafiltration rate obtained during 4-h exchanges with 3.86% glucose (left panel) and 7.5% icodextrin (right panel). The icodextrin data are from [64], the glucose data are from a randomly selected group of stable CAPD patients who underwent a standard peritoneal permeability analysis. Note that a high MTAC creatinine is associated with a low transcapillary ultrafiltration rate on glucose and with a high transcapillary ultrafiltration rate on icodextrin

Peritoneal Permeability in Systemic Diseases

Uremia

The uremic state is probably associated with more permeable serosal membranes than is the nonuremic situation. This is illustrated by the easy development of pleural and pericardial effusions. Increased capillary permeability has also been reported in the lungs during chronic uremia [324]. A similar increase has been found for the permeability characteristics of the peritoneal membrane during 3-h dialysis exchanges, when three patients with chronic renal failure were compared to four patients with normal renal function who were dialyzed because of psoriasis [325]. The uremic patients had higher transport rates for uric acid, phosphate, and protein than those with psoriasis, indicating a

larger effective peritoneal surface area in the uremic patients. The intrinsic permeability to macromolecules was not investigated in this study. On the other hand, decreased clearances of urea and creatinine have been reported during intermittent peritoneal dialysis in patients with severe hyperparathyroidism [326]. In acute renal failure due to rhabdomyolysis caused by heat stress and exercise, decreased peritoneal clearances have also been reported for creatinine and uric acid, but not for urea [327].

Diabetes Mellitus

Patients with diabetes mellitus have an abnormal microcirculation. Capillary basement membrane alterations with thickening and loose areas of the fibrillar meshwork are especially common [328]. Increased microvascular permeability to proteins is also present [328]. This may be due to loss of glycocalyx [105]. Peritoneal clearances of exogenously administered radiolabeled albumin in rats undergoing peritoneal dialysis have been found higher in animals with alloxan-induced diabetes mellitus than in those with gentamicin-induced renal failure [329]. This was especially the case in the rats with the most severe diabetes. A more recent study reported increased D/P ratios of low molecular weight solutes [330]. The findings in animal models cannot simply be applied for the situation in chronic peritoneal dialysis patients. The continuous exposure to extremely high dialysate glucose concentrations leads to diabetiform membrane alterations, such as reduplicated basement membranes [331], and neoangiogenesis [332] with deposition of collagen IV [333]. Vasculopathy, and especially venular subendothelial hyalinosis have also been described [334]. This may obscure differences between diabetic and nondiabetic patients that might have been present in the initial phase of peritoneal dialysis. Therefore, the various studies should be interpreted with caution.

Low peritoneal clearances of creatinine and urate have been reported in one patient with severe diabetes mellitus treated with intermittent peritoneal dialysis [335]. In contrast, the MTAC values of urea, creatinine, and glucose in a larger group of diabetic CAPD patients were similar to those of patients with renal failure due to a primary renal disease [336–338] (Table 6.6). In one study a dependency of D/P creatinine on peritonitis incidence has been described [339]: patients with a high incidence have higher D/P ratios than nondiabetic patients and patients with a low incidence had lower ratios. Reduced ultrafiltration was present during periods of hyperglycemia [339]. Patients studied during the initial period of CAPD had higher D/P ratios for creatinine than nondiabetic controls in one study [399], and lower transcapillary ultrafiltration rates in another one [340]. This could however not be confirmed in a more recent analysis [341]. Peritoneal protein losses in diabetic CAPD patients are not different from those of other patients [242, 342, 343]. As serum albumin concentrations are often low in some of them [313], this can mask increased permeability to macromolecules. In accordance with the findings in alloxan-induced diabetes in rats [329], clearances of albumin, transferrin, and IgG have been reported 30% higher in diabetic than in nondiabetic CAPD patients [246]. However, when larger numbers of patients were studied, the difference was no longer significant (Table 6.6). The explanation for this is probably the large variability in the effective peritoneal surface area and intrinsic permeability in the patients with a primary renal disease.

Systemic Lupus Erythematosus

Low clearances for urea, creatinine, and urate have been reported in one patient with fulminant systemic lupus erythematosus (SLE) and severe hypertension, treated with intermittent peritoneal dialysis [335]. More recent data

Table 6.6 Comparison of peritoneal permeability characteristics between 46 patients with a primary renal disease and 38 patients with systemic diseases. Permeability to low-molecular-weight solutes is expressed as mass transfer area coefficient (MTAC), that of proteins as clearance (Cl). Mean values ± SEM are given

	Primary renal disease ($n = 46$)	Systemic lupus erythematosus ($n = 7$)	Systemic sclerosis ($n = 2$)	Diabetes mellitus ($n = 23$)	Amyloidosis ($n = 6$)
MTAC creatinine (mL/min)	9 ± 0.4	10 ± 1	12 ± 1	10 ± 1	14 ± 2*
MTAC glucose (mL/min)	9 ± 0.4	11 ± 1	10 ± 1	11 ± 1	13 ± 2
Cl albumin (μL/min)	92 ± 6	92 ± 19	118 ± 11	97 ± 7	110 ± 21
Cl IgG (μL/min)	50 ± 3	47 ± 12	61 ± 2	53 ± 5	59 ± 13

*$p < 0.05$ versus primary renal disease

show that the prognosis of SLE patients on renal replacement therapy is similar to those with a primary renal disease [344]. In the literature, more detailed data on CAPD in SLE have only been reported in 16 patients [345–348]. Solute transport rates were published in four CAPD patients, indicating a normal vascular surface area and a decreased intrinsic permeability to macromolecules [337, 338]. This could not be confirmed when larger number of patients were studied (Table 6.6).

Systemic Sclerosis

Patients with systemic sclerosis can be treated with peritoneal dialysis, despite their low life expectancy [344]. Low peritoneal clearances of low-molecular-weight solutes have been reported in one patient on intermittent peritoneal dialysis [349], but essentially normal values were found in another one [350]. CAPD treatment has also been described to give good metabolic control [351] and acceptable clearances of low molecular weight solutes [352]. Data on solute transport in two patients are given in Table 6.6.

Amyloidosis and Paraproteinemia

Peritoneal dialysis as renal replacement therapy in patients with amyloidosis and/or paraproteinemia has given satisfactory clinical results [347, 350, 352]. Evidence for a large peritoneal surface area has been reported in four patients with amyloidosis [336, 348, 353]. This may be of importance because peritoneal dialysis can be used to remove immunoglobulins and light chains from the body, thereby preventing further amyloid formation, hyperviscosity syndromes, and, perhaps in some cases, reverse renal insufficiency in patients with nephrotoxic light chain–induced renal failure [354, 355]. Solute transport data in six patients with amyloidosis are given in Table 6.6.

It can be concluded that the presence of a systemic disease has no uniform effect on the permeability characteristics of the peritoneal membrane during CAPD, although some patients may present with abnormal high or low MTAC values. However, such abnormal values can also be found in patients with a primary renal disease. This implies that peritoneal dialysis should not be abandoned in patients with systemic diseases, because of the expectation of an abnormal peritoneal permeability.

Peritoneal Permeability During Infectious Peritonitis

Inflammation causes hyperemia, and therefore changes in the permeability characteristics of the peritoneal membrane are likely to occur. "Membrane failure," as judged from deteriorating biochemical control, has been reported in four of 35 intermittent peritoneal dialysis (IPD) patients with peritonitis [356]. In contrast, increased clearances of creatinine and urea during peritonitis have been found in four IPD patients who were studied both in the absence of, and in the presence of, peritonitis [357]. As the effluent volume was similar, increased permeability caused by inflammation was the most likely explanation.

The most striking clinical finding in CAPD patients with peritonitis is impaired net ultrafiltration, leading to weight gain and other signs of fluid overload [358]. This phenomenon is associated with increased transport of low-molecular-weight solutes and increased absorption of glucose [81, 121, 359–362]. These phenomena point to an increased vascular peritoneal surface area caused by hyperemia. This leads to rapid disappearance of the osmotic gradient, and thus to reduced net ultrafiltration. In this situation a high-molecular-weight osmotic agent should be able to induce more transcapillary ultrafiltration. This was confirmed by the use of icodextrin, which led to increased, instead of decreased, net ultrafiltration during peritonitis [363, 364]. The maximal intraperitoneal volume during peritonitis is reached at about 1 h after instillation of the dialysis fluid, compared to 2.5 h after recovery [81]. This may explain why a decrease in net ultrafiltration has not been observed during peritonitis in IPD patients. The steep rise in the intraperitoneal volume during the initial phase of a dwell is caused by high transcapillary ultrafiltration rates during this period, as shown with dextran 70 [121]. No evidence has been found for a decreased free water transport [365]. A contribution of an increased fluid absorption from the peritoneal cavity is equivocal. It was suggested in a study using autologous hemoglobin as a volume marker [81, 366] and also, but to a minor degree, in a study using kinetic modeling of fluid transport [18]. However, in a more recent study using dextran 70 no effect of the inflammatory reaction on peritoneal fluid absorption could be established [121]. The alterations in peritoneal transport during peritonitis return to normal values within 1–2 weeks after recovery from the infection [362, 367].

Protein loss in the dialysis effluent is also markedly increased during peritonitis [81, 246, 357, 360, 367, 368]. In contrast to CAPD, the losses in IPD can be as high as 48 g per dialysis and often remain elevated for several weeks [367]. These proteins could be produced locally, or originate from the circulation [369]. Serum proteins are quantitatively the most important in peritoneal effluent. The increment in their clearances of more than 100%, during peritonitis, favors increased transport [81, 249], due both to the increased effective surface area and increased peritoneal permeability to macromolecules [246]. In a longitudinal study in CAPD patients with peritonitis, Zemel et al. showed an increase in the vascular peritoneal surface area and a decrease in the restriction coefficient to macromolecules during the acute phase of the inflammation [149]. The decreased restriction coefficient, pointing to an increased permeability of the peritoneum, returns to normal values within 1–2 days [121, 149], but the vascular surface area remains increased for a longer time.

Possible causes for the changes in surface area and permeability include endotoxin and complement activation [368], as well as prostaglandins [121, 140, 141, 150], IL-6 [146, 149], TNFα [143, 149], and local production of nitric oxide [121, 153, 155]. Inhibition of the inflammatory reaction with indomethacin reduced dialysate prostaglandin concentration, and had some effect on the restriction coefficient to macromolecules [150]. The importance of the relative contributions of all these mediators in the functional alterations of the peritoneal membrane during infectious peritonitis is not known.

Peritoneal Solute Transport During Long-Duration Peritoneal Dialysis

Mass transfer area coefficients or D/P ratios are mainly determined by the vascular peritoneal surface area. This is not a static, but a dynamic parameter, because it can be altered by the number of perfused peritoneal capillaries, that is the effective surface area, or by the number of capillaries. An increase in the number of peritoneal vessels occurs in long-time PD [332, 333]. This leads to high volumes of MTAC and D/P ratios and, and also to a rapid absorption of glucose in the dialysate. The ensuing decrease in ultrafiltration is discussed in Chapter 17. Two prospective longitudinal studies on peritoneal solute transport with a follow-up exceeding 5 years have been published [370–372]. In the study of Selgas et al. [370], a slight increase of MTAC creatinine with time on dialysis during 5 years was found. The increase in D/P creatinine was more pronounced in the study of Davies et al. [371, 372]. Some other studies reported the presence of a U-shape: an initial decrease was followed by a subsequent increase of the MTAC creatinine [298, 373, 374]. In retrospect, such a U-shape can also be found in the study from Spain [370]. It suggests that patients may have relatively high MTACs in the first (few) years on peritoneal dialysis, possibly due to release of vasoactive mediators by mesothelial cells. The subsequent decrease may be caused by a decrease of mesothelial cell mass [334]. The neoangiogenesis that can develop during long-term peritoneal dialysis is the most likely explanation for the following increase.

No study has shown an increase or decrease in peritoneal total protein loss in relation with the duration of peritoneal dialysis [375–377]. When peritoneal clearances of individual serum proteins were examined, no effect of the time on peritoneal dialysis was found [373, 376, 377]. However, when the clearances of these proteins were used to calculate the peritoneal restriction coefficient for macromolecules (see section on size-selectivity), an increase of this parameter was found in long-term CAPD patients [93, 377]. The increase in the restriction coefficient to macromolecules was not present after 2 years of CAPD [373], but was evident after 4 years [93, 377]. It points to an increased size-selectivity of the peritoneal membrane. Whether this is caused by a reduction in the average radius of the large pore system, or by fibrotic interstitial changes, is unknown.

Chapter 7
Physiology of High/Fast Transporters

R.T. Krediet

Patients on peritoneal dialysis have large interindividual differences in the velocity of solute equilibration between plasma and the dialysate [1]. In an attempt to standardize assessment of this variability, Twardowski et al. developed the peritoneal equilibration test (PET) [2]. In the PET solute transport after a standardized dwell of 4 h is expressed as the dialyse/plasma (D/P) concentration ratio of various solutes. D/P creatinine had a mean value of 0.65, but it ranged from 0.34 to 1.03 [3]. A similar range was reported in another study using the PET [4]. Based on D/P creatinine, patients have been divided into four transport categories: low, low average, high average, and high [3]. This categorization was based on the mean value and the standard deviation (SD). Low is less than 1 SD, low average is between the mean and –1 SD, low average is between the mean and +1 SD, and high is above 1 SD. The cut-off levels are: <0.50 for low, 0.50–0.65 for low average, 0.65–0.81 for high average, and >0.81 for high transporters. About 10% of prevalent PD patients can be classified as high transporters [5].

It should be appreciated that the net mass transfer of a solute is not only dependent on its D/P ratio, but also on the amount of drained dialysate: the peritoneal clearance is calculated as (D/P) × the drained volume. For solutes that are in (near) equilibrium, the D/P ratio approaches 1. In this situation the peritoneal clearance is almost exclusively determined by the drained volume. This is especially relevant for high transporters. These patients have a rapid disappearance of the glucose-induced osmotic gradient, caused by a high glucose absorption rate. It is not just a theoretical consideration: high transporters had a higher absorption of glucose after a dwell of 6 h, but a smaller intraperitoneal volume, while the removal of urea creatinine, sodium, and potassium was significantly lower than in the other transport categories [6]. A more detailed analysis of sodium kinetics showed that, irrespective of transport status, 69% of sodium transport is by convection, but that the high transporters had a significantly higher absorbed and lower removed sodium mass [7]. Therefore, the terms *high* and *low transport* are confusing. Patients who show a rapid equilibration could better be labeled fast transporters. Similarly the term *low* should be replaced by *slow*.

Fast Transport Status and Prognosis

The determination of peritoneal transport status was originally used to give recommendations on the dialysis prescription. For instance, the proposed treatment for fast transporters was either nightly intermittent peritoneal dialysis or daily ambulatory peritoneal dialysis [8]. In both modalities a long dwell is avoided to minimize absorption of the dialysis solution, and thereby trying to avoid the development of overhydration.

Wu et al. were the first to describe a higher drop-out rate in fast transporters when compared to other transport categories [9]. In 1998, two papers were published that reported a decreased survival for fast transporters [6, 10]. In a study from Sweden, prevalent continuous ambulatory peritoneal dialysis (CAPD) patients had a 2-year patient survival of 64%, which was significantly lower than the survival for the other transport categories. This effect was independent of age, gender, height and urine production. Diastolic blood pressure and bodyweight were higher in the fast transporters. All the deaths among the fast transporters were caused by cardiovascular diseases. These data suggest that overhydration may have been important. In the Canada-USA (CANUSA) study, performed in more than 600 incident CAPD patients, a PET was performed at enrollment [10]. No difference among the groups was found for patient survival, but fast transporters had a lower 2-year technique survival and a lower combined patient and technique survival. Fast transporters were older, more often male, and more often had diabetes mellitus and a lower serum albumin concentration. However, their nutritional status was not different from that of the other transport

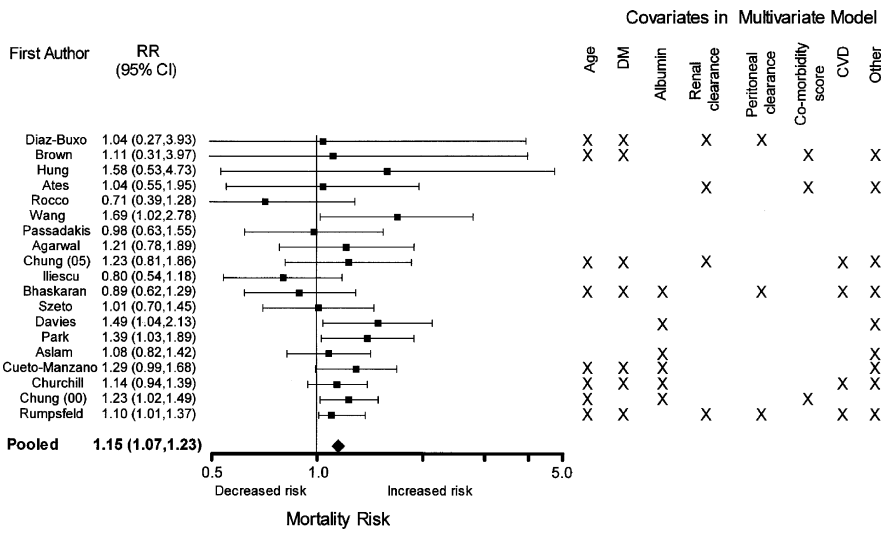

Fig. 7.1 Results of a meta-analysis on the mortality risk of patients with a fast peritoneal transport status. Taken from reference [28] (Brimble KS et al. Meta-analysis: peritoneal membrane transport mortality and technique failure in peritoneal dialysis. J Am Soc Nephrol 2006; 17: 2591–2598) with permission of the first author and of Lippincott, Williams and Wilkins

groups. Although residual renal function tended to be better in fast transporters, this was not significant. Fast transporters had a higher peritoneal creatinine clearance, a lower PET drain volume and a Kt/V_{urea} of 1.58/week compared to an average value of 1.68/week for the other transport categories. The cause of death was vascular in 73% of all patients. Taken together these data from the CANUSA study also suggest volume overload due to impaired peritoneal ultrafiltration as an important cause for the decreased patient and technique survival in fast transporters.

A large number of studies on mortality in fast transport patients has been published since then [11–27]. Among the 19 studies that assessed patient survival, five reported an increased mortality, while the other 14 showed no significant effect of peritoneal transport status. A recently published meta-analysis [28] done in 6,654 incident and prevalent PD patients showed a statistically significant overall increased relative risk of death in fast transporters of 1.15 (Fig. 7.1). A number of remarks can be made, however: 1) The majority of patients comes from one study [26]. 2) Four out of five studies showing a significant effect were done in CAPD patients [7, 12, 21, 25]. The fifth study, that is the large one from Australia/New Zealand, only found an effect in CAPD patients, not in those treated with APD [26]. In the two studies performed exclusively in APD patients, no effect of peritoneal transport status was present [14, 27]. 3) With the exception of the study by Brown et al. in APD patients [27], no study included patients in whom icodextrin was used for the long dwell. 4) A relative risk of 1.15, as reported in the meta-analysis, means that the chance of death is increased with 15%. Given a death rate in PD patients of about 15% per year, it means that the number of patients that die in 1,000 patient years will increase from 150 to 173. For comparison, the relative risk of death for start with hemodialysis compared to peritoneal dialysis is 1.59 in the United Kingdom [29], 1.16 in Denmark [30], and 2.33 in The Netherlands [31].

It can be concluded that the relationship between a fast peritoneal transport status and excess mortality has only been established in patients on CAPD treated with conventional PD solutions. The excess mortality is about 15%.

Physiology of Fast Transport Status

Diffusion through the so-called small pores is the most important transport mechanism for low molecular weight solutes that accumulate due to kidney failure. The rate of diffusion is determined by the product of the mass transfer area coefficient (MTAC, the maximum theoretical clearance by diffusion at time zero) and the concentration gradient between plasma and dialysate. Plotting MTACs of various low molecular weight solutes versus their free diffusion coefficient in water shows the presence of a power relationship between them [32]. It means that the relationship is linear when plotted on a double logarithmic scale. The slope of the regression line obtained when doing this for low molecular weight solutes was 1.24, which is close to 1.0. This is the expected value when the relationships between the magnitude of MTACs would only have been dependent of free diffusion. Consequently it is unlikely that the peritoneal membrane offers a size-selective hindrance to the transport of low molecular weight solutes. It implies that the MTACs or D/P ratios are mainly dependent on the number of perfused peritoneal microvessels, that is the vascular peritoneal surface area. This is discussed in more detail in Chapter 6.

The presence of a fast transport status reflects the presence of a large vascular peritoneal surface area. This area is not a statistical, but a dynamic property, because it is not only dependent on the number of microvessels but also on the number of perfused microvessels. The former is the anatomic surface area, the latter is often referred to as the effective peritoneal surface area. As discussed in Chapter 6, many vasoactive substances can influence the effective peritoneal surface area.

Types of Fast Transport Status

Inherent Fast Transporters

The prevalence of a fast transport status in new PD patients differs widely. Values of 7% [20] and of 29% [33] have been reported. In most studies an inherent fast transport status was present in 15–17% of the patients [10, 16, 34]. The last study comprised 523 incident PD patients with a fast transport status. Multivariate analysis revealed that this condition was associated with higher age, Maori/Pacific Islands racial origin, a BMI exceeding 25 kg/m^2, but not with co-morbidity. Male gender and the presence of diabetes mellitus were associated with a fast transport status in the CANUSA study [10]. A study from Korea confirmed that inherent fast transporters had a higher proportion of men, but – in contrast with the study from Australia/New Zealand – also a higher proportion of patients with co-morbid diseases and a lower initial serum albumin concentration [16].

Peritoneal transport status is a refection of the peritoneal vascular surface area, which can be influenced by vasoactive substances (see above). Besides urea and creatinine, the concentrations of which are determined by peritoneal transport, many substances can be detected in peritoneal effluent of PD patients that are locally produced or released. These include interleukin-6 (IL-6) [35, 36], vascular endothelial growth factor (VEGF) [37], and the mesothelial cell mass marker cancer antigen 125 (CA 125) [38]. Cross-sectional analyses in prevalent PD patients have shown significantly higher plasma and dialysate concentrations of IL-6 and VEGF in fast/fast average transporters than in slow/slow average ones [39]. Also, a strong correlation is present between the MTAC creatinine and effluent VEGF attributed to local production [37]. However, studies from Portugal in incident patients found no correlation between D/P creatinine and effluent or serum IL-6 [40]. Also, no differences were present between fast/fast average and slow/slow average transporters for serum VEGF, serum IL-6, and effluent IL-6. Only effluent VEGF was significantly higher in the fast/fast average transporters [41]. A similar finding was reported was reported in a study from The Netherlands [42]. These findings contrast those of a study from Sweden, in which a correlation was found between D/P creatinine at baseline and plasma dialysate IL-6 [43]. Population differences in inflammation may explain these differences. The average serum C-reactive protein (CRP) concentrations were 6 mg/L in the study from Portugal [41], 5 mg/L in the study from The Netherlands, in which patients with diabetes mellitus were excluded [42], and 15 mg/L in the study from Sweden [43].

Cultured mesothelial cells are able to produce various cytokines, chemokines, and prostaglandins, some of which are vasoactive [reviewed in ref. 44]. These include IL-6, IL-8, and monocyte chemoattractant protein-1 (MCP-1), but not tumor necrosis factor (TNF)α, the concentration of which in peritoneal effluent of uninfected patients is dependent on diffusion from the circulation [45]. The in vitro production of the above substances is especially marked after stimulation, for instance with TNFα. In contrast, VEGF is spontaneously produced in large quantities by ex vivo cultured peritoneal mesothelial cells from PD patients [46]. Also, CA 125 is constitutively released by mesothelial cells. This release is not influenced by stimulation with cytokines [47].

Based on these data, it can be hypothesized that the magnitude of the mesothelial cell mass is indirectly involved in the regulation of the effective vascular surface area. Old data in cross-sectional studies on relationships between effluent CA 125 and peritoneal transport are equivocal. Some reported a positive correlation with D/P creatinine [48], while others were unable to establish this [49]. The discrepancy might be due to differences in the duration of peritoneal dialysis. As illustrated in Fig. 7.2, a correlation between effluent CA 125 and peritoneal solute transport is only present during the first two years on peritoneal dialysis (unpublished data). Especially in incident patients correlations are present between patients solute transport, effluent CA 125, and effluent VEGF [40–42]. By using a linear regression analysis to analyze the relationship between MTAC creatinine and effluent CA 125 in incident patients it was shown that this was not influenced by age, gender, and serum concentrations of acute phase proteins [42]. However, it was weakened when effluent VEGF was added to the model, but not when this was done for effluent IL-6 [42]. These data suggest that CA 125 in new PD patients is an independent determinant of the MTAC creatinine and that its effect is partly mediated by locally produced VEGF, presumably from mesothelial cells.

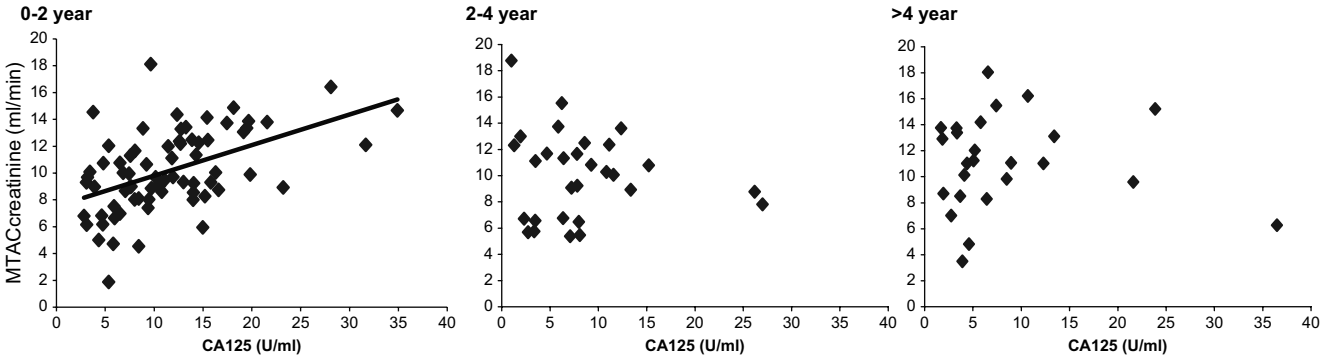

Fig. 7.2 Relationship between effluent CA 125 and the MTAC creatinine according to the duration of peritoneal dialysis. Only during the first 2 years a relationship is present

Table 7.1 Differences between the two types of an inherent fast transport status

Inherent fast transporters		
	Associated with co-morbidity	Associated with CA 125
Vascular surface area increase	Effective/anatomic	Effective
Cause	Inflammation	Vasoactive hormones produced by mesothelial cells
Time course	Poor prognosis	Spontaneous resolution

Taking all the data discussed above into account, the various results suggest that two types of inherent fast transporters can be distinguished: one related with co-morbidity and inflammation and another one related to mesothelial cell mass and/or function. The characteristics of these two types are shown in Table 7.1. The latter type is likely to disappear spontaneously with the duration of PD [32], because effluent CA 125 decreases during longitudinal follow-up [41, 50]. Although both types may cause ultrafiltration failure, the inherent fast transport status associated with CA 125 is unlikely to contribute to the excess mortality of fast transporters because most patients will have residual urine production. However, the type associated with co-morbidity and inflammation is likely to have a poor prognosis.

Acquired Fast Transporters

Here, two types can be distinguished. One occurs during peritonitis, the other one may develop during long-term PD. The characteristics are shown in Table 7.2.

Acute infectious peritonitis leads to an inflammation-induced peritoneal hyperemia. This causes some increase in peritoneal blood flow [51], but a much more marked increase of the transport of low molecular weight solutes [51, 52] and especially serum proteins [51–53]. It appeared that the changes in the parameters for the effective peritoneal vascular surface area were mediated by IL-6 and TNFα, while those for the intrinsic permeability of the peritoneum were associated with IL-6 and prostaglandin E2 [53]. The resulting decrease in ultrafiltration [51, 52] was purely due to a rapid decrease of the osmotic gradient, without signs of an impaired contribution of free water transport [54]. The vast majority of peritonitis episodes are cured by antibiotic treatment and peritoneal transport characteristics usually return to baseline in a few weeks [55].

Table 7.2 Differences between the two types of an acquired fast transport status

Acquired fast transporters		
	Associated with peritonitis	Associated with long-term PD
Vascular surface area increase	Effective	Anatomic
Cause	Infection	Glucose induced neoangiogenesis
Time course	Reversible after cure	Ultrafiltration failure

Patients on long-term peritoneal dialysis can develop ultrafiltration failure. This occurs in about one third of patients treated for 4–6 years [56, 57]. It is not only associated with a fast peritoneal transport status, but also with impaired free water transport [57–60]. Peritoneal neoangiogenesis induced by dialysis solutions is the main cause for this phenomenon [61–63]. It is also associated with low effluent CA 125 levels, suggesting extensive damage of the peritoneal dialysis membrane [57]. Most of the patients with this type of fast peritoneal transport status have no residual urine production. Therefore they are at great risk for the development of overhydration, which will lead to an increased mortality. Indeed, two studies performed in anuric patients have shown a relationship between peritoneal ultrafiltration and risk of death [64, 65].

Treatment of Patients with a Fast Transport Status

General principles of treatment include preservation of urine production and adjustments of the peritoneal dialysis prescription. Urine production can be preserved by avoidance of nephrotoxicity and the use of high-dose loop diuretics. The latter increase urine production, but have no effects on GFR [66] or its time course [67]. The use of an ACE inhibitor reduces the natural decline of residual GFR [68]. Modifications of the dialysis prescription consist of the use of icodextrin for the long dwell and/or the use of APD with short cycles. Two randomized studies showed that icodextrin treatment led to a significant reduction of total body and extracellular water and left ventricular mass [69, 70].

Specific treatment aimed at the cause of the fast peritoneal transport status is not always possible and also not always necessary. An inherent fast transport status associated with high effluent CA 125 levels requires no specific treatment. The condition is likely to disappear by itself. Treatment of the underlying condition of an inherent fast transport status associated with inflammation and/or co-morbidity should be attempted but is often impossible. This is especially the case for the malnutrition, inflammation, and arthrosclerosis syndrome, where an integrated approach should be investigated [71]. Prevention of the development of a fast transport status associated with long-term PD primarily consists of a reduction to the exposure to glucose and/or glucose degradation products [72]. The use of the so-called biocompatible PD solutions is promising in long-term animal models [73], but a sustained membrane protective effect in patients has not been established yet.

Chapter 8
Animal Models for Peritoneal Dialysis Research

M.M. Zweers and P.J. Margetts

The concept of peritoneal dialysis as a therapeutic modality for end stage renal disease was first demonstrated by Putnam in 1923 in a canine animal model [1]. Over the past 30 years, as peritoneal dialysis has been increasingly used and modified as a therapy for renal failure, animal models have been used to understand the physiology of the peritoneum membrane, and to test new therapeutic interventions to improve the outcomes of patients treated with peritoneal dialysis.

The physiology of the peritoneal membrane has been studied in a variety of models using predominantly rats and rabbits [2], but other larger animals have also been studied. The usual technique employed is to instill peritoneal dialysis solution into the peritoneum of an animal and sample the fluid and blood over time to assess solute transport, reabsorption, and ultrafiltration.

Animal models are also used extensively to understand the immune response to infection and nonbiocompatible dialysis solutions in chronic and acute settings applying advanced techniques such as intravital microscopy [3]. With the publication of human peritoneal biopsy studies [4, 5] it has become clear that the peritoneal membrane changes over time on dialysis. These changes have been studied in animal models in order to understand the underlying mechanisms. Animal models have also been used extensively to study possible therapeutic interventions such as novel dialysis solutions and pharmacologic agents.

Experimentation to understand the basic molecular mechanisms of peritoneal membrane injury have traditionally been carried out in mesothelial cell culture systems. Recently, with the use of transgenic animals and gene transfer techniques, pathways leading to peritoneal membrane injury have been studied in vivo.

Acute Peritoneal Dialysis Models

The most straightforward animal model utilized is the introduction of a fluid into the peritoneal cavity and the study of the effects on transport parameters or inflammatory response. These models have recently utilized mouse, rat, rabbits, and sheep. These procedures have been carried out to better understand the anatomy and physiology of transport across the peritoneal membrane. Additionally, different dialysis solutions, or therapeutic agents, have been introduced in order to assess the potential clinical utility in peritoneal dialysis patients.

Model for Assessment of Peritoneal Transport Properties

A standard acute model of peritoneal dialysis exposure involves anesthesia of the animal and maintenance in homeostasis [6]. A temporary catheter is inserted in the peritoneal cavity and dialysis solution is infused. A volume marker such as radiolabeled albumin, is added. Over the course of the peritoneal solution dwell samples are taken. Intraperitoneal volume can be measured, along with transcapillary ultrafiltration and solute transport out of the peritoneal cavity. With measurement of small solutes, dialysate to plasma ratios or mass transfer area coefficients [7] can be calculated. This allows for an assessment of peritoneal membrane transfer properties or effective peritoneal surface area. The latter is, in essence, that part of the peritoneal membrane that is involved in solute transport. Intrinsic peritoneal permeability is characterized by the restriction coefficient of a solute, an expression of the peritoneal size selectivity. A restriction coefficient of 1.0 indicates free diffusion of the solute; a higher

DOI 10.1007/978-0-387-78939-2_8,

restriction coefficient implies the presence of a size selective barrier. An example of size selectivity is the transport of macromolecules such as albumin and IgG [8].

Transport properties appear to be similar among different animal models and humans. However, there are notable differences. For example, rabbits demonstrate higher lymphatic absorption rates and clearances of macromolecules [7]; rats demonstrate greater glucose transport [9], and mice have lower macromolecular transport [10] compared with humans. In a study of peritoneal transport in response to an acute dwell, mouse transport data was similar to values found for rats [11]. Interestingly, Ni et al. also compared males and females and found female C57Bl/6 mice displayed less sodium sieving perhaps related to decreased aquaporin-1 expression. Volumetric measurement techniques have, in general, been validated with the caveat that only small volumes are removed for analysis [12]. An acute effect of PD fluid on the vasculature leading to vasodilation early in the dwell and increase in solute transport, has been identified [13]. The experimental procedure must be outlined in detail as small changes in technique such as the type of anesthesia used [14] and additives to PD fluids such as heparin [15] may have an effect on solute transport.

Solute transport across the peritoneal membrane depends on the characteristics of the membrane and the surface area involved. In an attempt to eliminate this second variable, Flessner et al. have developed an in vivo technique where the peritoneum of an anesthetized animal is exposed surgically, and a column is fixed to the surface [16, 17]. Standardized solutions and volume markers are added to the column, and solute transfer parameters are calculated. The area as a variable in solute transport is thus eliminated.

Anatomic/Physiologic Observations from Acute Models of Peritoneal Dialysis

The acute model of a single peritoneal fluid dwell has led to many important observations. From an anatomic perspective, the differences between the visceral, parietal, and diaphragmatic surfaces for lymphatic drainage and solute transport have been studied. The parietal peritoneum has been identified as the more important component of solute transport [18]. Lymphatic drainage across the diaphragm appears to be the most important route for macromolecular removal as seen both in rats [19] and sheep [20]. From these studies and others, it is clear that lymphatic drainage to the peripheral circulation is a minor route for macromolecular transport, and that local uptake by tissues is the major pathway [19].

The contact area between PD fluids and the peritoneal membrane has been studied in different ways. Using MRI in rats, Fischbach et al. demonstrated that only 30–40% of the peritoneal membrane was in contact with a standard dwell in the rat [21]. Using radiolabeled markers and autoradiography after an acute dwell in mice, Flessner et al. demonstrated about 40% of the peritoneal surface area in contact with a large inoculum of PD fluid (10 mL) [22]. They also demonstrated techniques to increase the contact area and therefore solute transport [22, 23]. The vascular surface area is an important determinant of solute transport, but the role of peritoneal blood flow has been somewhat more controversial. Rosengren et al. demonstrated a measurable decrease in solute transport in an acute dwell in rats where blood flow was limited by exsanguination of 25% of blood volume [24]. Contrary to this, using columns attached to peritoneal tissue, Flessner et al. identified no significant change in solute transport with up to 70% reduction in peritoneal blood flow, aside from some minor changes noted in the transport across the hepatic peritoneal surface [17]. Despite these somewhat discordant findings, it can be concluded that, overall, blood flow is a minor determinant of peritoneal solute clearance.

Over time on dialysis, the peritoneal membrane develops striking increases in interstitial matrix. The interstitium of the peritoneal membrane has therefore increasingly been studied using animal models. In a recent, novel technique, Rippe et al. directly measured interstitial colloid pressure in the peritoneum using implanted wicks in rats exposed to a single dwell of PD fluid [25]. The acute loss of colloid interstitial pressure may be related to a wash out of macromolecules such as hyaluronan from the peritoneal membrane [26]. The net effect is to significantly increase the hydraulic conductance of the interstitium after a single PD fluid dwell.

The basic mechanisms of solute and water transport have been studied using acute dwells of PD fluid, generally in rats [9, 19]. More recently, studies in transgenic mice have demonstrated the importance of aquaporin-1 in free water transport across the peritoneal membrane [27]. Peritoneal macromolecular transport was studied by Rosengren et al. in caveolin-1–deficient mice and showed that macromolecular transport was not dependent on vascular caveolae [28]. This same group used an acute dwell in rats cooled to 19°C to demonstrate that macromolecular transport is a passive rather than active process [29].

Important changes in attachment and morphology of mesothelial cells have been studied in rat [30] and rabbit [31] PD fluid studies. In an interesting adjunct study to the peritoneal biopsy registry [5], even minor mishandling of rat peritoneal tissue was shown to cause extensive artifactual changes, in the mesothelial cell layer [32].

More recently, the effects of acute exposure to PD fluid and high glucose concentration has been studied in rats with regard to outcomes such as anorexia [33], and changes in adipokine profiles [34].

In acute dialysis studies, therapeutic interventions have been carried out to alter or improve peritoneal solute transport and ultrafiltration. Different solutions such as low sodium [35] and biocompatible solutions have been studied [36, 37] and a broad array of pharmacologic interventions have been profiled [38]. One caveat to the use of the rat as an animal model for acute or chronic exposure to icodextrin is the observation that rats have increased intraperitoneal amylase that leads to rapid degradation of icodextrin and alteration in its properties as an osmotic agent [39].

Peritoneal Inflammation/Peritonitis

Models Utilized

Peritonitis is still the major complication of peritoneal dialysis. Animal models have been utilized to understand the impact of infection on the peritoneal membrane structure and function, and the complex peritoneal immune response. Several methods have been utilized to induce injury to the peritoneal tissues in order to mimic changes in peritoneal dialysis patients, to understand pathophysiology, and to evaluate therapies.

The standard animal model involves the introduction of bacteria or a proinflammatory bacterial product such as lipopolysaccharide (LPS) or *Staphylococcus epidermidis* supernatant [40] into the peritoneal cavity. The size of the inoculum needs to be optimized to allow measurable effects without significant mortality [41]. The bacterial species is also likely of significance but has not been studied in detail. Devuyst et al. have developed a unique model where normal skin flora is used as the infective agent in an attempt to more closely mimic human peritonitis [42]. LPS has been used as a single intraperitoneal injection in dosages between 50 and 200 μg [43], which induces a characteristic inflammatory response and leukocyte recruitment. Overexpression of inflammatory cytokines such as TNFα– or IL-1β by adenovirus mediated gene transfer to the peritoneum of rats has also been used to evaluate the effects of isolated inflammatory cytokines on structural peritoneal membrane changes [44].

The single dose of infective or inflammatory agent has been modified by various researchers to produce desired effects. In an attempt to create a more chronic model of peritoneal inflammation, multiple doses of LPS have been given alone or in association with chronic PD infusion [45]. Bacterial inoculum has also been incorporated into a model of chronic PD fluid infusion in order to assess the effect of PD fluid exposure on the inflammatory response [46]. Alternatively, *S. aureus* has been incubated with dextran microbeads and injected into the peritoneum to create a prolonged pro-inflammatory and fibrogenic response [47]. Inflammatory agents have also been combined with other peritoneal injuries, such as uremia, to identify the various complex interactions occurring in PD patients [48]. Transgenic animals have been used in order to clarify the details of the peritoneal immune system and effects on the peritoneal membrane. The role of IL-6 as a master switch between acute and chronic inflammation has been demonstrated using IL-6 transgenic mice [40]. The importance of nitric oxide as a mediator of peritoneal membrane functional alterations after an inflammatory stimulus has been assessed using animals lacking endothelial nitric oxide synthase (NOS) expression [49].

Measurements of Outcome

The complexity of the peritoneal immune response has been investigated using animal models of acute peritoneal inflammation. In the assessment of interventions meant to alter the effectiveness of the immune response, the simplest outcome measurement is clearance of bacterium as measured in the peritoneal effluent. For example, in one study, uremia did not alter the clearance of bacteria in a combined model of bacterial inoculation after chronic PD fluid exposure [46], whereas caspase inhibitors blocked neutrophil apoptosis and enhanced bacterial clearance [50].

Leukocyte vascular interactions have been studied in detail using intravital microscopy [3]. Intravital microscopy involves the analysis of blood vessels in the mesentery of the large bowel. The large bowel is exteriorized using carefully controlled techniques. The mesenteric segment is superfused with different dialysis solutions and numerous variables can be simultaneously analyzed. Aside from leukocyte endothelial interaction, these variables include blood flow rate, macromolecular permeability, and microvascular density [51].

Peritonitis leads to a well-documented increase in solute and protein transport with a subsequent loss of ultrafiltration capacity. These parameters are commonly assessed as outcomes after acute peritonitis in these studies [43, 52–55]. The elaboration of chemokines [46] and cytokines [48] important in the inflammatory response have been evaluated. Longer-term outcomes such as angiogenesis and fibrosis have also been assessed [44, 47].

Interventions

Various interventions have been studied in animal models of peritonitis in order to assess efficacy at improving antibacterial responses, or mitigating the effects of peritonitis on the structure and function of the peritoneal membrane. Extracellular matrix components such as n-acetylglucosamine [48], hyaluronan [53], and heparin [56] have all been studied in animal models of peritonitis for their anti-inflammatory properties. Prostaglandins have vasoactive properties and have been implicated in vascular and solute transport changes associated with peritonitis. Prostaglandin inhibitors, such as indomethacin, have therefore been studied in rabbit models of acute peritonitis and have shown benefits in improvement in solute transport [55] and protein leak [54]. Other interventions, such as NOS inhibition [57] and alternative dialysis solutions, have been studied in animal models [43].

Other Models of Peritoneal Injury

Over time, the peritoneal tissues of PD patients undergo fibrosis and angiogenesis. This process leads to altered transport properties and ultrafiltration dysfunction. In the extreme, some patients develop a fulminant fibrogenic process termed encapsulating peritoneal sclerosis (EPS). Researchers have tried to mimic these processes using animal models so that the pathophysiology can be clarified and therapeutic agents can be tested.

Chronic Peritoneal Exposure Models

A variety of chronic peritoneal infusion or exposure models have been developed, mainly in rats and predominantly designed to investigate effects of dialysis solutions on peritoneal membrane structure and function and to evaluate therapeutic interventions. Presumably, these in vivo models have the ability to provide valuable information on the major pathways involved in peritoneal transport pathophysiology, morphological alterations, and local defense mechanisms. These models should be applied to evaluate a clear hypothesis with adequate detailing of methodologies used to obtain the parameters of interest. The varied approaches, applications, and methodologies used in chronic peritoneal exposure models most recently have utilized rats.

Mortier and colleagues [58] elegantly reviewed a variety of animal models that are currently used in PD research. To briefly reiterate the rat models: the chronic exposure models comprise the direct intraperitoneal injection model (with or without anesthesia) and the so-called "open" and "closed" systems with indwelling catheters. The open systems comprise two approaches: 1) a sterile tube is inserted into a permanent peritoneal indwelling catheter for each exchange of dialysis solution [59], and 2) a permanent peritoneal catheter through which the dialysis solution is introduced [60, 61]. The so-called "closed" models all have a subcutaneous reservoir in the neck attached to a peritoneal catheter from silicon or polyurethane (Fig. 8.1). These models differ in actions to prevent, for example, peritoneal infection or fibrin formation–induced catheter obstruction, or no preventive measures at all [62–65]. The pros and cons of the chronic exposure models in rats are summarized in Table 8.1.

Chemical Irritants

Chlorhexidine

Chlorhexidine was used as a sterilizing agent peritoneal dialysis patients to prevent peritonitis until it was found to be associated with an increased risk of encapsulating peritoneal sclerosis. It has since been used in a rodent model of peritoneal injury. In general, a daily or every other day intraperitoneal injection of chlorhexidine gluconate and 15% ethanol dissolved in saline is administered in mice [66] or rats [67]. The response involves submesothelial thickening, fibrosis, and angiogenesis that persists and matures during the course of injections [66]. It is likely that these effects reverse to some extent after cessation in injections, but that has not been well documented. As opposed to observations from human peritoneal biopsy samples, there is a significant inflammatory response to chlorhexidine evidenced by infiltration of macrophages [68].

Numerous interventions have been used in this model, mainly targeting angiogenic responses [68–70], heat shock protein [71], or angiotensin converting enzyme [72].

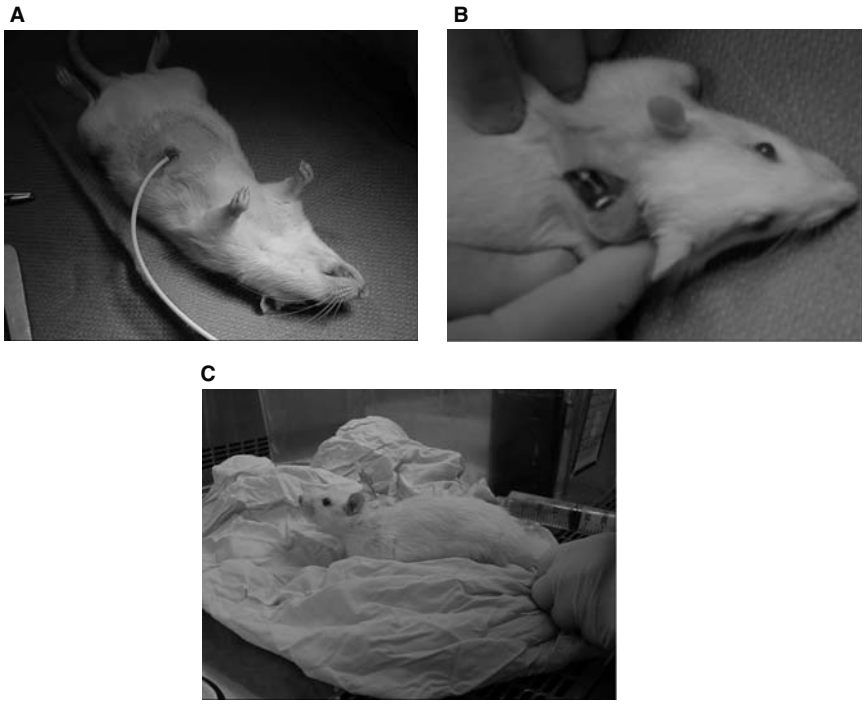

Fig. 8.1 Peritoneal catheter placement in a rat.(a)Introduction of the catheter tip into the peritoneal cavity. Thereafter the catheter is tunneled subcutaneously to the neck where the reservoir will be attached to the catheter. (b) The reservoir is attached to the catheter and placed subcutaneously in the neck. (c) Percutaneous infusion in the reservoir performed in an awake rat

Acidic Dialysis Solution

This model has been described by a few researchers [73, 74]. Daily injection of very low pH (pH 3.5) solution into the peritoneal cavity of rats over 40 days led to changes suggestive of encapsulating peritoneal sclerosis with fibrosis, cocooning of the bowels, inflammatory infiltrate, and adhesions. Angiotensin converting enzyme inhibition appeared to ameliorate this injury [73].

Other

Several other agents have been used in developing peritoneal injury models. A single injection of silica suspension in rats induced a significant fibrogenic response [75]. Fang at al. used this model to test the effects of pentoxifylline and showed significant benefit in the fibrogenic response. This model was carried out to 15 days after a single injection of silica, and it is not clear what the longer-term effects of this agent are.

In an interesting model of peritoneal injury, Gotloib et al. used a single injection of the oxidant agent deoxycholate to induce a severe oxidative injury to rats [76]. They demonstrated acute changes in solute transport and mesothelial cell morphology suggestive of acute inflammatory injury. Of note, they examined a group of animals 30 days after this single injury, and observed persisting solute transport abnormalities in the histological setting of peritoneal fibrosis.

Potassium cyanate injected into the peritoneum of rats induced a mild fibrotic response [77]. In a more dramatic model, sodium hypochlorite (bleach) was injected repeatedly to induce an obvious fibrogenic response [78]. In a second, related model, a single injection of bleach was followed 2 weeks later by an injection of blood. This combination led to fibrin formation and abdominal cocooning reminiscent of encapsulating peritoneal sclerosis [79].

Effects of Systemic Diseases on the Peritoneum

Uremia

Peritoneal biopsies taken from patients who have chronic kidney disease but before initiation of dialysis, demonstrated increased submesothelial thickening [5]. A partial nephrectomy of 70–85% in rats has been used in order to understand this phenomenon. The level of uremia and the duration of renal insufficiency, chronic or more acute, affect the applicability of the chronic exposure models and the development of peritoneal pathology. Five-sixths or 85% nephrectomy induces a 2–4 fold increase in plasma creatinine and urea [80]. Kakuta at al. [81], Zareie at al. [80], and

Table 8.1 Chronic peritoneal exposure models in rats

Model	Pro	Con
Injection model without anesthetic [107]	– Simple set up and cheap – No additional surgery	– No drainage – Risk of trauma to muscle, bladder, intestine, intraperitoneal bleeding – Repeated needle sticks – Introduction of infection
Injection model with anesthetic [108]	– Reduced risk of trauma – Reduced risk of infection – Possible up to 20 weeks	– Idem as injection without anesthetic – Anesthetic may affect peritoneal permeability [109] – Repeated anesthetics may influence metabolic status
Open system 1) using a sterile catheter in permanent tube to install and drain PDF [61]	– Easy instillation and drainage of PDF – Imitates PD more closely	– Extra step to introduce sterile tube – Risk of infection due to open connection and extra step – Substantial drop-out due to infection/obstruction
Open system 2) using the permanent tubing as catheter [60]	– Idem open system 1) – PD possible up to 24 weeks [110]	– Less steps to introduce PDF intraperitoneally – Reduced but still substantial risk of infection – Substantial drop-out due to catheter obstruction/infection
Closed system 1) subcutaneous reservoir in the neck attached to the peritoneal catheter (silicon/polyurethane), no preventive measures	– Less risk of infection than open systems	– No drainage – Reduced but still substantial drop-out due to catheter obstruction/infection – Expensive catheters
Closed system 2A) subcutaneous reservoir in the neck attached to the peritoneal catheter with heparinized PDF [16, 63, 65]	– Less drop-out due to catheter obstruction and adhesion formation	– No drainage – Modulates inflammatory cell activity, proliferation, and neoangiogenesis
Closed system 2B) subcutaneous reservoir in the neck attached to a heparin-coated peritoneal catheter [63]	– Less drop-out due to catheter obstruction and adhesion formation – Not the adverse of effects of heparin related adverse effects	– Very expensive catheters
Closed system 3) subcutaneous reservoir in the neck attached to the peritoneal catheter with prophylactic antibiotics [33, 62, 64]	– Prevents infection when administered during the whole experimental period – Antibiotics did not exert an adverse effect by itself on peritoneal function or structure	– Risk of introducing multiple resistant bacterial strains
Uremia: ~85% Nx up to 13 weeks [59, 80, 81]	– The more severe renal insufficiency may more rapidly induce uremia-related peritoneal alterations	– High morbidity/mortality in comparison with 70% Nx – Intraperitoneal infusion period only ~6 weeks, which may not be enough to induce significant peritoneal changes [80]
Uremia: ~70% Nx up to 16 weeks with nephroprotective diet [111]	– Infusion period up to 16 weeks: to induce more pronounced exposure related peritoneal alterations – Mimics chronic renal insufficiency better	– Less drop-out due to reduced renal insufficiency related morbidity/mortality – A longer infusion duration necessary to induce chronic pathology, therefore an increased risk of drop out exists.

others [2, 82] reported additive effects to the development of peritoneal alterations such as increased vessel density, when uremic and uremia with 6 weeks of peritoneal dialysis fluid exposed animals were analyzed.

An initial attempt to build a realistic, more clinically relevant model of uremia-induced peritoneal injury involved the complete removal of rat kidneys with subsequent maintenance on a catheter based peritoneal dialysis regimen [61]. The authors report the results after 4 days of dialysis.

The partial nephrectomy model has been used to confirm the effect of uremia on the structure and function of the peritoneal membrane [82]. More recently, the interaction between uremia and advanced glycation end products (AGE) has been studied in a uremic model [83]. Use of antibodies against the receptor of AGEs led to an improvement in the uremic-induced peritoneal membrane changes.

Diabetes

Microstructural alterations to the peritoneum resemble diabetic nephropathic changes including vasculopathy, extracellular matrix deposition, and basement membrane duplication. This likely represents the extensive exposure to a high glucose environment experienced by the peritoneum of PD patients. In light of this observation, researchers have used animal models of systemic diabetes to induce peritoneal damage. The original model was characterized by Stoenoiu et al. and involved the induction of diabetes using streptozotocin [84]. Four to 6 weeks after induction of diabetes, rats displayed increased solute transport, angiogenesis, increased NOS, and AGE expression. This model was subsequently used in conjunction with blocking antibody therapy to demonstrate the importance of VEGF [85] and receptor for AGE [86].

Genetic/Cellular Manipulation

Transgenic Mice

The present ability to alter the genetic environment in vivo has allowed peritoneal dialysis researchers the ability to begin to dissect the basic pathways involved in injury to the peritoneum. Mice with gene mutations or deletions are a powerful tool that has only recently been applied to peritoneal dialysis research.

To date, transgenic mice have been used mainly to study effects of single proteins on functional characteristics of the peritoneum after an acute dwell. For instance, the importance of aquaporin-1 in water transport and sodium sieving has been elucidated using aquaporin-1 knock out mice exposed to a single hyperosmolar dialysate dwell [27, 87, 88]. Caveolin-1–deficient mice lack vascular caveolae and have been studied in order to clarify the mechanism of macromolecular transport [28]. In a combination model, endothelial NOS-deficient mice were exposed to an infectious insult in order to understand the role of NOS in functional changes in peritonitis. The importance of IL-6 in the peritoneal inflammatory response has also been evaluated in transgenic animals [40].

Gene Transfer

The mesothelial covering of the peritoneum is epithelial-like and is thus theoretically suitable for a variety of gene therapy vectors. To date, adenovirus have been used most commonly. Two studies have identified the distribution and duration of expression of a marker protein after adenoviral transfer. When transferred in a small volume, gene expression is marked in peritoneal mesothelial cells [89], whereas in larger volumes, the vector is transferred to a wider cell population in the submesothelial tissue and beyond [90]. In a rabbit model, distribution of the adenovirus was enhanced when administered in icodextrin rather than phosphate buffered saline [91]. Overall, expression persists for 10 to 14 days, making this a very transient system. Adenovirus also induces a strong inflammatory response persisting for 72 h after delivery [92]. Adenovirus have been used to study fibrogenic events [89] (Fig. 8.2), inflammatory cytokines [44], epithelial mesenchymal transition of mesothelial cells [92], and as antiangiogenic therapy in a model of chronic PD fluid exposure [93].

Cell Transplantation/Depletion

The peritoneum offers a large surface area of fairly readily accessible cells that are easy to culture and manipulate. This has led researchers in the direction of cell-based therapies. The observation that the peritoneal mesothelial cells become

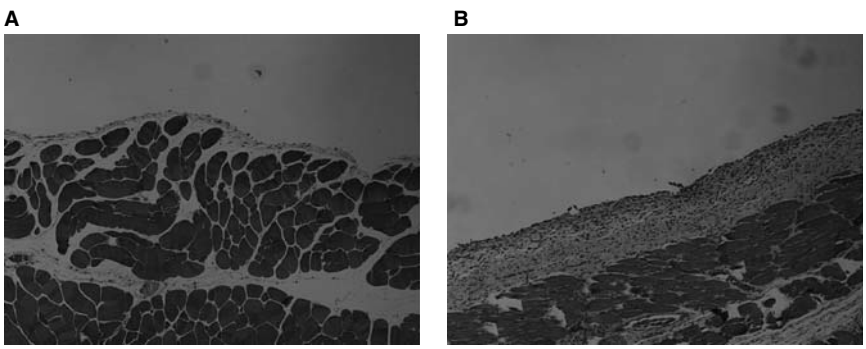

Fig. 8.2 (a) Mouse peritoneum 7 days after treatment with adenovirus expressing active TGFβ-1 demonstrates submesothelial expansion, fibroproliferation, and angiogenesis. (b) Mouse treated with control adenovirus demonstrates normal mouse peritoneal structure. Trichrome, 50× magnification

damaged and the peritoneum denuded over time on dialysis, or with acute peritonitis, has led to the fairly straight forward approach of autotransplant of mesothelial cells after damage. An initial positive study in rabbits led to this experimental approach being tried in a patient after peritonitis, with apparently successful implantation [94]. Hekking et al. have tackled this problem in a rat model of peritoneal injury, and have demonstrated successful implantation [95]. However, they also noticed that autologous mesothelial cell transport for some reason initiated an inflammatory reaction that had a negative impact on peritoneal structure [96].

Two studies have evaluated the possibility of using transplanted mesothelial cells as vectors for gene therapy [97]; in one case, an inducible promoter was used so that expression could be controlled exogenously [98]. Finally, an interesting model used to decipher the cellular basis of peritoneal injury allowed for the selective deletion of fibroblasts. A transgenic animal that expresses thymidine kinase under a fibroblast specific promoter was developed. Using chlorhexidine to induce peritoneal injury, the importance of fibroblasts in the propagation of peritoneal injury was described [99].

Measurements Tools in Animal Models for Peritoneal Dialysis Research

In order to elucidate the basic mechanisms of changes in the peritoneum in the models discussed above, tools have been developed at a molecular biology level and applied to peritoneal dialysis research.

Angiogenesis

Solute transport correlates with vascular surface area [100]. Because of this, many animal models are assessed for angiogenesis and angiogenic factors. Studies have used von Willebrand factor [92], CD31 [68], or α smooth muscle actin [65] immunostained sections of submesothelial or omental tissue to quantify vascularity. Simple counting or computerized image analysis has been used to assess stained sections. Vessels have been directly visualized using intravital microscopy of mesenteric windows and angiogenesis directly assessed along with vascular permeability to macromolecules [85]. Protein expression of angiogenic growth factors such as VEGF and NOS have been made by Western blot of omental tissue [82], in peritoneal dialysis effluent [89], or by quantitative immunohistochemistry [81]. Gene expression has also been assessed by extracting mRNA from peritoneal tissues and assaying by PCR [90] or quantitative real-time PCR extracted from peritoneal tissues [92]. Because each individual method has potential flaws and may be over interpreted, it is valuable to have concordant results from several different assays such as gene expression, protein expression, and immunohistochemistry.

Stem cells are increasingly recognized as having a potential role in peritoneal membrane injury, and these can be identified using a cell surface marker such as CD34 [69].

Fibrosis

Data from peritoneal biopsy studies have demonstrated that submesothelial thickening or fibrosis is the major finding in patients on peritoneal dialysis. It has been hypothesized that both angiogenesis and fibrosis are important in damaging the peritoneal membrane and leading to long-term functional changes such as ultrafiltration failure. Fibrosis is therefore an increasingly important outcome to be measured in animal studies.

The hallmark of fibrosis is the accumulation of extracellular matrix. Methods of evaluation include assays for hydroxyproline (a component of collagen), Western blot for collagen, or quantitative microscopy of sections stained for picrosirius red, or immunostained for collagen [71] or other extracellular matrix components. Picrosirius red staining and hydroxyproline assay has been compared favorably, especially in omental tissue [101]. Often, submesothelial thickness is taken as a surrogate marker of fibrosis, but correlation with other markers of fibrosis is lacking. A simple adhesion score has been developed [47].

Numerous fibrogenic related molecules have been assayed by immunohistochemistry, Western blot, or for gene expression by PCR. These markers include AGE, heat shock proteins, and TGFβ. Matrix metalloproteinases and their inhibitors are important in maintenance of fibrosis and have been assayed using gene expression analysis and zymography [102]. Finally, epithelial mesenchymal transition has recently been identified as an important initiating factor in peritoneal fibrosis and different techniques have been developed to assay for this process [83, 92].

Inflammation/Immune Response

Inflammation is an important component of peritoneal injury and response to peritonitis. This remains an important area of PD research and assays for inflammatory responses are used widely in animal models. Simple assays include bacterial clearance after acute peritonitis [103], along with simple counting of inflammatory cells [44]. Milky spots on the omental surface provide an estimate of leukocyte recruitment to the peritoneal cavity [104]. More sophisticated assays of peritoneal immune response include assays of the complement pathway [15, 58], or chemokine response [105].

Summary

The peritoneal membrane is a relatively simple structure, but the physiology and pathophysiology associated with peritoneal dialysis is complex. The interaction between the dialysis fluid, the structural components of the peritoneal membrane, the anatomic surface area, blood flow and vascular response is impossible to model in a cell culture system. Although useful mathematical models have been developed [106], understanding the peritoneal tissues as a dialysis membrane requires animal models. A variety of models have been developed to better understand peritoneal physiology, acute and chronic response to dialysate, and the molecular mechanisms of peritoneal injury and response. Insights derived from this work have led to advances in our understanding of the peritoneal membrane, new solutions for peritoneal dialysis, and new potential targets for therapeutic intervention. The goal of this work is to preserve the peritoneal membrane and improve outcomes for patients reliant on peritoneal dialysis. Through all this, researchers must maintain careful documentation of models utilized and a critical understanding of the potential and limitations of these models.

Chapter 9
Pharmacological Alterations of Peritoneal Transport Rates and Pharmacokinetics in Peritoneal Dialysis

N. Lameire and W. Van Biesen

In the first part of this chapter, the effects of pharmacological manipulations on peritoneal transport will be discussed. Increased understanding of peritoneal transport mechanisms may lead to the development of clinically useful methods to augment peritoneal transport efficiency. In this chapter, only pharmacological tools for influencing peritoneal transport will be discussed. A detailed discussion of the physiology of peritoneal transport is provided in other chapters of this book. In the second part of this chapter, the pharmacokinetic concepts underlying transperitoneal drug transport and their implications for rational and safe use of drugs in patients treated with peritoneal dialysis (PD) will be discussed. Basic concepts of pharmacokinetics will be briefly reviewed as a starting point to elaborate further on general pharmacokinetic principles in patients with decreased renal function and in patients on PD. Tables with data and guidelines for prescription of specific drugs will be presented. An update on the most recent pharmacokinetic studies in PD will be provided.

Peritoneal Membrane Transport

(For details on peritoneal membrane transport, see Chapter 6.) Peritoneal transport comprises three processes that occur simultaneously: 1) diffusion, 2) ultrafiltration, and 3) fluid reabsorption. Transport of low-molecular-weight solutes during PD is primarily diffusive, whereas convective solute transport becomes more important with their increasing molecular weight. The absorption of intraperitoneally administered macromolecules is linear in time, irrespective of molecular size or concentration. Total removal of a solute is dependent not only on the peritoneal transport rate but also on the total drained dialysate volume. The latter is determined by the instilled volume and the net ultrafiltration. The effective peritoneal surface area used for transport of solutes is determined both by the number of perfused capillaries (and thus by splanchnic blood flow) and by the contact of the dialysate with the peritoneal surface.

It should be noted that diffusion in general does not depend on peritoneal blood flow, which at 50–100 mL/min, is already more than adequate relative to the mass transfer area coefficient (MTAC) values of even the smallest solutes. The ability of vasoactive substances to influence peritoneal transport is thus not related to their ability to increase peritoneal blood flow, but to the associated recruitment of larger numbers of perfused peritoneal capillaries that increase the effective peritoneal surface area. It should be realized that the proportion of peritoneal blood flow involved in peritoneal transport is unknown, and it is possible that in some areas of the peritoneum blood flow may limit diffusion.

Ultrafiltration occurs because of the osmotic gradient between the hypertonic dialysate and the isotonic capillary blood. Ultrafiltration is determined by a number of factors such as the hydraulic conductance of the peritoneal membrane, perhaps reflecting the density of small and ultrasmall pores in the capillaries as well as the distribution of the capillaries in the interstitium. A recent review on the mechanisms of peritoneal ultrafiltration has been published [1].

Recent experiments using knockout mice for aquaporin [2] provide direct evidence for the role of AQP1 during PD. The results validated essential predictions of the three-pore model: i) the ultrasmall pores account for the sodium sieving, and ii) they mediate 50% of ultrafiltration (UF) during a hypertonic dwell. Other factors are the reflection coefficient of the osmotic agent, the hydrostatic and osmotic pressure gradients, and the sieving process (for detailed review see other chapters in this book). Fluid absorption occurs via the peritoneal lymphatics at a relatively constant rate. This absorption occurs partly directly via the subdiaphragmatic lymphatics or, more importantly, through absorption into the tissues of the parietal wall where it is subsequently taken up by local lymphatics and perhaps by

peritoneal capillaries. The determinants of peritoneal absorption are the intraperitoneal (IP) hydrostatic pressure and the effectiveness of the lymphatic system.

Role of Electric Charges on the Transport Across the Peritoneal Membrane

Anionic sites predominantly composed of heparan sulfate and chondroitin sulfate are a constant feature of basement membranes of the microvasculature [3–5]. They are particularly abundant in fenestrated capillaries, some of which have been identified in human parietal and diaphragmatic peritoneum [6]. These anionic charges could, at least theoretically, restrict the diffusive and convective passage of charged solutes across the membrane. There is a paucity of data concerning the influence of the peritoneal membrane anionic sites on transport of charged macromolecules across the peritoneum. It is well established that an increased peritoneal permeability to albumin in diabetic animals is observed like in many other capillary beds. Shostak and Gotloib [7] could attribute this phenomenon to a reduced density of microvascular and submesothelial negative charges, equivalent to that induced by diabetes in other capillary beds. More recently, administration of aminoguanidine preserved both submesothelial and subendothelial electronegative charges in diabetic rats and restored the hyperpermeability for albumin [8].

Leypoldt and Henderson [5] demonstrated that peritoneal transport rates for cationic dextrans were less than for either neutral or anionic dextrans. These results differ from what one should expect. On the other hand, negatively charged amino acids such as glutamic acids show a slower transperitoneal mobility compared to neutral or positively charged amino acids [9]. In contrast, based on the determination of peritoneal clearances of ten different proteins and their isoforms, Buis et al. [10] concluded that the peritoneal membrane was not a charge-selective barrier for the transport of macromolecules between blood and dialysate. The effect of electrically charged drugs on peritoneal transport will be discussed later.

Part I. Pharmacological Alterations of Peritoneal Transport

Better knowledge of the pharmacological alterations of peritoneal transport that occur in PD patients may be useful for several reasons:

1. Co-morbidity is high in renal failure and these patients are exposed to a multitude of drugs that may affect the peritoneal transport of solutes and water. Knowledge of the effects of such agents on transport parameters can influence the appropriate selection of a drug.
2. There may be need for augmenting the peritoneal diffusive capacity. A redefinition of adequacy targets of PD has emerged over recent years. Many studies have focused attention on optimizing the quantity of solute clearance in an attempt to improve clinical outcome. Dialysis dose is currently quantified in terms of small solute clearances, fractional urea (Kt/V), and creatinine clearance rates. The target small solute clearances have been a source of some controversy and in many studies the amount of the residual renal function (RRF) has been a major confounding factor in the correct interpretation of the results. Where the magnitude of the RRF has a direct influence on outcome, it has been more difficult to demonstrate a similar effect for peritoneal clearance, at least within the range of dose prescriptions in typical clinical use. In particular the ADEMEX (ADEquacy of PD in MEXico) study showed no difference in technique or patient survival, or quality of life between a standard dose and a higher peritoneal clearance regimen [11, 12].
3. A major cause of cardiovascular morbidity and mortality, and also of technique failure, in PD, is the inadequate removal of fluid across the peritoneal membrane. A better knowledge of fluid transport (filtration and transcapillary and lymphatic absorption) may open possibilities for pharmacological manipulation of the peritoneal ultrafiltration capacity, or chemical modification of the dialysate, in order to prevent excessive fluid reabsorption from the peritoneal cavity.
4. Although to date the biocompatibility of the PD fluids has greatly improved, still adverse interactions of both the "classical" and the "new" solutions with the peritoneal membrane may provoke structural and functional alterations in the membrane which may end in peritoneal fibrosis [13–16]. Treatment with vasoactive and/or anti-inflammatory agents could be attempted in order to decrease these adverse effects.
5. When PD is used to remove exogenous toxins, it is usually mandatory that removal rates be maximal. Conversely, when protein loss is excessive it may be judicious to decrease the transport rates, at least of larger solutes.
6. Finally, pharmacological manipulation of peritoneal transport has increased our understanding of peritoneal physiology.

This part of the chapter will describe the several pharmacological manipulations on peritoneal transport, seeking enhanced understanding of transport mechanisms and clinically useful methods to either augment transport or to preserve the structural and functional integrity of the membrane.

Drugs Acting on the Peritoneal Blood Flow and Their Impact on Solute Transport

Greatly improved mass transport must depend on augmentation of blood flow or peritoneal permeability or area, just as hemodialyzer efficiency increases with larger surface area dialyzers, more permeable membranes, and higher blood flow rates. As stated above, the ability of vasoactive substances to influence peritoneal transport is not directly related to their ability to increase peritoneal blood flow, but rather to the associated recruitment of larger numbers of perfused peritoneal capillaries that increase the effective peritoneal surface area.

A detailed overview of the anatomy and physiology of the peritoneal circulation is discussed in Chapter 4 of this book.

Despite several lines of evidence suggesting that peritoneal blood flow should be high enough to avoid any limitation in solute clearances and ultrafiltration, the real impact of effective peritoneal blood flow on the efficiency of PD is still controversial [17]. Recent experimental work has suggested that, at least in some circumstances, peritoneal ultrafiltration and solute clearances may be blood-flow limited [18].Values of the peritoneal capillary blood flow vary between 50 and 100 mL/min, based on peritoneal gas clearances in animals [19]; others have found lower values [20]. In uremic humans, an indirect estimation of effective peritoneal capillary blood flow found values between 100 and 200 mL/min [21]. The impact of the application of the distributed model of peritoneal circulation and the hypothesis of the "nearest capillary" have recently been discussed and the reader of this chapter is referred to that paper [22]. In stable continuous ambulatory peritoneal dialysis (CAPD) patients, values ranging from 20 to 151 mL/min with a median value of 66 mL/min were found [23–25]. All these values assume that gas clearances represent the "effective" peritoneal blood flow. When mesenteric blood flow is doubled, the clearances of small solutes such as urea increase by 30–50% [26], consistent with a resting blood flow that exceeds the maximal rate at which the capillary diffusion capacity can completely clear the perfusing blood [27]. This is compatible with the results obtained by Douma et al. [24], finding an increase in MTAC of small molecules without a change in peritoneal "effective" blood flow as measured by the MTAC of CO_2.

The splanchnic vascular bed can sequester blood, excluding it from, or releasing it into, the circulation as systemic volume changes. Thus, hemodynamic effects of drugs can influence splanchnic blood volume and flow rate considerably. Because drugs usually affect the splanchnic blood flow and volume pari passu, changes in peritoneal transport that result from the altered volume can be misinterpreted as flow rate mediated. There is also evidence to suggest that splanchnic blood volume, rather than flow rate, determines the degree of peritoneal mass transfer [28]. For example, the volume contraction induced by the systemic administration of dihydroergotamine results in lower peritoneal clearances of potassium, urea, and phosphate [29], and this effect is due to a reduction in blood volume. On the other hand, both volume expansion by dextrose infusion [30] and sodium chromate-induced hepatic venous stasis increase these parameters. Current opinion prevails that, under physiological conditions, peritoneal blood flow does not limit the transfer of solutes. However, the effective blood flow available for transport will only be a fraction of the total blood flow through the tissues surrounding the peritoneal cavity, because most of the exchange capillaries are too far from the cavity to be active in the exchange process [31], or they are contained in tissues not in contact with the solution in the cavity [32]. In contrast, in the "nearest capillary" theory of Ronco [33], it is hypothesized that the capillaries positioned closest to the mesothelium are dilated and have a low blood flow, while the most distal capillaries have a higher blood flow, but with a less effective diffusion due to interstitial resistances. The resulting "effective" peritoneal blood flow in this hypothesis would be a limiting factor for solute clearance.

As outlined in Chapter 6, most data obtained in experimental animals, as well as in humans, suggest that the effects of small peritoneal blood flow changes on solute transport are probably limited.

The regulation of the mesenteric circulation is very complex (for further details, see Chapter 6). It is sufficient here to remind that both extrinsic and intrinsic autoregulatory control mechanisms exist. In the latter, the venous pressure and the ingestion of meals also have an effect. Food ingestion increases intestinal blood flow and this functional hyperemia is mediated by certain gastrointestinal hormones such as gastrin and cholecystokinin. Autoregulation of blood flow, i.e., the maintenance of a constant blood flow over a range of perfusion pressures, is not as well developed in the intestinal circulation as in other vascular beds, such as those in the brain and kidney. The principal mechanism responsible for mesenteric autoregulation is metabolic, i.e., any intervention that results in an oxygen supply that is inadequate for the requirements of the tissue prompts the formation of vasodilator metabolites. However, a myogenic

mechanism probably also participates. Adenosine is a potent vasodilator in the mesenteric vascular bed and may be the principal metabolic mediator of autoregulation.

Influence of Drugs Reducing Peritoneal Blood Flow

Drugs Decreasing Peritoneal Blood Flow

Catecholamines

To explore vasoactive effects on peritoneal transport, catecholamines have been studied in animals undergoing PD. Gutman et al. [34] noted lower increments in dialysate urea with large IP doses of dopamine in anephric dogs, but did not measure dialysate volume. Because blood pressure increased, the lower urea accumulation in the dialysate was attributed to splanchnic vasoconstriction. To offset vasoconstriction, Parker et al. [35] added an α-adrenergic blocker to the dialysis fluid. With IP phentolamine and IV dopamine, peritoneal clearances increased in dogs. In human patients, however, Chan et al. [36] observed no effect of low (4 mg/L) or high doses (20–160 mg/L) of IP dopamine on dialysate urea, creatinine, or phosphate.

In rabbits, IP dopamine caused dose-related (0.6–1.8 mg/kg) increases in peritoneal urea clearance [37]. The increments occurred with lower doses than those used by Gutman et al. [34] and drug concentrations (10–30 mg/L) within the range studied by Chan et al. [36].

IV 1-norepinephrine significantly decreased peritoneal clearances of urea and creatinine in unanesthetized rabbits [36, 37]. Dose-dependent decrements of the peritoneal clearances correlated with the pressor response [38]. Comparable pressor doses of IV dopamine increased clearances of urea and creatinine to 145% of control values, whereas low doses had minimal and inconsistent effects [38]. Osmotic water flux increased only slightly (from 0.18 to 0.24 mL/kg/min) but significantly. Because dopamine vasoconstricts venules relatively more than arterioles as compared to norepinephrine [39], augmented water flux could be mediated by increased hydrostatic pressure rather than a change in hydraulic permeability. The augmented transport is attributed to dopamine receptor-mediated mesenteric vasodilation and, in part, by general α-adrenergic vasoconstriction increasing blood pressure, while mesenteric blood flow is maintained. Although dopamine may not be suitable for augmenting efficiency of routine PD, these data strongly suggest that dopamine should be preferable to 1-norephinephrine when vasopressor therapy is required during PD.

Only minimal increments in fluid and solute flux occurred with ibopamine, an oral dopamine analogue, whether given by mouth, IV, or IP to normal rabbits [40]. Interestingly, the dialysate to plasma ratio for norepinephrine was 1.17 in CAPD patients, suggesting local production in the peritoneal cavity [41]. An unexpected correlation was found between the dialysate levels of norepinephrine and the effective peritoneal surface area, represented by the MTAC for creatinine.

Recent in vitro studies have investigated the effects of epinephrine on the electrical transmesothelial resistance (R(TM)) of the isolated parietal sheep peritoneum by means of Ussing-type chamber experiments [42]. A parietal peritoneal planar sheet was mounted in a Ussing-type chamber and epinephrine (10^{-7} Mol) was added to the apical and the basolateral side. The R(TM) was measured before and serially after the addition of epinephrine for 30 min. As active ion transport is temperature-dependent, all measurements were performed at 37°C. The addition of epinephrine to the basolateral side within 1 min induced a dramatic increase of R(TM) which decreased thereafter progressively to reach control values again after 15 min. A similar effect of epinephrine on the apical side was apparent with a rapid rise and a subsequent decrease of R(TM). A clear association between the R(TM) and active ion transport was established from previous studies. The results of this study indicate a rapid action of epinephrine on the parietal peritoneum permeability. Similar results were obtained with visceral peritoneum [43].

Vasopressin and Angiotensin

Vasopressin and angiotensin cause a generalized vasoconstriction with a disproportionate reduction in mesenteric blood flow [44]. Parenteral administration of vasopressin to anesthetized dogs decreased peritoneal clearances of small solutes, consistent with a hormonally mediated reduction in mesenteric blood flow [45, 46]. Since inulin clearance increased slightly under these circumstances, a concurrent increase in membrane permeability has been postulated [47], in accord with the accelerated transport that occurs in isolated membrane preparations [48].

Angiotensin II is probably mainly involved in the control of mesenteric blood flow during volume depletion. The effect of angiotensin II (AII) on peritoneal permeability and lymphatic absorption in the rat was studied by Go et al. [49]. AII was added to the dialysate and it decreased the transcapillary ultrafiltration rate from 15.7 ± 2.8 mL/4 h dwell

in control to 5.7 ± 1.5 mL/4 h dwell. Lymphatic absorption was increased in a dose-dependent fashion with no change in clearances of urea nitrogen or inorganic phosphate.

Drugs Increasing Peritoneal Blood Flow

Although the mechanisms of a decrease in solute transport by a reduction in peritoneal blood flow are important, much more attention has been paid to the study of the possibilities for augmenting peritoneal transport by systemic or IP administration of vasodilating drugs. Many studies suggest that peritoneal clearances will increase only if a vasodilator selectively affects the splanchnic vasculature or is applied locally, e.g., by IP instillation. When administered IV such drugs may cause widespread vasodilation, decreasing blood pressure, splanchnic perfusion, and splanchnic volume, thereby lowering peritoneal transport rates. To date, membrane-active agents have augmented transport only when applied locally, i.e., instilled intraperitoneally.

Increased splanchnic perfusion augments peritoneal clearances of larger solutes at least as much as the transport of smaller solutes. This suggests an increase in peritoneal surface area or permeability resulting from vasodilation, attributed to dilation of the functional peritoneal capillaries combined with perfusion of more capillaries. Spreading the same wall mass over a larger circumference decreases the wall thickness and stretches pores. Intercellular junctions widen, accelerating mass transport [50]. Raising blood flow by local application of vasodilators also opens previously closed capillaries, increasing the surface area available for transport [51, 52]. In the resting state, blood may circulate predominantly through metarterioles. Enhanced perfusion opens more capillaries, exposing blood to a more permeable surface. Furthermore, vasodilators with a predominant venular site of action may cause greater increases in diffusion rates, but arteriolar dilators may increase the ultrafiltration rate. By increasing blood flow, diffusion and ultrafiltration may occur throughout a greater length of the capillaries than occurs under resting conditions.

Depending on the nature of the vasodilating agent there may be an increase (arteriolar relaxation), decrease (lowered venular tone), or no change (balanced effects) in capillary hydrostatic pressure. This hydrostatic pressure may affect capillary diameter, volume, and permeability and is a major determinant of the filtration rate through the capillary. The solute transfer of small molecules, measured by their MTAC, is usually markedly increased during the first 15 min of PD dwells. Besides being caused by initial arteriolar vasodilation and. hence, recruitment of capillary surface area, other explanations for this rapid increase are possible. These include an initial discharge (or saturation) of solutes from (in) the interstitium or an increased mixing, i.e., "macrostirring" caused by the exchange procedure per se [53].

These possibilities have been investigated during acute PD in rats, by assessing the mass transfer coefficient for 51Cr-EDTA as a function of time [53]. The discharge effect was studied by saturating the peritoneal interstitium with 51Cr-EDTA by IV tracer infusion prior to each dwell. The potential effect of initial vasodilation was studied by adding isoproterenol to the dialysis fluid. Finally, the potential influence of an increased interstitial "macrostirring," induced by high glucose concentrations, was investigated by comparing 1.36% glucose with 3.86% glucose dialysate. The conclusion of these experiments was that vasodilation, but not interstitial discharge (or loading), may explain the sharp rise in mass transfer occurring during the initial part of PD dwells. In addition, "macrostirring," induced by the exchange procedure per se, may also be important.

Specific drugs may directly affect the permeability of the capillary or the mesothelium [54]. Drugs that influence membrane charge, cell volume, cell metabolism, or intercellular junction may directly influence peritoneal permeability without affecting flow rates.

Isoproterenol

Isoproterenol, a β-adrenergic agonist, relaxes the mesenteric vascular bed. In patients with reduced peritoneal clearance, Nolph et al. improved transport rates by adding isoproterenol (0.06 mg/L) to the dialysis solution [55, 56]. Mean clearances increased to the lower range of normal but only transiently, and improved significantly, though not in all patients [57]. No systemic effects of IP isoproterenol were detected even with cardiac monitoring. Such use of isoproterenol has been explored in greater detail in animals. In acute studies in anesthetized dogs, IP isoproterenol increased urea and creatinine clearance by 45 and 30%, respectively, but subpressor IV doses did not augment transport [34]. In unanesthetized rabbits, 0.04 mol/kg of IP isoproterenol raised urea and creatinine clearance by 50%, but osmotically induced water flux was unaffected [58]. No systemic effects were observed. Despite raising mesenteric blood flow to 188% of control by IV isoproterenol, Felt et al. [26] found no increase in clearances. With IP isoproterenol a comparable flow increase raised peritoneal inulin and creatinine clearances by 27 and 18%,

respectively. The disparity in blood flow and clearance changes suggests that capillary blood volume may be as important as blood flow in mediating changes in permeability.

Vasodilator Gastrointestinal Hormones

Secretin is a polypeptide gastrointestinal hormone that increases mesenteric blood flow by as much as 100% above baseline when given in pharmacological doses [59]. Secretin, like cholecystokinin, increases predominantly hepatic blood flow. Slight increments in urea and creatinine clearances occurred with IV secretin and cholecystokinin [60]. IV, but not IP secretin (10 U/kg) increased osmotic water flux in rabbits [60]. The endogenous release of cholecystokinin or secretin or their intra-arterial infusion relaxes precapillary sphincters and increases the capillary filtration coefficient [61]. Gastrin, structurally similar to cholecystokinin, also increases mesenteric blood flow [59]. The effects of secretin and cholecystokinin on mesenteric blood flow are additive and potentiated by theophylline [62]. This hormonal mesenteric vasodilation is attributed to direct relaxation of vascular tone, presumably mediated by cyclic AMP.

Glucagon is structurally similar to secretin, but has a more potent effect on the mesenteric circulation. When administered IV, immediately before dialysis, glucagon significantly increased peritoneal clearances of urea and creatinine in nonanesthetized rabbits [60, 63]. The same dose given IP did not affect clearances. Since this large molecule should traverse the peritoneum slowly, hormonal activity presumably occurs at the endothelial rather than at the mesothelial surface. In dogs, IV infusion of about 30 μg/kg/h glucagon increased mesenteric arterial blood flow and peritoneal inulin but not creatinine clearance, unlike IP [26]. Glucagon did not affect peritoneal water flux during dialysis in rabbits [60]. The separation of the effects of all these gastrointestinal hormones on diffusive and on convective transport, suggests the possible use of different pharmacological agents acting additively.

Prostaglandins

Arachidonic acid (AA) was recently, investigated for its vascular permeabilizing potential in the rat peritoneal cavity and for its mechanism of action [64]. The antagonistic potential of antioxidants (vitamin E, vitamin C, and troxerutin) was also evaluated. Vascular permeability was equated to the rate of extravasation of Evans blue dye from plasma into the peritoneal cavity. IV arachidonate induced an immediate, dose-related, and significant increase in permeability, which was comparable to the effect induced by similar doses of serotonin. Aspirin reduced the arachidonate-induced permeability by 75%, but, interestingly, neither the stable thromboxane A(2) receptor agonist U46619 (prostaglandin H(2) endoperoxide epoxymethane) nor prostacyclin were able to increase peritoneal vascular permeability. In contrast, the permeabilizing action of arachidonic acid was very sensitive to antioxidant agents. Thus, vitamin C and the flavonoid compound troxerutin fully abolished arachidonate-induced permeability, whereas vitamin E had only a partial effect. In conclusion, IV administration of AA strongly enhanced peritoneal vascular permeability in the rat, apparently via free radical generation.

There is evidence that the mesothelial cells, when exposed to cytokines, show a time-dependent increase in the levels of both COX-1 and COX-2 mRNA, with the greatest increase being seen for COX-2. These data demonstrate specific stimulation of eicosanoid metabolism in human peritoneal mesothelial cells (HPMC) by peritoneal macrophage-derived cytokines, indicating the possible importance of these mediators in the activation of IP prostaglandin synthesis [65].

Depending on the local concentration of the specific terminal enzymes, e.g., endoperoxide reductase leading to placental growth factor (PGF) 2α or endoperoxide isomerase leading to prostaglandin E2 (PGE2), a given product predominates in a given tissue. Regional blood flow is one determinant of enzyme activity. In the circulation, the prostaglandins are degraded during a single passage through the lung, thereby acting only locally with the exception of prostacyclin and thromboxanes, which have half-lives of a few minutes. Prostaglandins of the PGA, PGE, or PGI series are vasodilators, whereas PGF2α and thromboxanes are potent vasoconstrictors [66, 67]. These prostaglandins act locally in arterial walls to influence vascular tone and modulate the response of vascular smooth muscle to other vasoactive agents [68], for example, by modifying vasoconstrictor responses [66].

IP instillation of PGA1 or PGE1 moderately increased peritoneal clearances of urea and creatinine in nonanesthetized rabbits, whereas PGE2 significantly raised creatinine clearance to 132% and urea clearance to 180% of control values [69]. In contrast, IP administration of the vasoconstrictor PGF2α decreased peritoneal clearances to 80% (urea) and 82% (creatinine) of control [69]. These prostaglandins did not affect fluid flux and were ineffective when given IV. Neither IV nor IP administration of prostacyclin affected peritoneal solute or water transport significantly, nor did prostacyclin show pronounced effects on peritoneal transport under baseline conditions. Oral pretreatment with sulfinpyrazone, a potent stimulator of prostaglandin synthetase, did not alter peritoneal clearances significantly [70]. When mefenamic acid, a prostaglandin synthetase inhibitor, was administered either IV or IP to unanesthetized

rabbits in doses sufficient to inhibit platelet function, neither the peritoneal clearances of creatinine or urea nor water flux changed [70].

Oral pretreatment of rabbits with indomethacin blocked platelet aggregation but did not change clearance or ultrafiltration rates significantly [70]. IP indomethacin increases the size of pinocytotic vesicles and narrows intercellular spaces in the rabbit [71]. Alteration of prostaglandin synthetase affects both vasoconstrictor and vasodilator prostaglandins. Hence, regional blood flow may remain unchanged. Yet, when vasodilator prostaglandin activity predominates to compensate for increased renin-angiotensin activity or ischemic vascular disease, aspirin and indomethacin decrease regional blood flow. However, the reduction of clearances induced by IV 1-norepinephrine, which should be accompanied by vasodilator prostaglandin stimulation, is exaggerated by pretreatment with indomethacin in only half of the animals so studied. These results suggest that endogenous prostaglandins do not play a major role in regulating peritoneal blood flow under ordinary circumstances. However, in patients who depend on vasodilator prostaglandins to maintain organ perfusion, blockade of prostaglandin synthetase could impair transport, and a history of exposure to such drugs should be sought if clearances are low. Intraperitoneally, the prostaglandin precursor AA (1.5–5.6 mg/kg) increased creatinine clearance and urea clearance, suggesting an effect of endogenous prostaglandins, but systemic use of indomethacin did not block this increase [70, 72].

In patients with peritonitis, the increased solute transport rates are accompanied by augmented prostaglandin release, abnormalities that can be blocked by indomethacin [73]. However, this effect was not confirmed in a longitudinal study in peritonitis [74].

The effects of nitroprusside on the peritoneal circulation and transport have been detailed in Chapter 4.

Other Vasodilators

No consistent change in peritoneal clearance of urea or creatinine was observed in patients given IP hydralazine, which decreased blood pressure slightly [57]. Theophylline acts as a nonselective antagonist of two types of adenosine receptors that mediate opposite effects on vascular tone [75]. In rabbits, changes in solute and water fluxes were inconsistent after IP or IV aminophylline in doses exceeding the therapeutic range [76]. Presumably widespread vasodilation blunted any potential gain in peritoneal blood flow.

Diazoxide caused a modest increase in peritoneal clearances of urea and creatinine and a significant decrement in blood pressure when IP administered to patients [57]. An increase in ultrafiltration rate approaching 50% of control values was found inconsistently. The IP administration of 5 mg of phentolamine to patients did not influence peritoneal solute transport rates, nor did it affect osmotic water flux [57].

In anesthetized rats, histamine raised only modestly the clearances of urea and inulin, whereas bradykinin augmented these clearances more substantially [77]. Histamine causes overt capillary dilation and increases permeability with protein exudation, which can be blocked in rabbits by both H1 and H2 receptor antagonists [78]. Minimal effects of histamine on small solute transport may reflect decreased plasma volume due to protein loss. In isolated rat mesentery, viewed by television microscopy after fluorescein labeling, protein exudation is also demonstrable with histamine [50]. Dilation is most prominent in the venous end of the capillary and similar changes are noted with nitroprusside.

The effects of calcium channel blockers on peritoneal mass transport have been studied by several investigators. In the anesthetized rat model, verapamil and diltiazem, given locally, modestly but significantly increased peritoneal clearances of urea without enhancing protein losses [79]. Kumano et al. [80] explored the effects of the IP administration of nicardipine, diltiazem, and verapamil in rats. All three vasodilators caused a decrease in blood pressure, which was associated with a decrease in net ultrafiltration rate. The drugs increased peritoneal net fluid absorption rate in a dose-dependent way. Nicardipine and verapamil increased the permeability to urea and glucose but not to protein. Diltiazem caused no change in permeability. Significant augmentation of small solute clearances and ultrafiltration associated with diminished glucose reabsorption were reported with IP verapamil and nifedipine in CAPD patients [81, 82]. In hypertensive CAPD patients, oral nifedipine administered in blood pressure-controlling doses significantly increased peritoneal clearances of creatinine and β2-microglobulin, associated with higher glucose reabsorption, while the rate of ultrafiltration remained unaffected [83]. These studies suggest that calcium channel blockers act on the arteriolar end of peritoneal capillaries without a consistent effect on venular permeability.

A recent clinical study evaluated the effects of oral losartan, prazosin, and verapamil on peritoneal membrane transport during a peritoneal equilibration test (PET), as well as the effects on creatinine clearance (CrCl), Kt/V urea, 24-h protein in drained dialysate, and drained volume [84]. None of the studied drugs significantly modified the peritoneal transport of creatinine, glucose, urea, sodium, potassium, or total protein as evaluated by PET. Verapamil significantly increased peritoneal CrCl, weekly Kt/V urea, and drained dialysate volume. It was concluded that oral administration of losartan, prazosin, and verapamil did not modify the peritoneal transport of solutes during a 4-h

PET, but oral small solute clearances and 24-h drained dialysate volume. Verapamil could thus be considered as an alternative in patients requiring increased dialysis dose and/or ultrafiltration.

In rats, modest increases in urea clearance and glucose absorption and a marked exaggeration of protein loss was seen following IP instillation of very large doses of captopril, an angiotensin-converting enzyme inhibitor [85]. These increments, despite drug-induced systemic hypotension, may reflect increased blood flow, surface area, or permeability. In the above-mentioned study by Kumano et al. [80], captopril was also investigated after IP administration. Captopril increased membrane permeability to small and large molecular solutes, with a consequent decrease in ultrafiltration rate. In a clinical study [86], six hypertensive CAPD patients received IP enalaprilat and five of them also received oral enalapril. After IP enalaprilat, blood pressure declined significantly, and plasma angiotensin-converting enzyme (ACE) activity was suppressed below detectable limits. There were no changes in peritoneal transport characteristics. In contrast, in another study in CAPD patients, glucose, creatinine, and β2-microglobulin transport rates were increased after oral administration of hypotensive doses of enalapril [83]. Smaller doses of oral captopril significantly reduced peritoneal protein loss in diabetic CAPD patients, with only a small decrease in their mean blood pressure [87].

Coronel et al. [88] evaluated the action of irbesartan, an angiotensin receptor blocker (ARB) with a long half life, on proteinuria, peritoneal protein losses, and peritoneal transport. After 30 days of treatment with irbesartan (145 ± 72 mg/day), and no changes in blood pressure level as compared with baseline, a reduction in proteinuria, decreased peritoneal protein losses at 4 h and 24 h dwell time, decreased peritoneal Kt/V urea, and increased peritoneal creatinine clearance were observed. Levels of serum albumin, prealbumin, and transferrin increased after treatment with irbesartan. Treatment with irbesartan in PD patients apparently modifies peritoneal transport and reduces peritoneal and urinary protein loss. This effect probably has a positive impact on nutritional parameters.

Using a sophisticated intra-abdominal camera, Ishida et al. [89] tested several antihypertensive drugs on the peritoneal capillaries in renovascular hypertensive dogs with mild renal insufficiency. The diameters of the small arteries of the peritoneum were measured after 3 days' oral administration of placebo, a selective ARB, or benazepril, an ACE inhibitor, or amlodipine, a calcium antagonist. A similar decrease in blood pressure was observed with all drugs. The diameter of the small vessels increased by 28% in dogs receiving the ARB and by 24% in dogs receiving benazepril, as compared with only 3% in dogs receiving the calcium antagonist.

Besides the hemodynamic effects that blockers of the angiotensin pathway may exert on the peritoneal structure and function, angiotensin is also thought to contribute to peritoneal fibrosis when the membrane is exposed to high glucose concentrations in PD [90], and ARBs may have a key role in preventing fibrosis as they may inhibit the TGF-beta1-Smad pathway [91]. However, another recent study found no differences in the protective effect on the membrane of either an ACE inhibitor or an ARB [92], but the expression of AQP-1 and AQP-4 in the mesothelium was significantly suppressed, accompanied by loss of peritoneal ultrafiltration in ACEI- and ARB-treated compared with control rats [93]. These results suggest that the renin-angiotensin system plays an important role in the regulation of water transport in the peritoneum and that administration of ACEI or ARB in patients CAPD should be carried out with caution.

The influences of a variety of other agents on peritoneal mass transport have been explored.

Statins have anti-inflammatory properties that may be of value in modulating responses to injury. The capacity of atorvastatin to modify peritoneal alterations secondary to hypertonic glucose were recently explored [94]. Administration of atorvastatin resulted in preserved ultrafiltration, protein loss, and peritoneal thickness.

Atrial natriuretic peptide (ANP) is a hormone with well-known diuretic and vasodilating properties. It has recently been reported that ANP could increase peritoneal fluid formation and increase peritoneal solute clearance. Recent studies in rats [95] suggest that ANP may decrease peritoneal fluid absorption by 51%, partially because of decreasing the direct lymphatic absorption, resulting in a significant increase in peritoneal fluid removal and small solute clearances. While the basic diffusive permeability of the peritoneal membrane was not changed, the peritoneal glucose absorption was retarded by adding ANP to peritoneal dialysate, perhaps through interaction of ANP with glucose metabolism.

The peritoneal transport rates of potassium and iodide-131 increased when streptokinase or serotonin was administered systemically to anesthetized dogs [45]. Whether these agents affect peritoneal permeability directly, or augment blood flow, remains to be determined.

In sedated rabbits dialyzed with a hypertonic dialysis solution, 0.25% procaine hydrochloride increased peritoneal urea and inulin clearances by more than 60% [96]. The effect persisted for at least 1 h after procaine was discontinued. Procaine may augment transport by vasodilation. However, the addition of procaine to either side of the isolated mesothelium increased transport, after a transient decrease. This effect may be due to disruption of the microfilaments of tight junctions between cells.

Using direct videomicroscopy of the peritoneal vasculature in rats, Mortier et al. [97] found that local application of acetylcholine, nitroglycerin, verapamil, and papaverine caused significant vasodilation of mesenteric arteries in the absence of any effects on systemic BP. Nitroglycerin 10^{-4} Mol induced a maximal and rapidly reversible vasodilation and acts independently of the endothelium.

The nitric oxide system and the peritoneal circulation and transport (see also Chapter 4).

Nitric oxide (NO) is the final common pathway for many of the vasodilating processes, including nitroprusside. Besides the expression of aquaporins (see below), Devuyst et al. [98] investigated the expression of endothelial nitric oxide synthase (eNOS) in 19 peritoneal samples from normal subjects, from uremic patients treated by hemodialysis (HD) or PD, and from nonuremic patients using Western blotting and immunostaining. eNOS was located in all types of endothelium and was up-regulated in the three patients with ascites and/or peritonitis. An adaptation of the L-citrulline assay to measure specific NOS activities within the peritoneum was more recently described; it appeared that the peritoneum lysate assayed for NOS activity can also be used for characterizing NOS isoform expression by immunoblot analysis [99].

Nitric oxide (NO) generation within the peritoneum could potentially affect peritoneal transport by increasing capillary vasodilatation, and increase peritoneal permeability during episodes of bacterial peritonitis. As peritoneal mesothelial cells have a common embryological derivation with endothelial cells, then mesothelial cells could potentially be a major source of locally produced NO. Davenport et al. [100] measured NO in fresh and spent dialysate effluent (SPDE) from uninfected CAPD patients, and from those during episodes of bacterial peritonitis. The results suggest that HPMC may be an important source of locally generated NO within the peritoneal cavity under basal conditions, but as they do not contain iNOS, the increased NO produced during episodes of acute bacterial peritonitis is more likely due to a combination of increased NO production by peritoneal endothelial cells and transmigrating macrophages. NO is very rapidly converted into nitrite and nitrate and the dialysate concentrations of both products have been used to estimate peritoneal NO production. In contrast to nitrite in plasma, which is rapidly converted to nitrate, nitrite in fresh and spent dialysis fluid is stable [101]. However, interpretation of such results should be made with caution. It is likely that the L-arginine–NO pathway is not the only route for generating nitrate, and that nitrate and nitrite are not acceptable measures of biologically active NO [102].

It is well known that different isoforms of NO synthase exist; the two most relevant ones in PD being eNOS and iNOS. The latter is induced whenever immunological stimulation is present. Peritoneal macrophages are an important source of iNOS [103–105]. Combet et al. [106] were able to demonstrate a strong increase in total NOS activity in an experimental model of peritonitis in the rat. This increase was inversely correlated with peritoneal free-water permeability. It is thus conceivable that the elevated levels of nitrate in peritonitis are derived from iNOS activity and not from the "hemodynamically active" pool of eNOS.

With these reservations in mind, nitrate in plasma and dialysate was measured [107] in stable CAPD patients and in patients with 11 peritonitis episodes in the acute phase and after recovery. The correlation between the MTAC of nitrate and the MTAC of creatinine indicated diffusion from the circulation and not local production of NO in the stable patients. From these studies it was suggested that D/P ratios of nitrate exceeding 1.0 during the acute phase of peritonitis are probably the result of local NO production, which may contribute to the marked vasodilation during peritonitis.

An important animal study showed that chronic uremia induces permeability and structural changes in the peritoneum, in parallel with AGE deposits and up-regulation of specific NOS isoforms and growth factors. These data suggest an independent contribution of uremia in the peritoneal changes during PD and offer a paradigm to better understand the modifications of serosal membranes in uremia [108]. Another study of the same research group demonstrated that long-term exposure of the human peritoneal membrane to dialysis solutions led to a significant increase in vascular density and endothelial area in the peritoneum in association with an up-regulation of NOS, vascular endothelial growth factor (VEGF), which co-localized with the advanced glycation end product pentosidine deposits. These data provide a morphologic (angiogenesis and increased endothelial area) and molecular (enhanced NOS activity and endothelial NOS upregulation) basis for explaining the permeability changes observed in long-term PD [109].

More recent studies have also suggested a major role for nitric oxide (NO) in the permeability changes and loss of ultrafiltration induced by acute peritonitis. Both in eNOS wild-type and knockout mice [110, 111] or with NOS blockade in wild-type mice the potential role of NO in peritonitis was explored. The results revealed that the permeability modifications and structural changes induced by acute peritonitis were significantly reversed in eNOS knockout mice, resulting in a net increase in ultrafiltration [110]. These results confirm that increased NO mediates permeability modifications during acute peritonitis. Breborowicz et al. [112] studied peritoneal transport of small and large solutes, and net ultrafiltration in rats during PD with glucose 3.86% solution, where L-NAME was used as an additive to dialysis fluid. In addition, the effect of IP L-NAME during acute peritonitis induced by lipopolysaccharides

was evaluated. L-NAME increased the peritoneal selectivity and net ultrafiltration. Lipopolysaccharides alone induced a significant decline in net ultrafiltration while, together with L-NAME, no changes in transperitoneal transport of small and large molecules was observed, nor a significant decline in net ultrafiltration. L-NAME given intraperitoneally reduced both local and systemic production of NO, which might explain its effects on peritoneal transport.

The effects of conventional and more biocompatible solutions on the peritoneal circulation will be discussed in Chapter 12.

Dipyridamole

Dipyridamole rapidly but transiently vasodilates [113] and has a sustained antiplatelet effect, which may explain the restoration of clearances towards normal in patients with intravascular platelet aggregations [114]. Peritoneal transport of urea and creatinine increased by 43 and 70%, respectively, in patients with normal vasculature given oral 300 mg/day of dipyridamole [115]. In rabbits, IV or IP dipyridamole increased urea and creatinine clearances by 39 and 16%, respectively [114]. The limited effectiveness and the transient vasodilator response of dipyridamole are reflected by two randomized control studies that did not demonstrate significant increases in peritoneal transport [47, 116]. Reduced peritoneal transport rates complicating some vascular diseases (vasculitis, diabetes mellitus, lupus, etc.) are improved by dipyridamole [117]. The augmentation of peritoneal transport rates persists after dipyridamole vasodilation abates, and is attributed to its antiplatelet effect. Peritoneal clearances of patients with normal vasculature improve only minimally and transiently with oral or IP dipyridamole [114]. Nevertheless, dipyridamole may be useful for selected patients when systemic disease with platelet thrombi affects mesenteric vessels, and an oral agent is preferred.

Alterations of the Electric Charges

Charged macromolecules may interact with peritoneal anionic sites, altering membrane ultrastructure and permeability. In rats, local administration of protamine, a polycation, markedly increases peritoneal permeability to inulin and, to a lesser extent, urea, associated with a partial disruption of the mesothelial junctions [118]. In rabbits, protamine-induced rise in peritoneal permeability to proteins can be reversed by heparin, which provides additional evidence for the physiological importance of negative electric charges on the membrane [119]. Also cationic poly-L-lysine augments peritoneal permeability for urea, inulin and albumin, while with the anionic poly-L-glutamic acid there was an opposite trend in rats [120]. These results were confirmed in a rabbit model by Pietrzak et al. [121]. Agents such as poly-L-lysine, polybrene, and procaine hydrochloride block the negative charges on the capillary walls and higher mass transports ensue, especially for charged solutes [122]. A poly-L-lysine -induced modest increase in the transfer rate of large uncharged molecules such as dextrans may be attributed to an effect on pore dimensions.

These findings contrast with those of Breborowicz et al. [123], who found decreased hydraulic permeability of the mesothelium in vitro when exposed to cationic ferritin or Alcian blue. In vitro studies of isolated mesothelium, however, may not relate closely to in vivo conditions, in which the capillary wall and interstitium are the more important transfer barriers. Further evaluation of polycations as transport accelerators, particularly for patients with impaired peritoneal transfer capacity, is undoubtedly warranted.

Influence of Pharmacological Substances on Peritoneal Convective Transport

As outlined in the chapter of peritoneal physiology, according to the three-pore model [124], the existence of a third, ultrasmall pore or aquaporin could explain the dissociation between water and sodium transport observed during PD, mainly when using hypertonic dialysis solutions. Aquaporin-1 has recently been recognized as the molecular correlate to such channels and positive staining for aquaporin-1 has recently been reported in the endothelial cells of the peritoneum of normal and uremic subjects [98, 125]. Aquaporins can be inhibited by mercurials, and in a study by Carlsson et al. [126], $HgCl_2$ was applied locally to the peritoneal cavity in rats, dialyzed with a hypertonic 3.86% glucose solution. $HgCl_2$ treatment reduced water flow and inhibited the sieving of $Na+$ without causing any untoward changes in microvascular permeability, compared with that of control rats. At least eight isoforms of aquaporins are now described, and besides aquaporin 1, aquaporins 3 and 4 are also present in the peritoneum [127].

Imai et al. [128] used a rat model of peritoneal sclerosis and could demonstrate that, in this model, the expression of AQP-1 and AQP-4 were significantly suppressed, and ultrafiltration volume was lost. The use of prednisolone in this

model completely restored the expression of AQP-1 and AQP-4, and peritoneal function improved. These findings were later confirmed by Stoenoiu et al. [129], who demonstrated that corticosteroids were able to induce an upregulation of aquaporin 1 in the peritoneal membrane with an associated increase in transcellular water transport across the peritoneal membrane.

Some drugs can also specifically affect the capillary filtration coefficient, i.e., the volume filtered per unit of pressure per unit of time (mL/mm Hg/min). The rate of ultrafiltration is largely determined, however, by the osmotic gradient across the peritoneum induced by dextrose. The gross ultrafiltration rate and solute mass transfer are offset by dialysate absorption; hence, lowering lymphatic flow rates raises net ultrafiltration and peritoneal clearance of solutes.

Diuretics

The addition of 1 mg/kg of furosemide to hypertonic PD solution augmented sodium movement, accompanying osmotically induced water flux in rabbits [130]. Normally, electrolytes do not accompany water in the same concentration as exists in plasma water, suggesting that membrane charge impedes transport, a phenomenon that is interrupted by furosemide. IP furosemide also caused an increase in peritoneal urea clearance, but no demonstrable changes in transport rates occur in patients undergoing intermittent PD when treated systemically with this diuretic. Moreover, oral administration of furosemide did not affect sodium, potassium, or water transport in patients undergoing CAPD [131]. Furosemide, however, does increase the peritoneal transport of uric acid and of barbiturates [132]. Intraperitoneally, 1.25 mg/kg of ethacrynic acid did not affect sodium flux accompanying the bulk flow of water across the peritoneum, but augmented urea clearance to about 165% of baseline [130]. Patients treated by CAPD may experience a restoration of lost ultrafiltration capacity after treatment by furosemide or by hemofiltration [133]. A specific effect of furosemide has been postulated, but correction of an overexpanded splanchnic volume by decreasing glucose absorption was able to restore the ultrafiltration capacity.

Amphotericin B (AmB)

AmB increases the rate of ultrafiltration per osmotic gradient, i.e., the ultrafiltration coefficient [134]. Above 0.5 mg/kg there is no dose effect, and it is effective only from the serosal side [134, 135]. AmB creates channels in biological membranes for solute and water penetration. Increments in peritoneal solute clearances are only modest and can be accounted for by enhanced convection [134]. Peritoneal mass transport of sodium also increases. Because osmotic ultrafiltrate during PD is hyponatric, the sodium gradient so established is an impediment to water transport that is cancelled by AmB [135]. IP use of use of AmB has been reported to increase ultrafiltration during short peritoneal dwell in rabbits. However, IP AmB did not increase peritoneal fluid removal after 4 h of dwell in a rat model [136]. Although the basic membrane permeability may not be altered by this drug, the D/D0 ratio for glucose and dialysis-over-plasma concentration ratio (D/P) values for urea, sodium, and total protein, as well as the diffusive mass transport coefficient values for these solutes did not differ among the different experimental groups (with and without AmB). However, the D/P values as well as the diffusive mass transfer values for potassium were significantly higher in the drug-treated animals as compared to the control group, resulting in significantly higher potassium clearances in the AmB-treated animals as compared to the control group. These higher clearances for potassium in the AmB groups may suggest a local release of potassium due to the cytotoxic effect of AmB. The contribution of water release from local cells to the increase in IP volume in animals treated with a high dose of AmB cannot be ruled out. Based on these results, it was concluded that AmB is not useful for improvement of PD efficiency [136]. Another experimental study with IP administration of AmB in rabbits [137] found also that the drug acutely enhanced a change in IP volume during a 1-h dwell after 3-day IP treatment with a low dose but did not affect peritoneal solute permeability. This was likely mediated by transcellular water channels, but not by aquaporin-1. No beneficial effects on the ultrafiltration were found with prolonged treatment or with the higher dose. Also these investigators found that AmB has no major clinical relevance in treatment of ultrafiltration failure in PD patients.

Beta-Blockers (β-Blockers)

Use of β-blockers has been associated with peritoneal ultrafiltration failure [138]. Of 13 patients with ultrafiltration failure, 12 had used β-blockers, compared to 18 patients without these problems, where only two patients used these drugs. Possible mechanisms explaining this observation have been reviewed [139]. From a theoretical point of view, either a decrease in portal venous pressure or an increase in lymphatic absorption is a possible mechanism.

Increasing Ultrafiltration Rates by Miscellaneous Drugs

Secretin increases the hydraulic permeability of the peritoneal membrane [140]. This selective action on the splanchnic bed occurs from the vascular side only. The aminonucleoside puromycin also induces this effect on peritoneal capillaries [141]. Chlorpromazine (2 mg/L) IP increases the ultrafiltration rate and solute clearance, largely by increased convection and presumably by its surfactant effect [142]. This drug decreased surface tension of the dialysate.

Neostigmine decreases the rate of lymphatic flow and thereby increases net ultrafiltration in rats [143]. Anticholinesterase agents have complex hemodynamic effects that could influence peritoneal transport and increase gastrointestinal motility, which would enhance dialysate mixing.

Higher ultrafiltration rates due to diminished glucose reabsorption were reported with IP calcium channel blockers in CAPD patients [81, 82]. Ronco et al. [17] suggested that maximal rates of ultrafiltration are inhibited by the steep curvilinear rise in plasma protein oncotic pressure in the peritoneal capillaries, reflecting the limited blood flow rate. Maher et al. [144] demonstrated that the ultrafiltration coefficient decreases in rabbits as IP dwell is prolonged, suggesting some concentration polarization, which could be corrected by increasing turbulence at the membrane interfaces. Increased absorption of dextrose will accompany most manipulations that enhance solute permeability and hence dissipate the glucose osmotic gradient faster, reducing ultrafiltration. Insulin is required to maintain low plasma glucose levels and achieve the maximal gradient. Exogenous insulin added intraperitoneally does not increase the glucose mass transfer coefficient [145].

Lymphatic Absorption

Lymphatics are the primary route for absorption from the peritoneum of isotonic dialysate including macromolecules, particles, and formed blood elements [146]. Most absorption occurs via the subdiaphragmatic lymphatics, with lesser amounts via the mesenteric lymphatic vessels [147]. Yet before reaching lymphatic channels macromolecules are probably distributed in the large peritoneal tissue compartment [148] (see Chapters 5 and 6 in this book).

The rate of lymphatic flow from the peritoneum correlates positively with ventilation (diaphragmatic movement) and negatively with end-expiratory pressure; it decreases with erect posture and with dehydration [149].

In the rat PD model, neostigmine increased net ultrafiltration and solute transport by reducing the cumulative lymphatic absorption, without an increase in total transcapillary ultrafiltration [143]. Lower doses of IP failed to influence lymphatic absorption in CAPD patients [150], but the animal data were confirmed by a report of a CAPD patient suffering from myasthenia gravis who required high oral dosage of this drug [151]. In another animal study, phosphatidylcholine augmented net ultrafiltration and solute clearances without increasing flux of water and solutes into the peritoneal cavity, thus acting by reducing lymphatic reabsorption [152]. Similar results were reported in a clinical study [153]. It has been suggested that phosphatidylcholine affects peritoneal fluid kinetics through its cholinergic action [154]. These studies indicate that limiting lymphatic absorption is a potential mechanism for augmenting peritoneal clearances that should be explored further.

The Study of Different Additives to the Dialysate

Hyaluronan

Using the rat model it has been found that peritoneal absorption was significantly reduced and peritoneal small solute clearance substantially increased by adding to the peritoneal dialysate 0.01% hyaluronan, a long polysaccharide chain that consists of repeating disaccharide units of N-acetylglucosamine and glucuronic acid [155, 156]. It is speculated that the effect of hyaluronan is due to the accumulation of a restrictive filter "cake" of hyaluronan chains at the tissue–cavity interface [156].

Hyaluronan plays an important role in tissue hydraulic conductivity and has been shown to exhibit a high resistance against water flow. It can thus act in tissue as a barrier against rapid changes in tissue water content [157], impeding the efflux from the peritoneal cavity. This effect of hyaluronan is both size- and concentration-dependent [156].

It is also possible that exogenous high-molecular-weight hyaluronan stabilizes the endogenous hyaluronan, which forms a stagnant layer at the mesothelial cell surface [158]. Effluent dialysate from CAPD patients stimulates production of hyaluronic acid by human mesothelial cells and acts synergistically with cytokines, such as interleukin (IL)-1 [159]. It has been shown that normal human mesothelial cells in vitro surround themselves with a particular matrix, "coat," containing mainly hyaluronan [160]. In a prospective, randomized crossover study [161], PD patients

were submitted to three dialysis treatments using the following PD solutions: 1) a commercially available PD solution (Dianeal PD-4, 1.36% glucose), 2) Dianeal PD-4 containing 0.1 g/L hyaluronan (HA), and 3) Dianeal PD-4 containing 0.5 g/L HA. There were no significant differences in net UF or peritoneal volume profiles among the three treatments. Mean net UF calculated using residual volumes, estimated by RISA dilution, tended to be slightly higher during treatment with solution containing 0.1 and 0.5 g/L HA. These data support the acute safety of HA when administered IP to PD patients. Although not statistically significant, there was a trend toward decreased fluid reabsorption during treatment with HA.

N-acetylglucosamine

Related to the effects of hyaluronan, N-acetylglucosamine (NAG) has been used either as osmotic agent for PD [162, 163] or as an additive to classical dialysate. Chronic PD with dialysis solution supplemented with NAG (50 mmol/L) causes accumulation of glycosaminoglycans in the peritoneal interstitium, which results in a change of peritoneal permeability [164]. Supplementation of the dialysate with NAG could enhance the synthesis of hyaluronan by the mesothelial cells, since hyaluronan contains both glucuronic acid and NAG. In rats, equivalent concentrations of NAG and glucose were associated not only with a greater ultrafiltration with NAG [163], but also with a greater in vitro synthesis of hyaluronan [162].

Chronic PD in rats with a solution supplemented with NAG showed an accumulation of polyanionic glucosaminoglycans in the submesothelial interstitium that must be associated with a decreased hydraulic permeability of that tissue [165].

Glycosaminoglycans (GAGs)

Enhanced IP synthesis of GAGs increases the permselectivity of the peritoneum and preserves its function during chronic PD [166–168]. To verify whether the favorable effects of GAGs are purely functional or involve a morphological amelioration of the peritoneal membrane structure, a study was carried out in an animal model of plasticizer-induced peritoneal fibrosis [169]. Subtotally nephrectomized rats received either placebo, plasticizers (IP), or GAGs (SC), or plasticizers (IP) and GAGs (SC). In plasticizer-treated animals, peritoneal function tests and morphology were dramatically deranged. On the contrary, the SC administration of GAGs in plasticizer-treated rats maintained the peritoneal physiology and normal structure. The SC administration of GAGs apparently protects peritoneal functions by affecting the remodeling of the peritoneum, rather than by a purely functional or simple mechanical effect.

Heparin

In an animal model of chronic PD with repeated dwell studies it was shown that heparin may improve peritoneal fluid transport, possibly due to better healing and reduced peritoneal inflammation [170]. In a clinical study, Sjoland et al. [171] showed that IP tinzaparin reduces peritoneal permeability to small solutes and increases ultrafiltration in PD patients. In a recent experimental study [172], exposure to PD fluid induced activation of IP complement formation of C3a(desArg) and increase of C5a-dependent chemotactic activity, and coagulation (formation of thrombin–antithrombin complex) and recruitment of neutrophils. In the case of IP injection, neutrophil recruitment and complement activation were inhibited by low-molecular-weight heparin (LMWH). LMWH inhibited thrombin formation, reduced complement-dependent chemotactic activity, and increased the IP fluid volume, indicating an improved ultrafiltration.

Chondroitin Sulfate (CS)

CS, another naturally occurring polyanionic polymer GAG has been tested as an alternative osmotic agent or has been added to saline [173] or conventional dialysis solution to enhance peritoneal ultrafiltration [167]. In the presence of CS, net peritoneal ultrafiltration increased, while absorption of glucose and horseradish peroxidase from the peritoneal cavity decreased [173, 174]. It is postulated that the polyanionic CS molecules are trapped in the peritoneal interstitium, thus decreasing its hydraulic conductivity and permeability, which in turn increases net fluid removal during PD because of its slower absorption from the peritoneal cavity.

Phosphatidylcholine

In 1985, Grahame et al. detected the presence of surface-active material (phospholipids) in the peritoneal effluent of CAPD patients [175].The surface-active material, lining the peritoneal membrane, is mostly composed of phosphatidylcholine (lecithin). Peritoneal efficiency may be altered by the constant removal of phosphatidylcholine and other phospholipids in the dialysate effluent [175]. A decrease in dialysate phospholipids was reported in patients with a low ultrafiltration capacity and in those with peritonitis [176]. IP phosphatidylcholine promptly raised the ultrafiltration rate, while after oral administration about 30 days were required to achieve this effect. It was suggested that lecithin administration restored the normal peritoneal surfactant lining [176]. To explain augmentation of ultrafiltration after phosphatidylcholine, another group proposed that these phospholipid molecules bind to the anionic sites on the luminal side of the mesothelium, creating a water-repellent surface that diminishes the thickness of the unstirred dialysate. This would augment diffusion of solutes from blood to the peritoneum while the hydrophobic lecithin molecules would impede water absorption, favoring ultrafiltration [177].

In rabbits, phosphatidylcholine increases net ultrafiltrate volume [177], an effect that becomes significant only after hours of PD, and does not show up during hourly exchanges.

Clinical studies have shown that a phosphatidylcholine premixed dialysis solution significantly enhances ultrafiltration also in patients without ultrafiltration loss [153], but other results were controversial [178, 179]. Besides its surfactant effect, phosphatidylcholine may impede lymphatic absorption [152]. In rat experiments, administration of 50 mg/L phosphatidylcholine to a dialysate of 4.25% glucose leads to a reduction in lymphatic absorption without increased transperitoneal transport of water. However, in in vitro experiments, phosphatidylcholine was cytotoxic to human mesothelial cells, as indicated by the release of lactate dehydrogenase from their cytosol. These results suggest that the positive short-term effect of the addition of phosphatidylcholine to the dialysis solution (i.e., an increase in ultrafiltration) may be masked by its deleterious action on human mesothelial cell membrane [180].

Dioctyl Sodium Sulfosuccinate (DSS)

Dioctyl sodium sulfosuccinate (DSS) is a surfactant and has been shown to increase peritoneal small solute clearance. Penzotti and Mattocks [181, 182] accelerated peritoneal transport of labeled urea and creatinine in sedated rabbits by adding a variety of surface-acting agents including DSS and setyl trimethyl ammonium chloride. Dunham et al. [183] found a dose-dependent rise in creatinine and urea clearances when docusate sodium was given intraperitoneally to tranquilized rabbits. The effect persisted for 5 h. DSS was found to increase peritoneal fluid and small solute removal whereas the peritoneal solute transport rate did not change [184].

Cytochalasins

These molecules disrupt microfilaments of cellular junctions. IP cytochalasin D raises the clearances of creatinine and urea in the rabbit, consistent with augmented diffusion through intercellular gaps [185]. Similarly, cytochalasin B, D, and E increase permeability of the peritoneum to urea, inulin, and albumin in rats [186]. Only cytochalasin B effects were clearly reversible, which may relate to its unique ability to affect carrier proteins of the cell membrane.

Antioxidants and Free Radical Scavengers

Breborowicz et al. [187] tested the effect of L-2-oxothiazolidine-4-carboxylate (procysteine), a precursor of intracellular cysteine, on the function of human mesothelial cells in culture. Procysteine stimulated the proliferation of these cells and decreased their spontaneous death rate. The cells, when pretreated with procysteine, were resistant to injury by free radicals. Procysteine also reversed the cytotoxic effects of a mixture of essential and nonessential amino acids on the cells. The same drug was also studied in an in vivo model of lipopolysaccharide (LPS)-induced peritonitis in rats [188]. The addition of LPS to dialysis fluid increased the white blood cell count and the nitrite level (index of NO synthesis) in the dialysate. Simultaneous addition of procysteine to the dialysis fluid prevented an increase of while blood cells, but not of nitrites in the dialysate. The IP inflammation was accompanied by a decrease in net transperitoneal ultrafiltration, an increase in the absorption of glucose, and a loss of protein into the dialysate. Procysteine partially reversed the effect of peritonitis on net ultrafiltration.

Peritoneal leukocytes from rats exposed to LPS showed a reduced concentration of glutathione, an effect that was reversed in the presence of the drug. These results show that the addition of procysteine to dialysis fluid modified the peritoneal reaction to acute inflammation. The same group [189] showed that supplementation of IP infusion of saline with vitamin E decreased the peroxidation of peritoneum estimated as the malondialdehyde (MDA) level in rats'

omentum. However, the permeability of the peritoneum to glucose and protein in vitamin E-treated rats was increased. Vitamin E appeared to be cytotoxic to human mesothelial cells, as measured by inhibition of their proliferation, and this effect was irreversible.

Influence of Drugs on Peritoneal Mesothelial Cells

The short-term effects of antineoplastic agents such as methotrexate, doxorubicin, and mitoxantrone on the integrity of human peritoneal mesothelial cells (HPMC) membrane and mechanisms of intracellular potassium transport were assessed [190]. There was no evidence of significant cytotoxicity to either methotrexate, doxorubicin, or mitoxantrone. However, methotrexate diminished Na,K,ATPase activity and simultaneously enhanced 86Rb transport via a furosemide-sensitive pathway. Mitoxantrone reduced the furosemide-sensitive 86Rb influx in a dose-dependent manner. These data demonstrate that antineoplastic agents interfere with HPMC function, which might contribute to the oncostatic-induced peritoneal toxicity. The same group investigated the effects of insulin on the Na + /K(+)-ATPase expression and activity in human peritoneal mesothelial cells [191]. A time- and dose-dependent increase in the Na + /K(+)-ATPase activity was found. This effect appears to be mediated by an increase in [Na +]i and is not related to alterations in Na + /K(+)-ATPase subunit mRNA expression.

Transport Acceleration of Specific Solutes

Removal of barbiturates may be accelerated by increasing dialysate pH with Tris buffer, thereby influencing the rate of nonionic diffusion [192]. Alkalinization of peritoneal dialysate by THAM also raised uric acid transport [193]. Drugs that counteract the membrane anionic charge should enhance removal of charged solutes. Adding albumin to a PD solution enhances removal of barbiturates [194], ethchlorvynol [195], and salicylate [196], and is expected to augment the clearance of numerous other drugs that circulate bound to plasma proteins, such as quinine and phenytoin. For lipophilic drugs such as glutethimide and short-acting barbiturates, transport can be enhanced by adding lipid to the dialysate [197]. In general, for treating severe overdosage, the removal of drugs by PD is too slow. Specific effects such as chelation, however, may influence concentrations of drugs and certain uremic metabolites.

Peritoneal Protein Loss Attenuation

In a preliminary study, captopril significantly reduced protein loss into the peritoneum in diabetic CAPD patients, presumably by modulating vasoconstrictive responses of peritoneal capillaries [87]. In rabbits a marked increase in protein elimination into the peritoneum occurred after addition of histamine, an effect blocked by its antagonist [78]. Because histamine may be involved in the pathogenesis of hypersensitivity reactions to drugs, leachables or contaminants of the dialysis solution, antihistamine agents could be of value in such circumstances.

Several lines of evidence support the role of intact anionic sites on the peritoneal transport barrier in the restriction of the passage of charged macromolecules to the peritoneal cavity. Partial neutralization of anionic sites may account for the findings from an animal study in which dialysate pH adjustment from 5.6 up to 7.4 significantly increased peritoneal protein loss in the presence of nitroprusside [51]. Another group demonstrated that, in rabbits, transperitoneal protein loss was substantially enhanced by protamine. Neutralization of protamine with heparin prevented this effect [119]. In an animal study [5], blood to peritoneum transport rates of cationic DEAE dextran were less that those of both neutral dextran and dextran sulfate. The effects of chondroitin sulfate have been described above.

Conclusions of Part I

It is easy for clinicians as well as basic scientists to forget that the peritoneum, unlike synthetic hemodialysis membranes, is alive. The mesenteric circulation is remarkable for its size and complexity, and until recently not much was known about its physiology. The numerous drugs and hormones that affect mesenteric blood flow and membrane physiology have predictable effects on peritoneal transport parameters [198, 199]. Patients undergoing chronic dialysis often take several drugs, many of which have hemodynamic and membrane transport effects. The influences of these agents on the peritoneum must be ascertained. Patients treated for acute problems, for example, in

an intensive care unit, are exposed to an even greater abundance of drugs potentially altering transport. Rational use of drugs and other physiological manipulations in patients maintained by PD requires an understanding of their effects on peritoneal blood flow and permeability. It is naive to consider the peritoneum as an inert membrane with constant blood flow and transport characteristics. Further investigation of the interactions of drugs and the peritoneum may identify optimal methods for augmenting transport efficiency safely.

Part II: Pharmacokinetic Aspects of Peritoneal Transport of Drugs

This part of the chapter has been divided in two major sections: the first section covers some basic pharmacokinetic concepts in the presence of normal and abnormal renal function. More detailed information on this subject is available in standard textbooks and reviews on pharmacokinetics [200–202] and in chapters of textbooks in nephrology [203, 204]. Also in this first section a general discussion on the major factors determining the transperitoneal transport of drugs after systemic and IP administration will be provided.

In the second section the pharmacokinetic data obtained with drugs, commonly used in continuous ambulatory or automated PD (CAPD or APD) patients, have been listed in tables. Following each table, recommendations for possible dose adaptations in PD patients are provided.

Basic Pharmacokinetics

Drugs produce their therapeutic or toxic effects in biological systems by reacting with receptor sites or other sites of action located in target tissues. The intensity of these effects is, in most cases, determined by the concentration of the drug in the direct environment of the site of action (the "biophase"). It is not possible to determine drug concentrations in the biophase. However, all tissues are supplied by blood (or plasma). Although often a complex relationship exists between the drug concentration in the biophase and that in plasma water, the latter is an alternative and more accessible site to measure the drug concentration. Responses to a particular drug are therefore commonly related to the concentration of the drug (or in some cases of its metabolites), in plasma water. After administration of a drug, absorption from the site of administration to the plasma (in case of extravascular administration), distribution from the plasma to organs and tissues, and elimination by biotransformation (predominantly in the liver) or by excretion of the chemically unaltered parent drug (predominantly via the kidneys) take place. However, after biotransformation, the metabolites are often excreted by the kidneys, even when the parent drug is not. In the situation in which the metabolite(s) is pharmacologically active, dose adaptation in renal failure of drugs that are not primarily eliminated by the kidney may be necessary. As a consequence of these events, drug concentrations in plasma water, and in the biophase, change with time, as does the pharmacological effect.

In addition, drugs can be bound to proteins, and their effect may depend on the free/protein-bound ratio. With the usual methods, however, total plasma drug concentrations are measured, i.e., free drug and drug bound to plasma proteins together. If the protein binding of the drug is constant, total drug concentration in plasma water can be used as an index of free drug concentration. If, however, the protein binding of the drug has changed, e.g., because of renal failure or by interaction with other drugs, this relationship will change and the intensity of effect will be smaller or larger than expected for a particular total plasma drug concentration.

Compartmental Models

Pharmacokinetics involve the mathematical description of the time-course of the concentration of the drug (and, in some cases, its metabolites) in biological fluids after its administration. In most models, compartments are used; it is important to realize that a pharmacokinetic compartment does not necessarily correspond to a given anatomical body fluid compartment. The time-course of the plasma drug concentrations can usually be adequately described by a one-compartment model, in which the body is viewed as one space, in which the drug is distributed rapidly and homogeneously. Although this is an oversimplification, such a one-compartment model is often satisfactory for the study of the pharmacokinetics of a drug, e.g., in order to determine its optimal dosage.

A two-compartment model (Fig. 9.1) consists of a central and a peripheral compartment. The central compartment includes the plasma, but also the extracellular fluid of highly perfused organs such as heart, lung, liver, and kidney. The peripheral compartment involves the compartment in which the drug is distributed at a slower rate. Transfer between

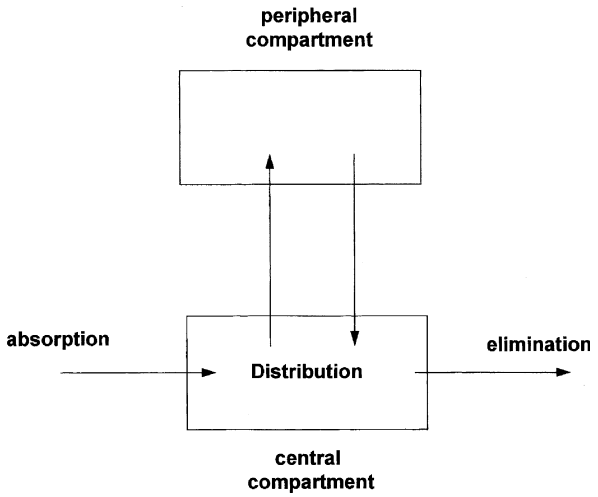

Fig. 9.1 Schematic representation of a two-compartment model

the two compartments is slow, and changes in concentration in one compartment will only be accompanied by changes in the other compartment with a certain delay. What parts of the organism belong to the central or to the peripheral compartment will depend upon the physicochemical characteristics of the drug, and of the general condition of the tissues involved. In a patient with sepsis, for example, the separation between central ("vascular") and peripheral ("interstitial tissue") compartments has greatly disappeared by the generalized hyperpermeability of the capillaries. Although three- and even more-compartmental models describe the situation more correctly, they are difficult to handle and their use is usually not needed.

Plasma Concentration–Time-Course

In Fig. 9.2 the time-course of the plasma concentrations of a drug after IV injection of a single dose is shown for both a one-compartmental and a two-compartmental model. Factors such as absorption, distribution, elimination, and excretion usually follow first-order kinetics. When first-order kinetics apply, the changes in concentration occurring are proportional to the drug concentration at that particular moment. After absorption and distribution are completed, the fall of the plasma concentration is only determined by elimination. As illustrated in Fig. 9.2, if elimination follows first-order kinetics, the log concentration versus time curve in a two-compartment model is a straight line. From the plasma concentration–time curve a number of pharmacokinetic parameters can be calculated. These are useful in the procedures for dose adaptation in different situations.

The elimination serum half-life of the drug ($t_{1/2}$), is the time taken for the plasma concentration as well as the amount of drug in the body to decrease by 50%. A closely related parameter is the elimination constant (K_e), where:

$$K_e = 0.693/t_{1/2} \tag{9.1}$$

The apparent volume of distribution (V_d) of a drug relates the total amount of drug in the body to the concentration of drug in plasma at the same moment.

The V_d can be calculated from:

$$V_d = D/C_0 \tag{9.2}$$

where D equals the dose given and C_0 equals the plasma concentration at the time 0, the time of administration. The V_d can be calculated only when the dose of the drug entering the body is known; that means when the drug is either given IV or if the exact amount absorbed is known.

The V_d provides an estimate of the extent of distribution of the drug throughout the body. If there is important uptake of the drug by the tissues, a V_d several times larger than the total body fluid volume (approximately 42 L for a body weight of 70 kg) can be found.

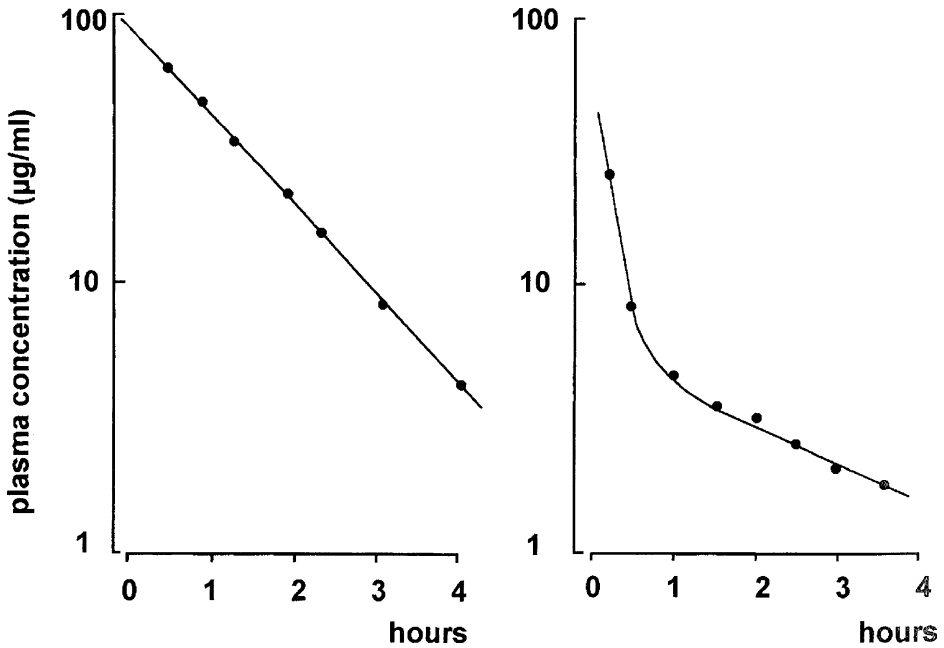

Fig. 9.2 Plasma concentrations as a function of time; in the left panel the logarithm of the plasma concentration is plotted for a drug for which a one-compartmental analysis is appropriate. In the right panel, log plasma concentrations are shown for a two-compartmental analysis. After the distribution phase there is a linear decay of the concentration, corresponding to the elimination phase

One of the important factors determining the size of the apparent V_d is the degree of plasma protein binding. The relationship between the apparent V_d of a drug and its protein binding is as follows:

$$V_d = V_B + V_T(F_B/F_T) \tag{9.3}$$

V_B and V_T are the volumes of water in blood and in tissues, respectively, and F_B and F_T are the fractions of free drug in blood and tissues, respectively. An increase in F_B without a proportional increase in F_T would produce an increase in the apparent V_d.

The apparent V_d can also be calculated from the area under the plasma concentration versus time-curve (AUC), and K_e:

$$V_d = D/AUC \times K_e \tag{9.4}$$

or

$$V_d = (D \times t_{1/2})(AUC \times 0.693)$$

Total body clearance or total plasma clearance is the volume of plasma that is cleared completely of the drug per unit time: it gives an estimate of the efficiency of the elimination of the drug by organs such as liver or kidney. Total body or plasma clearance is the sum of the clearances by the individual elimination routes, mainly biotransformation in the liver and excretion by the kidneys. For some substances elimination takes place only via the kidney, and then total body clearance equals renal clearance.

Total body clearance (Cl_{tot}) can be calculated by means of the equations:

$$Cl_{tot} = 0.693\ V_d/t_{1/2} \tag{9.5}$$

$$Cl_{tot} = D/AUC \tag{9.6}$$

Although clearance can be calculated from V_d and $t_{1/2}$, it does not depend on these parameters. On the other hand, $T_{1/2}$ of elimination is dependent not only upon the clearance, but also upon the V_d. Although gentamicin and digoxin are both cleared by the kidneys to approximately the same extent as creatinine (this means at a rate of approximately

120 mL/min in a normal situation), the elimination $T_{1/2}$ of digoxin is 36 h, while that of gentamicin is only 2 h. This is due to the fact that the V_d of digoxin is more than 500 L, while that of gentamicin is only about 15 L. When elimination in different situations is compared (for example, in patients with renal failure compared to healthy individuals, or in predialysis patients compared to those on dialysis), clearances and not only half-lives should be calculated whenever possible. Elimination $T_{1/2}$ should not be confused with duration of action. The latter is determined by the time during which drug concentrations are above a minimal effective concentration (MEC). For antibiotics, usually the minimal inhibitory concentration (MIC) of the susceptible antibiotic is considered.

The duration of drug action is dependent not only on the elimination $T_{1/2}$ of the drug but also on the dose given, bioavailability and of the drug distribution.

Total body clearance can be measured exactly only after IV drug administration or when the bioavailability, F, is known. Drugs are, however, often administered orally without knowing their exact bioavailability.

While the pharmacokinetic behavior of a drug is usually studied after single-dose administration, it is of utmost importance to know what happens after chronic administration of a drug. For some drugs at the moment of the second administration the amount still present in the body is negligible, so that after the second administration concentrations in the plasma will be similar to those after the first administration. This is, for example, the case when, in patients with normal renal function, gentamicin (with an elimination $T_{1/2}$ of 2 h) is administered three times a day. When, however, drugs are administered at dosing intervals shorter than four half-lives, an important fraction of what was introduced with the last administration is still present at the time of the second dosage. Consequently, the concentration after the second dose will be higher than that after the first dose, i.e., accumulation of the drug occurs. In that case, steady-state concentrations are obtained only after a number of administrations. The time to reach steady-state plasma concentrations depends only on the $T_{1/2}$, and is approximately four to five times the $T_{1/2}$ of the drug. For example, for digoxin, with its $T_{1/2}$ of 1.5 days, this works out at approximately 1 week. If the steady-state levels are to be achieved earlier, a loading dose of the drug must be given. The extent of accumulation (i.e., how much higher the steady-state levels will be than those after the first administration) depends on the $T_{1/2}$ and the dosing interval.

Pharmacokinetic Alterations in Patients with Decreased Renal Function

In patients with renal failure the fate of a drug can be altered profoundly. Gastrointestinal absorption after oral administration of a drug may be impaired in uremic patients because gastrointestinal pH or motility are altered. Biotransformation of drugs can be decreased or increased in uremic patients. There is also much interest in alterations in plasma protein binding of drugs in these patients. For a number of acidic drugs, which are mainly bound to plasma albumin, binding is often markedly decreased, due either to a decrease in albumin concentration in the plasma or to a decrease in the affinity at the binding sites; the decrease in affinity can be due to structural changes of the albumin molecules or to the presence of endogenous inhibitors. Some basic drugs bind mainly to α1-acid glycoprotein (α1-AGP). In renal failure the binding of these drugs may be increased due to the elevated α1-AGP concentrations in the plasma. These changes in protein binding can markedly affect the calculated pharmacokinetic parameters, and they can in some circumstances lead to changes in free drug concentration in plasma, to changes in efficacy and to side-effects.

Most important, of course, is the decrease in renal excretion of the drug. The renal clearance of a drug is usually decreased proportionally to the decrease in glomerular filtration rate. If renal excretion is the only elimination route of the drug, total body or plasma clearance will be reduced to the same extent. For substances that are only partly eliminated by the kidneys, the alteration in total body clearance will depend upon the relative importance of the renal versus the nonrenal elimination. It should, however, be re-emphasized that it is not because a drug is not eliminated via the kidney, that total body clearance is not altered in patients with renal failure. For example, hepatic clearance can also be affected by a change in protein binding or because of accumulation of other molecules. However, the V_d of drugs in these patients is often also different due to the changes in binding in plasma or in tissues. The plasma $T_{1/2}$, which depends on both V_d and Cl, is therefore not always a good parameter of the drug clearance in these patients. For example, digoxin is not bound to a significant extent to plasma proteins, but it is bound extensively to tissues of the kidneys, liver, and myocardium. This binding is decreased in patients with renal failure. As apparent from Eq. 9.3, a decrease in drug tissue binding without a corresponding decrease in drug plasma binding results in a decrease in the apparent V_d. In several studies it has been observed that the V_d of digoxin is significantly smaller in patients with chronic renal failure (230–280 L versus 500 L in normals).

The pharmacokinetic changes in chronic renal failure can, mainly after chronic administration of a drug, lead to important changes in total and free plasma concentrations, if the dose is not adjusted. Drug concentrations in the body can be much higher and the time to reach steady state (at a higher level) can be increased if the $T_{1/2}$ is prolonged. This

explains why, in patients with renal failure, a loading dose is often needed. Thus, for many drugs, dose adjustments will be necessary in chronic renal failure. The mean steady-state levels (Css) that will be achieved in a given situation can be calculated with the following equation:

$$\text{Css} = (F \times D)/(Cl_{\text{tot}} \times T) \tag{9.7}$$

where F = fraction absorbed, T = the dosing interval, and D the maintenance dose. This can also be expressed as:

$$\text{Css} = (F \times D)/Cl_{\text{tot}} \times T) \tag{9.8}$$

From these equations the maintenance dose needed for a given Css can be calculated. The many nomograms available for calculation of maintenance doses are based on these principles.

The loading dose (D*), i.e., the dose needed to obtain a given Css at once, can be calculated by the equation

$$D* = V_{\text{d}} \times \text{Css} \tag{9.9}$$

Pharmacokinetic Alterations in Patients on PD

PD can alter the pharmacokinetics of a drug, depending upon the route of administration of the drug and rate of removal via the dialysate. This can necessitate dose adaptations.

Pharmacokinetics of Drugs After Systemic Administration: Assessment

Plasma and dialysate concentrations can be measured as a function of time. To evaluate whether systemic kinetics are affected by dialysis, serum $T_{1/2}$, V_{d} and total body clearance (and in some cases residual renal clearance) can be calculated and compared to the values obtained in terminal chronic renal failure patients without dialysis. The amount recovered from the peritoneal dialysate over the period of time (Aper), can be used to assess the need for dose adaptation. This amount should be viewed in relation to that lost in the body over the same period of time by other routes, such as hepatic biotransformation or residual renal excretion.

The PD clearance (Clper) can be calculated from the equation:

$$\text{Clper} = (\text{Apert1} - \text{t2})/\text{AUC t1} - \text{t2} \tag{9.10}$$

where Aper t1 – t2 is the amount recovered in the dialysate over a given time period and AUC t1 – t2 is the area under the plasma concentration curve over the same time period. The peritoneal clearance should be compared to the total body clearance (Cl_{tot}). Indeed, the increased plasma clearance that can be found with dialysis is dependent of the peritoneal clearance of the drug, the residual renal clearance and the nonrenal clearance.

Factors Influencing Peritoneal Drug Clearance After Systemic Administration

The dialysis clearance of a systemically administered drug in the PD setting will depend upon factors that are summarized in Table 9.1. The peritoneal membrane characteristics have been described in the first part of this chapter. Only some of the other factors will be discussed below.

Dialysate Flow Rate

The most important factor in determining the magnitude of the peritoneal clearance of a drug is the dialysate flow rate, which is around 6–7 mL/min in CAPD. Small solute peritoneal clearances are largely dialysate flow-dependent. During the long dwells of CAPD, the transport rate of small solutes per unit of time is high at the beginning of the dwell and decreases with time because diffusion equilibrium is either obtained or approached. With increasing molecular weight of the solute the transport rate during the dwell becomes more homogeneous.

The dialysate flow rate is greater during the rapid exchanges in some automated PD (APD) regimens. This explains why, during the rapid exchanges in APD programs, clearances of solutes with low molecular weight are increased. During the rapid exchanges of continuous cyclic PD (CCPD) (for example, four exchanges of 2.5 L over 8 h overnight, followed by a long diurnal dwell time of 10–12 h), the dialysate flow rate can be around 15–20 mL/min, values much greater than those for CAPD. Dialysis clearances during the short dwell times could be higher, because sink conditions tend to be maintained. It could be that during the rapid exchanges a significant fraction of a systemically given drug is removed through the peritoneum.

The first comprehensive reviews on the pharmacokinetic principles in the antibiotic treatment of peritonitis in APD have been published by Diaz-Buxo et al. [205] and Manley and Bailie [206]. Results from various APD and comparative CAPD pharmacokinetic studies were reviewed. In APD patients, antibiotic half-lives were shorter during the cycler exchanges. Antibiotic peritoneal clearance was greater in patients treated with APD than those treated with CAPD regimens. Antibiotic clearance depends upon RRF and dialysate flow rate.

Table 9.2 is taken from [206] and shows that the peritoneal clearances of different antibiotics are systematically higher in APD than in CAPD. To ensure that maximal antibiotic bioavailability occurs with intermittent IP dosing, it is recommended that the antibiotic-containing dialysate must dwell at least 4 h to ensure an adequate antibiotic depot in the body.

To determine the impact of dialysate flow rate (DFR) on cefazolin pharmacokinetics in PD patients, Manley et al. [207] performed a meta-analysis of published reports, and the data were analyzed based upon low DFR ($\leq$ 5.50 mL/min) or high DFR ($>$ 5.50 mL/min). Published literature provided data on 55 PD patients (12 high DFR, 43 low DFR). Regardless of data origin a prominent coefficient of determination ($p < 0.0001$) existed between DFR and all cefazolin pharmacokinetic data except peritoneal clearance. These findings demonstrate that an increased DFR leads to an increased rate of cefazolin clearance in APD patients. Clinicians dosing cefazolin in PD patients using a higher DFR than that used to determine cefazolin pharmacokinetics should use increased doses or prescribe lower/comparable DFRs. Data are not yet available for patients prescribed very high DFRs (e.g., continuous flow PD).

Table 9.2 Comparison of various antibiotic clearances in CAPD and APD patients (from [206])

	Dialysate flow (mL/h)		Peritoneal clearances (mL/min/1.73m^2)	
Antibiotic	APD	CAPD	APD	CAPD
Cefazolin	416.7	333.3	2.2 ± 0.7	1.0 ± 0.3
Tobramycin	416.7	333.3	4.2 ± 0.9	1.1 ± 0.8
Vancomycin	416.7	333.3	2.1 ± 0.7	1.2 ± 0.5
Piperacillin	416.7	333.3	5.3 ± 1.1	3.6
Fluconazole	500–687.5		11 ± 2.7	4.3–5.5

However, the concentration of most systemically administered drugs achieved in the drained dialysate after 2 h will be much lower than after long dwells so that the total amount of drug removed over 24 h in APD will be not much different from CAPD. We therefore suspect that the daily peritoneal removal of most drugs after systemic administration is also in the APD setting, as a rule, clinically unimportant.

The Molecular Weight of the Drug

The molecular weights of most drugs range between 100 and 700 Da, with some notable exceptions such as vancomycin (MW 1,450), insulin (MW 6,000), and Epo (MW 30,400). The diffusion of a solute from blood to dialysate is inversely proportional to the square root of the solute mass, both in HD and PD [208, 209].

Drug Protein Binding

Since only unbound, free drug is available for diffusion, a drug with a high plasma protein binding usually shows a low peritoneal clearance. The effect of plasma protein binding on the peritoneal transport of IV administered β-lactam antibiotics has been investigated in rats [210]. The antibiotic concentration–time profiles obtained in the dialysate were compatible with the concept that only unbound antibiotic is available for peritoneal transport. Although Flessner et al. [211] reported that bovine serum albumin is transferred through the peritoneal tissues from plasma to the peritoneal cavity in rats, the capillary membrane permeability of cephalosporins was 5–17-fold higher than that of albumin. Therefore, even if molecules bound to albumin can be transported through the peritoneal membrane, the contribution of this fraction is probably minor. For practical purposes this implies that the peritoneal membrane plays no important role in the transport of endogenous substances highly bound to proteins [212]. Dialysate concentrations of proteins are lower than serum concentrations and the protein binding of drug molecules in the peritoneal compartment is believed to be of minor clinical significance [213]. Based upon these considerations, a reasonably accurate formula for the prediction of the peritoneal clearance in CAPD after systemic administration of drugs has been proposed [214], where:

$$\text{Clper(mL/min)} = 75\sqrt{(\text{fU})}/\sqrt{(\text{MW})} \tag{9.11}$$

In this formula, fU represents the free fraction in the serum and MW the molecular weight of the drug. This formula is valid for a 2 L dialysate and a 6 h dwell, in the absence of peritonitis. Erythromycin, for example, has a molecular weight of 730 and a free fraction of 0.30; therefore, the peritoneal clearance is estimated to be 1.52 mL/min. The validity of the formula was tested by comparing the predicted values with the observed clearances in 19 clinical studies. A linear regression analysis yielded a correlation coefficient of 0.958.

A drug with a low molecular weight (<500 kDa) and with a low plasma protein binding can have a clinically relevant PD clearance.

Need for Dose Adaptation After Systemic Drug Administration in PD

The dialyzability of a drug in any dialysis strategy is clinically relevant only when at least two conditions are fulfilled. First, the dialysis clearance should be at least 30% higher than the endogenous total plasma clearance; otherwise the additive effect of dialysis clearance on overall drug elimination is negligible [215]. Second, the V_d of the drug should be less than 1 L/kg body weight. If V_d is larger, only a small fraction of the drug is available in the plasma for elimination via dialysis, and the amount of drug removed is small, even for a high clearance. Since in terminal chronic renal failure for most drugs, the total endogenous drug plasma clearance is higher than 20–30 mL/min, and the V_d is more than 1 L/kg body weight, the peritoneal drug clearance rarely contributes significantly to drug removal in the CAPD setting. Therefore, additional dose adaptations for CAPD beyond the recommendations for terminal chronic renal failure are very rarely necessary. Notable exceptions are drugs with a small V_d, low protein binding and a small total plasma clearance in uremia.

The presence of peritonitis does not significantly influence the magnitude or rapidity of drug transport into the peritoneal cavity after systemic administration. For example, the peritoneal clearances of netilmicin and of ciprofloxacin in patients with or without peritonitis were not different [216, 217].

Studies after systemic administration of a drug are of interest not only to evaluate the need for dose adaptations to maintain adequate systemic concentrations, but also for knowing the dialysate drug concentrations. The low peritoneal drug clearance does not exclude that, for example, for an antibiotic, therapeutically effective concentrations

can be achieved in the dialysate after systemic administration, due to the low volume (2–3 L) in which the drug diffuses. The rapidity with which therapeutic concentrations are achieved in the dialysate may be influenced by the presence of peritonitis. For example, after IV administration, therapeutic vancomycin concentrations in the dialysate are reached after 30 min of dwell in peritonitis patients, vs. 2–4 h in a noninflamed peritoneum [218].

The concentrations of antibiotic drugs that are achieved in the dialysate after systemic as well as after IP administration must be viewed against their activities against the strains that are isolated from patients with peritonitis. As pointed out by several workers, used PD fluid is a better medium to test these activities than the classically used broth [219–221]. Furthermore, recent work has shown that culturing conditions, dialysate manipulations, and adherence capacity of germs are critical factors affecting antibiotic activity [222]. For drugs that are metabolized by equilibrium-rated reactions to metabolites that are removed by PD, a higher total clearance of the parent drug may also be present during PD, even if the drug itself is not found in the dialysate. Thus, the absence of the drug in drained dialysate does not mean that total clearance of that drug is not altered by CAPD. An example of this phenomenon has been described for mycophenolate acid and its metabolite mycophenolate glucuronide, where a significant amount of mycophenolate acid was removed in the dialysate, almost completely in its glucuronidated form [223].

Pharmacokinetics of Drugs After IP Administration

Peritoneal transport is also of interest with regard to IP administration of drugs. For example, the IP doses of insulin or Epo required to achieve adequate systemic concentrations, or of antibiotics for local treatment of peritonitis, need to be carefully calculated. There are two sources of blood supply to the organs of the peritoneal cavity, one to the parietal and the other to the visceral peritoneum; both layers are rich in lymphatic circulation. The venous blood of visceral peritoneum returns to the portal circulation, while the venous return from the parietal peritoneum drains into the systemic rather than into the portal circulation. Earlier pharmacokinetic studies have indicated that, after IP injection, drugs such as atropine, caffeine, glucose, glycine, and progesterone are absorbed predominantly via the visceral peritoneum [224]. Therefore, these drugs, when introduced IP, are subject to immediate handling by the liver and some of them might undergo a first-pass metabolism. After IP administration, drug concentrations can be measured as a function of time in both dialysate and plasma. In view of the low peritoneal clearance of drugs after systemic administration, the rapid drug disappearance out of the peritoneum when the drug is given via the IP route is at first sight surprising. It is, however, merely the consequence of pharmacokinetic factors, i.e., V_d and protein binding. The contrast between the small dialysate volume and the very large V_d of the drug in the body, leads to a high concentration gradient. This is illustrated for vancomycin in Fig. 9.3 (adapted from [225]).

Studies after IP administration of glycopeptides show that bioavailability increases with dwell time. The data in Fig. 9.4 (from [226]) show that bioavailability is highly variable at early dwell times so that, to ensure consistent absorption of an intraperitoneally administered drug, short dwell times are not recommended. This may be relevant for APD patients who receive antibiotics intraperitoneally during the rapid exchanges. It is likely that these patients may not be receiving their full dosages due to decreased dwell time in the peritoneal cavity. The bidirectional passage of a drug molecule across the peritoneum is influenced by the same factors that regulate the passage of creatinine, urea, and glucose, the molecules commonly used as markers of membrane transport status. Therefore, it is hypothesized that correlations exist between the pharmacokinetic variables used to describe and predict drug disposition in the PD patient and the transport parameters readily available for that patient. If so, these measures (peritoneal equilibration test (PET)), Kt/Vurea, and creatinine clearance (CCr)) could be used to individualize the PD patient's antibiotic regimen, drugs could be more accurately dosed, and better outcomes possibly achieved. Elwell et al. attempted to determine the correlations between pharmacokinetic variables and patient membrane transport characteristics [227]. This retrospective study re-evaluated data collected during previous pharmacokinetic studies for IP administered cefazolin, ceftazidime, and gentamicin in CAPD patients, and IV cefazolin and tobramycin in APD patients. Prominent correlations were found between renal CCr and renal Kt/V, with renal clearances of for CAPD cefazolin and ceftazidime, and for APD tobramycin and cefazolin. Correlations of total and renal CCr with drug CLtotal were found in the pooled cefazolin group. Total CCr also correlated well with cefazolin total clearance in the APD group, although the correlations between the PET classification and drug clearance were difficult to interpret due to few data in the APD cefazolin group. However, there was a trend observed between cefazolin CLp and the 4-h PET values for D/P creatinine. Future studies will be needed to establish a firm relationship between peritoneal membrane characteristics and peritoneal drug clearances. The high protein binding of some drugs in the plasma, versus a negligible protein binding in the dialysate, further promotes this apparent one-way diffusion from dialysate to blood.

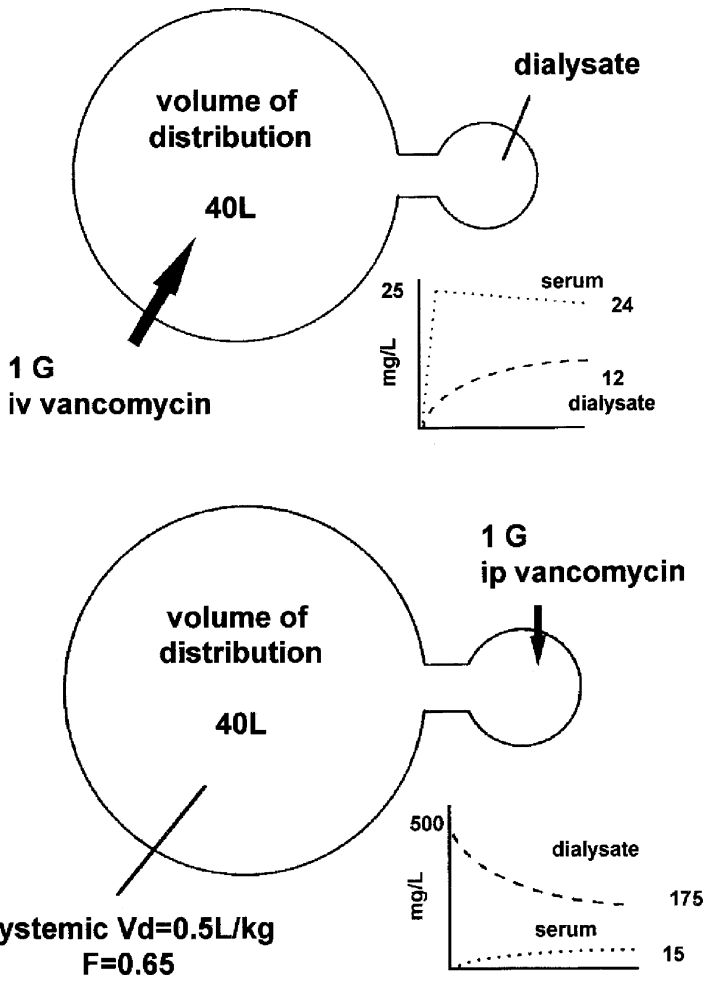

Fig. 9.3 Upper part: Model of pharmacokinetics in PD after IV administration of 1 g of vancomycin into a theoretical VD of 40 L (0.5 L/kg in an 80 kg patient). The inset shows the relationship of serum and dialysate concentrations over the duration of the 4-h dwell, which started at the same time as the IV administration. Lower part: Model of pharmacokinetics of vancomycin in PD after IP administration of 1 g of vancomycin into a 2 L exchange in a patient with a theoretical volume of 40 L. The inset shows the relationship of serum and dialysate concentrations over the 4-h duration of the vancomycin-containing exchange

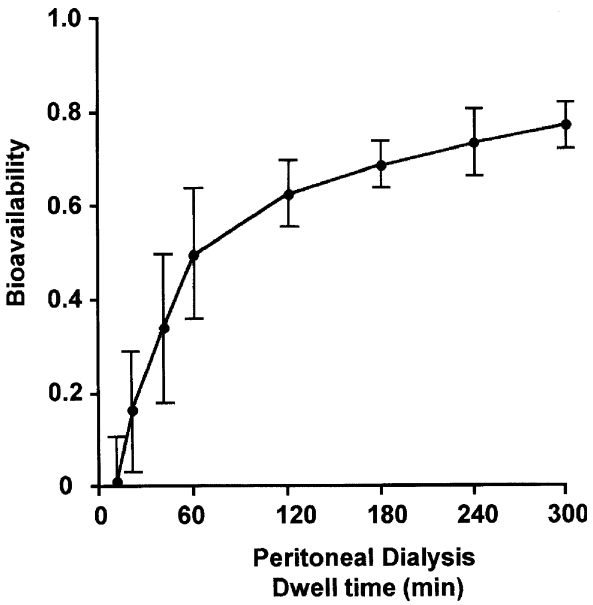

Fig. 9.4 Relationship between systemic bioavailability and dwell time when teicoplanin is administered intraperitoneally. Bioavailability was calculated by comparison of AUC values following single IP and IV doses, as well as from the amount of drug remaining within the peritoneal cavity with time. From Brouard et al. [226], with permission

Factors Affecting Transperitoneal Drug Absorption After IP Administration

These factors are summarized in Table 9.3; only a few of them will be discussed here; some of them have been described in the first part of this chapter. An important factor influencing drug transport after IP administration is the electric charge of a drug. As outlined in the first part of this chapter, there exist anionic charges on the peritoneal basement membrane and capillaries subjacent to it [6, 228]. The presence or absence of these peritoneal anionic charges can influence transperitoneal absorption of cationic drug molecules such as aminoglycosides. We and others have, however, shown a much-enhanced transperitoneal absorption of gentamicin, netilmicin, and tobramycin during peritonitis [217, 229, 230] (see below). These observations are difficult to explain if electric charges are important in their transport. Similarly, conflicting effects on the transport of gentamicin with IP heparin, a negatively charged drug, have been reported. One earlier study reported lower blood gentamicin concentrations with IP heparin [231], while another study revealed that heparin caused an increase in transport of uncharged molecules such as urea and creatinine and of the positively charged gentamicin [232].

It is possible that incorporation of proteoglycans such as heparin, hyaluronic acid, or chondroitin sulfate in the peritoneal membrane alters peritoneal transport by mechanisms other than by electrical charge, as was shown by Hadler [233]. The effects of these molecules on peritoneal transport have been discussed separately in the first section of this chapter.

As the electrical charge of a molecule in solution depends upon the pH of the fluid, theoretically at least, drug transport characteristics could change when bicarbonate-containing dialysate solutions are used. It is, however, accepted that the conventional (acidic) glucose-containing dialysate solutions rapidly correct their pH to physiological values after instillation. Studies in rats have shown that a significant proportion of the transport of macromolecules from the peritoneal cavity to the plasma is via convective transport via peritoneal lymphatic absorption [234, 235].

As reviewed by a number of authors [212, 236–238], the systemic absorption of IP antibiotics varies from 50 to 80% within a dwell period of 6 h in CAPD. The amount absorbed can easily be measured by subtracting, from the amount of drug initially instilled, the amount of drug that is present in the first peritoneal outflow. This, however, assumes that there is no degradation of the drug over the time interval in the dialysate. Most commonly used antibiotics are stable in peritoneal dialysate, either alone or in combination, or in the presence of additives such as insulin or heparin [239–243]. However, for some cephalosporins a degradation of 12–6%, and for rifampicin a degradation of 6%, was found in CAPD solutions or in effluent over 6 h [239]. This may lead to an overestimation of the amount of drug absorbed after IP administration. Vancomycin is not stable at basic pH, and complex formation may occur after addition to bicarbonate-containing dialysate.

More recent studies have further explored the stability of antimicrobial chemical and bioactivity of antibiotics. Dooley et al. [244] evaluated the stability of gentamicin, vancomycin, and gentamicin and vancomycin in combination, and the stability of the bioactivity of ceftazidime, admixed in standard PD solutions and then maintained over a 14-day

period at room temperature or under refrigeration. Antibiotic concentration by immunoassay did not significantly deteriorate over 14 days for vancomycin or gentamicin when either room temperature or refrigerated samples were studied. By bioassay, gentamicin and ceftazidime, but not vancomycin, lost moderate but significant activity over 14 days when refrigerated bags were assayed (except for an insignificant decrement in gentamicin in the combined vancomycin and gentamicin bags). Bags stored at room temperature, in general, lost significant bioactivity over 14 days, but to levels where clinical efficacy would still be expected. The vancomycin bioassay performed on the combination bags demonstrated a remarkably enhanced bioactivity, presumably reflecting synergy with gentamicin. These data indicate thus that these antibiotics admixed with PD fluids retain a stable chemical activity, whether refrigerated or kept at room temperature, for at least 14 days.

Voges et al. [245] evaluated the stability of gentamicin, tobramycin, netilmicin, vancomycin, cefazolin, unfractionated heparin, and low-molecular-weight heparin when added to four different PD solutions (Extraneal® (Baxter Healthcare, Castlebar, Ireland); Physioneal®, Nutrinea®, and Dianeal® (Baxter Healthcare, Grosotto, Italy)) in new, non-PVC Clear-Flex containers. Netilmicin, vancomycin, cefazolin, and heparin in Physioneal®, Nutrineal®, Extraneal®, and Dianeal® were stable for at least 24 h at 25°C and for an additional 4 h at 37°C. Gentamicin in Nutrineal®, Extraneal®, and Dianeal® was stable for at least 24 h at 25°C and for an additional 4 h at 37°C; gentamicin in Physioneal® was stable for less than 24 h at 25°C. Tobramycin® in Nutrineal® and Extraneal was stable for at least 24 h at 25 °C and for an additional 4 h at 37°C; tobramycin in Physioneal® and Dianeal® was stable for less than 24 h at 25°C

Vancomycin stability in icodextrin has also been tested [246]. Premixed vancomycin-icodextrin PD solutions, whether stored refrigerated or at room temperature, were recently found to be stable for up to 7 days. However, it is recommended that these solutions be kept refrigerated whenever possible. Solutions stored at body temperature were stable for up to 24 h, permitting the practice of prewarming solutions prior to administration.

A faster and more important absorption of antibiotics such as aminoglycosides, vancomycin, piperacillin, and various β-lactam antibiotics in peritonitis patients has been frequently demonstrated[217, 229, 230, 247–249]. Figure 9.5, taken from the paper by De Paepe et al. [229], illustrates the difference between peritonitis and nonperitonitis. It is also apparent, that after IP administration of gentamicin, the decrease in dialysate concentration is much more pronounced than the increase in plasma concentrations. This is not surprising as the V_d of the body is much larger than the volume of the PD fluid. Equal concentrations of gentamicin in serum and dialysate were achieved at approximately 24 h. The clinical relevance of the higher systemic availability during peritonitis is questionable for drugs with a wide therapeutic toxic margin. However, if a drug with a narrow therapeutic index is only negligibly cleared after transport to the systemic circulation, systemic accumulation after repetitive IP administration of the drug could occur. After chronic administration of gentamicin into the PD fluid for 2–3 weeks, plasma concentrations approach the end of dwell-time dialysate concentrations [229]. This can lead to potentially toxic concentrations and necessitates dose reduction. After IP

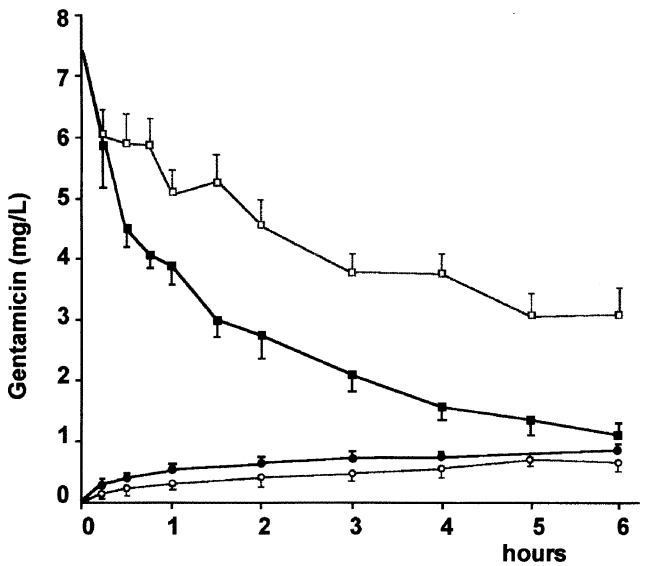

Fig. 9.5 Concentrations (mean ± SEM) of gentamicin in serum (○) and dialysate (□) in five patients without peritonitis and in serum (●) and dialysate (■) in five patients with peritonitis. Gentamicin was added in a concentration of 7.5 mg/L to the dialysate at time 0

administration of a single dose of 0.6 mg/kg of gentamicin, both total body clearance and the mean serum concentrations at 24 h were significantly lower in patients with, compared to patients without RRF [250].

Adverse Effects

Rapid transperitoneal drug absorption may cause adverse systemic effects. The "red man syndrome" has been described after rapid IP administration of 1 g of vancomycin diluted in 2 L of dialysate [251]. Drugs, when given intraperitoneally in therapeutic doses, may also cause peritoneal irritation. This has been described with a fixed combination of cilastatin/imipenem [212], AmB [252–255], certain brands of vancomycin [256], methylene blue [257], and angiotensin I [258].

Effect of PD on Drug Plasma Protein Binding

There are only a few studies in which the influence of PD, notably CAPD, on drug binding has been assessed. Drug protein binding of acid drugs in PD patients is expected to be lower than in undialyzed or HD patients. This may be secondary to the often poor nutritional status of these patients, as reflected by serum albumin concentrations in the lower normal range, the continuous peritoneal losses of proteins during the dialysis process, and accumulating endogenous compounds competing for occupation of binding sites. Changes in protein binding and total and free concentrations of digitoxin have been reported for CAPD and hemodialysis patients. The binding of digitoxin was $94.7 \pm 1.5\%$ in CAPD, significantly less than that observed in HD patients ($96.2 \pm 1.3\%$). Following a 0.1 mg oral dose of digitoxin, the mean free serum concentrations in CAPD and HD were 0.8 and 0.9 ng/mL, respectively, which is not significantly different [259]. One can also expect that in some malnourished PD patients the binding to serum albumin of several acid drugs may be lowered, possibly leading to elevated free drug concentrations. Protein binding of the antifungal drug ketoconazole was also lower in CAPD patients (98.5%) than in control subjects (99%) [260].

The influence of CAPD on the concentrations of α1-AGP in serum and dialysate and on the serum binding of two basic drugs (oxprenolol and propranolol) and of one acidic drug (phenytoin) has been reported [261]. Before starting CAPD treatment, the protein binding of oxprenolol and propranolol was higher, related to the elevated serum levels of α1-AGP concentrations in uremia [262], while the binding of phenytoin was lower than in healthy volunteers. During the first week after starting CAPD, the serum α1-AGP concentrations rose with a concomitant increase in the binding of oxprenolol and propranolol. Subsequently, however, the α1-AGP levels and the binding of oxprenolol and propranolol decreased to the values found before starting CAPD. The binding of phenytoin, which was lower than in normal healthy volunteers, did not show any change during CAPD. It must, however, be emphasized that, in general, changes in plasma protein binding of a drug only exceptionally lead to relevant changes in plasma drug concentrations. Changes in free drug concentration are immediately associated with changes in the V_d of the drug which "buffer" against major fluctuations in free drug plasma concentrations.

Peritoneal Pharmacokinetics of Common Drugs and Dose Recommendations

Description of the Tables

Since the tables in the previous edition of this book described the pharmacokinetics per class of drug studied during CAPD or CCPD, and most of the drug information on protein binding, elimination $T_{1/2}$, V_d and total plasma clearance in the presence of normal renal function, and on elimination $T_{1/2}$ and total plasma clearance in end-stage chronic renal disease (ESRD) have not changed, the tables of the previous edition have been reproduced in this chapter. However, the studies on pharmacokinetics of new drugs, not covered in the previous edition, or more recent pharmacokinetic data in PD of older drugs will be discussed under the respective drug classes. For a more general pharmacokinetic information on individual and more recent drugs outside the field of PD, the reader is referred to recent standard textbooks [263–265].

The pharmacokinetic data have been updated from reports published up to the beginning of 2007. Many papers contain results obtained in crossover studies after either IV, oral, or IP administration. Therefore, the data published per individual paper have been included in the tables. The dose/route column indicates the dose and the route of drug administration in each respective study. When available, the loading dose or maintenance dose is given. Data on serum $T_{1/2}$, maximal – or, occasionally, steady state (SS) – serum concentrations achieved, total plasma clearance and

peritoneal clearance are given. A comparison of these values with data obtained in normal renal function and in terminal renal failure shows the effect of PD on these parameters. Finally, the percentage of dose either removed from the body by PD (in case of systemic administration) or absorbed across the peritoneal membrane (after IP administration) is provided, whenever it has been calculated. Each table is accompanied by a brief discussion of the need for dose adjustment in PD, for drugs that are frequently used in these patients.

Pharmacokinetic Data in CAPD

Tables 9.4–9.14 summarize the pharmacokinetic data on systemic and IP drug administration in CAPD.

Cardiovascular Drugs (Table 9.4*)*

Based on the pharmacokinetic data, dose adaptation for digoxin is not necessary in CAPD patients beyond that for ESRD.

Data on pharmacokinetics of ACE inhibitors are scarce. In a study of five patients on CAPD, captopril was detectable in the dialysate after a single dose of 50 mg. However, the impact on total elimination varied widely between individuals [266]. After 24 h, only 0.5% of a dose of 2.5 mg quinaprilat was removed by PD. The elimination $T_{1/2}$ of quinaprilat is prolonged in patients with renal failure, and an inhibition of >90% of ACE was observed after administration of 2.5 mg of quinaprilat in CAPD patients. This dose can thus be recommended as starting dose in CAPD patients. Fosinoprilat was found to be cleared only to a limited extent by PD. Fosinoprilat, however, is also cleared by biliary secretion, that might compensate for the reduced renal clearance. In six CAPD patients, serum ACE activity remained significantly suppressed at 24 and 48 h after administration of 10 mg fosinoprilat [267]. The moderate pharmacokinetic alterations observed in these patients compared to those with normal renal function suggest that in most CAPD patients initial dose modifications are not necessary.

The pharmacokinetics and pharmacodynamics of ACE inhibitors and ARBs in ESRD have been extensively reviewed by Sica and Gehr in 2002 [268]. Table 9.5 is taken from this review, summarizing the protein binding, the hemodialysance, and the mode of systemic clearance of most of the currently used ARBs. The pharmacokinetics and pharmacodynamics of losartan and its active metabolite, E-3174, were studied in hypertensive CAPD patients [269]. Following a 1-week washout period, subjects received 100 mg of losartan orally for 7 days. On days 1 and 7, hemodynamic and hormonal responses were determined, as were pharmacokinetic parameters on day 7. The values of AUC0-24 and $T_{1/2}$ for losartan and E-3174 were 95 ± 49.9 μg/min/mL and 176 ± 82.1 μg/min/mL and 172.5 ± 86.7 min and 628 ± 575 min, respectively, and are similar to those of normal subjects and subjects on HD. Peritoneal clearance of losartan and E-3174 was negligible. In conclusion, the dose of losartan in CAPD patients should not be reduced compared with patients with normal renal function and the peritoneal elimination of the drug is negligible. Table 9.6, adapted from a review by Barbour and McKindley [270], provides some maintenance dose recommendations for various cardiovascular drugs in renal failure and during HD and PD treatment.

Table 9.7 summarizes the studies with β-lactam antibiotics and glycopeptides. In general, the amount of penicillin lost in the peritoneal cavity after systemic administration is negligible; on the other hand, the transperitoneal absorption can be as high as 90% in the presence of peritonitis. First-, second-, and third-generation cephalosporins have been extensively studied. Based on the adequate dialysate levels that are achieved after oral administration (cephadrine or cephalexin), some authors have used this group of antibiotics as first choice for initial treatment of peritonitis either as single drug or in combination with other drugs [271–275].

Cefazolin

CAPD patients without active peritonitis received a single IP dose of 1 g of cefazolin sodium for a 6-h dwell [276]. The bioavailability was found to be 77.9 ± 3.1%, V_d 0.20 ± 0.05 L/kg, and plasma $T_{1/2}$ 39.9 ± 25.4 h. Mean total, renal, and peritoneal clearances were 4.5 ± 2.3, 1. 4 ± 1.1, and 3.5 ± 1.8 mL/min, respectively. Mean plasma and dialysate concentrations at 24 h were 42.8 ± 14.3 and 31.8 ± 11. 7 μg/mL, respectively, well above the MIC of susceptible organisms. A once daily IP cefazolin dose of 500 mg/L gave desirable pharmacokinetic attributes for use as a suitable alternative to vancomycin for empiric treatment of CAPD-associated peritonitis.

In more recent years, cefazolin has been studied, either in combination with aminoglycosides and more in particular in APD. A study in Thailand [277], following the International Society for Peritoneal Dialysis (ISPD) 1996 recommendations for empiric treatment of peritonitis, studied the pharmacokinetics of a continuous IP cefazolin and

Source: Adapted from Barbour and McKinley [270].

once-daily IP aminoglycoside administration. Cefazolin was administered as loading and continuous maintenance doses of 500 and 125 mg/L dialysate, respectively. Gentamicin, 0.6 mg/kg body weight, was given IP once daily. Duration of treatment was 120 h, serum cefazolin reached levels higher than the recommended levels (8 μg/mL) at 3.3 min after drug administration, and persisted through the 5-day duration of the study. Dialysate cefazolin levels during the studied period also were persistently higher than the recommended values. The peak serum gentamicin levels were lower than the suggested values of 4 μg/mL, whereas the trough serum gentamicin levels were higher than the minimal toxic concentrations (2 μg/mL). Dialysate gentamicin levels were higher than therapeutic concentrations for only 4.75 h in each day. It was difficult, using pharmacokinetic studies, to adjust the dosage regimen of gentamicin to achieve appropriately therapeutic levels in both serum and dialysate. It was concluded that the ISPD 1996 recommended dosage of continuous IP cefazolin was appropriate for the treatment of CAPD-related peritonitis, but once-daily IP gentamicin administration, had less therapeutic benefit.

The combination of cefazolin and tobramycin was also studied in APD patients [278] after a single IV dose of cefazolin (15 mg/kg) and tobramycin (0.6 mg/kg). Cefazolin and tobramycin half-lives were markedly shorter on cycler than off cycler. Mean serum and dialysate concentrations were above MIC of susceptible organisms throughout the

24-h period for both drugs. A model was developed to examine serum and dialysate concentrations after intermittent IP administration of 15 mg/kg cefazolin and 0.6 mg/kg tobramycin. The model-predicted IP cefazolin provides adequate serum and dialysate concentrations for 24 h. Intermittent IP tobramycin doses must be 1.5 mg/kg for one exchange during the first day and then given as 0.5 mg/kg thereafter. It was concluded that the current empiric dosing recommendations for PD-related peritonitis may be adequate for cefazolin (15–20 mg/kg); however, tobramycin doses must be changed to 1.5 mg/kg IP on day 1, then to 0.5 mg/kg IP thereafter in APD patients.

Ceftazidime

After IP administration of 1 g ceftazidime, serum concentrations reach therapeutic levels within 30 min and are maintained for more than 24 h. A V_d of 16 L was found. Overall, use of 1–1.5 g once daily or 15 mg/kg body weight has been recommended [279, 280]. The pharmacokinetics and dynamics of ceftazidime in CAPD peritonitis were recently explored in Thai patients [281]. In accordance with the ISPD 2000 recommendations, the antibiotic regimen comprised continuous IP cefazolin and once-daily IP ceftazidime. Cefazolin was administered as loading and continuous maintenance doses of 500 and 125 mg/L dialysate, respectively. Ceftazidime (20 mg/kg body weight) was given IP once daily. Duration of treatment was 96 h. Following ceftazidime administration, serum ceftazidime levels were above 8 μ/mL, the recommended MIC throughout 24 h. Dialysate ceftazidime levels were below the MIC for total periods of 4.19 and 6.26 h in day 1 and day 4, respectively. The clinical response rate to the empiric regimen was 90%. It was concluded that once-daily IP administration of ceftazidime according to the ISPD 2000 recommendation could not provide adequate therapeutic levels of ceftazidime in dialysate throughout 24 h. Despite this finding and the poor post-antibiotic property of ceftazidime, the empiric regimen including once-daily IP ceftazidime yielded good clinical outcome The objective of the recent study of Sisterhen et al. [282] was to determine whether a continuous maintenance

dose of IP ceftazidime (125 mg/L) in the absence of a loading dose would maintain adequate serum and dialysate concentrations to be effective in the treatment of peritonitis. Mean serum concentrations at completion of the short rapid cycles and at 24 h were 28.92 ± 13.64 and 23.92 ± 11.93 μg/mL, respectively. Serum bioavailability at 24 h was 74 ± 6%. Mean dialysate concentrations at completion of the short rapid cycles and at 24 h were 87.43 ± 19.18 and 32.06 ± 6.27 μg/mL, respectively. All patients achieved serum and dialysate ceftazidime concentrations greater than the MIC within 4 h.

Cefotaxime

Cefotaxime is metabolized in the liver to an active metabolite, which is primarily excreted by glomerular filtration and tubular secretion. However, dose reduction is necessary only when the CrCl falls below 5 mL/min. Several studies explored the pharmacokinetics of cefotaxime in CAPD [283]: a high proportion of the IP administered cefotaxime is absorbed into the circulation and therapeutic serum levels can be obtained after IP administration; no further dose adaptation is needed for patients on CAPD.

Cefepime

The clearance of cefepime, a third-generation cephalosporin, is 15 mL/min in CAPD patients, with a peritoneal clearance of 4 mL/min [284]. For IV administration, 1–2 g every 48 h is recommended [285]. It has a low protein binding value, and a relatively low V_d; therefore, a once-daily IP administration is probably not recommended, and the IV route should be preferred. Elwell et al. [286] recently determined the pharmacokinetics of IP cefepime in six APD patients. All patients were administered a single IP dose of cefepime (15 mg/kg) over a 6-h dwell. Patients then underwent a fixed APD regimen consisting of the first 6-h dwell, followed by an 8-h dialysate-free period and a subsequent series of three overnight APD exchanges. One hour after IP administration, serum cefepime levels exceeded the MIC (8 mg/mL) for susceptible organisms. The mean serum and dialysate concentrations at 24 h were 15.8 ± 3.6 and 6.2 ± 2.3 mg/mL, respectively. Bioavailability was 84.3 ± 6.2%, V_d 0.34 ± 0.07 L/kg, and serum $t_{1/2}$ was 13.8 ± 3.2 h. Total, peritoneal, and renal clearances were 16.5 ± 4.4, 4.3 ± 0.7, and 3.5 ± 2.5 mL/min, respectively. It was concluded that IP cefepime dosed at 15 mg/kg resulted in adequate serum concentrations in APD patients at 24 h post dose. Pharmacokinetic predictions suggest that most APD and CAPD patients would achieve adequate serum cefepime concentrations if treated with standard doses of 1,000 mg given IP once daily.

Cefpirome can be administered both IP and IV. Dialysis clearance by PD is negligible.

Moxalactam is a semisynthetic β-lactam antibiotic with activity against a broad range of Gram-positive and Gram-negative aerobic and anaerobic bacteria. This antibiotic exists as two stereoisomers with different antimicrobial activities. Several pharmacokinetic studies in CAPD patients have shown that, after IV administration, dosage adjustment to account for loss of moxalactam via the peritoneal cavity is not necessary. It appears further that there are no significant differences between R-Mox and S-Mox kinetics in CAPD patients [287].

Piperacillin

For piperacillin, whether or not in combination with tazobactam, dose adaptations should be made according to RRF. During CAPD, 5.5% of piperacillin and 10.7% of tazobactam are removed by dialysis over 28 h [288]. Another study [289] assessed the pharmacokinetics of IP administration of the combination piperacillin/tazobactam (PIP/TAZ) to patients on CAPD with and without *Pseudomonas* peritonitis. All patients were given an IP loading dose of 4 g/0.5 g PIP/TAZ. Twenty-four hours after the initial dose, a maintenance dose of 0.5 g/0.0625 g PIP/TAZ was administered with each dialysate exchange for a period of 1 week. After the loading dose, the highest plasma Cmax was 51.6 ± 21.25 μg/mL and appeared at 1.5 ± 0.45 h. During the maintenance period plasma PIP concentration was 5.2 ± 4.75 μg/mL. Tazobactam was detected in the plasma of one patient only. The concentration of TAZ in the dialysate fluid during the maintenance period was 2.3 ± 0.5 μg/mL. It was concluded that piperacillin administered IP at 4 g reached plasma concentrations comparable to IV administration and were considered therapeutic (above the MIC90 for *Pseudomonas aeruginosa*) in CAPD patients with or without peritonitis. The maintenance dose, however, should be augmented. Tazobactam could not be detected in the plasma of most patients and the therapeutic implications of IP administration of TAZ cannot be directly correlated to IV administration.

The pharmacokinetics of IV piperacillin in APD patients were recently studied [290]. Eight patients received a single IV dose of piperacillin (35 mg/kg actual body weight). GFR and piperacillin clearance values were normalized to 1.73 m2. Dwell times used in the patients on APD were 2.25 ± 0.06 h on cycler and 7.26 ± 0.14 h off cycler. Piperacillin $T_{1/2}$ was not statistically different on or off the cycler (on cycler 1.99 ± 0.39 h, off cycler 4.39 ± 5.4 h) and remained

insignificant. Piperacillin total Cl was 31.29 ± 6.02 mL/min. Renal Cl and PD Cl accounted for 8.8 and 16.8% of total clearance. Mean piperacillin serum and dialysate end-of-dwell concentrations were above MIC of susceptible organisms (8 μg/mL) for the three cycler exchanges only. The predicted serum and dialysate concentrations, using a one-compartment model, suggest that IV piperacillin 4,000 mg would provide adequate concentrations for susceptible organisms over a 12-h period. Thus, the current IV piperacillin dosing recommendations of 4,000 mg every 12 h for PD-related peritonitis are appropriate for patients on automated PD, but intermittent IP piperacillin is not recommended.

Glycopeptide Antibiotics

The two major drugs in the class of glycopeptide antibiotics are vancomycin and teicoplanin. *Staphylococcus aureus* and *Staphylococcus epidermidis* are almost always susceptible to vancomycin. Concentrations of 5 μg/mL or less are inhibitory although some strains require 10–20 μg/mL. Vancomycin is a large molecule (around 1,500 Da) and has a low serum protein binding. In ESRD its $T_{1/2}$ is very prolonged [200–250 h]. Pharmacokinetic studies after IV administration in CAPD patients show a low peritoneal clearance, which, however, increases during peritonitis. Although it has been claimed that CAPD does not require dose adjustment, serum drug levels should be followed in patients with substantial RRF [291]. As the *V*d of vancomycin (0.5 L/kg) is large in comparison with the IP volume, there remains a high concentration gradient between dialysate and plasma after IP administration (Fig. 9.12 from [291]). Therefore, vancomycin is rapidly absorbed into the circulation. When the dialysate is drained, and new dialysate is instilled, it rapidly becomes saturated with vancomycin from the blood, and adequate IP levels of vancomycin are obtained. Because of this phenomenon, a single high dose (15 mg/kg) of vancomycin is sufficient to obtain adequate dialysate levels. Whether, from a microbiological point of view, vancomycin is still the antibiotic of first choice in the treatment of PD-related peritonitis, is a matter of debate. The growing concern on the emergence of vancomycin-resistant enterococci in the United States has forced the Ad Hoc Advisory Committee to classify vancomycin from agent of choice to agent to be avoided (see Chapter 19 in this book). Other centers, however, having a high incidence of methicillin-resistant staphylococci (MRSA), have recommended a center-tailored therapeutic approach of peritonitis where vancomycin is still regarded as the first choice [292].

There are few studies of the pharmacokinetics of vancomycin and gentamicin in PD patients and the influence of antibiotic concentrations on treatment outcome. Concerns about resistance to ceftazidime and potential of aminoglycoside toxicity make the choice of empiric antibiotics difficult. Blunden et al. [293] retrospectively collected data from 613 patients on PD between 1 June 2002 and 31 December 2005 and adopted a protocol that minimized aminoglycoside exposure to patients with RRF and carefully monitored serum antibiotic concentrations. There were no statistical differences in mean day-5 vancomycin concentrations for CAPD versus APD and for anuric versus not-anuric patients. However, low levels (<12 mg/L) were recorded for 12.8% CAPD and 15% APD patients. These remained low at day 10 in 16% patients (25% if not anuric), despite incremental dosing. Vancomycin concentration did not predict cure or relapse of Gram-positive or culture-negative peritonitis. Gentamicin concentration (>2 mg/L in >50% patients) did not predict outcome of Gram-negative and culture-negative peritonitis. Moreover, cure rates were the same irrespective of whether gentamicin was continued for 14 days or was switched to ceftazidime after 5 days.

This important study concluded that the International Society for PD (ISPD) dosing guideline for vancomycin in CAPD and APD patients produces adequate serum concentrations of the antibiotics in the vast majority, but that large incremental dosing of vancomycin is needed if day-5 levels are low; especially for not-anuric patients. While evidence of gentamicin toxicity in PD remains controversial, ISPD dosing regimen resulted in high levels for >50% patients. High gentamicin concentrations did not correlate with treatment success, but switching gentamicin to ceftazidime at day 5 appeared safe and limited aminoglycoside exposure. Increasing vancomycin and gentamicin concentrations do not appear to improve cure rates and alternative strategies (such as combination treatment) should be considered for future research.

The pharmacokinetics of a single dose of IV vancomycin (15 mg/kg total body weight) were recently studied in 10 APD patients [294]. Dwell times were 2.3 ± 0.1 h on cycler and 7.3 ± 0.1 h off cycler. Vancomycin $T_{1/2}$ was significantly different on-cycler than off-cycler (11.6 ± 5.2 h versus 62.8 ± 33.0 h). Vancomycin total Cl was 7.4 ± 2.0 mL/min. Renal Cl and PD Cl accounted for 23.6 and 28.0% of total Cl, respectively. Mean vancomycin serum and dialysate end-of-dwell concentrations were above MIC of susceptible organisms (5 mg/mL) for the first cycler and the second ambulatory exchanges only. This study suggests that, to provide adequate concentrations for susceptible organisms over a 24-h period, current intermittent vancomycin dosing recommendations for PD-related peritonitis need to be changed to 35 mg/kg IP on day 1, then 15 mg/kg IP thereafter (i.e., once daily) in APD patients.

Little information is available on the disposition of vancomycin during chronic PD in children. This problem was recently studied [295] following IP administration of vancomycin in children receiving short-dwell APD and long-

dwell CAPD. A 6-h exchange containing vancomycin 500 mg/L, using an exchange volume of 1,100 mL/m^2 body surface area (BSA), was followed by 4-, 6-, and 8-h antibiotic-free exchanges. The 8-h exchange was followed by three to four 90-min antibiotic-free exchanges. The bioavailability of vancomycin during a 6-h IP exchange was 70 ± 5%, resulting in a delivered dose of 12.0 ± 1.8 mg/kg, and a 6-h serum vancomycin concentration of 23.3 ± 7.2 μg/mL. Total body vancomycin clearance measured 10.72 ± 4.52 mL/min/1.73 m^2 BSA, while PD clearance measured 2.78 ± 1.08 mL/min/1.73 m^2 BSA and accounted for 29 ± 11% of total vancomycin clearance. Dialysis clearance during long-dwell (CAPD) and short-dwell (APD) regimens was similar accounting for 25 ± 13% and 32 ± 12% of total body clearance, respectively. It was concluded that IP absorption and dialysis clearance of vancomycin in children receiving PD are similar to those reported in adult dialysis patients. In contrast, total body clearance of vancomycin was increased and the $T_{1/2}$ decreased in children, due to increased elimination by nonrenal nondialysis routes. For intermittent IP vancomycin therapy in children with peritonitis, an IP load containing vancomycin 1,000 mg/L (or 30 mg/kg), followed by a single full-fill (1,100 mL/m^2 BSA) daily exchange, containing vancomycin 250 mg/L (or 7.5 mg/kg), from day 2 until the end of treatment will maintain a vancomycin dialysate concentration of >4 μg/mL.

Teicoplanin is a glycopeptide that is mainly excreted via the renal route and has a prolonged terminal $T_{1/2}$ in renal failure. In PD patients with peritonitis the serum $T_{1/2}$ was 508 ± 193 h, and the V_d was 0.48 L/kg [296]. A recent pharmacokinetic study with teicoplanin was performed in anuric CAPD patients [297]. One single IV dose of 10 mg/kg teicoplanin was administered and blood and dialysate were sampled at regular time intervals for 48 h post drug infusion. Teicoplanin serum levels above 10 μg/mL, the level desired to treat systemic infections, were detected for 24 h after administration. All dialysate concentrations were very low. Teicoplanin presented two phases of elimination: an early first phase and a late second phase. Mean Cmax was 75.56 μg/mL, mean $T_{1/2}$ of the early elimination was 3.34 h, mean $T_{1/2}$ of the late elimination was 61.68 h, mean AUC-time curve was 1,491.92 mg × h/L, mean clearance rate was 10.68 mL/min, mean apparent V_d was 0.80 L/kg, and mean V_d at steady state was 0.22 L/kg. The mean dialysate excretion was only 3.16% and the peritoneal clearance was 0.023 mL/min. Teicoplanin can thus be administered at 10 mg/kg every 24 h for the therapy of systemic infections in patients undergoing CAPD. However, its IV administration should be avoided in the treatment of peritonitis, because the achieved dialysate concentrations are very low.

Table 9.8 summarizes the data with quinolones, aminoglycosides, trimethoprim-sulphamethoxazole, and miscellaneous antibiotics. Pharmacokinetic data in CAPD of some of these antibiotics have been reviewed by us [217]. Fluoroquinolones have a large antibacterial spectrum, including Gram-negative bacteria and staphylococci. Most fluoroquinolones are well absorbed after oral administration and have a favorable pharmacokinetic profile. Janknegt [298] has summarized the pharmacokinetic and clinical studies with ciprofloxacin, ofloxacin, pefloxacin and fleroxacin in CAPD patients. Fractions of dose of quinolones removed by CAPD range between 1 and 2% at 24 h after dosing [299–301], probably due to the large V_d of these agents. As the IP levels of quinolones are reportedly low during the first 24 h of oral therapy, an IP loading dose is recommended [302]. It is of note that the concomitant administration of antacids significantly reduces the gastrointestinal absorption of the quinolones.

Although in CAPD therapy with quinolones requires dose adjustment as for patients with ESRD, high drug IP concentrations can be achieved after IV or oral administration, making these substances, at least theoretically, attractive alternatives to conventional treatment of CAPD peritonitis (for review and dose recommendations see refs [298, 302]. An additional study with oral ofloxacin in peritonitis was performed by McMullin et al. [303] in CAPD patients who received once-daily 400 mg oral ofloxacin for 7 days for the treatment of bacterial peritonitis. Ofloxacin, desmethyl ofloxacin, and ofloxacin-N-oxide accumulated over the course of therapy and could still be detected in serum and dialysate 5 days after the end of therapy. The mean elimination $T_{1/2}$ of ofloxacin in serum was 32 ± 7 h, desmethyl ofloxacin 45 ± 26 h, and for ofloxacin-N-oxide 44 ± 15 h. The total mean recovery of ofloxacin and its metabolites from the dialysate was 15.4%. This regimen results in serum and dialysate concentrations likely to be effective for the treatment of infection for at least 10 days.

Ciprofloxacin pharmacokinetic data in APD (CCPD) patients after administration of two doses of ciprofloxacin 750 mg orally every 12 h were recently studied by Yeung et al. [304]. The following results were obtained: serum $T_{1/2}$ 10.1 ± 1.2 h, Cmax 2.7 ± 0.5 mg/L, T_{max} 1.6 ± 0.1 h after the first dose, and peritoneal clearance 1.2 ± 0.1% of the total body clearance. While all patients achieved serum AUC-time curve above the MIC for *Escherichia coli* and *Klebsiella* species after the first dose, only two patients achieved this goal for *Pseudomonas aeruginosa*. End-of-dwell dialysate concentrations were above the MIC for *E. coli*, *Klebsiella* species, and *P. aeruginosa* after the second dose. Ciprofloxacin in an oral dose of 750 mg every 12 h in CCPD patients may thus be useful for empirical Gram-negative coverage of CCPD peritonitis and for treatment of documented peritonitis caused by sensitive *E. coli* or *Klebsiella* species.

A recent open-label, parallel-group study determined the pharmacokinetics after a single oral 600-mg dose of garenoxacin in subjects with severe renal impairment, including patients on CAPD [305]. Compared with healthy controls, garenoxacin, AUC, and Cmax were increased by 51% and lowered by 20%, respectively, in subjects with severe renal impairment. The terminal $T_{1/2}$ was prolonged in subjects with severe renal impairment compared with

healthy controls (26.5 ± 7 vs. 14.4 ± 3 h, respectively). In subjects receiving HD or CAPD, removal of garenoxacin from systemic circulation was relatively inefficient (HD, 1.5–11.5%; CAPD, 3%), suggesting no need for a supplemental dose of garenoxacin after dialysis.

The pharmacokinetics after IP administration in CAPD have been studied for ofloxacin, pefloxacin, and ciprofloxacin; the latter has also been studied in CCPD [306]. During CAPD, the half-lives of ciprofloxacin, pefloxacin, and ofloxacin are 10, 17–21, and 25 h, respectively. Adequate peritoneal ofloxacin levels were reported in the second and third exchanges after a single IP dose of 200 mg in the first exchange [307]. For fleroxacin, a mean dialysate to plasma concentration ratio of 0.5–0.6 can be expected after a short dwell of 4 h [301]. Therapeutic concentrations in the peritoneal fluid can be achieved in CAPD patients using an oral loading dose of 800 mg fleroxacin and a daily maintenance dose of 400 mg.

Aminoglycosides

After systemic administration of aminoglycosides a substantial fraction of the administered dose is removed over 24–48 h. The peritoneal clearance adds approximately 20–30% to the total removal from the body and clinically relevant concentrations in the dialysate are achieved after IV administration. This significant peritoneal clearance is due to the low protein binding and the small V_d of these drugs. It is recommended that plasma levels should be measured regularly, especially in repeated usage [250]. For all aminoglycosides tested, an important absorption has been observed after IP administration; there is a significantly higher systemic bioavailability in peritonitis compared to nonperitonitis patients. Continuous IP administration of aminoglycosides in patients with peritonitis leads to more or less constant plasma levels and carries the risk for ovotesticular toxicity and further decrease in RRF [308]. In order to decrease this potential ototoxicity and nephrotoxicity, once-daily administration seems to be preferable. Once-daily dosing with aminoglycosides is possible due to their important post-antibiotic effect. After IP administration of 0.6 mg/kg gentamicin, $T_{1/2}$ was 35.8 h, and V_d was 0.23 ± 0.08 L/kg [250]. A higher dose, 1 mg/kg, was recommended to obtain sufficient plasma and dialysate levels during 24 h.

Kim et al. [309] found that in peritonitis, the blood levels of netilmicin after a loading dose of 100 mg IP were the same irrespective whether the maintenance dose was either 0.6 mg/kg IP once daily, or 15 mg/2 L IP, four times daily. This study suggested thus that once-daily IP or continuous IP netilmicin may be empirically recommended to CAPD peritonitis patients but that the once-daily IP method may be the most convenient method. As mentioned earlier, aminoglycoside pharmacokinetics, in particular tobramycin, have in recent years been studied in association with cephalosporins (see above).

Aztreonam, a monobactam is effective against Gram-negative bacteria, with greater safety and a more predictable action in dialysate compared to aminoglycosides. The pharmacokinetics of aztreonam have been studied after both IV and IP administration in CAPD patients. Based on these data, several authors have described favorable results in Gram-negative peritonitis, including some *Pseudomonas* infections, with the IP route of aztreonam alone [310, 311], or in combination with cefuroxime [312] or vancomycin [313, 314].

The pharmacokinetics of roxithromycin were determined following a single oral dose to patients on PD. Serum elimination $T_{1/2}$ was doubled compared to healthy individuals. Less than 5% of the dose was recovered in dialysate over 48 h, and dialysate concentrations were low. Administration every 48 h is recommended [315].

It is of note that macrolides can inhibit metabolization, and thus affect the plasma levels of many other drugs. Serious adverse interactions are therefore possible, and dose adaptations for these medications (e.g., cyclosporin, oral contraceptives) are necessary when macrolides are administered.

Azithromycin is an azalide antibiotic with a similar antibacterial spectrum to erythromycin but with greater Gram-negative activity, a more favorable pharmacokinetic profile, and with improved absorption and higher sustained tissue concentrations compared with erythromycin. The pharmacokinetics and PD clearance of azithromycin were studied following a single 500-mg oral dose of azithromycin in eight CAPD patients without peritonitis [316]. Cmax concentrations occurred at 2–3 h with 0.35–1.35 μg/mL .The mean elimination $T_{1/2}$ was 84.55 h, and plasma clearance was 21.93 L/h. This compares with values of greater than 40 h and 40.8 L/h reported in healthy volunteers. After 8 h, the mean dialysate concentration was 0.07 μg/mL; the PD clearance was only 0.06 L/h. Azithromycin is thus not substantially removed by CAPD in the absence of peritonitis and cannot be recommended for widespread use in this setting at present.

Linezolid

Only rare case reports have described the use and limited pharmacokinetic data with linezolid, an antibiotic that is indicated in vancomycin-resistant enterococci (VRE) and vancomycin-intermediate-susceptible or -resistant

staphylococci (VISA and VRSA, respectively). After either IV [317] or oral [318] administration of 600 mg of linezolid, the $T_{1/2}$ ranged between 8.7 and 8.3 h, which is longer than given by the company information. A good penetration into the peritoneal cavity was observed.

Fusidic Acid

Because fusidic acid is metabolized and excreted by the liver, it is generally assumed that renal impairment has no effect on serum concentrations. Patients on CAPD were given the same dosage regimen for seven doses [319]. Accumulation was seen and, in the majority of patients, steady-state pharmacokinetics had not been achieved by the third day. The mean Cmax values for the first dose and for the seventh dose were 16.0 and 33.9 mg/L, respectively. Fusidic acid concentrations of 1.0–2.3 mg/L were detected in PD fluid in six of the seven CAPD patients. There was a tendency towards increased $T_{1/2}$ with repeated dosing. Protein-binding of fusidic acid in patient serum samples was 87.6–94.6%.

Anti-Tuberculosis Medication

An extensive in-depth review on anti-tubercular therapy in renal failure, including the pharmacokinetic aspects of these drugs in PD, has recently been published by Launay-Vacher et al. [320]. This review should be consulted for recommendations of dosing of the common and more recently developed antitubercular drugs.

Ahn et al. [321], administered nine patients on CAPD a conventional oral dose of antituberculosis medications and plasma and peritoneal fluid concentrations of isoniazid and rifampicin and pyrazinamide were measured. Average Cmax levels of isoniazid, rifampin, and pyrazinamide were 3.3, 6.5, and 30.9 mg/L, respectively, all of which much exceed the MIC for *Mycobacterium tuberculosis*. Peritoneal fluid concentrations of isoniazid and pyrazinamide were maintained well above the MICs for *M. tuberculosis*; however, the dialysate concentration of rifampicin was below the therapeutic range most of the time. Thus, for the treatment of systemic or pulmonary tuberculosis in CAPD patients, no dose adjustments are required for isoniazid, rifampicin, or pyrazinamide but for the treatment of tuberculous peritonitis, oral rifampin therapy is not expected to be effective because of its low peritoneal fluid concentration.

The two agents used in anaerobic infections, metronidazole and ornidazole, have a low peritoneal clearance and only 10 and 6% of the dose, respectively, are removed by the peritoneum [322, 323]. The dosage in CAPD patients is therefore the same as in undialyzed, uremic patients [324].

Table 9.9 summarizes the data for antiviral and antifungal drugs. An extensive recent review of antiviral drug therapy, including pharmacokinetic data in renal failure and dialysis is available [325].

Acyclovir has significant activity against HSV-1, HSV-2, and Varicella zoster virus (VZV). Acyclovir seems to have a three-compartment pharmacokinetic profile in CAPD patients [326]. Mean total plasma clearance was 46 mL/h/kg, 12% of which was due to PD. Acyclovir has an apparent V_d of 62.5 L, with a protein binding of less than 20%. It was found [327] that the doses recommended for ESRD patients (1,600 mg) led to supratherapeutic levels of acyclovir in CAPD patients, increasing the risk of neurotoxicity, which was reported in two patients [328]. Based on computer modelling, a daily oral dose of 600–800 mg is recommended [327].

As mentioned above, acyclovir-induced neurotoxicity is reported to be associated with high serum drug levels even when following the recommended reduced doses for this renal failure population. In view of the high oral bioavailability of valacyclovir (the L-valyl ester of acyclovir), the risk of neurotoxicity becomes more prominent [329]. In 12 CAPD patients who were administered a single oral dose of 500 mg valacyclovir, acyclovir was analyzed. High interpatient variations were observed with acyclovir apparent total clearance values of 7.238 ± 4 L/h and $T_{1/2}$ values of 22.27 ± 16.82 h. However, dosage simulations confirmed supratherapeutic acyclovir concentrations for all participants when following the recommended dose of 1,000 mg valacyclovir/24 h for varicella-zoster infections.

Ganciclovir is extensively used as an antiviral agent for cytomegalovirus (CMV) infections in immunocompromised patients. Sommadossi et al. [330] reported higher, although highly variable, values for V_d in patients with renal failure (V_d 0.41 ± 1.5 L/kg) compared to normal volunteers. Ganciclovir has a low molecular weight and a low protein binding (1–2%) and is thus effectively cleared by HD. However, due to the large V_d compared to the dialysate volume, removal of ganciclovir by PD is negligible, and the doses should be adapted as for patients with renal failure. It is of note that, due to an important tubular secretion, CAPD patients with RRF have a ganciclovir clearance higher than the creatinine clearance [331].

Izzedine et al. described the pharmacokinetics of ritonavir and nevirapine in a CAPD patient suffering from HIV infection [332]. Ritonavir does not appear in the peritoneal dialysate, but like in the study by Taylor et al. [333], the dialysate concentration of nevirapine was almost 50% of the plasma concentration so that monitoring of plasma levels during therapy with this drug in CAPD patients with HIV is recommended. In the study by Taylor et al. [333] the

pharmacokinetics of nelfinavir (1,250 mg bid) were also described. Nelfinavir, like ritonavir, does not cross the peritoneal membrane due to its large size and high protein binding.

Cidofovir

Brody et al. [334] found that in patients receiving cidofovir that the mean cidofovir clearance in subjects with normal renal function was 1.7 ± 0.1 mL/min/kg, which decreased with declining renal function as indicated by the regression equation. The mean V_d at steady state did not change significantly in subjects with kidney disease and cidofovir serum elimination $T_{1/2}$ was significantly increased in subjects with severe renal impairment. Cidofovir was not significantly cleared during CAPD. It was concluded that in patients with varying degrees of renal insufficiency aggressive dosage reduction of cidofovir is necessary.

Oseltamivir is an antiviral drug used in prophylaxis and therapy for influenza and its dose reduction is recommended for patients with ESRD. However, dosing recommendations are not available for treatment or prophylaxis of influenza in these patients. Robson et al. [335] assessed the pharmacokinetics and tolerability of oseltamivir in patients undergoing HD and CAPD. In this open-label, multiple-dose study, patients received 30 mg oral oseltamivir suspension over 6.5 weeks. This dose was predicted to be suitable for ESRD patients based on a two-compartment model. CAPD patients received six doses given once weekly after a dialysate exchange. In CAPD patients, mean Cmax after the first and sixth doses were 885 and 849 ng/mL, respectively. The mean AUC values for days 1–6 and days 36–43 were 33,400 and 32,400 ng h/mL, respectively. Oseltamivir was well-tolerated. In conclusion, a 30-mg dose of oseltamivir given once weekly in CAPD provides sufficient exposure to oseltamivir carboxylate to allow safe and effective anti-influenza treatment and prophylaxis.

No pharmacokinetic data for PD patients are available for foscarnet, and dose adaptations are recommended as in ESRD. One case report described a serum $T_{1/2}$ of 45.8 h for a patient on CAPD (normal renal function 4.5 h). CAPD clearance of foscarnet was calculated to be 4.5 mL/min with a total clearance of 8.8 mL/min [336].

Studies in a limited number of CAPD patients treated with zidovudine suggest that no further modification from the renal failure dosage regimen is necessary [337, 338]; however, great interpatient variability in its pharmacokinetics was noted [338].

Didanosine is an antiretroviral agent used for treatment of HIV infections. In patients with renal failure, elimination $T_{1/2}$ was reported to be prolonged to 3.6 ± 0.8 h as compared to 1.5 ± 0.5 h in normal renal function. CAPD has little effect on the removal of didanosine; dose reduction to one-fourth of the daily dose is thus recommended (a single administration), in patients on CAPD as well as in nondialyzed end-stage renal failure patients [339].

Antifungal Drugs

Information on the pharmacokinetics of antifungal drugs in PD patients is disappointingly scarce. Most studies are limited to occasional measurements of serum and/or dialysate levels during treatment for fungal peritonitis.

Amphotericin (AmB) is highly protein-bound and circulates in the blood in a complex of high molecular weight (200,000–300,000). It penetrates very poorly in the peritoneal fluid after systemic administration. The data are, however, conflicting [340–342]. Chemical peritonitis causing abdominal pain after IP administration of AmB B has been observed [252–255]. It has been proposed that for IP use the dialysate should be adjusted to a neutral pH to prevent aggregation [343]. AmB has been used in an IV dose of 0.5 to 1 mg/kg body weight, combined with an IP dose of 2–3 mg/L dialysate [344]. AmB induces the formation of pores and channels in the cell membrane, causing leakage of potassium and magnesium. This is probably the reason why the drug increases transcapillary ultrafiltration (see Part I, above); however, the chemical drug-induced peritonitis may also play a role in this phenomenon [345]. Studies of the absorption of AmB B after IP instillation are lacking, although the large V_d and the high protein binding are expected to favor its transfer to the blood stream.

Systemically administered fluorocytosine penetrates well into the peritoneal fluid [341]. The usual loading dose of 20–30 mg/kg in uremic patients is followed by a maintenance doses of 15 mg/kg. Serum levels of fluorocytosine should be monitored since toxicity is expected when serum levels exceed 100–125 μg/mL. This has mainly been tried with IP administration of 100–200 mg/2 L, together with IV AmB B [255, 346] or in a dose of 150 mg/L in combination with oral ketoconazole 400 mg daily [347].

Fluconazole is effective for both superficial and systemic fungal infections. The pharmacokinetic profile of orally administered fluconazole shows a low plasma protein binding, and a long plasma $T_{1/2}$, allowing once-daily dosing. The bioavailability is excellent. A good penetration of fluconazole into the dialysate after a single oral dose of 100 mg in

CAPD patients has been found [348]. When given systemically the dose should be the same as in undialyzed patients [349]. With IP administration the recommended dose is 150 mg in a single 2 L dwell, every 48 h.

Dahl et al. [350] investigated the pharmacokinetic characteristics of IP fluconazole in APD (CCPD). Five patients received a single dose of IP fluconazole 200 mg during their long daytime dwell. The bioavailability of IP fluconazole was $96 \pm 2\%$ over a 12-h dwell, absorption $T_{1/2}$ was 2.5 ± 1.2 h, serum elimination $T_{1/2}$ was 71.65 ± 12.76 h, and V_d was 0.66 ± 0.13 L/kg. Peritoneal clearance was 5.96 ± 0.93 mL/min and proportional to the total dialysate volume. Renal clearance was proportional to renal creatinine clearance. Current treatment guidelines for fungal peritonitis suggest fluconazole 200 mg intraperitoneally every 24 h. These data suggest that this dose, administered every 48 h, is more than sufficient to maintain serum and peritoneal concentrations above the MIC for most *Candida* species.

A single-dose pharmacokinetic study of itraconazole has been performed in patients with ESRD, including five CAPD patients [351]. The systemic pharmacokinetics of itraconazole were not affected by CAPD and the drug could not be detected in the dialysate. Oral administration of ketoconazole in CAPD patients revealed extremely low peritoneal clearances [253, 260]. After oral administration of 400 mg ketoconazole, Johnson et al. reported mean serum concentrations of 2.3 μg/mL, while the D/P ratio was only 0.03 after 5 h.

Table 9.10 covers the drugs used in gastroenterology. H2 antagonists are frequently described in dialysis patients. Studies have been performed with cimetidine, ranitidine, and famotidine [352–355]. Dosage reduction necessary for undialyzed patients, should be applied for patients on PD. No pharmacokinetic data on nizatidine or roxatidine in CAPD are available and it can be presumed that these drugs have a negligible peritoneal clearance.

To our knowledge omeprazole, a proton-pump inhibitor, has not been studied in CAPD patients. In patients with ESRD its pharmacokinetics are not significantly different from those in healthy subjects and the drug is not detected in dialysis fluid during HD [356]. One can therefore expect that omeprazole could be administered in uremic and CAPD patients at the usual dose of 20 mg/day. Lansoprazole and pantoprazole are also completely metabolized. The elimination $T_{1/2}$ of lansoprazole seemed to be prolonged in patients with moderate, but not in those with severe renal dysfunction. HD did not seem to influence the plasma concentrations of lansoprazole, probably due to a very high protein binding (97–99%) [357]. Lansoprazole also has some renally cleared active metabolites. The data with pantoprazole in patients with renal impairment are difficult to interpret, and further studies are required to clarify the controversial observations made until now [356].

With cisapride, a gastrokinetic drug, in a dose of 5 mg/L dialysate four times per day, excellent results were obtained in two diabetic CAPD patients suffering from gastroparesis. The IP dose produced the same plasma levels as the oral or IV doses of 30 and 10 mg, respectively [358]. In HD patients the terminal $T_{1/2}$ of cisapride was 9.6 ± 3.3 h and the V_d was 4.8 ± 3.3 L/kg. Cisapride was not found in the dialysate, in contrast with its metabolite norcisapride. The authors conclude that dose adaptation is not necessary [359].

Table 9.11 summarizes the data of IV erythropoietin (Epo)(11a), subcutaneous Epo(11b), and IP Epo(11c). A number of interesting pharmacokinetic studies have been performed with Epo in PD. With subcutaneous (SC) administration, Epo is slowly absorbed with a Tmax around 20–24 h. The SC bioavailability compared to IV dosing ranges between 10 and 36%. PD itself has no significant effect on the removal of Epo.

Human pharmacokinetic studies on IP administration of Epo show a very low bioavailability (ranging from 2.5 to 8.5%) when diluted in 2 L of dialysate, but this increased to $41.4 \pm 7.2\%$, when administered into a dry abdomen [360, 361]. The problem of low bioavailability of IP Epo when diluted in dialysate, can be overcome by using high dosages of Epo or low volumes of dialysate. Frenken et al. [362] utilized 100 U/kg intraperitoneally, diluted in 1 L of dialysate over a 9 h dwell thrice weekly and observed a slow but significant increase in hematocrit; Nasu et al. [363] reported an excellent hematocrit response when Epo in a high dose of 300 U/kg, diluted in 2 L dialysate, was given.

Bioavailability is further improved by instilling the dose into a dry peritoneum [364]. The pharmacokinetics of a single 100-U/kg IP Epo alfa in eight CAPD patients was studied after the instillation into a dry peritoneum and allowing a dwell for 8 h. CAPD was then resumed. A 14-h effluent dialysate sample was collected to determine Epo alfa recovery. The extent of Epo alfa absorption was significantly greater than previously reported for a 4-h dry dwell. The mean dose-normalized AUC using the 8-h dry dwell dosing technique was $6{,}331 \pm 2{,}536$ mIU · h/mL which was significantly greater than the value of $2{,}589 \pm 1{,}450$ mIU · h/mL from a previous study using a 4-h dry dwell. The absorption of Epo alfa administered by IP route is thus improved by extending the time the dose resides in a dry peritoneum.

To establish the effectivity of administration of IP Epo in a small amount of fluid in children with renal anemia on CAPD, it was found [365] that administration of Epo in a specially designed bag containing 50 mL NaCl 0.9%. leads to a decrease in the required dose from 262 to 194 U/kg/week while hemoglobin levels remained stable.

To compare the efficacy of IP and SC administration of Epo alfa, a 32-week prospective, randomized, crossover study was designed [366]. Twenty adult PD patients receiving stable doses of SC Epo alfa were enrolled in the study and were randomly assigned to receive either SC or IP Epo at the start of the study. Dose adjustments were made to

maintain baseline hematocrit ± 3%. Following 16 weeks of treatment, patients crossed over to the other route for an additional 16 weeks. IP Epo alfa was administered into an empty peritoneal cavity for approximately 8 h before resuming dialysis. End-of-study IP Epo alfa doses required to maintain target hematocrit were given twice weekly ($n = 1$), once weekly ($n = 11$), or once every other week ($n = 1$). The AUC for IP Epo alfa was larger than for SC administration and the slope of the 16-week dose-requirement curve was greater for IP administration, suggesting greater dose stability for SC administration. Paired analysis indicated greater IP intrapatient dose requirements. The mean difference in SC versus IP doses was 5,000 ± 1,510 U/week. It was concluded that IP Epo alfa may be a suitable alternative for some patients for whom SC dosing is undesirable. Darbepoetin (DarbEpo) is a hyperglycosylated analogue of recombinant human Epo which has an increased terminal $T_{1/2}$ in animal models. Macdougall et al. [367] extended these observations to humans. The single-dose pharmacokinetics of Epo alfa (100 U/kg) and an equivalent peptide mass of DarbEpo were compared following IV bolus in 11 stable PD patients. This was followed by an open-label study to determine the single-dose pharmacokinetics of an equivalent peptide mass of DarbEpo by SC injection in six of these patients. The mean terminal $T_{1/2}$ for IV DarbEpo was threefold longer than for IV Epo (25.3 versus 8.5 h), a difference of 16.8 h. The AUC-time curve was significantly greater for DarbEpo and the clearance was significantly lower (1.6 ± 0.3 versus 4.0 ± 0.3 mL/h/kg). The V_d was similar for both preparations. The mean terminal $T_{1/2}$ for SC DarbEpo was 48.8 h. The Cmax of SC DarbEpo was approximately 10% of that following IV administration, and bioavailability was approximately 37% by the SC route.

To characterize the pharmacokinetics of DarbEpo alfa and covariate relationships in HD and PD patients, Takama et al. [368] recently collected data from 63 HD and 68 PD patients who received IV DarbEpo alfa and applied pharmacokinetic modelling to them. The results of this analysis suggest no dosage regimen change is warranted for DarbEpo alfa in HD and PD patients over the range of distribution of covariates included in this study.

IP administration of iron dextran leads to an efficient absorption of iron. However, severe toxicity to the peritoneal membrane was found, precluding the use of concentrations higher than 2 mg/L [369]. Until now, intraperitoneal administration of iron dextran seems not to be recommendable.

Recombinant Human Growth Hormone (GH)

GH therapy is effective in the treatment of growth failure related to GH resistance among children with chronic renal failure. Recombinant human GH (MW 21,000) was intraperitoneally instilled and showed an immediate absorption with peak serum GH levels obtained between 4 and 8 h following administration [370]. It is highly probable that this drug is, at least partly, transported via the lymphatics. However, the traditional route of administration of GH is SC injection. A study [371] explored the effectiveness and tolerability of IP administration of GH in prepubertal PD patients. Peak serum GH was achieved 4 h after administration and serum $T_{1/2}$ was 4.6 h. The mean height velocity increased from a baseline of 4.6 to 8.5 cm/yr in year 1 and 6.1 cm/yr in year 2. This study suggests, thus, that the IP route of administration of GH can be utilized in the treatment of short stature among children requiring PD therapy.

Relevant to IP therapy with Epo and growth hormone is the study by Schroder et al. [372] who performed an in vitro study in which radiolabeled Epo and recombinant human growth hormone were added to small-volume (50- and 250-mL) dialysis bags. Recovery was measured after 15-min dwells. It was found that the adsorption of Epo and growth hormone was minimal (less than 7%). This finding provides another argument in favor of IP therapy in pediatric PD.

Table 9.12 summarizes data for miscellaneous drugs. An interesting observation was made on the removal of ethosuximide and phenobarbital in an epileptic child by PD [373]. During a peritonitis episode, the daily dialysis time of 8 h (CCPD) was increased to 24 h and the patient developed convulsions. Apparently, a substantial amount of both anticonvulsant medications was removed via the peritoneal dialysate and supplementary doses of both drugs were needed to stabilize the patient.

Leakey et al. [374] described a 3-year-old asthmatic boy who developed acute renal failure, necessitating acute PD. His plasma theophylline concentrations remained therapeutic; yet the child developed the symptoms of theophylline toxicity while undergoing PD. Excessively high plasma concentrations of the principal theophylline metabolite, 1,3-dimethyluric acid, were found. The high concentrations decreased only when renal function recovered. Apparently PD is not able to remove this theophylline metabolite.

In a pharmacokinetic study of flurbiprofen, CAPD patients were used as representative patients with ESRD. Neither flurbiprofen nor its metabolites were detected in the dialysate [375].

PD patients have a decreased clearance of ethinyl oestradiol, leading to slightly higher serum concentrations compared to women with normal renal function [376]. Serum $T_{1/2}$ was 8.4 ± 4.1 versus 3.4 ± 1.6 h in PD patients and normal individuals, respectively, after a single oral dose, and 15.7 ± 3.3 vs. 14.3 ± 2.3 after multiple dosing.

Data on the pharmacokinetics of benzodiazepines in PD are scarce but CAPD patients had longer serum half-lives than controls and HD patients [377]. There were also higher free fractions of the drug. CAPD patients should thus be monitored for side-effects and the dose should be adjusted accordingly. Dose modification may not be necessary in renal failure for midazolam [378], but some reports of sustained activity of midazolam due to accumulation of metabolites in renal failure were reported in ICU patients with renal failure [379]. Zolpidem is an imidazopyridine that differs in structure from benzodiazepines and is approximately 92% protein bound. The free fraction increases to 14.9% in uremic patients, while the V_d increases, and elimination $T_{1/2}$ doubles [380]. Although exact data are not available, dose reduction in CAPD patients seems to be prudent.

Morphine

Conjugation with glucuronic acid represents the major route of biotransformation of morphine and the glucuronides, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G), are eliminated via the kidneys. Chronic renal failure should thus affect the disposition of M3G and M6G. Some patients undergoing long-term PD require pain treatment with morphine and the pharmacokinetics of morphine and its metabolites in CAPD patients after a single IV dose of 10 mg morphine-hydrochloride were investigated [381]. While the systemic clearance of morphine (1,246 $\pm$ 240 mL/min) was in the range observed in patients with normal kidney function, both M3G and M6G showed substantial accumulation. The AUC ratio of M3G:morphine and of M6G:morphine was 5.5 and 13.5 times higher than in patients with normal kidney function. Renal clearances of morphine, M3G, and M6G and dialysate clearances were extremely low. Therefore the accumulation of M6G and M3G in kidney failure is not compensated by CAPD.

Mycophenolate Mofetil (MMF)

Mycophenolate mofetil is a prodrug of the immunosuppressive agent mycophenolic acid (MPA). It is rapidly converted to MPA following oral ingestion. MPA is metabolized to MPA glucuronide (MPAG), which is renally excreted. After initiation of PD in patients with a GFR $<$ 10 mL/min, the AUC substantially decreased. The calculated clearance increased from 8.1 mL/min/kg in nondialyzed patients to 14.6 mL/min/kg in CAPD patients. MPA itself was found in only trace amounts in the dialysate. However, MPAG was found to be removed by PD for up to 2 g/12 h, representing removal of 1.2 g of MPA [223]. MacPhee et al. [382] examined the pharmacokinetics of MMF after an overnight fast of a single oral dose of 1 g in patients on HD or on PD. Plasma concentrations of MPA and MPAG were measured from 0 (predose) to 36 h after administration. The mean AUC for MPA was 55.7 $\pm$ 32.6 mg/L/h for HD patients and 44.7 $\pm$ 14.7 mg/L/h for PD patients, which is similar to the expected values for subjects with normal renal function. The mean Cmax for MPA was lower than would be expected for subjects with normal renal function (16.01 $\pm$ 10.61 mg/L for HD, 11.48 $\pm$ 4.98 mg/L for PD). MPAG clearance was prolonged with AUC approximately five times what would be expected in subjects with normal renal function. No MPA was detectable in HD or PD fluid, but small amounts of MPAG were detected in PD fluid in 3 out of 10 subjects. The accumulation of MPAG may be responsible for the poor gastrointestinal tolerance of this drug in dialysis patients and probably limits the maximum dose of MMF that can be tolerated.

Vitamin D Analogues, Bisphosphonates, and Cinacalcet

A recent excellent comparative review on the pharmacokinetics of vitamin D analogues in patients treated with HD and PD was published by Bailie and Johnson [383]. This review summarizes also the studies performed with the vitamin D analogues in CAPD patients, discussed in the previous edition of this book.

CAPD treatment is associated with peritoneal losses of vitamin D metabolites, contributing to the low serum levels of 25-OH-D3 and 25-OH-D binding capacity; losses of 1,25(OH)2D3 and 24,25(OH)2D3 in the dialysate average 6–8% of the plasma pool per day [384, 385].

IP calcitriol (CT) raises serum calcium and depresses serum PTH more effectively than increasing dialysis fluid calcium [386]. The CT and alfacalcidol should, however, be injected directly through the catheter port and not into the dialysate, as a substantial amount is otherwise adsorbed to the PVC bags [387, 388]. Salusky et al. [388] have studied the pharmacokinetics of CT after IV, oral, and IP administration of 60 ng/kg in CAPD and CCPD patients. The serum CT levels were similar after 24 h for the different routes of administration. The bioavailability of CT (AUC 0–24 h) was 50–60% greater after IV than after oral or IP administration. Comparable results were obtained by Joffe et al. [384], who determined appearance of 1,25-OH vitamin D3 after oral, IV, and IP administration of alfacalcidol [384].

Murakami et al. [389] recently investigated whether transperitoneal absorption of maxacalcitol (22-oxacalcitriol ; OCT) inhibited intact parathyroid hormone (i-PTH) in CAPD patients when the OCT was added to the PD fluid.

After injection of 20 μg of OCT into the peritoneal cavity of CAPD patients, the mean concentration of OCT in PD fluid rapidly decreased, from 25,268 pg/mL at 0 h to 1,694 pg/mL at 2 h and 44.9 pg/mL at 4 h. In contrast, the mean serum OCT level increased from the pretreatment level, which was below the detection limit of the assay, to 656 pg/mL at 0.5 h and a peak of 759 pg/mL at 1 h, and thereafter gradually decreased, to 713.8 pg/mL at 2 h and 555.8 pg/mL at 4 h. Mean i-PTH significantly decreased, to 83.9% of the baseline level at 1 h and thereafter stayed at around 90%. No consistent trends in calcium and phosphate levels were observed in these patients. Injecting OCT into the peritoneal cavity can thus significantly decrease i-PTH levels. Hamada et al. [390] evaluated the stability of physiological activities of CT and OCT in PD bags and to determine the CT or OCT dosage for IP administration: CT 1.5 μg or OCT 10 μg were added to different PD solutions, contained in different containers. Although the levels of CT and OCT in PD bags made of polyvinyl resins decreased by 70–75% immediately after injection, levels in PD bags made of polypropylene resins decreased only slightly. The concentration of CT mixed into the acidic solution in glass containers was stable; the decreased concentration of CT in the PD solution might be due to adsorption onto polyvinyl resins. The results showed good peritoneal transport of OCT but not rapid disappearance, unlike after IV administration. If peritoneal administration of vitamin D derivatives is contemplated, it is important to select the composition of the PD bag resins, the type of vitamin D analog, and time lag to use when deciding the dosage of injectable vitamin D preparations, such as OCT or CT. It appears that IP administration in overnight dwells might be useful for PD patients as a complementary vitamin D preparation.

Biphosphonates are becoming increasingly popular for treatment of osteoporosis, morbus Paget, and hypercalcemia. An excellent review on the use of these drugs including PD patients has been published by Rodd [391]. In general it must be remembered that these drugs are poorly eliminated across the peritoneal membrane after IV administration and that the doses should be reduced as in patients with ESRD without PD.

The major route of elimination of clodronate is renal excretion. Hence, the dose of clodronate should be reduced in renal failure. In one study [392], CAPD removed clodronate poorly from the circulation (7% of administered dose over 24 h), and most of the clearance was attributed to skeletal deposition of the drug. This uptake was related to parathormone levels. Clearance of clodronate after a single IV injection was 2.4 ± 0.6 mL/min. The V_d was 0.49 ± 0.34 L/kg, and elimination $T_{1/2}$ was 16.9 ± 4.7 h. D/P for clodronate was approximately 0.4 after a 6-h dwell. Data on pamidronate in PD are not available, but most probably the same recommendations as for clodronate can be made, and dose adaptations as in patients with severe renal failure should be made.

The pharmacokinetics and dynamics of cinacalcet in ten CAPD patients were recently studied [393]. Following single-dose administration of cinacalcet, there was no evidence of increasing exposure with increasing degree of renal impairment, and the pharmacokinetic profile was similar for all subjects regardless of whether they were receiving HD or PD. Protein binding of cinacalcet was similar in all groups and the level of renal function did not affect the pharmacodynamics (as determined by intact parathyroid hormone and calcium levels). No serious adverse events occurred during either study. Therefore, the dose of cinacalcet does not need to be altered for degree of renal impairment or dialysis modality.

Insulin

Insulin is one of the most commonly administered IP drugs in PD patients. Earlier studies demonstrated that IP insulin is absorbed into the portal venous circulation [394] and that IP insulin leads to a persistent positive portal–systemic difference [395]. A substantial portion (50%) of the portal venous insulin is degraded during first passage through the liver. Such IP treatment appears to improve glucose control and glucose stability without increasing the risk of hypoglycemia [396–400]. The intrapatient variation of the plasma-free insulin was markedly lower with continuous IP than with continuous SC or intramuscular insulin administration [401, 402]. This could be attributed to the considerably smaller insulin depot after IP administration. IP insulin administration is most effective in patients on PD if it is given into an empty peritoneal cavity, at least 30 min before the dialysate is instilled [403]; this creates a high peritoneum to plasma concentration gradient and avoids the adsorption of insulin to the peritoneal fluid bags. When radiolabeled insulin was added to the 2-L dialysate bags only 35% of the dose entered the peritoneal cavity [404]. In contrast, about 84% of 16 U of unlabeled insulin added per bag reached the peritoneal cavity when administrated directly through a port on the Tenckhoff catheter [405]. IP insulin is rapidly absorbed and is detected in the peripheral blood within 15 min of administration, and peak serum insulin levels are observed 30–45 min after administration into an empty peritoneal cavity [235]. These peak values are delayed until 90–120 min when insulin is added to the dialysate [406]. However, due to the partial hepatic inactivation of IP insulin, absorption kinetics and efficacy of IP and systemic insulin are difficult to compare by measurement of peripheral blood insulin levels. Wideroe et al. [235] found that fluid volume and osmolality of the solution in the peritoneal cavity decrease the transport rate of insulin, but not its bioavailability. A better blood glucose regulation after 120 min was found with IP administration in

dialysate as compared to administration into an empty abdomen [235]. A recent review [407] has covered the most important aspects of insulin administration to PD patients.

Peroxisome Proliferator-Activated Receptor (PPAR)γ Agonists

Pharmacokinetic profiles of PPARγ agonists make these drugs potentially suitable for their use in patients with type 2 diabetes and patients with chronic renal failure with and without dialysis (for review see [408]). Furthermore, the available glitazones have an adequate oral bioavailability and are extensively metabolized by the liver. Rosiglitazone is mainly metabolized by cytochrome P450 (CYP) 2C8 into inactive metabolites. Less than 1% of the parent drug appears in the urine in unchanged form [408, 409]. Both total and unbound plasma concentrations of rosiglitazone after a single 8-mg oral dose were not affected by the presence of mild, moderate, and severe renal insufficiency, thus indicating that the starting dose of rosiglitazone needs not be adjusted in patients with renal impairment [410]. Moreover, similar values of AUC–time curve, maximum Cmax concentrations, and $T_{1/2}$ were observed in a group of ten HD patients (nondialysis day) in comparison with a group of healthy individuals after a single 8 mg oral dose of rosiglitazone. Metabolites of pioglitazone are more active and are excreted predominantly in the bile. Both pioglitazone as its metabolites do not accumulate in chronic renal failure. The pharmacokinetic profile of pioglitazone was similar in healthy subjects and in patients with moderate and severe renal failure [411].

PPARγ agonists therapy in dialysis patients has shown adequate safety and tolerance profiles. In the study of Manley and Allcock [412], there were three hospitalizations for new or worsening congestive heart failure (CHF) in a group of 40 HD patients with type 2 diabetes treated with glitazones. Interdialytic weight gain significantly increased, 0.3 kg in rosiglitazone-treated patients. Rosiglitazone therapy has been well tolerated in both diabetic and nondiabetic uremic patients on CAPD. Edema in lower extremities and weight gain in approximately 2% of the patients have been reported [413, 414]. Altogether, these results suggest that PPARγ agonists might be an adequate alternative in the antihyperglycemic therapy of diabetic patients with CRF, regardless of the treatment used for renal failure. According to the American Heart Association and the American Diabetes Association recommendations, in patients without clinical data of CHF, but with one or more risk factors for its development, as it is the case in CRF patients, therapy with glitazones should be initiated at low doses, i.e, rosiglitazone 4 mg/day and pioglitazone 15 mg/day. The increases in dose should be gradual, with tight monitoring for signs of excessive weight gain, peripheral edema, and/or CHF [415].

Heparin

Heparin has an average MW of 15 kDa and consists of a heterogeneous group of anionic mucopolysaccharides, called GAGs (see Part I of this chapter). Heparin is the most frequently used drug in PD, for the purpose of preventing fibrin formation and catheter obstruction. Furman et al. [416] performed a pharmacokinetic study of IP heparin, assayed as the activated-partial-thromboplastin time (APTT) of dialysate added to control plasma. The $T_{1/2}$ of disappearance from the peritoneal cavity ranged between 8.26 and 12.77 h. Systemic blood coagulation was unaffected by a single IP dose of 10,000 U of heparin. Other investigators [417, 418] showed that heparin did transfer across the rabbit peritoneal membrane and, to a slight extent, in CAPD patients [419]. In a CAPD patient with deep-vein thrombosis, long-term IP application of low-molecular-weight (LMW) heparin in a dose of 8,000 antifactor Xa units/2 L, resulted in adequate and therapeutic plasma levels as measured by antifactor Xa units [420]. IP administration of heparin (1,000–2,500 U/L) without addition of ATIII is sufficient for prevention of IP fibrin formation in CAPD patients [419, 421].

Enoxaparin

Brophy et al. [422] studied the pharmacokinetics and pharmacodynamics of enoxaparin in healthy volunteers and HD and PD subjects. Antifactor Xa activity estimated the pharmacokinetics, whereas thrombin generation time (TGT) estimated the pharmacodynamics. Enoxaparin 1 mg/kg was given SC to all subjects. Antifactor Xa max and AUC(0-12) were similar between groups, but the TGTmax was significantly greater in the dialysis groups. The TGT remained significantly more prolonged throughout the 12-h study period, and there was a trend toward greater TGT AUC (0–12) for both dialysis groups. These results suggest that in dialysis patients, there may be accumulation of active heparin metabolites that are undetected by the antifactor Xa assay. Therefore, these subjects exhibit greater thrombin generation time prolongation despite similar antifactor Xa exposure.

Thrombin Inhibitors

Ximelagatran is an oral direct thrombin inhibitor and may be used as an anticoagulant for the prevention and treatment of thromboembolic disease. After oral administration, ximelagatran is rapidly absorbed and bioconverted to its active form, melagatran. Eriksson et al. [423] studied the pharmacokinetics of this drug in volunteers with norma and impaired renal function. All volunteers received, in a randomized sequence, a 3-mg SC injection of melagatran and a 24-mg immediate-release tablet of ximelagatran. In renal failure, the AUC and the $T_{1/2}$ of melagatran were significantly higher than in the group with normal renal function. This result was related to the decreased renal clearance: 12.5 and 81.3 mL/min after SC administration of melagatran and 14.3 and 107 mL/min after oral administration of ximelagatran, respectively. Ximelagatran and melagatran were well tolerated in both groups. It was concluded that after administration of SC melagatran and oral ximelagatran, subjects with severe renal impairment had significantly higher melagatran exposure and longer $T_{1/2}$ because of lower renal clearances of melagatran compared with the control group with normal renal function. These results suggest that a decrease in dose and/or an increase in the administration interval in patients with severe renal impairment would be appropriate. Pharmacokinetic studies in PD have not yet been performed with these drugs.

Desferrioxamine

A pharmacokinetic study of desferrioxamine and its iron and aluminium chelates has been performed in CAPD patients [424]. Desferrioxamine (10 mg/kg) was administered either intramuscularly or intraperitoneally. The AUC calculated from 0 to 12 h was about 20% lower after the IP than after the intramuscular administration. An advantage of the IP administration was, however, the progressive increase in plasma concentrations, without an unduly high peak. The fact that 8–12 h after administration the concentrations of desferrioxamine in plasma and peritoneal fluid were approximately the same, is consistent with the low binding of desferrioxamine to plasma proteins.

Desferrioxamine was given IV and IP in a CAPD patient in order to remove iron. Forty-five percent of the total amount instilled was recovered in the outflow dialysate [425]. An IP dose of 750 mg/day or 1,250 mg on alternate days led to removal of 73 and 39.6 mg iron, respectively, as compared with 75 mg removal per week after an IV dose of 1,500 mg thrice weekly. Several authors have used IP desferrioxamine successfully to remove aluminium in PD patients [426–428]. IP doses of 40 mg/kg were used over a 10-h dwell in one study [427] and 0.5 g into each 2 L dialysate to a total dose of 6 g was applied in another study [429]. In the latter study the aluminium clearance with desferrioxamine was 3.1 versus 2.5 mL/min without desferrioxamine. The enhanced removal of aluminium by PD persists for several days after a single administration of the chelator.

Anticancer Drugs

For cancers that have disseminated to the peritoneal surfaces, IP chemotherapy results in high drug concentrations locally with low systemic toxicity. Using a rat model, Mohamed et al. [430] compared the pharmacokinetics and tissue absorption of paclitaxel infused intraperitoneally in two isotonic carrier solutions: 1.5% dextrose PD solution and hetastarch (6% hydroxyethyl starch), a high-molecular-weight solution. The mean total quantity of drug remaining in the peritoneal cavity was significantly greater with hetastarch at 12 and 18 h. There was a 105% increase in the AUC ratio of peritoneal fluid to plasma paclitaxel concentrations with hetastarch versus PD. The use of IP paclitaxel with hetastarch carrier solution provides a pharmacologic advantage for a local-regional killing of residual tumor cells with decreased systemic toxicity. Similar results were obtained with docetaxel [431].

Melphalan

The use of heated intraoperative IP melphalan may provide a pharmacokinetic and clinical advantage in a group of gastrointestinal cancer patients who cannot be made cancer-free with cytoreductive surgery. Thirteen patients with residual disease following cytoreductive surgery for peritoneal carcinomatosis received IP melphalan (70 mg/m^2) in 3 l of 1.5% dextrose PD solution at 41–42°C for 90 min [432]. During the 90 min of treatment 87.2 ± 4.3% of the drug was absorbed from the perfusate/peritoneal fluid and 11.9 ± 2.1% was excreted in the urine. The AUC ratio of peritoneal fluid to plasma was 33.3 ± 11.8 with an average peak plasma concentration of 0.82 ± 0.24 μg/mL occurring at 28.5 ± 13.1 min. Concentrations of melphalan in tumor nodules on the peritoneal surface were approximately ten times higher than in plasma with an average peak concentration of 7.2 ± 4.2 μg/g. It was concluded that approximately 90% of the drug was absorbed during the 90-min procedure with a 30 times greater exposure of drug at the peritoneal

surfaces than in the blood. These data demonstrate that heated intraoperative IP melphalan could have a significant impact on the treatment of peritoneal surface malignancies.

PD and Removal of Contrast Media

To examine the elimination of iomeprol, its safety in clinical use, and its peritoneal permeability in CAPD patients with variable degrees of RRF, a nonrandomized comparative study was undertaken in CAPD and HD patients [433]. In all CAPD patients, plasma iomeprol clearance was markedly slow, with a biological $T_{1/2}$ of over 32 h. Over 80% of plasma iomeprol was eliminated during the 4-h HD. The plasma iomeprol elimination rate was significantly higher from 4 h after the iomeprol administration in CAPD patients with RRF (creatinine clearance of 3.8 mL/min), compared to those with a creatinine clearance of 0.6 mL/min. However, $T_{1/2}$ in patients with RRF was over 24 h. D/P creatinine was significantly correlated with D/P iomeprol. In view of the prolonged elimination rate of iomeprol in CAPD patients both with and without RRF, a HD procedure or intensive PD just after the use of iomeprol may be advisable to promptly remove circulating iomeprol.

Another contrast medium, gadodiamide was studied by Joffe et al. [434] in patients with severely reduced renal function (GFR, 2–10 mL/min), patients on HD, and patients on CAPD. Gadodiamide injection caused no changes in renal function. In patients with severely reduced renal function, the elimination $T_{1/2}$ of gadodiamide was prolonged (34.3 h $\pm$ 22.9) compared with data in healthy volunteers (1.3 h $\pm$ 0.25). An average of 65% of the gadodiamide injected was eliminated during a HD session, but only after 22 days of CAPD, 69% of the total amount of gadodiamide was excreted, reflecting the low peritoneal clearance. It was concluded that gadodiamide is dialyzable and can safely be used in patients with severely impaired renal function or those undergoing HD or CAPD.

Homocysteine and Vitamins

The amount of total homocysteine eliminated by PD and its relationship to peritoneal transport characteristics in CAPD have been explored by Vychytil et al. [435]. A significant influence of plasma total homocysteine concentrations, of the daily dialysate effluent volume and of the D/P creatinine on peritoneal elimination of total homocysteine was found. The daily peritoneal excretion of total homocysteine was 5.27 $\pm$ 2.81 mg. There was a positive linear association of the daily total homocysteine elimination with plasma total homocysteine concentrations. A significant linear correlation was observed between D/P creatinine and D/P total homocysteine, D/P free homocysteine, as well as D/P protein-bound homocysteine. The peritoneal elimination of total homocysteine primarily depends thus on the plasma total homocysteine concentration and elevated total homocysteine plasma levels cannot be reduced efficiently by PD.

Boeschoten et al. [436] have summarized earlier studies on vitamin status and vitamin losses in the dialysate in IPD and CAPD patients. They have performed a more complete analysis of plasma and 24 h dialysate losses of vitamin A, B1, B2, B6, B12, C, folic acid, E, and β-carotene in 44 CAPD patients. Vitamins B12, A, and E and carotenoids were not detectable in dialysate. In contrast, vitamins B2, B3, B6, C, and folic acid were excreted in the 24 h dialysate in amounts higher than in 24 h urine of individuals with normal renal function. The loss of vitamin B1 in dialysate was low. The authors recommend vitamin supplementations in CAPD patients for vitamins B1, B6, C, and folic acid.

Chapter 10
Peritoneal Dialysis Connectology

N.V. Dombros and V. Liakopoulos

Conventionally, term *connectology* refers to the body of available information and accumulated experience on the various systems of transfer sets, connecting devices, etc., that are used during the process of peritoneal dialysis (PD). This chapter will cover connectology as it refers to continuous ambulatory peritoneal dialysis (CAPD), with only a brief discussion of automated peritoneal dialysis (APD). Acute peritoneal dialysis is not discussed.

Following the initial rapid evolution of the various systems and connections, which accompanied the development of PD as a treatment of chronic renal insufficiency, there is a relative deceleration of the evolution of PD connectology. This fact could be attributed, on one hand, to the drastic decrease of the frequency of peritonitis, but, on the other hand, to a decline of PD expansion. Lack of evidence-based information or double-blind studies on connectology reflects this stagnancy.

Short History

Georg Ganter was the first who tried to put PD in clinical practice [1]. Back in 1923, in Germany, he used a sterile solution containing electrolytes and dextrose. This solution, placed in large boiled glass bottles, was instilled into the peritoneal cavity through a simple hollow needle, with a rubber tubing serving as the conduit between the bottle and the needle. Later, in the mid-1940s in Holland, P.S.M. Kop used porcelain containers for the dialysis solution, latex tubing, and a glass catheter to instill the solution into the patient's peritoneal cavity [2]. A couple of years later, in Massachusetts, A. Seligman, J. Fine, and H. Frank improved this system by using two catheters, one for the inflow and one for the outflow procedure [3]. In 1952, Arthur Grollman described for the first time a method for intermittent PD using 1-L glass containers with a cap that connected to plastic tubing attached to a flexible polyethylene catheter with very small holes in its distal end [4].

Morton Maxwell took one step further, by developing the "Maxwell Technique." He used two custom-made 1-L glass bottles with plastic tubing and a polyethylene catheter for the inflow. After a 30 min dwell, the fluid was drained back into the two original bottles placed lower than the patient's abdomen. This system simplified PD and made it more easily available [5].

In 1960, Fred Boen, working with B. Scribner in Seattle, introduced home PD, when he developed an automated unit using 40-L "carboy" containers equipped with an automatic device that would open and close a switch to lead the fluid in and out of the peritoneum during the 24 h of dialysis. These containers were filled and sterilized at the University of Washington and then delivered to the patient's home. Peritoneal access was achieved by placing a new catheter before each dialysis (once a week at that time) and removing it afterwards [6]. Boen's system was simplified by Henry Tenckhoff, working in the same center in 1963. He used a reverse osmosis water purification system mixed with a concentrated peritoneal fluid and a simple automatic PD machine. Later, Tenckhoff improved the silicone catheter originally developed by Russell Palmer [7] and completed an intermittent PD system [8]. During the same time, Norman Lasker in New Jersey introduced the first peritoneal cycler that used 2-L glass bottles and instilled warm dialysate in the peritoneal cavity [9].

In 1975, in Austin, Texas, Jack Moncrief and Robert Popovich conceived the method of CAPD using two 1-L glass bottles, plastic tubing, and Tenckhoff's catheters [10, 11]. However, a high incidence of peritoneal infections was the major drawback of their method (Fig. 10.1).

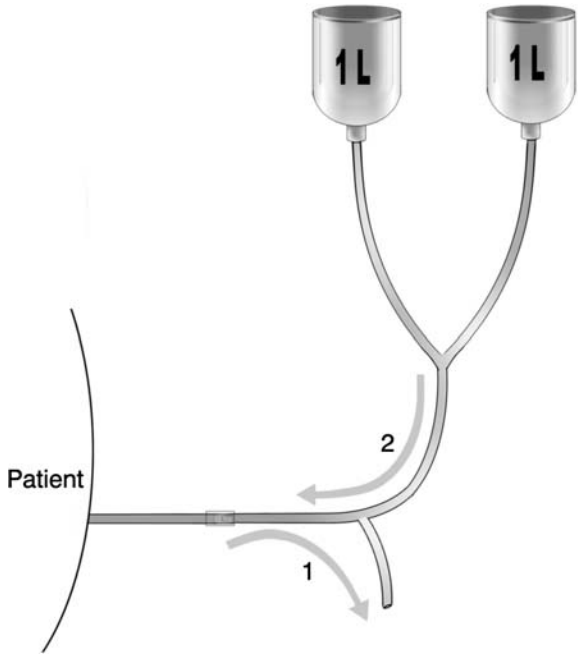

Fig. 10.1 The original CAPD system by R. Popovich and J. Moncrief

In the early 1970s, Dimitrios Oreopoulos had established a 70-patient intermittent PD program in Toronto Western Hospital, using Lasker's cyclers and Tenckhoff's catheters. He was using collapsible 2-L bags. Adopting the idea of CAPD, Oreopoulos developed a tubing with a spike on the one end, to fit into the bag, and a male press fitting on the other, to fit into the catheter. The empty dialysate bag was rolled up and remained attached to the patient's body until the next bag exchange. At that time, all 70 patients in the Toronto Western Hospital intermittent PD program were converted to CAPD. This gave a major push to the then newborn method, particularly because the peritonitis rate was reduced drastically from one episode per 10 weeks to one episode per 8–11 months [12]. "Peritoneal dialysis was here to stay" [13].

Ideal PD Delivery Systems

A PD system should be characterized by reliability, simplicity, ease of use, and acceptable cost. Its materials should be durable, biocompatible, easily disposable, and recyclable. Furthermore, the connection system should not add to the aesthetic drawback of the presence of the peritoneal catheter in the patient's abdomen. Most importantly, a PD system should be safe and effective in preventing PD-related infections.

Description of Various Delivery Systems

CAPD delivery systems include:

Nondisconnecting systems:

- Collapsible bags with simple spike (or Luer lock)
- Collapsible bags with simple spike and germicidal ultraviolet (UV) chamber
- Collapsible bags with simple spike and thermoclave
- ANDY® system (Y-set system)

Disconnecting systems:

- Y-set systems
- O-set systems (a subclass of the Y-set systems)
- T-set systems (a subclass of the double-bag systems)
- Double-bag (or twin-bag) with Y-set systems
- UV flash® system (Y-set sterilized by UV light)
- Safe lock®
- Safe lock 5F®
- ANDY-disc® system (double-bag Y-set system)
- Stay-Safe®
- UltraBag®
- Delta 4 system
- Gemini
- Gambrosol® Trio

The first PD delivery system that made the wide clinical application of CAPD possible was the wearable bag system introduced by Oreopoulos in the late 1970s [12] (Figs 10.2a–10.2c). In this "wearable" system, referred to as the "standard" system for many years, the catheter is connected to the bag *via* a titanium adaptor, which replaced the male press fitting and a piece of tubing and a spike or a Luer lock device. During each bag exchange procedure, the spent dialysate is drained from the peritoneal cavity to the empty bag, which is then disconnected and discarded. The next step is the connection of a new bag to the patient's catheter and the fresh dialysate is introduced into the peritoneal cavity. The empty bag is rolled up and remains attached to the patient until the next bag exchange (nondisconnecting system). This system achieved a significant drop in peritonitis rate. However, this rate was stabilized at approximately one peritonitis episode every year, mostly due to touch contamination.

A major improvement was the introduction of the Y-set system by Buoncristiani [14] (Fig. 10.3). A Y-shaped transfer set filled with disinfectant during the dwell time is connected permanently to the catheter. During the bag exchange procedure, one of the two free limbs of the Y transfer set is connected to a new bag containing the fresh dialysate and the other to an empty drainage bag. At the beginning of each exchange, the spent dialysate is drained from the peritoneal cavity into the empty bag. The Y-connecting tubing is then flushed with a small volume (~100 mL) of fresh dialysate drained from the new bag directly into the drainage bag (flush before fill). After that, the fresh dialysis solution is introduced into the patient's abdomen and the Y-set, along with the bags, is disconnected from the catheter (disconnecting system). With this technique, micro-organisms that happen to be inadvertently introduced into the system during the connection are flushed into the drainage bag.

A number of variants of the original Y-set have been introduced into clinical practice[15–17]. The most widely used are the long Y-set (a Y with two long free limbs) and the O-set (named from the shape it takes when the two free limbs are connected to each other during the dwell phase) (Figs 10.4a and 10.4b). In both systems the prosthesis is disconnected after each exchange. In some versions, the Y- or O-set is filled with disinfectant during the dwell time and reused in the next exchange.

The **double (or twin)-bag system,** introduced by Bazzato et al. [18], is similar to the Y-set system, but both bags (the one containing the fresh solution and the empty-drainage bag) are already connected to the Y-shaped tubing by the manufacturer. The Y-set lies on the bag side. Therefore, only one connection is required by the patient, that of the catheter to the free branch of the Y-set via a catheter extension (Fig. 10.5).

A modification of the double-bag system is the T-set, which consists of a catheter extension equipped with a very short lateral limb, through which, at the end of the exchange, before the disconnection of the bag, a disinfectant is injected, filling the catheter extension [19] (Fig. 10.6).

In the early years of the various Y-set systems, the tubing was rinsed with a hypochlorite disinfectant during bag exchange. However, a danger of accidental infusion of the disinfectant into the peritoneal cavity was always present. Many studies have confirmed that the "flush before fill" is the main preventive characteristic of the Y-sets [20–23]. Therefore, the use of the disinfectant has been abandoned by most manufacturers. In a recent position paper, Buoncristiani et al. [24] propose a double Y-set consisting of one Y-shaped connector mounted on the catheter and a second mounted on the distal end of the down flow tube of the fresh dialysate bag equipped with a special slider (manual or electromechanical) in order to overcome the injection of disinfectant into the peritoneal cavity.

Double-bag systems are currently the mainstay of treatment and they are considered as the "standard" PD delivery system.

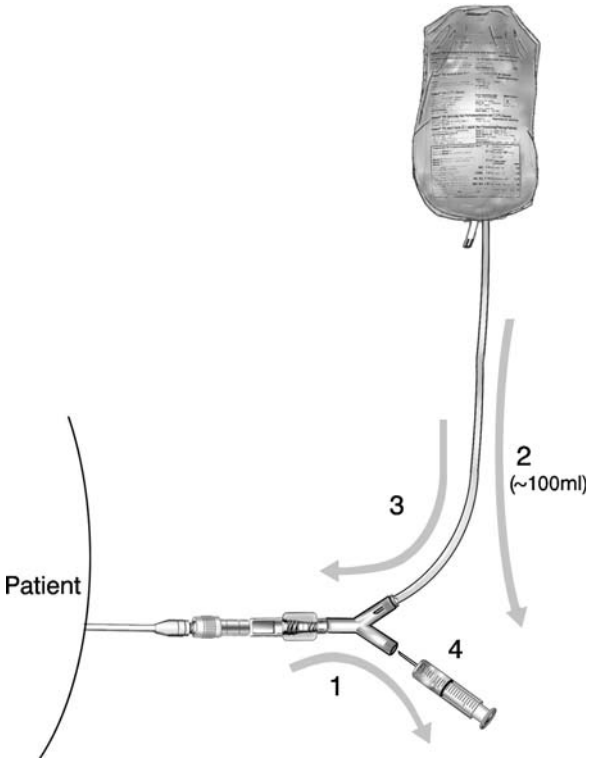

Fig. 10.3 The Y-set CAPD system. (1) drain, (2) flush before fill, (3) fill, (4) fill with disinfectant

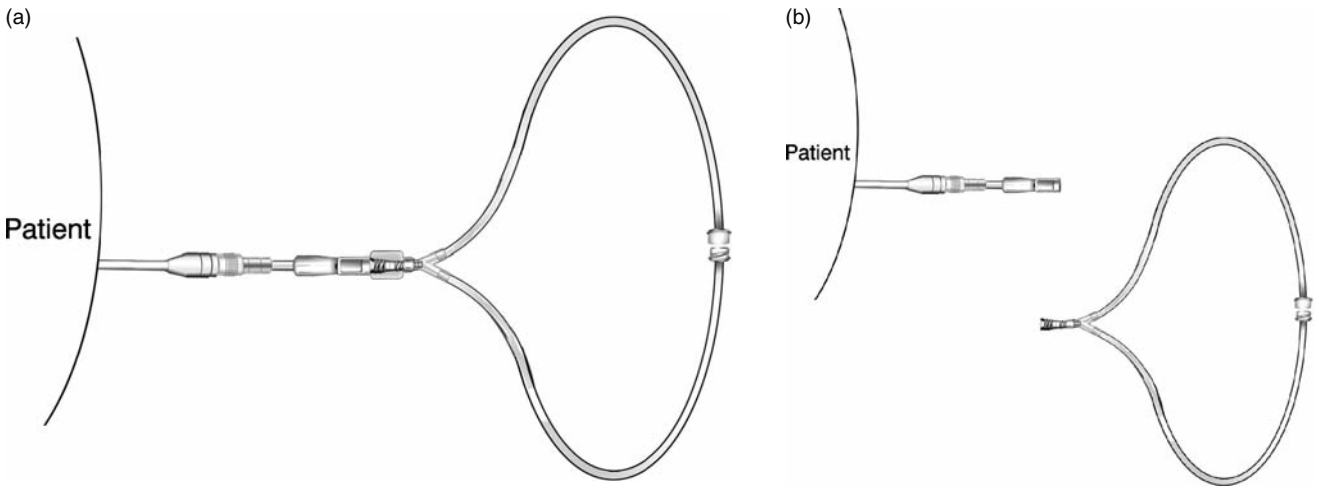

Fig. 10.4 The O-set CAPD system. (**a**) connected, (**b**) disconnected

Connection Devices (Connectors)

In the nondisconnecting systems era, a long transfer set, which consisted of a PVC tubing, was used to connect the catheter with the dialysate bag. The proximal end of this transfer set was connected through a male press fitting to the permanent peritoneal catheter. Frequent accidental disconnections at this point were accompanied by a high incidence of dialysate leak. The introduction of titanium adaptors (Fig. 10.7), which replaced the male press fitting connectors, reduced significantly these accidents and, consequently, peritonitis rates.

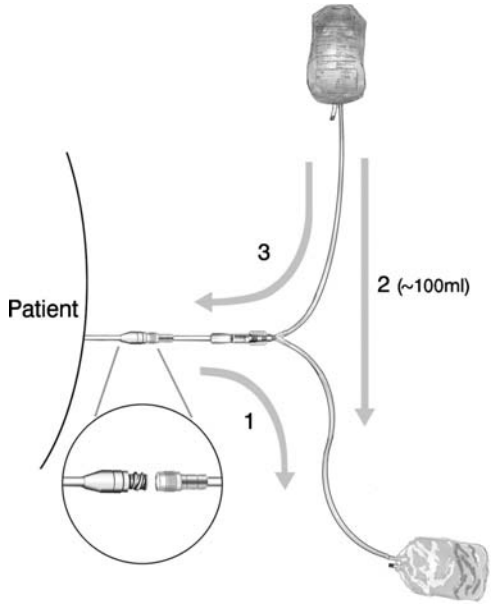

Fig. 10.5 The double-bag CAPD system. (1) drain, (2) flush before fill, (3) fill

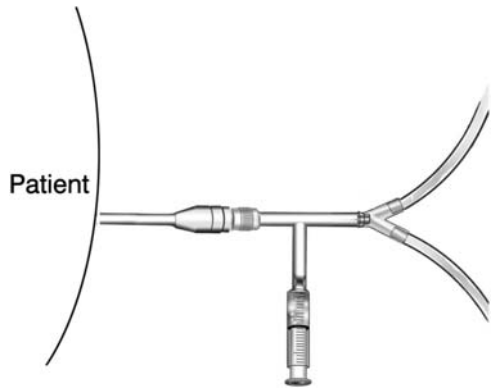

Fig. 10.6 The T-set CAPD system

The distal end of the transfer set was connected to the fresh dialysate bag via a spike (rigid pointed hollow plastic tube) (Fig. 10.8) or a Luer lock connector during each bag exchange procedure (Fig. 10.9). This procedure is associated with a high peritonitis risk due to touch contamination and, therefore, is not recommended [25]. In nondisconnecting systems, transfer sets were initially changed every week and later every month.

In disconnecting systems, a catheter extension tubing is securely screwed onto the titanium adaptor and is connected with the tubing of the dialysate bag at every bag exchange via a connection device that differs from one manufacturer to the other, as described below under "Internationally Available CAPD Delivery Systems". Material improvements have allowed catheter extension changes to be performed approximately every 6 months.

One type of connector was the Safe-lock®, consisting of a cone and a press-fit of the cone, which was deeply recessed, so that the path of the dialysate could not be touched. The Safe-Lock 5F® contained a spring-operated sealing valve inside the catheter, which regulated the dialysate flow in five steps. No extension sets were required and

Fig. 10.7 The titanium adaptor

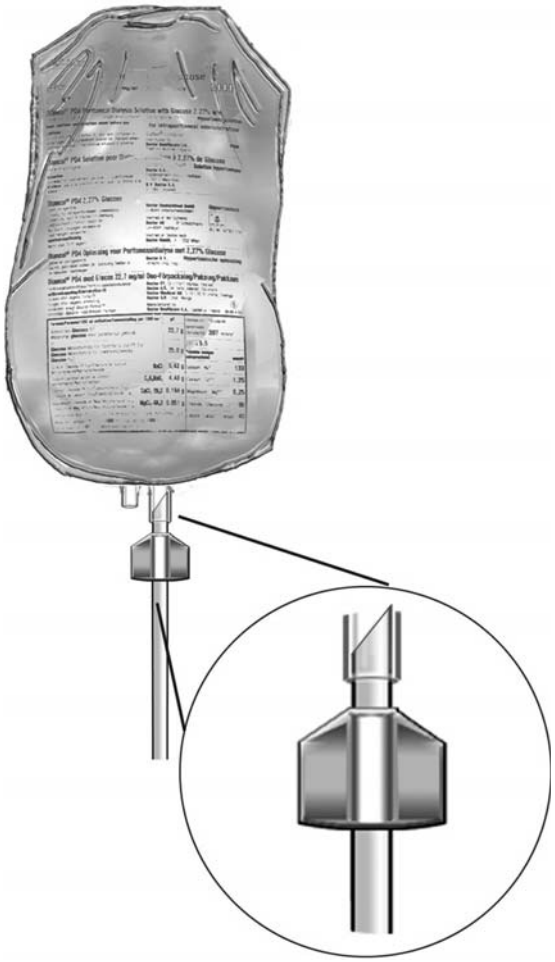

Fig. 10.8 A spike connector

between exchanges only the connector remained attached to the catheter. These two connectors were sprayed with an antiseptic solution both before and after the connection [26].

The Freeline® was a Y-set system where instead of the use of a disinfectant, the extension was closed with a cap containing an iodine impregnated sponge [26].

Another variation was the ANDY® system (nondisconnecting system), where, after the bag exchange, the Y-set was closed with an irreversible clamp and remained attached to the catheter acting as a cap until the next exchange [27].

Disinfecting Devices

In the era of "wearable" systems, the use of devices that could sterilize connecting surfaces was tempting. Ultraviolet (UV) light sterilization as well as heat sterilization, achieved with either electrical resistance or microwaves, were tested.

In a large randomized study by Nolph et al. [28] the UV-flash® disinfecting device did not prove effective in reducing peritonitis rate The authors recommended its use in less-skilled patients experiencing technique problems. Higher peritonitis rates were found in patients using UV-assisted "wearable" systems compared to patients using disconnecting systems [16]. However, these devices could prove useful in patients with impaired dexterity or vision, according to a retrospective multicenter study from Japan [29]. In vitro studies supported the germicidal effectiveness of these devices [30], but the results of a subsequent study by the same investigators, who quantified bacterial removal in disconnecting (Y-set and double-bag) systems, attribute the safety of these systems to the protective action of the design of the fluid path flow and the "flush before fill" [21].

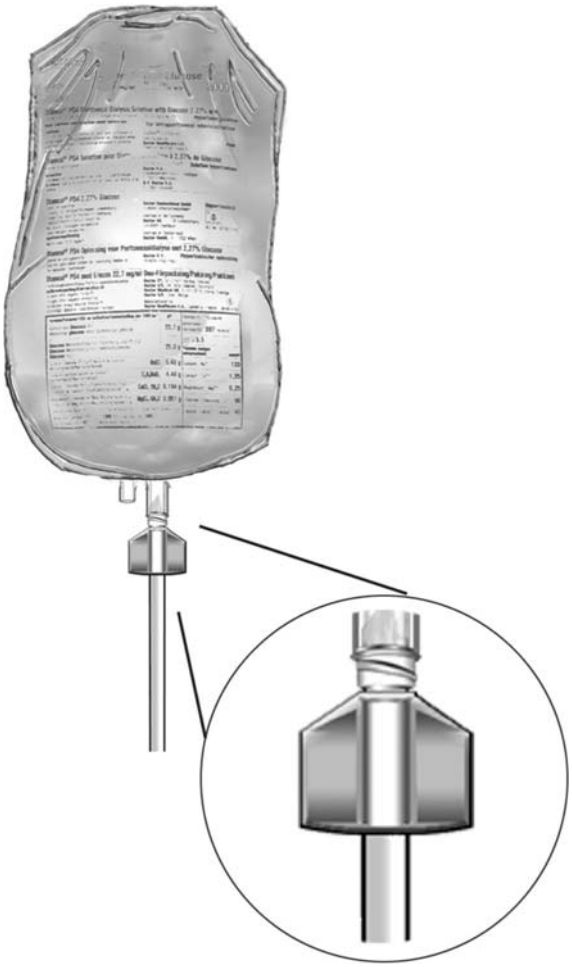

Fig. 10.9 A Luer lock connector

Other devices used heat for sterilizing the connection site. The Terumo Flame-Lock system used heating over a flame and ceramic connections with good results in reducing peritonitis rates [31]. The Fresenius Thermoclave device was used with the Safe Lock 5F® connector and gave good results, as well [32]. Low incidence of touch contamination and high patient acceptance was also reported with the use of the Sterile Connection Device, which used a heated blade to cut through parallel placed tubing of transfer set and fresh dialysate bag [33]. Another heat sealing device, although safe and simple, included the danger of serious burns for the patient or the caregiver and was very large and bulky [34]. Microwave moist-heat devices showed good in vitro results but did not prove practical [35, 36].

However, PD is considered a simple and patient friendly method without the complicated equipment of hemodialysis. All these devices added to the complexity and increased the cost of the method without substantial benefit for its safety and, therefore, their use has been mostly abandoned.

Internationally Available CAPD Delivery Systems

CAPD systems available internationally today, excluding locally manufactured and used ones, are, in alphabetical order of their manufacturers, the following (data provided by manufacturers after personal communication):

Baxter: The UltraBag® system is a double-bag system with a Luer lock connector. Different PD solutions are available (standard glucose, lactate/bicarbonate in dual-bag chambers, amino acid solutions, icodextrin solutions). Dialysate containers are made of PVC. Moreover, a special device for assisting patients during the bag connection (EZ-AIDE®) and a disinfecting device using UV light (UV flash® germicidal exchange device) are also available.

Bieffe: The Delta 4 system is a double-bag system with a Luer lock connector and a catheter extension cap containing povidone iodine. The dialysate container is made of Clear Flex®. The Clear Flex® has three layers. Starting from the outer layer these are made of polypropylene, polyamide, and polyethylene.

Fresenius AG: Stay-safe® and ANDY-disc® are both double-bag systems incorporating a special connector, the disc. After the initial connection of the disc to the extension set, all exchange phases are performed by turning the knob of the disc. At the end of the exchange an automatically introduced pin seals the lumen of the catheter extension. The tip of the extension is protected with a disinfectant-containing cap. Stay-safe® is the newer system of the two, offering more solution options (standard glucose, bicarbonate solutions, and dual chamber bags). The dialysate container is made of Biofine®, while the ANDY-disc® system uses PVC containers. Biofine® is made of polymers constructed exclusively from hydrogen and carbon atoms, the polyolenes.

Gambro: The Gambrosol® trio system is a double-bag system incorporating a special three-barrier connector and a prefilled tubing. The PVC containers have three compartments. An iodine containing cap is used for closing the catheter extension set.

Delivery Systems and Peritonitis

From the literature available so far, it becomes clear that disconnecting (Y-set and double-bag) systems are associated with lower peritonitis rates, compared to "standard" systems. All but one randomized controlled trial (RCT) or quasi-RCT comparing Y-set delivery systems to the "standard" systems showed that the number of CAPD patients who experienced at least one episode of peritonitis was significantly less for patients using the Y-set [37–43]. The exception was a study by Cheng et al. where this difference did not reach a statistically significant level ($p = 0.08$) [17]. All studies showed a significant improvement in peritonitis rates (episodes per patient-months) in favor of the disconnecting systems. These results are supported by a number of retrospective or observational studies [15, 44–47]. The length of the branches of the Y-set system, in one study, was not related to the incidence of peritonitis [48].

Three controlled studies where the "standard" system was compared to the double-bag systems showed a significantly reduced incidence of peritonitis with the latter systems [43, 49, 50]. Moreover, five controlled studies [43, 49, 51–54], where the two newer methods, that is, the Y-set and the double-bag systems were compared, consistently reported greater numbers of months per episode of peritonitis with the latter system. The superiority of Y-set or double-bag systems over "standard" systems and of double-bag over Y-set systems was confirmed by two meta-analyses of RCTs [55, 56].

Finally, two RCTs compared two double-bag systems: Stay-Safe® with UltraBag® and Andy-Disc® with Ultra-Bag®. The first study concluded that the two systems had similar incidences of peritonitis and exit-site infections [57]. The second study showed a trend towards greater peritonitis risk on the Andy-Disc® arm [58].

The Italian group that first described the Y-set reported a very low peritonitis rate (as low as one episode every 63 patient-months) [48]. Although such impressive results were not verified by others, a much improved peritonitis rate of one episode every 21–28 months was found in randomized studies comparing the new disconnecting systems with the "standard" [40, 50, 59]. Today, peritonitis rates are around one episode every 30 patient-months [60].

The routes through which an infectious agent can enter the peritoneal cavity and cause peritonitis are transluminal (touch contamination), periluminal (around the catheter), transmural (through the intestinal wall), hematogenous, and ascending (vaginal) [61]. The use of disconnecting systems led to a significantly lower danger of touch contamination. This is supported by the fact that the reduction observed in peritonitis rates after the introduction of disconnecting systems is mainly attributed to the reduction of infections with skin-related micro-organisms, like *Staphylococcus epidermidis*, while infections caused by *Staphylococcus aureus* or *Pseudomonas* species remained unchanged [40, 47, 49, 50, 62].

Delivery Systems and Exit-Site Infection

Two retrospective studies demonstrated a better exit-site infection rate in patients either on a Y-set [47] or a double-bag system [63], compared with patients on the "standard" system. However, in almost all randomized prospective controlled studies, the incidence of exit-site or tunnel infection is not related with the type of delivery system used. In particular, four studies comparing the Y-set with the "standard" system [17, 40–42], two studies comparing the double-bag with the Y-set [53, 54], and one study comparing a double-bag system with a "standard" one [50] demonstrated no significant difference in the rates of exit-site or tunnel infections. Similar results were published by Burkart et al. in two prospective, nonrandomized trials for Y-set versus "standard" systems [59, 64]. Only the study by

Kiernan et al. showed a trend towards lower exit site infection rate in patients using double-bag system compared with those using a Y-set (one episode per 12.5 patient months versus one episode per 28.5 patient months, respectively), but, again, the difference did not reach statistically significant levels [52]. Another RCT showed similar exit-site infection rates with two different double-bag systems (Stay-safe® and Ultrabag®) [57].

Delivery Systems and Ease of Use

Ballocchi et al. concluded that a double-bag system was rated as easy to use by the majority of their patients [65]. In a randomized study comparing double-bag systems versus Y-set systems, the former were considered more convenient and easier to handle [54], while the same group failed to find any differences in patients' acceptance between two different double-bag systems, at least after the first introductory month [57].

Delivery Systems and Technique Survival

It is difficult to assess the impact of a particular delivery system on technique survival, since so many other factors like ultrafiltration failure, peritonitis, catheter malfunction, etc., could play a decisive role. From the limited literature available, Tarchini et al. showed that the use of Y-set reduced the number of dropouts from the method, mainly due to the reduction in peritonitis rate [66], results that were confirmed by Port et al. in U.S. patients [46]. In another study, no difference in technique survival was found between patients using the "O" system and the "standard" system [17]. Finally, in a recent study comparing two double-bag systems, Wong et al. also showed no difference regarding technique survival [58].

Cost Effectiveness of Delivery Systems

Cost is a major concern for health systems, the cost of providing dialysis being a financial burden for insurance organizations, governments, and patients. Li et al. found that the extra cost required for the Y-system could be offset by other expenses required for infection-related morbidity of patients on the standard system [42]. In a Canadian study, Dasgupta et al. showed that the more expensive double-bag system resulted in significant savings due to reduction in peritonitis episodes and hospitalization rates compared to Y-sets [67]. Two randomized prospective trials proved that double-bag systems were more cost effective, compared with single-bag systems [43, 53].

CAPD Delivery Systems in Children

The data concerning the impact of delivery systems in children on PD are very limited. Some studies included children but made no special reference to this age group [41, 58, 59]. One retrospective study in children undergoing CAPD manifested a significantly lower peritonitis rate by the use of disconnecting (O- or Y-set) systems, compared with a nondisconnecting "standard" system [68]. Today, most children are on automated peritoneal dialysis (APD), a method more suitable to their lifestyle and special needs.

Comparison of CAPD Delivery Systems with APD

Automated PD machines (cyclers) are outside the scope of this chapter. However, the connections described here are also used for connecting the catheter extension with the tubing of the dialysate containing bags of a cycler.

In two studies where disconnecting systems had a lower peritonitis rate, as compared to "standard" ones, the former group included 259 APD patients out of a total of 968 patients on disconnecting systems [64, 69]. Comparisons of infectious complications between APD (by design a disconnecting system) and CAPD disconnecting (Y-set and Double-bag) systems are limited. In a randomized prospective study by de Fijter et al., APD patients had improved peritonitis rates but similar exit-site infection rates to patients on Y-set CAPD [70]. Another randomized study in a small number of patients (17 in each group) by Bro et al. failed to confirm these results [71]. In a nonrandomized prospective study from a Spanish center, APD resulted in lower peritonitis rate and similar exit-site infection rate,

compared with a Y-set CAPD system [72]. Retrospective or observational studies gave conflicting results. Two studies supported a lower incidence of peritonitis in CAPD patients using double-bag systems versus patients on APD [73, 74], while another found the two methods equal [75]. Finally, a study by Huang et al. showed a trend (with marginal statistical significance) towards lower peritonitis rates in APD patients [76].

Guidelines and Recommendations

Recommendations regarding PD delivery systems or connectology are made by only some of the guidelines published in the English language. In alphabetical order, these are:

British Renal Association [77]: *The use of disconnect systems should be standard unless clinically contraindicated (Evidence level A).*

Caring for Australians with Renal Impairment [78]: *Disconnect systems of CAPD result in lower rates of peritonitis than standard systems ("spike" or Luer lock) and the standard system should no longer be used (Evidence level A). Twin bag systems have lower rates of peritonitis than Y-disconnect systems and are recommended as the preferred CAPD technique (Evidence level A).*

European Best Practice Guidelines [79]: *Double-bag systems should be preferred, because they are more efficient in preventing peritonitis in CAPD patients. If double-bag systems are not available, any alternative Y-set system prevents peritonitis more effectively than any spike system (Evidence level A). Disinfecting devices have not demonstrated any significant reduction of peritonitis rates obtained by double-bag or Y-set systems (Evidence level A).*

International Society of Peritoneal Dialysis Guidelines [25]: *Spiking of dialysis bags is a high risk procedure for contamination of the system. "Flush before fill" reduces the risk of contamination (Evidence).*

The **Kidney Disease Outcomes Quality Initiative** [80] and the **Canadian Society of Nephrology** [81] have made no recommendations in their guidelines on the matter of PD connectology.

Glossary

Automated PD machine An electrical appliance specifically designed to perform peritoneal dialysis automatically, also known as a "cycler."

***Biofine*®** A material made up by polyolenes, which are polymers constructed from hydrogen and carbon atoms.

Catheter Refers to the permanent peritoneal catheter.

Catheter extension A piece of tubing connecting the catheter to the PD delivery system.

Clear flex® A registered trademark of Bieffe-Baxter. The Clear-Flex® bag is a three-layer laminate. Its inner layer is composed of polyethylene, the middle of polyamide, and the outer of polypropylene.

Connecting device A device of different designs (exclusively specific for each PD delivery system) used for the connection of the catheter or its extension to the delivery system. Synonym to connector.

Connector See connecting device

Cycler See automated PD machine

Dialysate The peritoneal dialysis solution.

Dialysate container The bag containing the dialysate, also known as "peritoneal dialysis bag."

Dialysate fresh The unused dialysate.

Dialysatespent The used dialysate, after its dwell into the peritoneal cavity.

Disconnecting system Also known as disconnect system, refers to those CAPD delivery systems that are disconnected from the patient between bag exchanges.

Disinfectant Any solution used for the disinfection of any connection site of a PD delivery system.

Disinfecting device A device of different designs using various sources of energy (heat, UV light) in order to disinfect the connection site of a PD delivery system.

Double-bag system A CAPD delivery system where both bags (the one containing the fresh dialysate and the empty drainage bag) are already connected to the Y-shaped tubing by the manufacturer.

Drain The action of outflow of the spent dialysate from the peritoneal cavity.

Drainage bag The bag into which the spent dialysate is drained.

Dwell The period during which the dialysate remains in the peritoneal cavity.

Fill The action of the inflow of the fresh dialysate from its container into the peritoneal cavity.

Flush before fill The action of flushing the tubing with a small volume (~100 mL) of fresh dialysate drained from the new bag directly into the drainage bag, followed by the fill.

Luer lock A type of tubing connector with threaded fittings for a secure connection and added leverage for seal disconnect. The concept for these connectors and adapters was developed by a German instrument maker whose name, Luer, still defines this unique design.

Nondisconnecting system Also known as nondisconnect system, refers to those CAPD delivery systems where the dialysate bag remains connected to the patient between bag exchanges.

O-set A variant of the original Y-set, named from the shape it takes when the two free limbs are connected to each other during the dwell phase.

Peritoneal dialysis bag See dialysate container

Peritoneal dialysis connectology A conventional term referring to the various systems of transfer sets, connecting devices, containers, adapters, etc., that are used during the process of PD.

Peritoneal dialysis delivery system A system incorporating all necessary parts and actions required for the process of bag exchange in peritoneal dialysis. Synonym to "peritoneal dialysis system."

Peritoneal dialysis solution See dialysate

Peritoneal dialysis system Synonym to "peritoneal dialysis delivery system."

PVC Polyvinyl chloride.

Spike A rigid, pointed, hollow plastic tube.

Standard PD system The nondisconecting or wearable PD system.

Titanium adaptor The Luer lock adaptor, made of titanium, connecting the catheter to its extension.

Transfer set The tubing connecting the catheter to the dialysate bag in the nondisconnecting system.

T-set A variant of the double bag system, which consists of a catheter extension equipped with a very short lateral limb, through which, at the end of the exchange, before the disconnection of the bag, a disinfectant is injected, filling the catheter extension.

Twin-bag system Synonym to "double bag."

Y-set A Y-shaped connecting tube. During the bag exchange procedure the main (vertical) limb of the Y-shaped connecting tube is connected to the catheter extension, while the second limb is connected to an empty (drainage) bag and the third one to a new bag containing the fresh dialysate.

Chapter 11
New Peritoneal Dialysis Solutions and Solutions on the Horizon

M. Feriani and R.T. Krediet

This chapter discusses 1) the effects of alterations in electrolytes, 2) amino acids, 3) icodextrin, and 4) biocompatible peritoneal dialysis (PD) solutions.

Effects of Alterations in Electrolytes

Magnesium

Magnesium is an important cation involved in several enzymatic reactions. The serum concentration of magnesium in dialysis patients depends on dietary intake and on the concentration of the cation in the dialysis solution. Normal values of total serum magnesium range from 0.65 to 0.98 mmol/L, while its diffusible fraction is about 55–60% of the total. Commercially available continuous ambulatory peritoneal dialysis (CAPD) solutions contain 0.25–0.75 mmol/L of magnesium. In such conditions, when 0.75 mmol/L magnesium and 1.5% glucose solutions are used in CAPD, a slight magnesium uptake from the dialysis solution usually occurs by diffusive gradient [1]. Kwong et al., however, have reported a negative dialytic balance with the same solution [2].

When ultrafiltration is increased by a 4.25% dextrose solution, convective removal counteracts diffusive uptake, yielding a negative magnesium mass transport in most patients [1]. Not only is peritoneal transport of magnesium influenced by diffusion gradients and ultrafiltration rates, but also by dwell time and peritoneal permeability because of the large hydrated radius of the molecule [1].

In most papers [3–6] the use of 0.75 mmol/L magnesium solutions resulted in elevated levels of magnesium in the serum. Hypermagnesemia is a common finding in dialysis patients [7]. While it is almost impossible to show abnormalities related to modestly elevated magnesium concentrations, when serum magnesium increases above 2 mmol/L symptoms of neuromuscular and cardiovascular toxicity are present [8]. Controversial reports concerning beneficial or deleterious effects of hypermagnesemia in dialysis patients have been published. Potential harmful effects include pruritus [9], altered nerve conduction velocity [10], and contribution to osteomalacic renal osteodystrophy by inhibiting bone remodeling [11]. Other authors pointed out that hypermagnesemia does not result in any clinical complication and, on the contrary, a protective role on soft tissue calcifications has been suggested [12]. A suppression of parathyroid hormone (PTH) [13] has also been suggested. This latter effect has recently been hypothesized to have a pathogenetic role in adynamic bone disease [14]. Despite such frequent hypermagnesemia, the muscle content of magnesium is generally not altered [15]. Therefore, the relationship of serum magnesium to intracellular magnesium concentration and total body magnesium in CAPD patients is unclear. Dietary magnesium intake is a function of protein intake. On the other hand, magnesium removal with standard 0.75 mmol/L magnesium solutions is negligible. In spite of these observations, CAPD patients do not display a continuous increase of serum magnesium levels, and stool magnesium losses may play a regulatory function [16].

To achieve a correct balance, Nolph et al. suggested lowering dialysate magnesium to 0.25 mmol/L [4]. The use of this solution did not cause hypomagnesemia, and most patients experienced a normalization of magnesium serum levels [4, 17]. In a more recent report, however, 64% of the studied CAPD population using the low magnesium containing CAPD fluid showed a reduction in serum magnesium levels [18]. Since hypomagnesemia has been associated with cardiac arrhythmias [19, 20] and various electrocardiographic abnormalities [21], serum magnesium levels should be monitored during treatment with these solutions. In addition, the use of an ion-selective electrode for

the measurement of the ionized magnesium, the active fraction of this cation, has shown that the correlation between total serum and ionized magnesium is less strong in CAPD patients than in normal subjects due to hypoalbuminemia and the increased complexed fraction of magnesium often present in dialysis patients [22]. This could imply that significant magnesium depletion can be present despite a normal serum value [23].

The use of lower or zero magnesium dialysate has also been investigated to permit oral treatment of hyperphosphatemia with magnesium salts as a calcium-free phosphate binder [24]. This, however, frequently results in a laxative effect, requiring careful monitoring of compliance to therapy and serum magnesium levels [25, 26].

Calcium

In the past, peritoneal dialysis fluids (PDF) contained 1.75 mmol/L of calcium. This concentration was chosen in order to ensure a positive calcium balance since, in uremic patients, the active vitamin D deficit leads to a reduction in calcium absorption from the gastrointestinal tract. In this condition serum calcium concentration is low, PTH is high, and a high-turnover bone disease often occurs. In addition, PTH was considered one of the most harmful "uremic toxins" because of its deleterious effects on several organs and functions.

While a negative balance may result from the use of 1.5 mmo/L dialysate calcium [27], kinetic studies suggest that CAPD solutions with 1.75 mmol/L of calcium (three exchanges with 1.5% glucose and one exchange with 4.25% glucose) generally lead to peritoneal calcium absorption and rapidly normalize total and ionized calcium serum levels [1–3, 28]. This was suggested to be beneficial in order to prevent progression of uremic osteodystrophy and calcium losses from the bone [6–29]. However, clinical studies did not confirm such a positive effect [27, 30–31].

Since normal serum concentration of diffusible ionized calcium ranges from 1.15 to 1.29 mmol/L, calcium is absorbed from PDF or lost into PDF depending on diffusive gradient direction [1]. In CAPD solutions, 30% of calcium is not ionized being "chelated" by lactate [2]. Ionized calcium probably crosses the peritoneum faster than chelated calcium. As a consequence, ionized calcium gradient is rapidly dissipated. The rapid increase in dialysate pH further contributes to this phenomenon decreasing calcium ionization in the solution [2]. A significant correlation between positive calcium balance and dialysate/serum gradient for ionized calcium has been found by using 1.75 mmol/L calcium solutions [2]. Blumenkrantz et al. have also reported that net dialytic calcium uptake inversely correlates with total serum calcium [32]. When ultrafiltration increases in hypertonic exchanges, calcium uptake tends to decrease [1] or even to become negative [2, 28]. Different rates of ultrafiltration may help to explain discrepancies among different studies. Convective removal counterbalances diffusive uptake and decreases dialysate/serum gradient because of a dilution effect [33].

Overall calcium mass-balance is also affected by gastrointestinal absorption. In CAPD patients, an empirical relationship has been found between dietary intake and gastrointestinal absorption [32]. One study found that 720 mg/day of dietary calcium intake resulted in an estimated average gastrointestinal absorption of 25 mg [32].

When new attention was paid toward the deleterious effects of the high phosphate serum levels often encountered in dialyzed patients, and the danger of aluminum toxicity contained in the aluminum-containing phosphate binders was recognized [34–37] (osteomalacia and encephalopathy), the calcium salts of carbonate and acetate were introduced as phosphate binders. Block et al. [38] have recently pointed out that hyperphosphatemia but also moderate to severe hyperparathyroidism and hypercalcemia are associated not only with bone disease but also with cardiovascular disease and greatly affects mortality in dialyzed patients. Calcium-containing phosphate binders were aimed to both reduce serum phosphate levels and hyperparathyroidism through an increase in serum calcium levels. However, if oral calcium supplementations are administered as phosphate binders, significantly greater amounts of calcium are absorbed from gastrointestinal tract. Assuming a daily phosphate intake of 1,000 mg in CAPD patients [39], 70% of this should be bound in the intestinal tract to maintain the balance [28]. This goal can be achieved with 6.25 g of calcium carbonate supplementation (2,500 mg of elemental calcium), which leads to an average gastrointestinal calcium absorption of 700 mg/day [40, 41]. Hence, in a standard patient, total calcium absorption from the diet and calcium carbonate is approximately 725 mg/day. In such conditions, a large number of patients may encounter an increased risk of hypercalcemia and soft tissue calcification [42].

A solution to this puzzle has been found by using a lower dialysate calcium concentration. This approach has been suggested to avoid the risk of calcium carbonate–related hypercalcemia [1]. Martis et al. [43] have calculated on theoretical bases that a calcium concentration of 1.25 mmol/L in peritoneal fluid would lead to a calcium removal of 160 mg/day when serum ionized calcium is 1.3 mmol/L and to a greater removal in the case of hypercalcemia. In a prospective clinical study, Hutchison et al. [17] have demonstrated that a 1.25 mmol/L calcium dialysate allowed the administration of larger doses of calcium carbonate with good control of serum phosphate, and maintained serum

ionized calcium near to the upper limit of the normal range. Parathyroid hormone was suppressed in the majority of patients and bone histology improved. Similar results have been achieved in a large multicentric study in which 1 mmol/L calcium solution has been used and low doses of vitamin D and calcium carbonate as phosphate binders have been orally supplemented [44]. However, in the long term, a great percentage of patients with low calcium dialysis fluid (23%) as compared to patients with 1.75 mmol/L calcium dialysis fluid (10%) experienced worsening of the preexisting hyperparathyroidism [45].

Low calcium PD fluids have been extensively studied by several investigators and the results confirm the benefit of this approach on uremic osteodystrophy [46–50]. Long-term usage of lower calcium dialysate by large numbers of patients raises the question of safety in cases of poor compliance to oral calcium carbonate supplementation. In 12 patient treated with 1.5% glucose and 1.25 mmol/L calcium solution, a net gain of calcium was demonstrated when the serum ionized calcium level was less than 1.25 mmol/L. This observation seems to prove that a very low risk of hypocalcemia is present in these patients [17]. However, there is a tendency to lose calcium regardless the serum-ionized calcium in patients treated with 4.25% glucose and low calcium solutions. Since a rapid exacerbation of hyperparathyroidism in some patients converted to low calcium dialysate without adequate oral calcium supplementation has been documented [51] in CAPD patients using two or more hypertonic bags per day and a low calcium solution, a careful surveillance of the mineral metabolism is needed.

In the last decade, the prevalence of type of bone lesions in PD patients has changed and adynamic bone disease has been increasingly recognized [52]. The term "adynamic bone disease" indicates a reduced activity of the physiologic process of bone remodeling with reduced synthesis of bone matrix, osteoblastic and osteoclastic activity, and a lack of osteoid accumulation. In this condition, patients are predisposed to the risk of poor healing of microfractures and to an increased incidence of fractures. In addition, since the calcium buffering effect of bone is diminished [53–55], patients with a positive calcium balance from calcium-containing phosphate binders and/or high-calcium PDF can be exposed to frequent episodes of hypercalcemia with calcium deposition in the vascular bed and myocardium that increase cardiovascular mortality [56]. In a large number of bone biopsies in an unselected end-stage renal disease (ESRD) population in Toronto, the percentage of adynamic bone disease was 61% in PD patients as compared with 36% in HD patients [57]. More recent observations confirmed these data (63% of adynamic bone disease in PD patients) [58].

The etiology of adynamic bone disease is unknown but several risk factors have been suggested [59–61], the most important probably being the oversuppression of PTH secretion and/or the lack of physiologic fluctuations in secretion. High calcium serum levels, positive calcium balance from calcium-containing phosphate binders, or high calcium PDF and vitamin D administration are the main factors involved in the PTH oversuppression. The role of the positive calcium balance in this condition is confirmed by the increase of serum PTH levels in patients treated with low calcium PDF and switched from calcium-containing phosphate binders to non-calcium-containing phosphate binders such as sevelamer [52].

The concerns about adynamic bone disease have changed the previous views on maintaining calcium serum levels of PD patients at the highest value of the normal range in order to reduce PTH secretion. The Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines [62] recommend PTH values from 150 to 300 pg/mL and a serum calcium $<$9.5 mg/dL. Recognition of the high prevalence of the adynamic bone disease in PD patients and the understanding of its supposed pathophysiology have added new indications to the use of low calcium PDF so that the formulation containing 1.25 and 1 mmol/L are now suggested by guidelines on PD.

Several studies have been performed comparing the effect on bone diseases of the high and low calcium PDF in adynamic bone disease PD patients. In the study of Sanchez et al. [63], no significant histological changes were recorded in the low calcium group (1.25 mmol/L) as compared with standard 1.75 mmol/L calcium PDF. As expected, PTH increased in the study group and calcium-containing phosphate binder medication was increased while no changes in serum calcium and phosphate levels were recorded.

A recent randomized study [64] comparing the effects of standard versus low calcium (1 mmol/L) PDF for an extended period of 16 months in CAPD patients with biopsy-proven adynamic bone disease showed in the study group an increase in bone formation rate to normal range being suppressed at baseline and no changes in the control group. Serum-ionized calcium significantly decreased despite an increase in calcium carbonate supplementation and PTH rose of about 300% in the low-calcium PDF group. Again, no changes in the standard calcium PDF were observed. Bone mineral content did not decrease during the study in either group, demonstrating no calcium loss from bone. In addition, in the study group hypercalcemic episodes decreased significantly while asymptomatic hypocalcemia occurred infrequently. Some patients in the low-calcium PDF did not change the bone histology due to an insufficient bone formation rate increase. The authors hypothesized that the relatively high doses of calcium carbonate were still able to maintain a positive calcium balance and the new calcium-free phosphate binders could add a further benefit in this condition.

The commercially available solutions for automated peritoneal dialysis treatments are substantially similar to those for CAPD. Andersen [65] reported that a positive calcium transfer from dialysis fluid can be obtained with a 2.16 mmol/L calcium concentration in dialysate both during 1.5% and 4% glucose 30 min dwell-time exchanges, while in automated peritoneal dialysis, the low-calcium dialysis solution (1.25 mmol/L) could result in a negative calcium balance [66]. Although there are no specific studies of calcium mass balance and calcium mass transfer in automated peritoneal dialysis (APD), it seems reasonable that, since larger volumes of fluid are utilized with greater ultrafiltration and shorter dwell times, the calcium balance would be negative or at least less positive than in CAPD [67]. This implies that a bigger dose of calcium containing phosphate binders and vitamin D supplementation could be used with less risk of hypercalcemia and PTH suppression. The major mineral metabolism problem could be the hyperparathyroidism. The new calcium mimetics or vitamin D analogues could be of value for treating this condition.

Low Sodium

Most commercially available dialysis solutions have a sodium concentration of 132–134 mmol/L, which is an average of about 5 mmol/L lower than the plasma sodium concentration. Because of this small concentration gradient, the transport of sodium is mainly determined by convection [68]. The magnitude of net convective transport is dependent on the balance between transcapillary ultrafiltration and the peritoneal absorption of the dialysate.

The diffusion of sodium can be increased by lowering the sodium concentration of the dialysis fluid. However, when this is done without raising the dialysate glucose concentration, keeping the osmolality constant, the increased diffusional transport is counteracted by a decreased removal by convection. [69]. The diffusion of sodium is dependent on the concentration gradient between plasma and dialysate, and on the mass transfer area coefficient. The latter has yielded values that are dependent on the experimental setting in which it was calculated. Using a conventional 3.86% glucose-based solution, an average value of 4 mL/mm has been reported during a period of isovolemia [70]. Values of 7–8 mL/min have been found using experimental dialysis solutions with a sodium concentration of 102–105 mmol/L [71, 72].

Single dwell studies have shown that sodium removal can be increased three-fold when a dialysate sodium concentration of 100 mmol/L is used [71]. This was confirmed in the only clinical study in which six overhydrated patients were treated with such a solution once daily for seven consecutive days [73]. Other significant effects included decreases of body weight and blood pressure. Clinical studies performed after these initial cases have only published in abstract form. Low or ultralow sodium-containing dialyis solutions have never been produced on a large scale and are currently not available.

Amino Acids

A high percentage of patients treated with peritoneal dialysis present different degrees of malnutrition [74]. Since CAPD patients absorb a substantial amount of glucose from the peritoneal dialysis solution and many of them become obese [75], it seems that protein rather than caloric deficit is the major problem for these patients. Continuous losses of amino acids (3–4 g/day) and proteins (8–15 g/day) into dialysate greatly contribute to this nutritional derangement [75, 76].

In the late 1960s, Gjessing suggested supplementing peritoneal dialysis solutions with a mixture of amino acids to correct serum amino acid abnormalities and to prevent obligate protein losses with dialysate [77]. More than 10 years later, Oreopoulos et al. proposed an amino acid solution in peritoneal dialysis both for nutritional supplementation and as an alternative to glucose as the osmotic agent. Experiments in a uremic rabbit model [78] and in peritoneal dialysis patients [79, 80] underlined the advantages of substituting glucose in the solution and improving nutritional support.

Osmotic Efficacy

Molecular weights of different amino acids range from 75 to 214 daltons. Since amino acid mixtures for PD usually contain a higher proportion of small-molecular-weight compounds, the average molecular weight represented in these solutions is approximately 100 daltons [81], which is lower than that of glucose. Nevertheless, the absorption rate of amino acids is not significantly faster than that of glucose. Since, at the fresh dialysis solution pH, some amino acids

are electrically charged, the hydration shell increases the relative Einstein-Stokes radius of the molecules. As a consequence, diffusion coefficients are smaller in comparison to uncharged molecules with equivalent molecular weight, and absorption velocity is reduced. It has been demonstrated that the D/P ratio for creatinine is near to that of glutamine (a near neutrally charged amino acid with almost the same molecular weight) but significantly higher than that of glutamic acid (negatively charged) and of lysine (positively charged), both with the same molecular weight of creatinine [82].

Several studies have been performed to evaluate the ultrafiltration capacity of amino acid solutions. A 2% amino acid solution was compared to a 4.25% glucose solution in an acute study on 6-h exchanges [80]. The two solutions induced equivalent amounts of ultrafiltration and similar amounts of urea, creatinine, and potassium removal. The initial dialysate osmolality was similar for the two solutions and similar dialysate osmolality changes during dwell time were observed. At the end of the exchange, 90% of the administered amino acids were absorbed. Later, the same group [83] reported a short-term study in which the ultrafiltration obtained with a 1% amino acid solution (osmolality 364 mmOsm/kg) was intermediate between that of 1.5% (osmolality 346 mmOsm/kg) and 2.5% (396 mmOsm/kg) standard glucose solution. Goodship et al. confirmed the observation of smaller but not statistically different ultrafiltrate volumes, comparing a 1% amino acid solution with a 1.5% glucose solution [84].

A comparison of ultrafiltration profiles and solute mass transfer between a 4.25% glucose (478 mmOsm/kg) and a 2.76% amino acid (501 mmOsm/kg) solution showed that intraperitoneal volume profiles were equal during the first 180 min of dwell. Later, the volume of amino acid solution tended to decrease more rapidly than that of glucose solution, leading to a nonsignificant decrease in net ultrafiltration at the end of the 6-h dwell time exchange [85]. The diffusive mass transport coefficient tended to be higher with amino acid solutions, but the difference was not statistically significant . Young et al. [86] studied ultrafiltration and D/P ratios of several proteins in an 8-h dwell time exchange using a 1% amino acid solution in comparison with 1.5% glucose standard solution. Volumes of dialysate at the end of the exchanges were significantly less after amino acid exchanges, although the osmolality decreased comparably during the dwell time. At the end of the study period (12 weeks), amino acid absorption and protein losses were increased as compared to the beginning of the study. The clearances of the studied proteins expressed as D/P ratios showed a 18–34% increase, respectively, at the beginning of the amino acid use and after 12 weeks. D/P ratios for creatinine showed a 7–10% increase, respectively, while no differences were observed for urea. The increase of the peritoneal permeability during the use of amino acid–based solution was attributed to an activation of complement by amino acids or their metabolites to produce C5a [87] and the generation of prostaglandin E2 [88]. The peritoneal permeability increase was reversed when standard glucose solutions were resumed [86].

Douma et al. [89] have reported a study on the peritoneal membrane permeability when a 1.1% amino acid solution is used: the mass transfer area coefficients of low-molecular-weight solutes (creatinine, urea, and urate) were significantly greater with amino acid solution compared to glucose solution. The clearances of the macromolecules were also greater with the amino acid solution, but the increase of albumin and IgG clearances was small and not significant. The transcapillary ultrafiltration rate was higher during the amino acid treatment, but no significant difference in net ultrafiltration was found. These data indicated a vasoactive effect of the amino acid solution: the increased peritoneal blood flow and the effective peritoneal surface area were probably caused by vasodilation. This was not associated with changes in intrinsic permeability to macromolecules or increased protein loss. This study also demonstrated that these effects were not due to nitric oxide activity (L-arginine contained in the amino acid solution could serve as a substrate for nitric oxide synthesis) nor to the peritoneal release of prostaglandins.

Despite the contradictory results of kinetic studies, in clinical practice amino acid solutions deliver ultrafiltration and small molecule clearances equivalent to those achieved with 1.36% glucose solutions. The differences among various studies probably reflect the difference in concentration and composition of amino acids in the employed solutions. The osmotic power produced by different solutions is not only expressed by the osmolality, calculated or measured, but also depends on the degree of absorption and metabolization of each amino acid [90].

Nutritional Efficacy

Nutritional value, changes in serum amino acid profile, amino acid absorption, and the effects on lipids and glucose metabolism of CAPD amino acid solutions have been evaluated in clinical studies. During the 30 years of experience and attempts to find out the best composition for the amino acid solution, several amino acid formulations of the CAPD solutions have been proposed and tested. Table 11.1 reports the amino acid composition of some of the most used. Clinical results were often conflicting because different amino acid composition solutions were used, different parameters were taken into account as markers for nutrition, different CAPD population were studied (malnourished

versus nonmalnourished, different caloric intake), different CAPD schedules were used (amino acid solution used in the overnight exchange versus in exchanges close to a meal).

The clinical results with solution A in Table 11.1 were rather discouraging, showing insufficient effects on nutritional parameters and some unwanted effects such as increased levels of blood urea nitrogen (BUN) (with symptoms of uremia), loss of appetite, and moderate to severe metabolic acidosis [83, 91–93]. The authors concluded that the amino acid formulation, the timing of administration, the patients' low caloric intake, or the patients' sufficient nutritional state could be responsible for the ineffectiveness of the amino acid solution and that the intraperitoneal supply of amino acids was probably used as a source of energy [94].

Following the these experiences, a new 1% amino acid solution was proposed and tested (solution B in Table 11.1). This solution was designed specifically for patients with renal insufficiency and its related amino acid derangements [95]. Thus, the essential amino acid proportion was increased and the lactate concentration was increased to 35 mmol/L.

The studies using the improved 1% amino acid solution demonstrated more beneficial effects than the previous solution in patients with signs of protein malnutrition and low dietary protein intake. Some nutritional parameters such as serum transferrin [96, 97], albumin [98], estimated nitrogen balance (99–100), and serum amino acid profile [93, 94] improved during the study. In all these reports, lipid metabolism improved, BUN increased, and acidosis remained a commonly concern. This was most likely due to the acid load delivered by salts of basic amino acids (lysine hydrochloride) and that arising from metabolism of sulfur amino acids to sulfate (methionine) [101].

In order to further improve the clinical efficacy, a new formulation of the amino acid solution has been proposed and tested (solution C in Table 11.1). Essential amino acid concentrations were increased as well as lactate concentration (from 35 to 40 mmol/L). Total amino acid concentration was increased to 1.1% in order to provide the same osmotic effect as the 1.5% standard glucose solution. This is the formulation now commercially available. A short-term crossover multicentric study in CAPD patients with signs of protein malnutrition has been performed [102]. The nitrogen balance, serum transferrin, and total protein increased in 19 malnourished patients using one or two 1.1% amino acid solution for 20 days. Dietary protein intake of 0.8 g/kg/day and caloric intake of 25–30 kcal/kg/day was prescribed to all patients. Because of the amino acid absorption from dialysis fluid, a total protein intake of 1.1–1.3 g/kg/day was achieved in all patients. Protein anabolism was positive, as directly determined from ^{15}N-glycine studies and indirectly from the plasma phosphate and potassium decrease. The amino acid pattern in plasma tended toward the normal range during the treatment phase and serum triglycerides and HDL cholesterol increased. Plasma total CO_2 significantly decreased, showing a tendency toward a metabolic acidosis mainly in patients treated with two exchanges per day of this solution.

A clinical evaluation of this amino acid solution was performed in a second study [103]. This was a 3-month prospective crossover study in 15 stable CAPD patients not necessarily malnourished. Only one exchange with amino acid was prescribed at lunchtime to couple amino acid absorption with energy intake. Serum albumin and transferrin

significantly improved both in patients with and without malnutrition. Plasma amino acid profile and total proteins did not change. Plasma bicarbonate levels also remained stable.

A prospective randomized study was also performed in order to compare the nutritional effects of the 1.1% amino acid solution with the conventional glucose solution in 54 malnourished patients [104]. After an initial significant increase in serum albumin, transferrin, prealbumin, and total protein, after 3 months of treatment these parameters did not achieve the statistical significance as compared with those of the 51 patients in the control group. However, in the tertile with the lowest albumin levels at the baseline, serum albumin and prealbumin remained significantly increased. In the tertile with the highest albumin levels at the baseline, the mid-arm muscle circumference increased significantly after 3 months of treatment. In the whole population treated with the amino acid solution, circulating insulin-like growth factor 1 (IGF-1) increased, while it slightly decreased in the control group.

In an acute study the amount of amino acids delivered by this amino acid solution was quantified [105]. It has been shown that the gain of amino acid during one exchange largely exceeded the daily losses of amino acid and proteins. This effect was independent of the peritoneal membrane transport type. Skeletal muscle amino acid uptake was increased after 6 weeks use of this solution in 10 CAPD patient [106] and, in an acute study using the ^{3}H-phenylalanine kinetics as indicator, muscle protein synthesis increased by 20% [107].

A short-term use of amino acid solution was also effective in improving net protein balance and converting nitrogen balance from negative to positive in patients on automated PD [108]. Other studies could not demonstrate an improvement in nutritional parameters in well-nourished CAPD patients treated with 1.1% amino acid solution [109, 110]. The longest experience with this amino acid solution was performed by Li et al. [111]. Sixty malnourished Chinese patients were randomized to receive either the amino acid or the conventional solution for 3 years. Normalized protein equivalent of nitrogen appearance (nPNA) and dietary protein intake increased while triglycerides decreased in the study group, Albumin and cholesterol remained stable in the treated group and decreased in the control group. No differences were recorded in mortality, hospitalization, drop out, and composite nutritional index between groups. The last report on the 1.1% amino acid solution is an observational study in 46 malnourished Korean patients [112]. After 1 year of treatment, mean serum value of blood urea, creatinine, lean body mass, nPNA, serum IGF-1 level, back lift strength and SGA score increased significantly. The other studied nutritional parameters (albumin, hand grip strength, anthropometry, and dietary intake) did not change and serum bicarbonate statistically decreased.

In conclusion, in malnourished CAPD patients a dialysis solution with a more appropriate amino acid composition may improve their protein nutrition and metabolic status. However, increased BUN levels and the tendency toward acidosis remain problems to be solved. The last point has been addressed by Jones et al. [113]. They tested a modified amino acid solution formulation (solution D in Table 11.1) in which acidogenetic amino acid concentrations (lysine, arginine ,and methionine) were reduced in comparison with the 1% amino acid solution (solution C in Table 11.1). In addition, aspartic and glutamic acids, two dicarboxylic acids that generate alkaline equivalents during their metabolism, were added. A substantially better acid-base status was achieved during the treatment with the modified amino acid solution as compared to the conventional amino acid solution.

Icodextrin

History

Icodextrin is the only high-molecular-weight osmotic agent that has been approved for use in peritoneal dialysis patients. The name icodextrin is derived from the Greek word *icosa* ("twenty") and the chemical name *dextrin*, describing a glucose polymer obtained by the partial hydrolysis of starch with a molecular weight of about 20,000 dalton [114]. Dextrins are polymers in which the glucose molecules are linked at the α1–4 position. This is different from dextran, where α1–6 linkages are present. The difference in the linkages is crucial in relation to the manner in which these polymers behave in the body. There are a number of enzymes that can attach themselves to the α1–4 polymer and break this bond, producing oligosaccharides, maltose, and eventually glucose. This is different from the α1–6 bond, which is more resistant to enzymatic cleavage.

Icodextrin as used for PD is prepared by hydrolysis of corn (maize) starch and purified enzymatically to maltodextrin. Using a number of filtration steps, the low-molecular-weight fractions are removed. This results in a dextrin preparation with a molecular weight range from 1,640–45,000 daltons. The average molecular weight is 16,800 daltons, and >90% of the bonds are of the α1–4 type.

The first clinical study using a single 6- and 12-h dwell with a 5% icodextrin solution was published in 1987 [115]. A comparison with a 1.36% glucose solution showed that net ultrafiltration at the end of the 6-h exchanges was greater

with the polymer, despite the lower osmolality of the polymer solution. For glucose, increasing the exchange time to 12 h led to absorption of the intraperitoneal volume in all patients, resulting in negative ultrafiltration; with the glucose polymer solution, ultrafiltration continued throughout a 12-h exchange. The absorption of the polymer averaged 14.4% of the instilled quantity after 6 h and 28.1% after 12 h, probably by uptake into the lymphatic system. Because α1–4 bonds are degraded by circulating α-amylase, the absorption causes a rise of the plasma maltose concentration of 0.79 mmol/L (about 0.3 g/L) after 12 h [115].

This initial observation resulted in a number of issues: 1) the use of the glucose polymer during the long exchange, 2) restriction of its use to one exchange per 24 h to prevent extensive maltose accumulation and allow peritoneal removal of maltose during the other exchanges, and 3) the concept of its action by colloid osmosis, similar to that of albumin [116]. This process is based upon the principle that fluid flow across a membrane permeable to small solutes occurs in the direction of relative excess of impermeable large solutes, rather than along the osmolality gradient.

The final preparation used for subsequent studies consists of a 7.5% icodextrin solution, lactate-buffered, with an osmolality of 285 mOsm/kg water. Its composition is given in Table 11.2.

Pathophysiology

The concept of colloid osmosis, leading to fluid transport mainly through the so-called small pores, has been confirmed by showing the absence of sodium sieving [117]. Using dextran 70 as a volume marker, the intraperitoneal volume showed a linear increase during at least 8 h [118], as shown in Fig. 11.1. The absorption of icodextrin averaged 21% after a 4-h dwell, suggesting uptake into the lymphatics similar to that of other intraperitoneally administered macromolecules [117]. The high and persistent fluid flux across the small pore system causes an increase in convective transport, leading, for instance, to an increase in the peritoneal transport of beta-2-microglobulin [117, 119].

Many studies have found a relationship between peritoneal solute transport rates and the efficacy of ultrafiltration on icodextrin [117, 118, 120]. The higher the D/P ratios or mass transfer area coefficients, the better the net ultrafiltration. The explanation is obvious: high D/P ratios suggest a large peritoneal vascular surface area, so more small pores are available for fluid transport. This relationship has been supported by the results of computer simulations [121] and by observations during peritonitis where more, instead of less, ultrafiltration was found [122, 123]. It appeared possible to adequately predict fluid kinetics on icodextrin with a modified three-pore model [124].

Kinetic studies with icodextrin in rats suggested intraperitoneal breakdown of icodextrin during the dwell, both in a stable situation and during peritonitis [125, 126]. However, this could not be confirmed in PD patients [127] and is probably due to the extremely high amylase concentrations in rats. This makes the rat unsuitable for performing kinetics studies with icodextrin.

The presence of a fast peritoneal transport status, reflecting a large peritoneal surface area, leads to a reduction in ultrafiltration with glucose-based solutions due to a high diffusion rate of glucose. As discussed above, icodextrin is especially potent in this situation, because the colloid osmotic pressure gradient remains stable for several hours. This has led to the use of icodextrin as salvage therapy in chronic PD patients with ultrafiltration failure. Some retrospective studies reported that icodextrin enabled patients who would otherwise have been transferred to hemodialysis to continue PD [128, 129]. This has been confirmed in a prospective study [130].

Table 11.2 Composition of 7.5% icodextrin compared to a 3.86% glucose solution

	Glucose	Icodextrin
Na + (mmol/L)	132	133
Ca++ (mmol/L)	1.25/1.75	1.75
Mg++ (mmol/L)	0.25/0.75	0.25
Cl– (mmol/L)	102	97
Lactate (mmol/L)	35/40	40
Glucose (g/L)	38.6	0
Dextrin (g/L)	0	75
Osmolarity (mOsmol/L)	486	285
pH	5.5	5.8

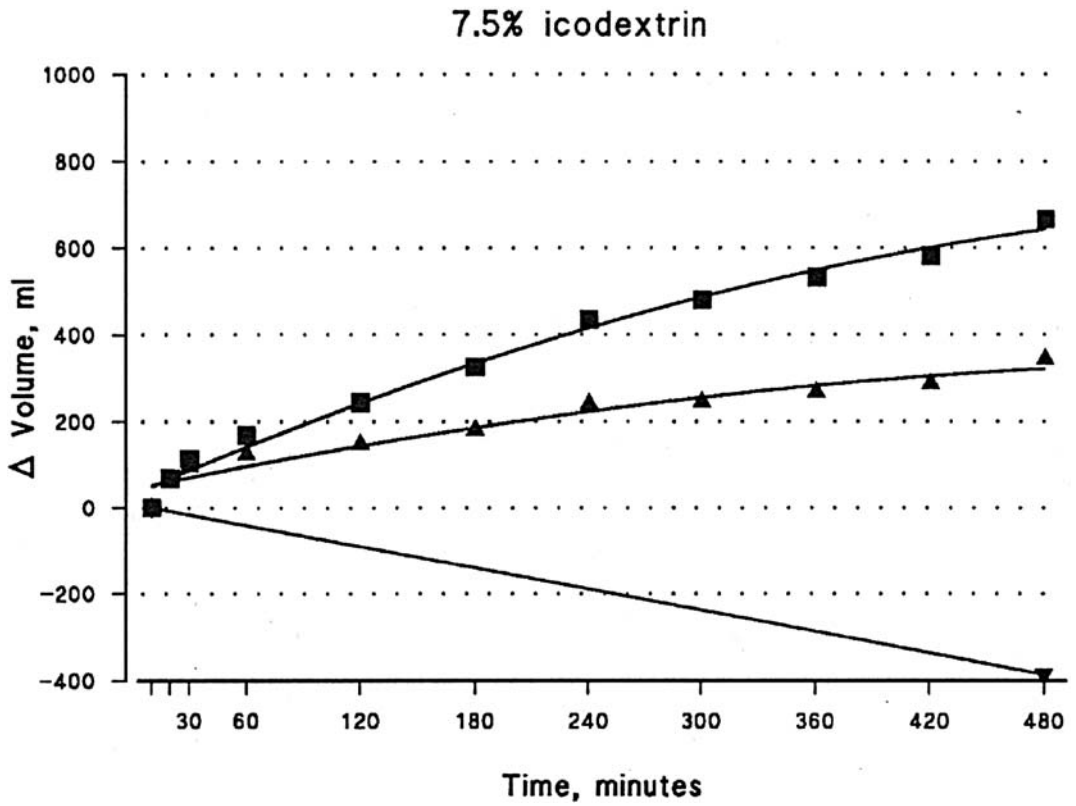

Fig. 11.1 The time course of peritoneal fluid kinetics during an 8-hour dialysis dwell using 7.5% icodextrin. The upper line represents the volume increase due to transcapillary ultrafiltration, the lower line represents the decrease in intraperitoneal volume caused by the effective lymphatic absorption rate. The middle line shows the almost linear increase in the in situ intraperitoneal volume. Taken from ref [118] with permission of the author and of Blackwell Scientific Publishers

Biocompatibility of Icodextrin

The following factors can contribute to the bioincompatibility of PD solutions: acidity, buffer, hyperosmolality, glucose, and glucose degradation products (GDP). Icodextrin contains no glucose, isosmolar, and the concentrations of GDPs are lower than those in a 1.36% glucose solution [131]. The first in vitro study of the biocompatibility of icodextrin showed no improvement compared to glucose-based solutions [132]. However, at neutral pH the secretion of interleukin (IL)-6 by monocytes was superior to that after exposure to a 1.5% glucose-based solution [133]. Improved phagocytosis by peripheral polymorph nuclear cells and monocytes has been described after stimulation with icodextrin compared to standard solutions [134]. Ex vivo studies have shown improved phagocytosis of peritoneal macrophages when isolated from icodextrin effluent, compared to those from glucose effluent [135]. Similarly, the proliferation capacity of mesothelial cells on icodextrin was better [136]. The cancer antigen 125 (CA125) appearance rate in peritoneal effluent probably reflects mesothelial cell mass and is used as an in vivo biocompatibility marker for new dialysis solutions [137]. This parameter was not influenced by acute [138] or chronic treatment with icodextrin [139], probably because it is always combined with other osmotic agents for the short dwells.

Randomized Controlled Trials with Icodextrin

Two large randomized controlled trials (RCT) have been published on the efficacy and safety of icodextrin in prevalent PD patients [140, 141]. The MIDAS study, performed in the United Kingdom, was done in CAPD patients and had a follow-up of 6 months [140]. Icodextrin for the long dwell was compared with glucose. Icodextrin showed superior ultrafiltration after an 8 h dwell than 1.36% glucose and similar to 3.86% glucose. Mean serum sodium decreased from 140 to 136 mmol/L, probably because of slightly increased serum maltose levels that remained stable throughout the

study. An overall CAPD-related symptom score was better for icodextrin, compared to glucose. The RCT performed in the United States comprised CAPD and APD patients, and had a follow-up of 1 year [141]. The results were similar to those of the MIDAS study. Mean net ultrafiltration was higher on icodextrin compared to 2.5% dextrose for the long dwell. Body weight was stable on icodextrin but increased in the 2.5% glucose group and less icodextrin than glucose patients reported edema. The beneficial results on long dwell ultrafiltration in APD were similar to those described in other studies [142, 143].

The effects of icodextrin on net ultrafiltration, especially in patients with fast transport rates of low-molecular-weight solutions (see the section on pathophysiology) have prompted more RCTs in this patient group. A multicenter RCT in APD patients with a fast average or fast transport status showed superiority of 7.5% icodextrin for the long dwell compared to 4.25% dextrose [144]. Another double-blind RCT in CAPD and APD patients with fast average or fast transport status and a urine production <750 mL/24 h, comparing 7.5% icodextrin with 2.2.7% glucose for the long dwell, showed a decrease in body weight, total body water, and extracellular fluid in the icodextrin group during a follow-up of 6 months [145]. The beneficial effects of icodextrin on volume status were also found by Konings et al., who additionally reported a reduction of left ventricular mass, assessed by echocardiography [146].

General Effects and Side Effect of Icodextrin

The better control of volume status achieved with icodextrin could lead to better control of blood pressure. This was indeed found in one study [147], but could not be confirmed in another [145]. A beneficial effect on lipids has also been reported [148], but this could also not be confirmed in a larger study [145]. Improvement of diabetic control has been reported as assessed from Hb1Ac levels and insulin requirements [149]. One study reported some better preservation of residual urine production [145], and in another small retrospective analysis better preservation of residual creatinine clearance was found in APD patients [150]. Confirmation of these unexpected findings is required.

The use of icodextrin has effects on some laboratory investigations. All studies have shown a decrease of plasma sodium of on average 3 mmol/L. It is likely to be caused by the increased plasma maltose concentrations, as a compensatory mechanism to avoid hyperosmolality. A significant discrepancy has been reported between glucose measurements using glucose dehydrogenese-based methods and methods obtained in the laboratory using a reference method, like hexokinase [151, 152]. These methods overestimate plasma glucose levels due to the presence of oligosaccharides (mainly maltose) in the circulation and are therefore unsuitable for use in patients on icodextrin.

Dialysis with icodextrin also interferes with the measurement of plasma amylase activity resulting in a reduction of amylase levels. Plasma amylase activity may be reduced by 90% [153, 154]. Consequently, because icodextrin does not affect lipase activity, lipase measurement should be used for the diagnosis of suspected pancreatitis in dialysis patients on icodextrin. Skin rashes are the most frequent side effect of icodextrin [144]. Their prevalence varies from 0–6% to 15% [155–157]. An incidence of 1 per 60 patients-years has been found in a large post-marketing survey [158]. The occurrence is not related to the presence of circulating dextran antibodies [159]. The rash is usually not severe and is self-limiting.

An epidemic of culture-negative peritonitis in icodextrin patients was first described in 1999 [160]. It was followed by many other reports [161–165]. The incidence peaked in spring 2002. It appeared to be due to contamination by peptidoglycans, which are components of the bacterial cell wall [166]. The problem disappeared after adjustment of the production process, leading to peptidoglycan levels below the detection limit. It should be appreciated, however, that peritoneal effluent cell counts in stable patients are higher on icodextrin than on glucose-based conventional solutions [167]. The meaning of this is unknown.

The Place of Icodextrin in Modern Peritoneal Dialysis

The use of icodextrin for the long dwell both in CAPD and APD is well established because of its superior ultrafiltration profile and reduced exposure to glucose and glucose degradation products. A skin rash is the most important side effect, but it is usually mild and its occurrence is relatively rare. It should, however, be appreciated that plasma sodium levels are on average 3 mmol/L lower compared to glucose and that a low plasma amylase activity is present. Self-assessment methods for blood glucose determinations will have to be checked for interference of maltose. When these precautions are taken into account, icodextrin is currently the preferred osmotic agent for the long dialysis dwells.

Mixing icodextrin with other osmotic agents, for instance, a small amount of glucose, has been investigated [168–170], but this solution has not been taken into production. More recently, an experimental solution consisting

of 6.8% icodextrin, 2.86% glucose, and a sodium concentration of 121 mmol/L reported superior ultrafiltration and sodium removal during a 15-h dwell, but its applicability is not known [171]. The use of icodextrin in a glucose and amino acids mixture has been investigated in short APD dwells and was associated with only moderate increases in plasma levels of icodextrin metabolites, while leading to a marked reduction in the absorption of glucose [172]. However, this approach is also experimental.

Biocompatible PD Solutions

The bioincompatibility of conventional PD solutions, as discussed in Chapter 27, has led to the development of dialysis solutions that were different in one or more of the following: buffer, pH, and glucose degradation products (GDPs). No changes were made in the concentrations of glucose. The rationale for focusing on buffer, pH, and GDPs lies in the results of in vitro biocompatibility studies. The most important ones have been summarized in [173]. The combination of a low pH with lactate caused a partly irreversible decrease of the intracellular pH [174]. Heat sterilization of dialysis solutions leads to the formation GDPs and to marked toxicity of cultured mouse fibroblasts [175]. GDPs consist of aldehydes and dicarbonyl compounds [176], of which 2,3-dideoxyglucosone might be the most toxic one. They also promote the formation of advanced glycosylation end products at a faster rate than glucose itself.

Based on the above considerations, four dialysis fluids have been developed and are available in Europe and parts of Asia. These are Trio® (Gambro), Physioneal® (Baxter), Balance® (Fresenius), and Bicavera® (Fresenius). Their characteristics are summarized in Table 11.3. The reduction in the content of GDPs and the use of bicarbonate as a buffer can only be achieved by the use of dialysis bags with two compartments, which are mixed just before inflow. To reduce the formation of GDPs, glucose should be sterilized at a low pH, e.g., pH = 3, and in a high concentration. In Trio® and Balance®, glucose is sterilized separately.

It is evident from Table 11.3 that the solutions are different with regard to pH and buffer. The amount of GDP is somewhat higher in Physioneal®, but still less than half of that in Dianeal®. When bicarbonate only is used as a buffer, supraphysiological concentrations (35–40 mmol/L) are required. In vitro studies, however, showed no adverse effect of this excess [133, 177–180] with the exception of one [181]. The results with the bicarbonate buffer were similar to those obtained with lactate after adjustment to a normal pH [178].

In Vitro -and Animal Studies

All biocompatible solutions showed superiority in in vitro studies, when compared with conventional PD solutions [133, 177–180, 182–185]. This has also been shown for their effects on cultured mesothelial cells, where the bicarbonate buffer did better than the lactate buffer [186]. The in vitro studies have been reviewed in [180, 187, 188].

Animal studies have mainly focused on direct effects of exposure on peritoneal vessels, on changes in imprints of liver mesothelium, and on effects of long-term exposure of the peritoneal membrane. Intravital microscopy of mesenteric vessels in the rat showed that a conventional 4.25% glucose dialysis solution induced maximal vasodilation of mesenteric arteries, resulting in doubling of the arterial flow [189]. A reduction in the bicarbonate content reduced this effect, and it was absent when a bicarbonate buffer was used. The same model was used to study leukocyte recruitment [190]. The inhibition of lipopolysaccharide (LPS)-stimulated recruitment by conventional PD fluids was lower when Bicavera® was used.

Replacement of lactate by bicarbonate caused less damage of murine liver mesothelial cells [191], but this was not confirmed in trypsin washout experiments in a rabbit model [192]. The presence of GDPs in the dialysis solution caused marked mesothelial toxicity after 10 weeks exposure [193]. Exposure of Physioneal® in rats for 12 weeks showed a reduction in the peritoneal content of advanced glycosylation end-products (AGE), but not in peritoneal pentosidine [194]. Morphological changes after 10 weeks exposure in rats also showed a reduction in angiogenesis [195]. This

Table 11.3 Characteristics of biocompatible PD solutions

	pH	Buffer	3-DG (μmol/L)	Source
Trio	6.3	Lactate	65	Gambro
Physioneal	7.4	Bicarbonate/lactate	253	Baxter
Balance	7.0	Lactate	–	Fresenius
Bicavera	7.4	Bicarbonate	42	Fresenius

3-DG: 3-desoxyglycosone

reduction in the number of vessels by Physioneal® was even 50% after exposure for 20 weeks [196]. In the latter study, less peritoneal fibrosis was also found. A lower number of peritoneal vessels and a reduction in peritoneal fibrosis, in combination with a reduction in the staining for endothelial nitric oxide synthase (eNOS), vascular endothelial growth factor (VEGF), picosirius red (stains fibrillary collagen), and AGE have later been confirmed, together with less mesothelial damage on Physioneal® [197]. The results of various animal studies have been reviewed in [198]. It can be concluded that the animal studies, also after long-term exposure, showed superiority in the preservation of peritoneal morphology and function of the biocompatible PD solutions compared to the conventional ones.

Ex Vivo Studies

Ex vivo studies have focused on functions of macrophages isolated from peritoneal effluent, on the properties of mesothelial cells cultured from the dialysate, and on substances that can be determined in effluent and that reflect some properties of peritoneal tissues. Peritoneal macrophages isolated after a 30 min dwell showed impaired secretion of tumor necrosis factor alpha (TNF-α) on conventional lactate buffered solutions [199]. This was unchanged after isolation from a bicarbonate solution but improved after a dwell with a bicarbonate/lactate fluid. Treatment with Physioneal® for 6 months resulted in a sustained improvement in peritoneal macrophage function [200]. The use of Balance® led to a reduction of epithelial-to-mesenchymal transition of mesothelial cells cultured from effluent when compared with a conventional solution [201].

Biocompatible dialysis solutions when used in prevalent patients have all been associated with an increase in the CA 125 concentration in effluent. This has been shown for Trio® [202], Physioneal® [203], Balance® [201, 204], and Bicavera® [205]. It is remarkable that these solutions, which are different with regard to buffer and pH, all show this phenomenon, suggesting an increase in mesothelial cell mass [137]. The data could be interpreted as a consequence of the reduced amount of GDPs present in all solutions, but this is still speculative.

Some studies showed a decreased effluent concentration of hyaluronan [202–204] while treated with biocompatible solutions. This substance has been suggested as a marker of inflammation and tissue remodeling in the peritoneal cavity. The results of studies of dialysate procollagen peptides have been equivocal [202, 203]. No consistent effects were found for effluent VEGF.

Clinical Studies

Clinical studies with biocompatible PD solutions have focused on inflow pain, correction of acid/base balance, effects on peritoneal transport, serum levels of AGEs, and whether or not an effect on residual renal function and patient survival is present.

A reduction of inflow pain on biocompatible solutions has been reported, which was statistically significant for Physioneal® [206] and just did not reach significance for Trio® [202]. This effect is likely to be due to the higher pH compared to conventional lactate buffered solutions [202]. The effect of a pure bicarbonate-based solution was less pronounced [206].

Replacement of lactate by bicarbonate resulted in a small increase in plasma bicarbonate in adult CAPD patients [207] and also in children treated with Bicavera® [205]. It appeared that the net bicarbonate gain was dependent on the ultrafiltration rate, plasma bicarbonate, and the bicarbonate content of the dialysis solution [208]. A comparison of a bicarbonate/lactate buffer with bicarbonate showed no differences in plasma bicarbonate or lactate concentrations [209, 210]. A randomized controlled clinical study comparing Physioneal® with the conventional solution showed that both solutions were equivalent with regard to plasma bicarbonate level and peritoneal solute transport [211]. A somewhat better ultrafiltration and a lower peritonitis incidence were also reported in that study, but these data have not been confirmed in other studies [212]. In general, no marked acute effects on peritoneal transport are present [213].

Glucose degradation products are low-molecular -weight solutes that are almost completely absorbed during a dialysis dwell. As stated above, GDPs lead to the formation of AGEs at a faster rate than glucose itself. It is therefore interesting that some clinical studies reported a reduction in the serum concentration of some AGEs while on biocompatible solutions. This has been described for total AGE and carboxymethyllysine in patients on TRIO® [214], and for imidazolone and carboxymethyllysine in the Eurobalance trial [204]. However, the decreases are small and the clinical relevance is unknown.

An unexpected effect of Balance® was found on residual renal function, which was better preserved than with the control solution [204]. These results will have to be confirmed to be sure that this effect has not been caused by chance. Another unexpected finding comes from the retrospective analysis done in Korea, where patient survival on Balance® was reported to be higher compared to treatment with conventional dialysis solutions [215]. However, the study has some methodological flaws, making the interpretation difficult. Obviously, more studies are required.

The Place of Biocompatible Solutions in Modern Peritoneal Dialysis

In vitro data, animal studies, and ex vivo data have shown beneficial effects of solutions with a reduced content of GDPs, often in combination with a higher pH and the inclusion of bicarbonate as a buffer. Clinical studies have not shown inferiority compared to the conventional solutions, and have shown some benefits, like less pain on infusion and lower serum levels of advanced glycosylation end products. It is noteworthy that, at present, the authors are not aware of any patient who developed encapsulating peritoneal sclerosis after treatment with biocompatible solutions exclusively. However, the results of more long-term studies will have to be known before determining their place in routine peritoneal dialysis.

Chapter 12
Automated Peritoneal Dialysis

P. Kathuria and Z.J. Twardowski

Automated peritoneal dialysis (APD) is a term used to refer to all forms of peritoneal dialysis that employ a mechanized device to assist in the delivery and drainage of dialysate. Automated cyclers are used in intermittent peritoneal dialysis (IPD), nocturnal intermittent peritoneal dialysis (NIPD), continuous cyclic peritoneal dialysis (CCPD), tidal peritoneal dialysis (TPD), and continuous flow peritoneal dialysis (CFPD) [1–3]. In addition, some patients on continuous ambulatory peritoneal dialysis (CAPD) may receive one or more nocturnal exchanges with a night exchange device [4].

Automated PD is a fast growing modality for renal replacement therapy. The growth of APD has been facilitated by the development of new smart machines and increasing physician knowledge and patient acceptance. These machines have easy-to-use interfaces and incorporate microchips and computer technology enabling choice of therapies, safety features, and modalities to optimize therapy. Individualized therapies can be delivered to meet the lifestyle needs of the patient while ensuring adequacy of dialysis and ultrafiltration. Automation has dealt with some of the limitations of CAPD, including ultrafiltration failure, complications of increased intra-abdominal pressure, treatment fatigue, and failure to achieve clearance goals, and to some extent with noncompliance. Furthermore, in the new millennium, APD is poised to deliver a dose range beyond conventional dialysis and has the potential to deliver biocompatible solutions with specific compositions to meet individual needs by online preparation or regeneration of dialysate [5].

There has been a steady increase in APD utilization over the years: in 1998, only 21% of global PD patients were on APD and this number has increased by 1–2% annually [6] to approximately 30% at the end of 2004 [7]. Peritoneal dialysis grew by 6% between 2003 and 2004, largely driven by a 10% increase in utilization of APD. Mexico, the United Kingdom, and Korea are countries with the highest utilization of peritoneal dialysis, wherein treatment with APD modalities accounted for 21%, 32%, and 5% patients, respectively, in 2004 [7]. The French peritoneal dialysis registry reported the use of APD increased from 23% in 1995 to 36% in 2005 [8].

In the United States, even though the prevalent patients on peritoneal dialysis increased to 25,825 in 2003, there has been an overall decrease in the utilization of peritoneal dialysis for incident patients (USRDS 2005 Annual Data Report) [9]. The number of new peritoneal dialysis patients peaked at 8,530 in 1995 and declined to 6,690 patients in 2003. Of these, 2,100 (31.3%) patients were started on CCPD. Fifty-six percent of prevalent PD patients were on APD [9]. An industry report evaluating dialysis trends in the United States looked at four large cohorts of patients initiating peritoneal dialysis in 2000–2003 and found that majority of patients selected APD as their modality with a trend towards greater utilization from 58% in 2000 to 64% in 2003 [10]. This aberrancy from the USRDS Data Report may be due to inaccuracies in reporting of PD modality and a number of patients being reported with unknown modality. A prior report from the same group found that the proportion of patients on APD was over 60% in all age groups except those above 80 years of age [11].

CCPD was the modality of choice for 26% for all incident end-stage renal disease patients of age from 0 to 19 years, per the 2005 USRDS Data Report [9]. The North American Pediatric Transplant Cooperative Study Registry reported that APD was the modality at initiation and as well as throughout peritoneal dialysis follow-up for almost 70% of incident pediatric dialysis patients between 1992 and 1998 [12].

History of APD

The first peritoneal cycler was described by Fred Boen et al. in the early 1960s [13, 14]. This device used a sterile dialysate prepared in the hospital and delivered to the bedside in 40-L carboys. Therapy consisted of multiple 2-L exchanges delivered over a 10-h period. An automatic solenoid device controlled delivery of the dialysate into the peritoneal cavity. In 1966, Norman Lasker and co-workers [15] described an automated cycler that became the forerunner of modern cyclers. This gravity-based machine utilized 2-L bottles of dialysate and disposable tubing. A preset volume of dialysate was delivered to the patient and was drained after a prescribed dwell time. At the same time as Lasker, Tenckhoff et al. [16] designed an automated system that mixed dialysate concentrate with distilled water processed by a "miniature still." This system proved to be expensive, bulky, and time consuming to use, and was soon abandoned. After the development of reverse-osmosis water, Tenckhoff et al. [17] adapted the technology to develop a new cycler. This cycler used reverse-osmosis water and a proportioning system to mix treated water with dialysate concentrate. Large amounts of dialysate could be easily prepared at a relatively lower cost. Higher glucose concentrations were achieved by adding hypertonic glucose to the mixture.

Cyclers were initially used for intermittent peritoneal dialysis (IPD). IPD was popular between 1970 and 1976 because the simplicity of the procedure permitted patients to perform home dialysis with or without the help of a partner [18]. Patients on IPD also enjoyed relative freedom between treatments to carry out other activities. However, IPD fell out of favor by the late 1970s because of poor outcomes due to inadequate dialysis and malnutrition [19–21]. In 1976, Popovich and co-workers [22, 23] described the concept of equilibrium peritoneal dialysis, moving the focus away from cycler-dependent treatments. They proposed that fluid left in the abdominal cavity over 4 h would equilibrate with blood urea. Five exchanges of 2 L each and 2 L of ultrafiltration would be required for controlling uremia. This method came to be called continuous ambulatory peritoneal dialysis (CAPD) [23]. The real revolution for CAPD came with the development of collapsible plastic bags for dialysate [24].

Interest in APD was revived by Diaz-Buzo et al. [25] and by Price and Suki [26]. They described the procedure called continuous cyclic peritoneal dialysis (CCPD), which is a form of automated equilibrium peritoneal dialysis. Patients receive three or four exchanges automatically at night and an additional exchange that remains in the abdomen through the day. The catheter is capped during the day and the patient starts the nocturnal exchange by emptying the peritoneal cavity.

A dialysis procedure that combined intermittent and continuous-flow technology was introduced in the late 1960s and early 1970s to increase the efficiency of IPD. This technique was initially introduced as recirculating peritoneal dialysis [27] and was later revived by Twardowski in 1989 and renamed tidal peritoneal dialysis (TPD) [28]. During this procedure, after an initial fill volume is instilled into the abdominal cavity, only part of the dialysate is drained and replaced by fresh peritoneal dialysis fluid with each cycle. The hypothesis behind this procedure is that leaving a "sump volume" in the cavity would improve clearances, as there would be constant contact between the peritoneal membrane and dialysate.

Peritoneal Dialysis Solutions

The traditional peritoneal dialysis solutions used for APD are the same as used for CAPD. The solutions are available in three different dextrose concentrations (1.5%, 2.5%, and 4.25% dextrose). The dextrose concentrations used for shorter dwells are generally 1.5% or 2.5%, while for the long dwell the preferable concentration is 2.5% or 4.25% to prevent excessive fluid absorption. The composition of the standard peritoneal dialysis solution is provided in Table 12.1. A problem occasionally seen in APD modalities using short dwells (NIPD, TPD) is the development of hypernatremia due to sodium sieving [29–32].

Several in vitro and in vivo studies have demonstrated the unphysiologic nature of conventional dialysis solutions [33–35]. Lactate, the low pH, high glucose, and glucose degradation products are likely the major determinants of

Table 12.1 Composition of standard solutions for automated peritoneal dialysis

Dextrose (%)	1.5, 2.5, 4.25
Sodium (mEq/L)	132
Potassium (mEq/L)	0
Calcium (mEq/L)	2.5–3.5
Magnesium (mEq/L)	0.5–1.5
Lactate (mEq/L)	35–40

bioincompatibility. Experiments by Breborowicz suggest that the cytotoxicity of peritoneal dialysis solutions is most evident immediately after instillation of dialysate and gradually declines within minutes of the dwell [35]. This decline in cytotoxicity occurs due to the residual intraperitoneal fluid and a rapid equilibration process in the peritoneal cavity. Since the impact of fresh peritoneal dialysis solutions is maximum at the beginning of the dwell time, there has been concern that the larger volumes of solution and more frequent exchanges during APD would cause a more rapid deterioration of the peritoneal membrane when compared with CAPD [36]. Comparison of CAPD and CCPD in an in vitro system showed no short-term detrimental effects on biocompatibility parameters indicative for peritoneal host defense, mesothelial cell integrity, and peritoneal fibrosis [36]. On the other hand, ex vivo studies on peritoneal macrophages have shown impaired local phagocytic and opsonic capacity with shorter dwells [37, 38].

With glucose-based therapies, the incidence of negative ultrafiltration during the long dwell is high [39]. This therapeutic failure with glucose-based solutions increases the requirements for enhanced ultrafiltration in the cycler-based nocturnal component of the therapy, resulting in the use of higher glucose tonicities and consequently greater glucose exposure [40]. Icodextrin is an alternative osmotic agent, which provides sustained ultrafiltration during the long dwell and is low in glucose degradation products [41–44]. It has a high molecular weight, which results in a sustained colloid osmotic gradient. Icodextrin is absorbed from the peritoneal cavity at a much slower rate than dextrose and consequently provides superior ultrafiltration per gram of absorbed carbohydrate [43]. Reduction of carbohydrate absorption may help reduce the metabolic complications of peritoneal dialysis [45]. In a computer-generated three-pore model, Rippe and Levin predict that ultrafiltration will keep increasing with icodextrin even after a 15-h dwell [46]. Most clinical studies in APD patients have shown that ultrafiltration with icodextrin is around 168–270 mL [41–44]. However, Finkelstein et al. in a study comparing icodextrin and 4.25% dextrose in high and high average transporters showed mean ultrafiltration with icodextrin in APD patients to be >500 mL with a dwell period of 14–16 h. Between 33 and 38% of patients in this study had negative ultrafiltration with 4.25% dextrose and none after 2 weeks of randomization to icodextrin [40]. A recent study showed maximum ultrafiltration with icodextrin dialysis solution in APD patients is achieved at 10 h, beyond which, increasing the dwell time does not lead to any significant increase in ultrafiltration [47]. Overall ultrafiltration with icodextrin during the day exchange in APD appears to be less than in the night exchange on CAPD. An upright posture and physical activity produce greater intraperitoneal pressure, resulting in increased lymphatic reabsorption during a daytime dwell [48].

A benefit of increased ultrafiltration with icodextrin is an increase in small solute clearances and sodium removal [40–43, 49]. The increase in sodium removal has been demonstrated to improve control of fluid balance [43, 49, 50]. Impact of icodextrin on blood pressure control on APD patients needs to be studied in a systematic manner with only one of the current studies showing improvement in blood pressure control [50]. With improved ultrafiltration, it was initially feared that there would be a negative impact on residual kidney function. However, current studies suggest that the use of icodextrin could preserve urinary volume and clearances compared to conventional peritoneal dialysates [49, 51].

Another benefit of icodextrin is that it produces less glycation of protein and appears more biocompatible [52]. The European Automated Peritoneal Dialysis Outcomes Study (EAPOS) measured longitudinal membrane function (solute transport and ultrafiltration capacity) annually in a prospective but nonrandomized cohort of 177 functionally anuric patients. The whole cohort experienced an increase in solute transport and reduction in ultrafiltration capacity at 12 and 24 months. A subgroup analysis according to glucose exposure and icodextrin use at baseline found these changes were accelerated and more severe in patients using either 2.27 or 3.86% glucose. Icodextrin use in these circumstances was associated with less deterioration in membrane function [53].

The use of icodextrin may cause a decrease in serum sodium and chloride levels. There is a decline in serum α-amylase activity, which likely has no clinical significance. A skin rash and exfoliate dermatitis may develop with the use of icodextrin [43, 54].

An innovative development from the standpoint of APD has been the introduction of bicarbonate solutions. These solutions are packaged in dual chambered bags or potentially, in the future may be generated online. The dual-chambered bags separate calcium and magnesium from bicarbonate. These bags contain physiologic concentrations of bicarbonate and allow dialysate to be delivered at a physiological pH. Furthermore, the two chambers allow glucose to be sterilized at a very low pH, minimizing the generation of glucose degeneration products [55]. Currently marketed are peritoneal dialysis solutions contain 25 mmol/L of bicarbonate with either 10 or 15 mmol/L of lactate, allowing for flexibility in control of acidosis. An alternative solution contains only bicarbonate (34 mmol/L) as a buffer (Table 12.2). On-line production of dialysate was first described by Tenckhoff [16, 17]. More recently, a machine used for online production of a replacement fluid for hemofiltration was adapted to produce peritoneal dialysate [56]. The machine utilizes reverse osmosis water and a proportioning system to mix a standard acid concentrate with a bicarbonate bath. Such systems could potentially decrease costs associated with high-volume therapies and offer customization of dialysate to meet the needs of an individual patient.

Table 12.2 Composition of bicarbonate-based peritoneal dialysis solutions

	Bic/Lac 35	Bic/Lac 40	Bicarb 34
Sodium (mEq/L)	132	132	134
Calcium (mEq/L)	1.75	1.25	1.75
Magnesium (mEq/L)	0.25	0.25	0.5
Chloride (mEq/L)	101	95	104
Bicarbonate (mMol/L)	25	25	34
Lactate (mMol/L)	10	15	0
Dextrose %	1.5, 2.5, 4.25	1.5, 2.5, 4.25	1.5, 2.5, 4.25
Ph	7.4	7.4	7.0–7.6
pCO_2 (mm Hg)	48	48	60

Bicarbonate-based peritoneal dialysis solutions are more physiological, and are especially indicated for children in whom hepatic conversion of the buffer lactate to bicarbonate is rate-limited, in patients requiring dialysis for acute renal failure, or those with hepatic dysfunction [57]. These solutions are associated with lesser infusion pain and improvement in biocompatibility parameters including enhanced phagocytic activity of peritoneal macrophages, reduced constitutive inflammatory stimulation, reduced advanced glycosylation end products accumulation, and better preservation of the mesothelial cell integrity [58, 59]. Children dialyzed with conventional peritoneal dialysis solutions may need additional bicarbonate to correct acidosis; a switch to bicarbonate [59] or bicarbonate/lactate solutions improves acid-base balance and may even cause alkalosis [60]. Subtle changes in solute transport may be noted on peritoneal equilibration tests during bicarbonate dialysis with a less steep creatinine equilibration curve suggesting reduced peritoneal vasodilation [59].

Amino acid–based peritoneal dialysis solutions may be an option for the malnourished patient on APD. A 1.1% amino acid solution provides ultrafiltration roughly equivalent to a 1.36% dextrose solution [61]. Studies have established the benefit of amino acid peritoneal dialysis solutions in continuous ambulatory peritoneal dialysis [62, 63]. For adequate absorption on APD, the amino acid solutions would have to be used for the long dwell. An option to achieve adequate ultrafiltration would be to combine an amino acid solution with glucose or a glucose polymer [64]. In a crossover study, combined administration of dextrose and amino acid in the peritoneal dialysate improved protein anabolism in APD patients [65].

Peritoneal Dialysis Cyclers

The use of sophisticated software and hardware has made the present generation of cyclers safe, reliable, and easy to use while allowing these devices to become compact and portable. Most cyclers offer built-in programs with options for all the varied modalities of automated peritoneal dialysis, including CCPD, classical IPD, NIPD, TPD, and CFPD. These machines are programmable for dialysis modality, inflow volume, fill, dwell and drain times per cycle, last bag fill options, and additional daytime automated exchanges. Most cyclers automatically monitor infusion and drainage rates. They increase treatment efficacy by eliminating lag-time between exchanges after a predetermined volume has drained and the drain has slowed below a certain threshold. The cyclers are equipped with on screen displays, which provide instructional steps, including troubleshooting alarms.

Recent sophistications include flash memory cards and modems. The memory card serves two functions: To program the patient's prescription into the cycler and to collect information about treatments. The card is programmed at the center with the desired prescription and then uploaded into the cycler. In some machines, the card can contain information about several prescriptions and the patient could choose the most appropriate for a particular session. The card also records details of each treatment, including ultrafiltration, total volume, fill volume, drain time, cycle time, and any alarms, eliminating the need for paper records. Information regarding compliance such as shortened or missed treatments, changes in fill volumes, and bypassed therapy phases are recorded. This information is easily converted by software into easy-to-interpret charts and graphs allowing for quick identification of problems. The data card can be brought by the patient for their visit or be uploaded to the center through a modem.

Cyclers are equipped with easy-to-install disposable tubings. The tubing manifold has several prongs for spiking dialysate bags and a single prong leading to the patient. Some cyclers provide for automatic connection and bag identification using laser bar-readers. The use of large-volume dialysate bags has reduced the costs of treatment, as well as the number of required connections. The dialysate is moved from the dialysate bags to a reservoir bag and then instilled into the patient. After the designated dwell time is complete, the dialysate is either emptied into a bag or

drained directly. The movement of dialysate through the cycler and in and out of the patient is mediated by gravity, pump-driven systems, or a combination of the two. Fluid is preheated in the reservoir bag, which is placed on a heater cradle. The preheating of the fluid is done more for the patients' comfort rather than to prevent hypothermia. Integrated scales allow accurate delivery of the fill volume and measurement of drainage and ultrafiltration volumes. Cyclers with pediatric treatment options can deliver volumes as small as 50 mL with the option of 10-mL increments [66].

Ronco et al. [66, 67] predict that, in the future, cyclers will be capable of optimizing therapy and delivering appropriate solutions. Machines will be equipped with sensors capable of measuring intraperitoneal pressure in addition to flow sensors. Segmental bioimpedance measurements may be incorporated to measure intraperitoneal fill volumes and ultrafiltration during rapid APD therapy. These devices will allow for detection of catheter malfunction as well as allow the machine to tailor make the next dialysis exchange with regards to osmolality, dwell time, and cycle volume. A fine control of ultrafiltration could be achieved by altering sodium and glucose concentrations in the dialysate. These futuristic machines will monitor pO_2, pCO_2, and pH in the effluent to perfect on-line production of bicarbonate-based dialysate with intelligent feedback. Measurement of urea and creatinine in the spent dialysate will permit assessment of adequacy. Biosensors capable of detection of white blood cells will help with the early diagnosis of peritonitis.

Physiology of Solute and Fluid Transport

Physiological principles of solute and water transport are discussed extensively in Chapter 6. APD modalities introduce a biphasic profile for both clearances and ultrafiltration behavior by the use of short dwell exchanges during the night and a day dwell that may be much longer than the overnight dwell in CAPD.

Solute Transport

Solute transport across the peritoneal membrane is dependent on diffusion and convection.

Solute Transport by Diffusion

The diffusive transport of solutes is a function of the membrane transport characteristics, dialysate flow rate, peritoneal capillary blood flow rate, concentration gradient, and time allowed for transport [68].

The membrane transport characteristics can be assessed by a variety of clinical tests. The most commonly used technique to evaluate the peritoneal transport characteristic is to measure the dialysate to plasma solute concentration (D/P) for particular solutes during an exchange with conventional peritoneal fluid. This procedure has been standardized by Twardowski et al. [69, 70], and named the peritoneal equilibration test (PET). Patients are classified into four membrane categories: high, high average, low average, and low. Other measures of peritoneal transport are the mass transfer coefficients (MTC) and the peritoneal permeability analysis [71–73]. The MTC is the solute clearance rate that would be achieved across the peritoneum in the absence of both ultrafiltration and solute accumulation in the dialysate. Various numerical models have been described to calculate the MTC. The standard peritoneal permeability analysis (SPA) is a modification and extension of the PET: glucose1.36% dialysate is used, to which dextran 70 is added for the calculation of fluid kinetics. Mass transfer area coefficients (MTAC's) of low molecular weight solutes, clearances of proteins and the change in intraperitoneal volume (IPV) are assessed.

High or rapid transporters tend to equilibrate small solute concentrations between dialysate and blood early in a dwell. These patients also absorb glucose early in the dwell. Once the osmotic gradient has dissipated, ultrafiltration ceases, and the dialysate returns are reduced because of reabsorption of fluid. These patients are best served by short dwell treatments. On the other hand, patients with low transport rates achieve peak ultrafiltration late during the dwell, and D/P ratios increase almost linearly over a long dwell. These patients benefit from continuous regimens, as the total dialysis time is crucial for adequate clearances [74]. These principles are illustrated in Fig. 12.1 and recommended peritoneal dialysis modalities are suggested in Table 12.3.

Several factors affect the MTC; important from the APD standpoint are the position during dialysis and the dialysate exchange volume (V_{ip}). Using the same V_{ip}, the MTCs for urea and creatinine were increased 24% and 19% in one study [75], and 15% and 9%, respectively in another study [76] in the supine position when compared with the upright position. In the supine position, the dialysate layers throughout the entire abdominal cavity, while in the upright position dialysate pools in the subumbilical region of the abdomen. The increase in the MTC is caused by increased contact of dialysate with

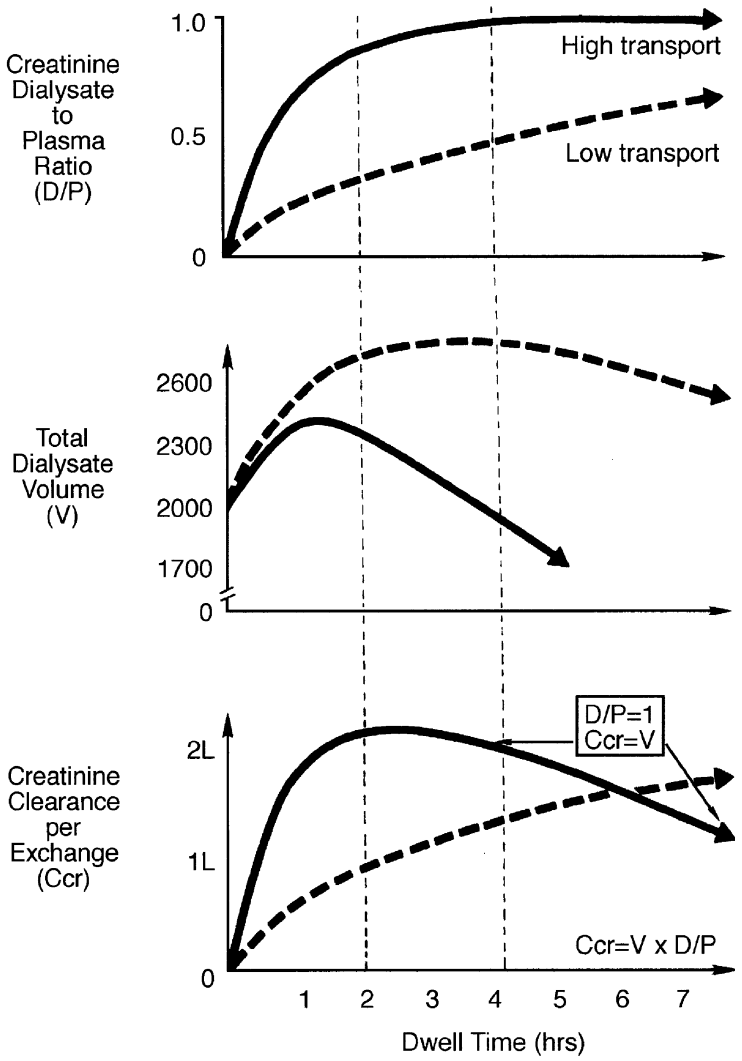

Fig. 12.1 Idealized curves of creatinine and water transport during exchange with 2 L of 2.5% glucose dialysis solution in patients with extremely low and high peritoneal transport characteristics. Upper panel shows dialysate to plasma ratio (D/P); middle panel shows total dialysate volume (V), which is the sum of infusion volume and ultrafiltration; lower panel shows creatinine clearance per exchange (C_{cr}). The curves in the lower panel are derived from those of the upper and middle panels. ——, high peritoneal transport; - - - -, low peritoneal transport. From Ref. [74] with permission

the peritoneal membrane. Additionally, in the supine position, dialysate is more accessible to the peritoneal membrane around the liver [76]. The peritoneal membrane around the liver accounts for up to 45% of the total MTC for the entire peritoneal cavity [77]. Portal blood flow also increases in the supine position [78].

An increase in the V_{ip} increases solute clearances by an increased plasma to dialysate concentration gradient and/or to an increased effective peritoneal area [79]. Schoenfeld et al. [80] observed a strong linear relationship between the peritoneal transport constant and V_{ip}. These correlations occurred over a range of 1–3.8 L of V_{ip}. Keshaviah et al. [81] found that the V_{ip} associated with peak MTC increased with increasing body surface area, and a fill volume of approximately 1,500 mL/m^2 body surface area provides a maximal MTC. Higher fill volumes do not improve dialysis efficiency further. A study using computerized tomography to assess the effect of increased dialysate volume from 2 to 3 L found an 18% increase in peritoneal surface area in contact with dialysate and consequently enhanced the MTC. In spite of a 50% increase in fill volume, the larger volume does not make contact with the entire peritoneal dialysis surface area [79]. Increasing the V_{ip} is a more effective means of increasing solute clearances than more frequent exchanges with lower V_{ip}. This practice also reduces dialysate transit time, or the non-dialytic period, and improves clearances. Increases in $V_{ip,}$ however, will increase the intra-abdominal pressure which may decrease ultrafiltration.

Table 12.3 Preferred peritoneal dialysis modality based on solute transport

Solute transport	Preferred modality
High	NIPD, CCPD, TPD
High-average	CAPD, CCPD, CCPD + CAPD, TPD + CAPD
Low-average	CAPD, CCPD, CAPD+ CCPD
Low	CAPD, HD

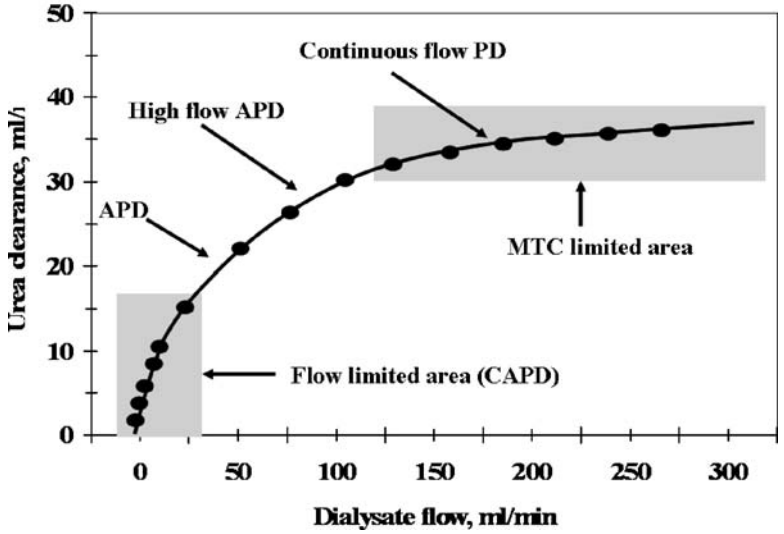

Fig. 12.2 Relationship between urea clearance in peritoneal dialysis and dialysate flow rate. From Ref. [82] with permission

The impact of dialysate flow on urea clearance is demonstrated in Fig. 12.2 [82]. The initial portion of the curve corresponds with the dialysate flow rates typical of CAPD (three to five exchanges per day). In this region of the curve, there is a steep correlation between urea clearance and dialysate flow rates. CAPD is, therefore, dialysate flow limited, and improved clearances may be achieved by increasing the number and/or the volume of exchanges. The second region of this curve is typical for APD. This region is affected by both the dialysate flow rate and MTC. As dialysate flow is increased in automated regimens, the dwell times become shorter, and an increasing proportion of exchange time is occupied by the inflow and drainage times [82, 83]. Although clearances may be improved by increasing dialysate flow, a point of diminished return will eventually be reached. Continuous flow peritoneal dialysis and tidal peritoneal dialysis try to address this issue by increasing contact time between dialysate and the peritoneal membrane. In tidal peritoneal dialysis, only part of the fluid is drained and replaced during an exchange [28]. Continuous flow peritoneal dialysis [84] through two catheters or a double-lumen catheter secures full contact of the dialysate with the peritoneal membrane, but at high flow rates, fluid channeling may restrict mixing [85].

The above illustrates that higher urea clearances can be achieved by increasing dialysate flow rates. Creatinine, urates, phosphates, and middle molecules equilibrate at a slower rate and hence clearances are lower than for urea. These kinetic characteristics of APD create adequacy discrepancies between Kt/V_{urea} and creatinine clearance [86]. The absorption of glucose is characterized by an exponential decay, shorter dwells reduce absorption of dextrose and improve ultrafiltration. Adequate ultrafiltration may be obtained while using low glucose concentrations in conjunction with high dialysate flow rates [86].

Solute Transport by Convection

Solutes accompany the bulk flow of water from the peritoneal capillary blood into the peritoneal membrane by convection (solute drag). For high-molecular-weight solutes, the convective transport is more important than the diffusive one. The magnitude of convective transport is determined by the ultrafiltration rate for the peritoneal membrane, the average solute concentrations within the membrane [87] and the sieving coefficient (S, describing the fraction of solute that passes through the membrane with water flow: $0 \leq S \leq 1$) [29, 30].

Although the sieving effect influences each solute, the important clinical consequence of sieving is related to sodium. The ultrafiltrate is usually low in sodium. Thus, dialysate sodium concentration is initially reduced in the dialysate and tends to increase late in the dwell due to diffusion of sodium into the dialysate and diminished ultrafiltration in longer dwells [29–32, 69]. During APD with shorter dwells, the net electrolyte removal per liter of ultrafiltrate remains far below the extracellular fluid concentration and severe hypernatremia and hyperosmolality may develop [88]. Ortega et al. [89] compared sodium removal in 36 patients undergoing CAPD and APD. Average peritoneal sodium removal was 195 mmol/day in CAPD and 87 mmol/day in APD, a difference attributed to lower ultrafiltration provided by APD. Part of the differences in ultrafiltration and sodium removal between CAPD and APD may be due to overfill of dialysis bags. In CAPD, the overfill is drained into the same bag submitted for laboratory analysis leading to an overestimation of ultrafiltration and sodium removal. The cycler patients use a single, smaller-volume flush that is discarded at the time of set-up and the cyclers provide fairly accurate estimates of instilled and drain volumes [90]. In a

larger study, Rodríguez-Carmona and Fontán [91] reported that total sodium removal was 210 mmol/day for CAPD and 91 mmol/day for APD, after taking into consideration overfill. Sodium removal of less than 100 mmol/day was present in 7.1% of CAPD patients and 56.4% patients on APD in their study. The use of icodextrin, supplementary diurnal exchanges, and longer nocturnal dwell times improves sodium removal in APD. An alternative is to reduce the dialysate sodium concentration. Since commercially available dialysis solutions do not offer this option, one may mix a 5% glucose solution (D5W) in appropriate proportions to achieve lower dialysate sodium concentrations [74].

Fluid Transport

Ultrafiltration

The net ultrafiltration is determined by the difference between the transcapillary ultrafiltration (TCUF) and absorption of fluid from the peritoneal cavity. The latter consists of transcapillary back-filtration and fluid uptake into the lymphatic system. The transcapillary ultrafiltration gradient is dependent on the hydraulic permeability of the peritoneum, its effective surface area, and the hydrostatic and the osmotic (colloid and crystalloid) pressure gradients [92, 93].

The transperitoneal crystalloid osmotic gradient is established by dextrose. The dissipation of dialysate/plasma glucose gradient during peritoneal dialysis is nonlinear, with a rapid initial decline followed by a slow decrement. The shorter nighttime cycles in APD take advantage of the high initial ultrafiltration rate. Further, the shorter the dwell time, the more preserved is the osmotic gradient and lower the difference for ultrafiltration across different membrane transport types. On the other hand, during the long daytime dwell, there is dissipation of the osmotic gradient and hence loss of the stimulus for ultrafiltration. High and high-average transporters are at most risk for negative ultrafiltration. This is best addressed by shortening the day dwell, or the use of higher dialysate tonicities or icodextrin [94].

The hydrostatic pressure in the peritoneal capillaries may be assumed to be 17 mm Hg [95]. The opposing hydrostatic pressure in the peritoneal cavity (intraperitoneal pressure) varies depending on the V_{ip} and posture and activities and may range from 5 mm Hg in the supine position, to over 20 mm Hg while standing and over 200 mm Hg with certain activities [96, 97]. In the supine position, the intraperitoneal pressure (IPP) is the least. However, with the use of larger volumes to augment clearances, the IPP will rise and impact transcapillary ultrafiltration and more so increase back filtration and lymphatic absorption [98].

Lymphatic Absorption

Along with ultrafiltration, there is a constant absorption of fluid from the peritoneal cavity. Fluid and solutes are reabsorbed directly by the lymphatics and also by a process of back-filtration into the peritoneal interstitium [99–101]. Fluid and solutes entering the peritoneal interstitium are taken up by the local lymphatics and capillaries. The IPP is a major determinant of egress of fluid from the abdominal cavity into the tissues lining the peritoneal membrane [100–102] and consequently the IPP influences the lymphatic absorption rate [98].

The subdiaphragmatic lymphatics account for the major portion of the fluid reabsorbed by lymphatics [99]. Lymphatic absorption is dependent on diaphragmatic movements and contact of fluid with the diaphragm. There is an increased contact of fluid with the subdiaphragm in the supine position and enhanced fluid absorption [103, 104]. Thus, in supine APD, two conflicting variables affect lymphatic fluid reabsorption: one, the lower IPP and two, the increased contact of fluid with the subdiaphragm.

Relationship Between Intraperitoneal Volume and IPP

Physical characteristics such as gender, body size, abdominal muscle tone, duration on peritoneal dialysis, and infused dialysate volume influence IPP. The empty peritoneal cavity has an IPP of 0.5–2.2 cm H_2O. The IPP rises in direct proportion to the amount of fluid infused into the abdominal cavity. Studies from APD show increases in IPP from 3.76 to 6.11 cm H_2O per liter of intraperitoneal fluid in the semi recumbent position [105–107]. Durand et al. demonstrated a rise in the IPP of 2 cm H_2O per liter of infused dialysate in the supine position [108]. A study measuring IPP in CAPD patients in the supine position found a strong inverse relationship between the dialysate volume/BSA ratio and IPP. This inverse relationship means that for any given fill volume, patients with smaller body size have a higher IPP than do patients with larger body size [109].

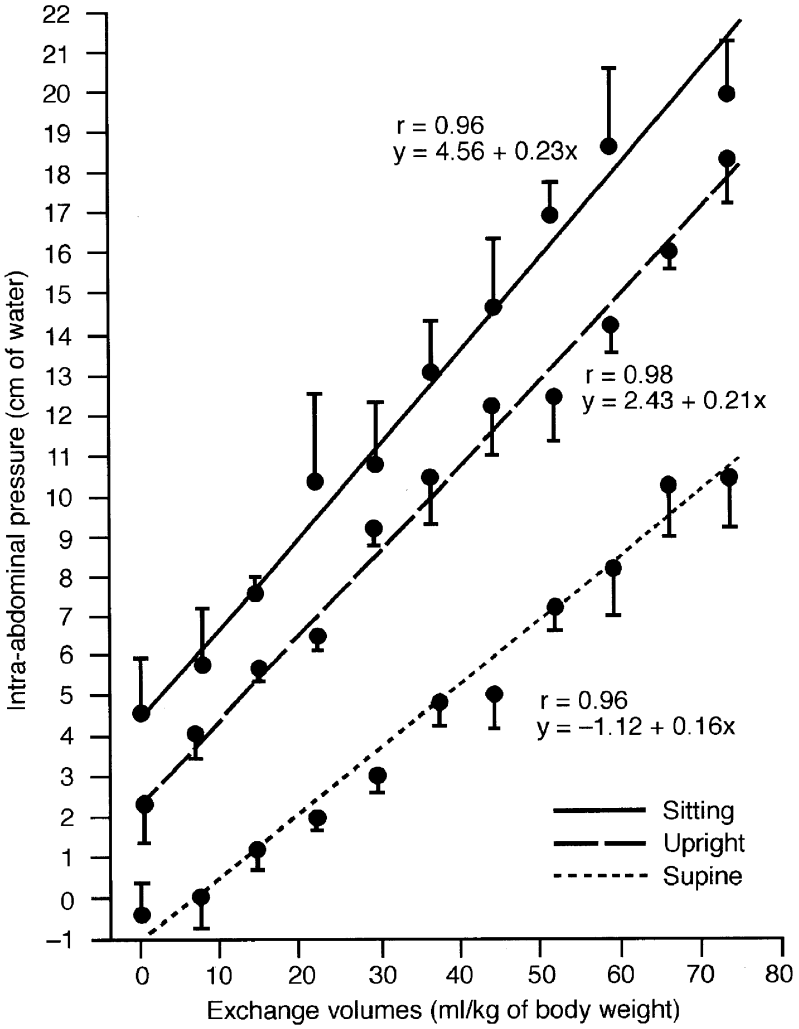

Fig. 12.3 Comparative effect of dialysate volume and patient position on intra-abdominal pressure. From Ref. [97] with permission

The relationship between IPP and V_{ip} is maintained regardless of the patient's position, but the slope of the curve does shift with changes in position. For any intraperitoneal volume, IPP is minimized by assuming the supine position; sitting leads to the highest pressures, and standing results in intraperitoneal pressures between those seen with sitting and lying down (Fig. 12.3) [96, 97, 107].

An increase in the IPP can cause a decrease in the net ultrafiltration [110]. A change in posture from supine to upright was associated in one study with a small increase in lymphatic absorption (+8%) and a decrease in transcapillary ultrafiltration (–5%), largely attributable to change in the IPP [104]. In another study, an increase in the IPP by 1 cm of water was found to cause a decrease in ultrafiltration of 74 mL at 2 h [111].

Dialysate Fill and Drain Profiles

It is generally known that dialysate fill rate is a function of fill height and patient position. The lower IPP in the supine position facilitates a higher fill rate for dialysate than in the upright position. Increasing drain height can also shorten the drain rates. Larger-bore catheters do not provide better fill rates, but may decrease the drain time [75].

The characteristic drain profile shows a bimodal pattern with high drain rate (>200 mL/min) for the initial 5–7 min, during which time over 80% of the dialysate is drained; followed by a very abrupt transition to a very slow drain rate (<50 mL/min) (Fig. 12.4) [75, 112]. A variable intraperitoneal volume is left at the breakpoint ranging from 0 to 1,200 mL, with an average of 500 mL [113]. This abrupt transition between outflow rates may happen due to bowelloops

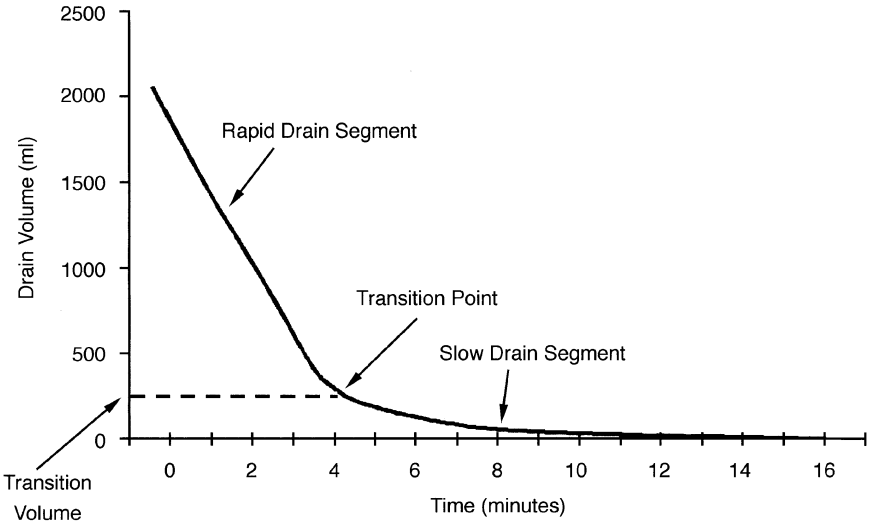

Fig. 12.4 Representative dialysate drain profile. From Ref. [75] with permission

collapsing on the catheter as the transition volume is approached, causing a significant reduction in outflow [75]. An alternative explanation is that the breakpoint may be due to a sudden drop in the conductance of the hydraulic system – when a critical intraperitoneal volume is reached, outflow from the abdomen becomes restricted [112]. The IPP is the force behind the drainage phases and at breakpoint, an equilibration between the V_{ip} and the IPP is possibly reached.

From the above discussion it is clear that a majority of the drain time during each cycle in APD is spent removing a small percentage of the total dialysate. Tidal peritoneal dialysis, wherein a tidal volume is exchanged in each cycle, utilizes only the rapid drain segment and obtains maximal benefit of this mechanism. A further refinement is breakpoint APD that refers to a tidal PD characterized by a variable reserve volume determined by the breakpoint allowing for optimization of drainage times. The effects of optimizing drain cycles are discussed subsequently in this chapter.

Factors Influencing Selection of APD

APD is the fastest-growing modality of peritoneal dialysis worldwide. However, there is a high variance in the use of APD in different areas of the world. Medical limitations, physician education and biases, availability and cost of equipment and supplies, patient preferences, social reasons, and reimbursement concerns impact the selection of dialysis modality [114].

The choice of APD over CAPD should initially be based on the patient's preference. The increased convenience of these treatments makes them more suitable for patients who have work commitments during the day. APD is the modality of choice in children and adolescents. The main reasons for these are the following: peritoneal diffusion is higher in children [115], freedom from bag exchanges in the daytime, no need for venipunctures, and no major effect on the work schedule of their parents [116, 117]. Elderly patients and those with manual or visual impairments who are dependent on assistance from others opting for peritoneal dialysis are best treated by APD to prevent overwhelming their partners or helpers [117, 118]. Patients, especially children who develop psychosocial problems due to distortion of body image by a protruding abdomen, should also be treated by APD [116].

From a physiological standpoint, the choice of peritoneal dialysis modality is best guided by the nature of the peritoneal membrane transport characteristics. Optimum therapy is achieved by matching modality and dwell times to the transport type of the patient [70, 74] (Table 12.3). Patients with high peritoneal transport characteristics and minimal residual kidney function (RKF) are best treated with APD to maintain adequate ultrafiltration. APD may need to be considered as a modality for patients with ultrafiltration failure. Larger patients and those with declining RKF needing higher fill volumes to achieve adequacy are candidates for APD as they may be more comfortable with doing these exchanges while supine. APD is a viable option for patients with complications due to increased intra-abdominal pressure (hernias, dialysate leaks, hemorrhoids, uterine prolapse, and back pain) [6]. From our earlier discussion, IPP is much lower in the supine position for the same dialysate exchange volume. Tidal peritoneal dialysis is indicated for patients who have drain problems or patients with infusion pain or pain at the end of a drain. APD may be offered to patients feeling burnout from CAPD [67].

However, APD is not an option for all patients. Higher costs due to the need of a cycler, disposable tubing, and generally larger dialysis volumes serve as a deterrent. Some patients may not accept the prolonged restriction to bed for the duration of overnight cycles or the dependence on a machine. There is a potential for sleep disturbances by machine alarms [118]. Sodium sieving may lead to hypernatremia, increased thirst, and poor blood pressure control [88].

Different Regimens of APD

Classical Intermittent Peritoneal Dialysis

Intermittent peritoneal dialysis (IPD) is a term used for dialysis regimens wherein periods on dialysis alternate with those when the peritoneal cavity is dry [3]. During classical IPD the patient receives several short dwell exchanges over 12–24 h with a dialysis dose between 40 and 60 L, several times a week but usually not every day. Though the procedure can be performed manually, automated cyclers or systems with on-line generation of dialysate are more practical. Treatments may take place in-center or at home.

Classical IPD is no longer used as a modality of chronic renal replacement therapy because of poor clearances and high morbidity and mortality [19–21]. However, the procedure continues to be used in countries where there are few alternatives for dialysis [119]. IPD may serve as an alternative to hemodialysis in patients needing immediate dialysis after peritoneal catheter placement. Small-volume supine dialysis is recommended during this period of catheter break-in. Cheng et al. [120] reported a higher incidence of pericatheter leaks, especially among diabetics started on IPD during the break-in period. IPD may be used as a transient therapy for patients who have hernias or leaks or those who have recently undergone abdominal surgery [121]. Some leaks may spontaneously seal off with lower intra-abdominal pressures on supine IPD. Another area of application of IPD is refractory heart failure on maximal medical therapy. Several studies have documented the reduction in morbidity days, and improvement in functional status [122–124]. Peritoneal ultrafiltration has not been shown to improve survival in most studies [125].

Nocturnal Intermittent Peritoneal Dialysis

Nocturnal intermittent peritoneal dialysis (NIPD) is an intermittent dialysis regimen performed every night, and may be considered to be similar to CCPD with a dry day (Fig. 12.5) [3]. NIPD treatments are performed overnight on a cycler. The dialysis usually lasts between 8 and 12 h. Dialysate volumes of 8–12 L are typically used for therapy per night, though larger volumes of dialysate and extended dialysis may be required for some patients.

The dry days eliminate 10–20% of small solute clearances achieved in a patient who is an average transporter on nightly cycles plus a wet day [126, 127]. Treatment of patients with NIPD has a greater impact on the clearance of middle molecules. The clearance of middle molecules is a time-dependent process, and dry days reduce clearances by 50% [126–128].

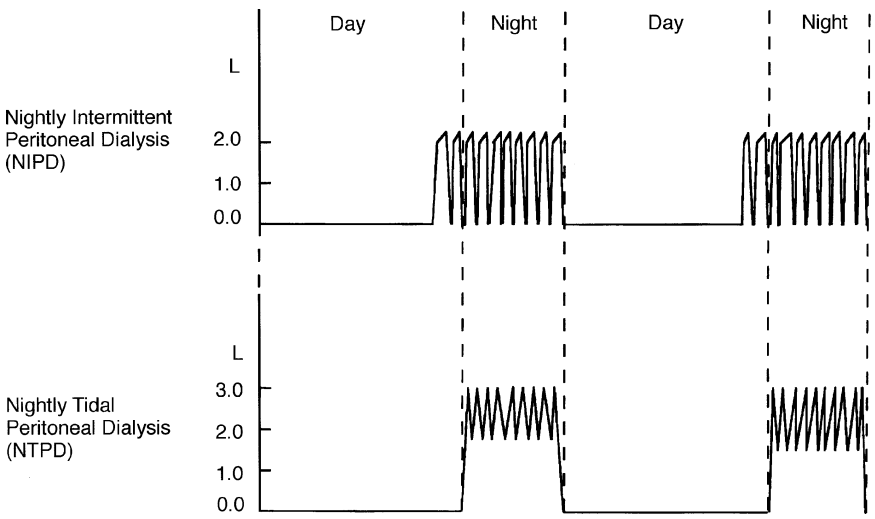

Fig. 12.5 Nightly peritoneal dialysis. Upper panel shows nightly intermittent peritoneal dialysis; lower panel shows nightly tidal peritoneal dialysis. From Ref. [3] with permission

NIPD may be an optimal modality for those with complications due to elevated intraperitoneal pressure, who are unwilling, or are not candidates for hemodialysis. Patients with high transport characteristics and those with type I ultrafiltration failure may also be treated with NIPD [74, 127]. Those patients with high levels of RKF may initially be treated with NIPD. This modality is not an option for subjects with large body surface area and those with average or below average transport characteristics with minimal or no RKF as adequacy parameters cannot be met [126]. NIPD does offer the psychosocial advantage of a better body image and lower glucose absorption leading to a better appetite. The costs of treatment run higher than with CAPD, and patients often do not accept the prolonged confinement to bed. Additionally, sodium sieving and the consequent low sodium in the ultrafiltrate may lead to hypernatremia, increased thirst, and worsening hypertension [88].

Continuous Cyclic Peritoneal Dialysis

Continuous cyclic peritoneal dialysis (CCPD) is a continuous automated peritoneal dialysis regimen [3] (Fig. 12.6). The technique is essentially a reversal of CAPD where the shorter exchanges are automatically provided at night while the longer exchanges are performed during the day. After the last nocturnal cycle the cycler is programmed to deliver a final exchange (last bag fill) of hypertonic dialysate or an alternative osmotic agent like icodextrin.

Small solute clearances are slightly lower in CCPD than in CAPD for the same dialysate flow [129, 130]. The total weekly clearances of middle molecules are the same as CAPD. The solute clearances may be improved by increasing the delivered intraperitoneal volume, increasing the number of nightly exchanges and duration on the cycler. A hybrid modality to increase adequacy and ultrafiltration is called PD Plus or CCPD + CAPD, wherein additional daytime exchanges are performed in addition to CCPD [131]. These daytime exchanges may be performed manually or by hooking back to the cycler.

This regimen is best suited for schoolchildren and employed patients who are frequently unable or unwilling to perform multiple daytime exchanges. Patients requiring assistance in performance of dialysis are better served by CCPD than CAPD. Connections and disconnections may be minimized to two, reducing burden on the provider. This is obviously an ideal choice for institutionalized patients.

Tidal Peritoneal Dialysis

Tidal peritoneal dialysis is a regimen combining intermittent and continuous-flow technology. The procedure attempts to increase efficiency by maintaining a reserve volume in the peritoneal cavity at all times, providing for uninterrupted solute clearance [28, 132]. In classical TPD, after an initial fill of the peritoneal cavity, only a portion of dialysate is drained and replaced by fresh dialysate (tidal volume) leaving the rest of the volume (reserve volume) in the peritoneal cavity (Fig. 12.5). Often the tidal volume is expressed as a percentage of the initial fill volume. For example with a 50% TPD with an initial 2L fill, subsequent tidal volumes would be 1L. Prediction of ultrafiltration is important to assure the reserve volume

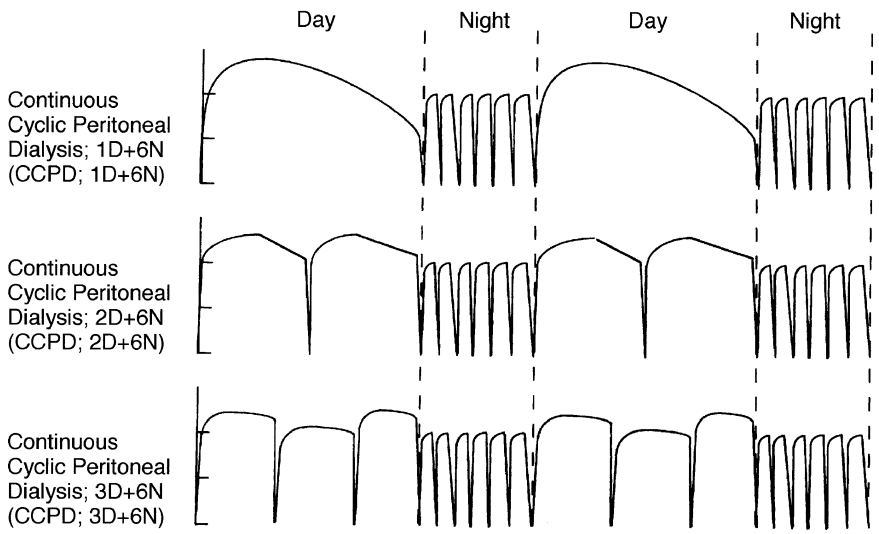

Fig. 12.6 Continuous cyclic peritoneal dialysis (CCPD). Upper panel shows standard CCPD with last bag fill; middle and lower panels show CCPD combined with additional daytime exchanges. From Ref. [3] with permission

remains unchanged. If ultrafiltration volumes are overestimated, the reserve volume would gradually be depleted. If ultrafiltration volumes are underestimated, the reserve volume will gradually increase leading to abdominal discomfort.

The initial studies comparing TPD and other APD modalities utilized much higher dialysate flow rates in TPD and found improved solute clearances. Among these studies was one by Flanigan et al. [132], which showed that utilizing 16 L of dialysate in TPD over 8 h provides equivalent clearances to 9.5 L for CCPD over 10 h. Protein losses were not increased on TPD. In another study, comparing CAPD, CCPD, 50% TPD, and 25% TPD, therapy with 50% TPD plus wet days was found to be most efficient, but once again had the highest dialysate flow [133].

Studies utilizing roughly similar amounts of fluid have found no benefit of TPD in increasing solute clearances. For example, in the Spanish Multicenter Study [134], patients were treated with CAPD, CCPD, and TPD for 2 months each. The treatment volumes were comparable between CCPD and TPD and ranged from 14 to 15 L/night and 1.8 to 2.0 L/daytime. CAPD was found to have the lowest creatinine and urea clearances. CCPD had the highest urea clearances and creatinine clearances were comparable for CCPD and 50% TPD. A study comparing solute clearances and ultrafiltration on TPD and traditional IPD found with dialysate flow rates of 18.5 mL/min, solute clearances and ultrafiltration volumes were higher on IPD than on TPD. With flow rates of 25.9 mL/min, the ultrafiltration volume was higher on IPD, but no difference was found for solute clearance. At flow rates of 44.4 mL/min there was no difference in ultrafiltration or solute clearances between the two modalities [135]. Piraino et al. [136] in a small study using a dialysate flow rate of 3.7 L/h for IPD and 3.8 L/h for TPD found no difference in small molecule clearances. Quellhorst et al. [137] reported that TPD to be more efficient than IPD using a treatment volume of 60 L/day.

Middle molecule removal is a function of time and TPD has not been shown to impact clearances of β_2-microglobulin [138]. Sodium sieving is more marked in short dwell therapies, but the few studies analyzing sodium removal in TPD have found little differences from other APD modalities [86, 139, 140]. Quellhorst et al. [137] have documented better blood pressure regulation with TPD than IPD, while Balaskas et al. [141] found no difference.

In conclusion, TPD does not increase small solute clearances above those obtained with other APD therapies. The advantage of TPD with a continuous contact between the peritoneal surface and dialysis fluid may be offset by the negative influence of a smaller concentration gradient between dialysate and blood. It has been suggested that inadequate mixing of the tidal volume with the reserve volume may cause this. TPD may be indicated for patients experiencing pain at the beginning of inflow and/or the end of drain. It may also be used in patients with mechanical outflow problems such as due to adhesions or improper catheter placement [142, 143]. In such instances, a high initial fill volume with low tidal volumes may allow PD to continue sans problems. TPD may be the preferable modality for patients with ascites wherein controlled drainage of fluid can be achieved rather than draining the entire abdominal cavity with each cycle [144].

Breakpoint APD

Breakpoint APD is a TPD modality characterized by a variable reserve volume determined by the point at which the drain rates transition into a slow drain rate as discussed above in a previous section. The breakpoint may vary for an individual patient from cycle to cycle and with change in position, intraperitoneal pressure, and catheter function besides other factors. By transitioning from a drain phase to a fill phase at the "breakpoint," the time spent draining a limited quantity of dialysate would be eliminated, improving efficiency. Computerized modeling as well as clinical studies have shown improved clearances with this modality [86, 145]. In one study, shortening the total drain time to include only the initial high outflow period increased urea clearance by nearly 10% during an 8-h APD treatment with six cycles and a total dialysate flow of 12 L in a patient with average membrane permeability (urea MTC approximately 15 mL/min). The increase in urea clearance was the result of increased dwell time with maximal dialysate volume. There was also improved sleep quality due to decreased alarms [145]. In another study comparing NIPD, 50% tidal PD, and breakpoint APD, Amici found a 10% improvement in clearances with breakpoint APD compared to tidal [113].

Continuous Flow Peritoneal Dialysis

Continuous flow peritoneal dialysis (CFPD) is a futuristic modality to augment small solute clearances by maintaining a fixed intraperitoneal volume with a constant flux into and out of fresh or regenerated dialysate through the peritoneal cavity. This system allows the use of high dialysis flow to improve clearance values close to the MTC (Fig. 12.2). There is no time wasted during inflow and drain and a continuous concentration gradient generates a solute flux that is maintained during the whole dwell time [146, 147].

CFPD would offer an option a patient to remain on peritoneal dialysis after failure of CAPD or standard APD to provide adequacy. Cruz et al. [148] have demonstrated peritoneal clearances of 42 mL/min for urea and 33 mL/min for

creatinine using a dialysate flow rate of 200 mL/min and a 2-L initial fill volume. They obtained a mean ultrafiltration of 16 mL/min with a 1.5% dextrose solution. Raj et al. [149] using a single lumen catheter with a "Y" adapter and a lower dialysate flow rate of 141 mL/min obtained mean urea and creatinine clearances of 26.5 and 24.1 mL/min, respectively. An ultrafiltration of 3 mL/min was obtained with a mean dextrose concentration of 0.73 g/dL. Thus, an added advantage of CFPD is the ability to use lower dextrose concentrations as the system continuously adds dextrose to the system. Consequent reduction in glucose absorption may prevent complications attributable to high glucose concentrations in the dialysate. Because of the high efficiency of the treatment, patients could dialyze during the night and be dry during the day. Though this would potentially allow the peritoneal membrane to regenerate, there would be a loss of middle molecule clearances whose removal is time dependent and not flow dependent.

CFPD requires large amounts of fluid (200–300 mL/min) to achieve maximal efficiency. The use commercially available peritoneal dialysis solutions would be associated with enormous cost and storage issues. Recirculating a moderately sized batch of dialysate until it saturates, though an option, would limit clearances. Another approach is the online production of dialysate as done for hemofiltration, which would allow individualization of therapy. The most viable option may be the use of a commercial dialysate followed by continuous extracorporeal regeneration of the spent dialysate by either a hemodialysis filter or adsorption using a sorbent column or a combination of the two. The protein in the dialysate would be concentrated and returned to the patient in the final exchange [147]. This may be complicated by loss of middle molecule clearances since these are extensively protein bound [146].

Two catheters or a double-lumen catheter would be needed to provide such high flow rates of dialysate, with special designs to prevent streaming. Another issue that needs to be addressed with current cyclers is the inability to assess and control ultrafiltration. With CFPD, the ultrafiltered volume needs to be matched by removal of extracorporeal fluid. A mismatch would lead to either abdominal overdistension or underfilling. Segmental bioimpedance coupled with intraperitoneal pressure measurements with closed-loop feedback in intelligent machines may provide an answer in the future.

Nighttime Exchange Device

The nighttime exchange device (NXD) allows CAPD patients one or more nighttime exchanges while reducing patient burden and improving clearances (Fig. 12.7). Though several patients on four or less exchanges may opt for this device as a lifestyle choice, the NXD is extremely helpful for patients prescribed five or more exchanges [4].

There is a physiological and kinetic advantage to using this system. Equilibrium of urea between peritoneal dialysis solutions and plasma occurs within 3–6 h of dwell. Dwell times longer than 6 h do not contribute any further to the removal of small solutes and require higher concentrations of dextrose to maintain ultrafiltration. In terms of efficiency, four exchanges every 6 h are more effective than three short and one long dwell. The supine position for

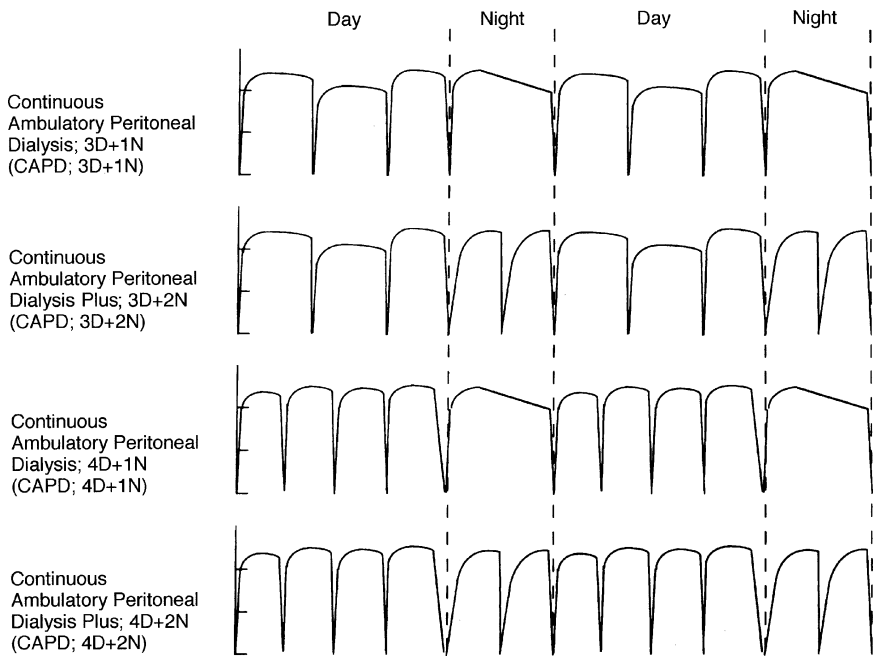

Fig. 12.7 Continuous ambulatory peritoneal dialysis (CAPD) and the use of the night exchange device (NXD). Panel 1 shows CAPD – three daytime exchanges and one bedtime exchange; panel 2 shows CAPD Plus – three daytime exchanges, one bedtime exchange, and an additional exchange delivered by the NXD; panel 3 shows CAPD – four daytime exchanges and one bedtime exchange; panel 4 shows CAPD Plus – four daytime exchanges, one bedtime exchange and an additional night-time exchange delivered by the NXD

the nighttime exchange(s) offers an opportunity to use higher V_{ip} maximizing the MTC without an increase in the IPP. Furthermore, patients retaining fluid due to the longer dwell at night on CAPD may also benefit from using the NXD. Patients switching to NXD only for lifestyle reasons, with no change in the number of exchanges, experience only a slight improvement in their solute clearances over baseline. In patients advised an additional exchange, the clearances increase significantly [150]. However, higher clearances may also be achieved by increasing the V_{ip} without changing the number of exchanges [81].

In summary, the major advantage of NXD is to help achieve adequacy in CAPD, as well in achieving net negative ultrafiltration in patients retaining fluid overnight [151].

Adequacy of Automated Peritoneal Dialysis

Background

Survival on dialysis is determined by the removal of nitrogenous waste products, correction of electrolyte and acid-base imbalance, and fluid removal to maintain normal volume status [152]. Adequate dialysis is defined as the dose of dialysis below which one observes a significant worsening of morbidity and mortality. The National Cooperative Dialysis Study (NCDS) [153] on hemodialysis gave rise to the concept that small solute clearances influence patient morbidity and mortality significantly, and these data were extrapolated to the peritoneal dialysis population.

Small solute clearances in peritoneal dialysis are conventionally quantified in terms of either urea clearance [Kt, (L/week)] normalized to total body water [V, (L)] and/or total creatinine clearance (C_{cr}) normalized to standardized body surface area (BSA).

A series of observational studies reported the importance of small solute clearances in defining adequacy among peritoneal dialysis patients [154, 155]. In 1997, the Kidney Disease Outcomes Quality Initiative (K/DOQI) Peritoneal Dialysis Work Group published a guideline for the adequacy of dialysis dose [156]. The K/DOQI recommended a weekly Kt/V of 2.0 in CAPD, 2.1 in CCPD, and 2.2 on NIPD. The initial creatinine clearance guidelines of 60 L/week/1.73 m^2 for all transport types were modified in the 2000 update of the guidelines to 50 L/week/1.73 m^2 for low and low-average transporters [157]. These guidelines were largely based on the results of the Canada-USA (CANUSA) study [155]; a reanalysis of this study showed that RKF predicted survival and not the peritoneal clearance [158]. Since then two randomized controlled studies in CAPD patients evaluating adequacy have been published. The ADEMEX (ADEquacy of peritoneal dialysis in MEXico) [159] found no difference in survival between groups having a mean total Kt/V of 2.27 and 1.80. Patients receiving a lower prescription had more deaths from congestive heart failure, uremia, and hyperkalemia. The Hong Kong study [160], a prospective randomized multicenter study, comparing three groups with total weekly Kt/V 1.5–1.7, 1.7–2.0, and >2.0 also did not find any difference in survival based on small solute clearances. The group with Kt/V of 1.5–1.7 had more anemia, inadequate dialysis, and ultrafiltration.

Observational studies in anuric CAPD patients suggest a minimum Kt/V urea of 1.7 as a minimum target. The Netherlands Cooperative Study on the Adequacy of Dialysis (NECOSAD), using time-dependent analyses of peritoneal clearances after achievement of anuria ($n = 130$) found no dose-response relationship between weekly Kt/V_{urea} and outcomes. Analyzing the data as a dichotomous variable, the investigators reported that a weekly $Kt/V_{urea} < 1.5$ was associated with an increased risk for death [161]. In an observational study from Hong Kong, patients at the onset of anuria with a baseline Kt/V_{urea} of less than 1.67 (based on a Kaplan-Meier analysis) had a significantly poorer patient survival, mainly confined to female patients [162].

No randomized controlled study addressing adequacy in APD has been performed. In a retrospective study involving a small sample of anuric CAPD and APD patients there was a trend to reduced mortality, although not statistically significant, in patients with peritoneal Kt/V urea above 1.85 [163]. Another study of 763 patients in which 34% of patients were on CCPD found that neither peritoneal Kt/V_{urea} nor peritoneal creatinine clearance were predictive of 1-year mortality [164]. The European Outcomes APD Study (EAPOS) [152] was a prospective multicenter study evaluating the feasibility and clinical outcomes of anuric APD patients ($n = 177$). Time-averaged creatinine clearance and baseline solute transport had no effect on patient or technique survival. Time-averaged analyses showed that age, subjective global assessment, and diabetic status predicted patient survival. Baseline ultrafiltration below 750 mL/day was predictive of poorer survival.

The above data establish the limitations of peritoneal small solute clearances in predicting outcomes of PD patients. Further, measured Kt/V_{urea} is not always the delivered Kt/V_{urea}. Nonadherence with exchanges, changes in timing of exchanges, variations in ultrafiltration volume, urinary output, and GFR may affect solute clearances. In addition, during automated peritoneal dialysis, the shorter nighttime exchanges provide a higher urea clearance than creatinine clearance.

Besides small solutes, protein-bound uremic toxins and middle-molecular-weight uremic toxins are important in the uremic syndrome. The removal of middle molecules is a function of the membrane area, membrane permeability, and time. Since time is the only variable, the total duration of dialysis is critical for the removal of middle molecule waste. Long dwells during the day contribute significantly to the clearance of middle molecules. The clearance of middle molecules in CCPD appears to be similar to CAPD. However, in NIPD with dry days, the time available for dialysis is reduced by 50%, and this dramatically reduces the clearance of middle molecules [126].

Several studies have demonstrated that peritoneal dialysis patients are overhydrated compared to hemodialysis and transplant patients [165, 166]. Furthermore, patients on APD have lower sodium removal and ultrafiltration than CAPD patients and consequently are more volume expanded [89, 91]. Some of the studies have been biased against APD because of not considering overfill of dialysis bags in their estimates [90]. The fluid status is associated with diastolic blood pressure, left ventricular hypertrophy, and mortality. The benefit of blood pressure and volume control has been demonstrated by Lameire [166]. Ates et al. [167] have demonstrated that better total sodium and fluid removal are factors effecting survival in peritoneal dialysis. In the EAPOS analysis, anuric patients on APD with baseline ultrafiltration below 750 mL/day had a poorer survival, but the effect of ultrafiltration disappeared in the time-dependent analysis [168]. Though greater fluid removal may indicate better volume control, it may also indicate a higher fluid intake. A higher fluid intake is more likely to be seen in healthier patients and the better outcomes with higher ultrafiltration and sodium removal may just be reverse causation [169].

Adequacy Recommendations

Guidelines from Kidney Disease Outcomes Quality Initiative (K/DOQI)

For patients with RKF (urinary volume >100 mL/day), the K/DOQI has recommended the minimum delivered dose of total small solute clearances (peritoneal and kidney), expressed as Kt/V_{urea}, should be at least 1.7 per week. Total solute clearances should be measured within the first month after initiating therapy and at least once every 4 months thereafter. If the patient has greater than 100 mL/day of urinary output, and RKF is being considered part of the total weekly clearance goal, a 24-h urine collection for urine volume and solute clearance should be obtained at a minimum of every 2 months. In patients with no RKF (urinary volume $\leq$100 mL/day), the minimum delivered dose of total small-solute clearance should be a peritoneal Kt/V_{urea} of at least 1.7 per week, measured within the first month of starting dialysis and at least once every 4 months thereafter [170]. Determination of creatinine clearance is no longer recommended for adequacy measurements by K/DOQI [164].

An emphasis on preserving RKF and maintenance of euvolemia is also incorporated into the guidelines. Important in preservation of RKF are the use of ACE inhibitors and angiotensin receptor blockers and avoidance of nephrotoxic exposure. Implementation of the goal of euvolemia involves close monitoring of urine volume, ultrafiltration, and physical examination including blood pressure. Restriction of salt and water intake, adjustment of the dialysis prescription as necessary, and use of loop diuretics to preserve or increase urinary volume are some suggested methods [170].

Other Guidelines

The International Society of Peritoneal Dialysis has made recommendations similar to the K/DOQI for small solute removals. Also recommended in APD patients is an additional target of 45 L/week/1.73 m^2 of creatinine clearance [171]. The European Best Practice Guidelines for PD recommend achieving a minimum Kt/V_{urea} of 1.7, a creatinine clearance of 45 L/week/1.73 m^2, and a net ultrafiltration of 1.0 L per day in anuric patients [172]. The Australian PD Guidelines advise the weekly Kt/V target should be =1.6/week. The minimum weekly corrected creatinine clearance (Ccr) target would be 60 L/week in high and high-average peritoneal transporters, and 50 L/week in low-average and low peritoneal transporters [173]. The Canadian Guidelines indicate that Kt/V_{urea} should be maintained at a minimum of 1.7 when the residual GFR is less than 4 mL/min. In patients with residual GFR greater than 4 mL/min, peritoneal Kt/V_{urea} may be maintained between 1.0 and 1.7.

The Automated Peritoneal Dialysis Prescription

The peritoneal dialysis prescription should take into consideration patient's body surface area (BSA), peritoneal membrane permeability properties, and amount of RKF. The presence of RKF makes it easier to achieve clearance

guidelines. Each 1 mL/min of corrected residual kidney creatinine clearance (C_{cr}) adds approximately 10 L/week/1.73 m^2 of creatinine clearance to the total C_{cr}. Similarly, for each 1 mL/min of urea clearance, 0.25 is added to the total weekly Kt/V for a 70-kg male. As the RKF declines with time the peritoneal dialysis prescriptions should be adjusted to maintain adequacy criteria.

The peritoneal transport characteristics are determined by the PET [69, 70], by mass transfer coefficients [71, 72], or by the standard permeability analysis [73]. The effect of peritoneal transport in influencing dialysis adequacy is both direct via solute clearance, and indirect via influencing ultrafiltration. A study assessing peritoneal transport characteristics of 1,229 patients found the group consisted of 15% low transporters, 33% low-average transporters, 37% high-average transporters, and 15% high transporters [94]. Low transporters are difficult to treat with APD unless they have substantial RKF. Body surface area and body weight affect the requirements for dialysis. Among the U.S. dialysis population, 75% of patients have a BSA >1.71 m^2 and a median BSA of 1.85 m^2.

The variables that may be manipulated in achieving adequacy are the dialysis modality, fill volume, number of exchanges and spacing, and duration of exchanges [129]. Computer-assisted kinetic modeling programs are available to help evaluate membrane transport characteristics and assist in writing prescriptions. Three major programs are available in the market: PD-Adequest® (Baxter Healthcare Corporation, Deerfield, Illinois, USA) [174], Patient-online (POL®) (Fresenius Medical Care, Bad Homburg, Germany) [175] and Personal Dialysis Capacity Test (PDC®) (Gambro, Lund, Sweden) [176]. These programs have user-friendly interfaces and use a mathematical model describing the peritoneal dialysis system. Data from a specific peritoneal function test needs to be entered for each patient [86, 177]. Even though prescriptions generated by the computer programs have reasonably close correlation with the actual measurement of 24-h urine and dialysate clearances, they are subject to errors. The errors relate to intraindividual biologic variability, population variability, lab errors and the use of peritoneal transport models that oversimplify the physiology of the peritoneal membrane. Furthermore, modeling expects a perfect performance of exchanges, which very often is not the case in real life [86]. Kinetic modeling is not meant to replace the actual measurement of clearance.

For a patient initiating APD with a residual GFR > 2 mL/min, the initial fill volume should range between 800 and 1,500 mL/m^2. The number of exchanges at night should be between three and five and the time on the cycler should range between 7 to 10 h. Dry days are not recommended except in patients with substantial RKF and in high transporters with small BSA. In anuric patients, higher doses of dialysis are required and low and low-average transporters with BSA exceeding 2.0 m^2 may not achieve adequacy with APD. Recommendations for initial therapy are summarized in Table 12.4, adapted from the National Kidney Foundation K/DOQI clinical practice guidelines for peritoneal adequacy: update 2000 [157]. General principles for APD therapy are summarized in Table 12.5.

The adequacy of the initial prescription must be assessed within the first month after initiating dialytic therapy and at least every 4 months thereafter. If the patient has a RKF that is being included in adequacy calculations, the RKF should be measured at a minimum of every 2 months. Inadequate dialysis may happen due to the dialysis prescription not being matched to the membrane transport characteristics, loss of RKF, insufficient time on the cycler or noncompliance, and a poorly functioning PD catheter.

The dialysis prescription can be optimized by increasing fill volumes. There is a theoretical linear relationship between body surface area and the volume of dialysate needed for optimal contact with peritoneal capillaries reaching a maximal at a fill volume of approximately 1,500 mL/m^2 [81]. Multiple studies have demonstrated that clearances rise as volume of dialysate is increased. In a study of 20 patients on either CAPD or APD, increasing fill volume by 1 L per

Table 12.4 Possible initial empirical dialysis prescriptions for CCPD

For patients with an estimated underlying GFR >2 mL/min	
BSA <1.7 m^2	4 × 2.0 L (9 h/night) + 2.0 L/day
BSA 1.7–2.0 m^2	4 × 2.5 L (9 h/night) + 2.0 L/day
BSA > 2.0 m^2	4 × 3.0 L (9 h/night) + 3.0 L/day
For patients with an estimated underlying GFR ≤2 mL/min	
BSA < 1.7 m^2	4 × 2.5 L (9 h/night) + 2.0 L/day
BSA 1.7–2.0 m^2	4 × 3.0 L (9 h/night) + 2.5 L/day
BSA > 2.0 m^2	4 × 3.0 L (10 h/night) + 2 × 3.0 L/day[a]

Source: NKF-K/DOQI Clinical Practice Guidelines for Peritoneal Dialysis Adequacy: update 2000 [157]

GFR = glomerular filtration rate; BSA = body surface area

[a] Consider combined hemodialysis/peritoneal dialysis or transfer to hemodialysis if the clinical situation suggests the need. These empirical prescriptions are based on modeling for patients with dialysate-to-plasma creatinine concentration ratio on PET of 0.71 at 4 h, BSA in the range above, and corrected residual kidney function of 2 mL/min or 0 mL/min

Table 12.5 General guidelines for APD therapy

1. Dialysis modality should be based on the ability of the regimen to provide adequate dialysis, the patients' preference, and their ability to perform the procedure.
2. APD prescriptions should be individualized based on membrane permeability, RKF, and BSA.
3. Computer prescription programs may be useful in designing prescriptions. Kinetic modeling, however, cannot replace actual clinical measurements of clearance.
4. Nightly intermittent peritoneal dialysis regimens should be avoided in all patients except high transporters with small body surface area or substantial RKF.
5. Anuric patients with low or low-average membrane transport characteristics should not be offered less than 24-h dialysis.
6. Delivered dose of dialysis and RKF must be periodically monitored. Prescriptions should be modified for a decline of RKF.
7. Clearances may be maximized by increasing the V_{ip} and/or the number of exchanges, minimizing drain time, and adding daytime exchanges.
8. Icodextrin may be used for the long dwell to improve clearances and ultrafiltration.
9. Compliance with prescriptions must be verified periodically.

RKF = residual kidney function; BSA = body surface area; V_{ip} = intraperitoneal exchange volume; IPP = intraperitoneal pressure

exchange increased urea and creatinine clearances by 26% [178]. In another study of CAPD patients, an increase in the dialysate fill volume of 1.5 L over 24 h increased peritoneal Kt/V_{urea} and creatinine clearance by 12% and 10%, respectively, and drain volumes by 20% [179].

Durand has recommended that fill volumes be optimized by monitoring of the IPP measured from the mid-axillary line, targeting a maximal of 18 cm H_2O [108]. These measurements should be done at atmospheric pressure. Whilst this is not a concern in disconnect systems, an air inlet is required for non-disconnect systems (such as APD) to negate the counter-pressure in the line and the empty bag. This is best achieved by introducing a trochar at the injection sit of the bag. On the other hand, Twardowski et al. [97, 180]. have demonstrated that there is poor correlation between IPP and tolerance of increased intraperitoneal volume. The best correlation of volume tolerance was with pulmonary function [97, 180]. Patients with the poorest tolerance of increased volume had a significant drop of the forced vital capacity at increased intraperitoneal volume with only small increase in IPP (Fig. 12.8). In a study from Mexico, even though

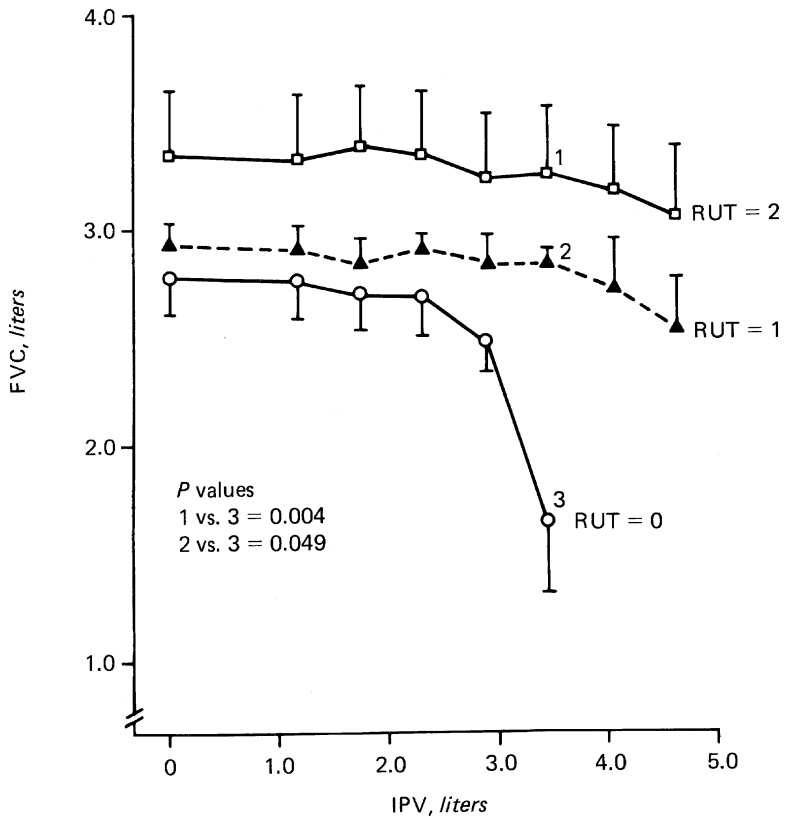

Fig. 12.8 Forced vital capacity (FVC) in the supine position in relation to intraperitoneal volume (IPV) in three groups of patients. Routine use of 3-L exchanges (RUT) = 2, patients routinely using 3-L volume exchanges; RUT = 1, patients occasionally using 3-L volume; RUT = 0, patients never using 3-L volume. From Ref. [97] with permission

larger dialysate volumes caused more discomfort, there was a lack of correlation between the discomfort score and the IPP [109]. The discomfort score was determined by asking patients to mark on a visual analog score their level of discomfort. When a 2.0-L dialysate volume was infused, the discomfort score for 86% of the patients was lower than 10, and that for 93% was lower than 50. With a 2.5-L dialysate volume infusion, 64% of patients had a discomfort score lower than 10 and 83% lower than 50. With a 3.0-L dialysate volume infusion, 44% of patients had a discomfort score lower than 10 and 64% lower than 50 [109]. Sarkar et al. [178] have shown that few patients are capable of discriminating between 2.0-, 2.5-, and 3.0-L dialysate volumes when infused blindly in random order. Most patients did not complain of discomfort in the face of a documented increase in their abdominal perimeter when 3.0 L of dialysate was infused. Thus, a majority of patients will be asymptomatic with higher fill volumes.

An alternative to increasing the fill volume is increasing the number of exchanges. More frequent cycling theoretically increases the time spent in filling and draining. A study by Perez et al. [140] evaluated this issue by comparing four different APD regimens for 1 week each. The prescriptions were for 9 h each and were all based on 2-L dwell volumes, but differed in the frequency of exchanges. They were 5 × 2 L, 7 × 2 L, and 9 × 2 L, as well as a 50% tidal peritoneal dialysis (TPD) prescription using 14 L. Higher dialysate flow rates achieved a higher small solute clearance across all membrane transport types as well as better ultrafiltration and sodium removal. The peritoneal urea clearance was significantly higher using 9 × 2 L exchanges as compared to the other three prescriptions. The peritoneal creatinine clearance was the lowest, with 5 × 2 L, and comparable between 7 × 2 L and 9 × 2 L therapies. The urea and creatinine clearances on TPD exceeded only those obtained with 5 × 2 L and were comparable to the 7 × 2 L regimen. Juergensen [181] has also reported that peritoneal Kt/V_{urea} and peritoneal creatinine clearance increase significantly when the frequency of exchanges and the total volume are increased across all transport types. Frequent cycling may negate the effects of lost time by the benefits of more frequent replenishment of the peritoneal cavity, with fresh dialysate maximizing diffusive clearance and the better-maintained osmotic gradient leading to better ultrafiltration. Such a regimen increases the cost of therapy and may be useful in some patients who cannot do a day exchange or tolerate a higher fill volume.

The use of daytime exchanges is more advantageous and cost effective. Based on kinetic modeling, Blake et al. [130] have demonstrated that in CCPD, addition of a daytime exchange is superior to further increases in the nightly dialysate volume (Fig. 12.9). In anuric patients, one to two daytime exchanges are required to meet the adequacy guidelines [152] unless one uses "high-flow" APD [182]. Increasing the time on the cycler is another option to achieve adequacy. The patient's lifestyle must be kept in consideration prior to modifying duration on the cycler. Compliance typically decreases if the total cycle time exceeds 9 h per session [183].

Management of Ultrafiltration

Volume overload is associated with congestive heart failure, left ventricular hypertrophy, and hypertension and is a predictor of poor survival [170]. It is therefore important to achieve a desirable target weight in a peritoneal dialysis patient where the patient is euvolemic. The edema-free state can be considered the minimum bracket for euvolemia. The weight below which undesirable clinical signs and symptoms such as hypotension and cramps develop can then be viewed as the maximum bracket for fluid removal. The weight range between these defined limits constitutes the

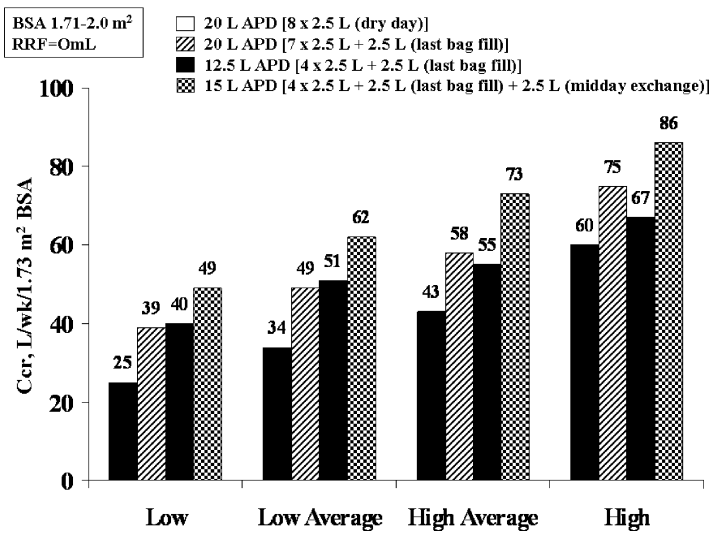

Fig. 12.9 The effect on creatinine clearance of wet days, increasing the number of exchanges, and adding a midday exchange to APD therapy prescriptions. The difference compared with a dry day is illustrated clearly in the first two bars of each membrane transport type. The effect of a midday exchange is shown in the last bar. From Ref. [130] with permission

clinical definition of desired weight – a highly variable and often complex target [184]. Maintenance of euvolemia requires attention to the peritoneal transport characteristics, protection of RKF, dietary counseling and enhanced compliance, use of loop diuretics, and control of hyperglycemia [94]. APD creates a biphasic profile for clearance and ultrafiltration with short nocturnal exchanges and a long daytime dwell. The shorter dwells provide for higher ultrafiltration rates because of a higher initial dextrose concentration. The membrane transport characteristics have a minimal effect on ultrafiltration with short dwells, while in the long dwell fast transporters have negative ultrafiltration [94]. Attention to the long dwell is essential in achieving euvolemia. If inadequate or negative ultrafiltration is seen, a midday exchange or switch to icodextrin must be considered [151]. Use of hypertonic glucose-based solutions that may cause peritoneal membrane damage should be minimized.

As regards the short dwells, frequent cycling could increase the inactive time and decrease net ultrafiltration but this has not been borne out in clinical studies [140, 181]. APD offers a unique ability to alter the tonicity of the dialysate by using bags of different tonicities since the cycler draws proportionally on all bags selected for a given

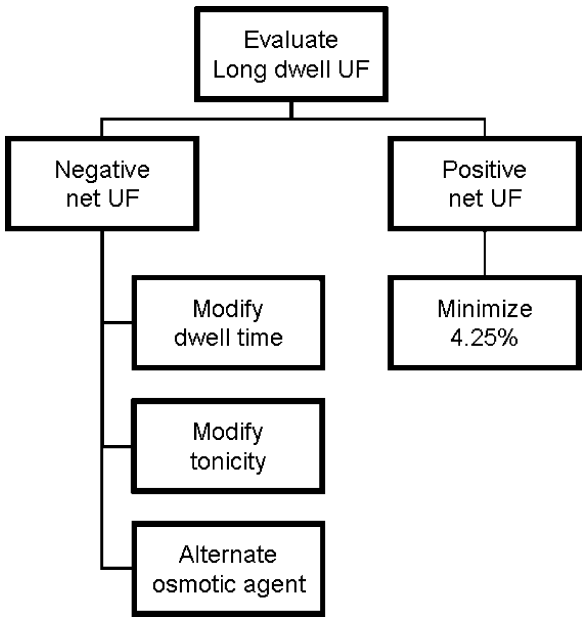

Fig. 12.10 Algorithm for fluid management in patients on PD: Management of the long dwell. UF: ultrafiltration. Modified from Ref. [151] with permission

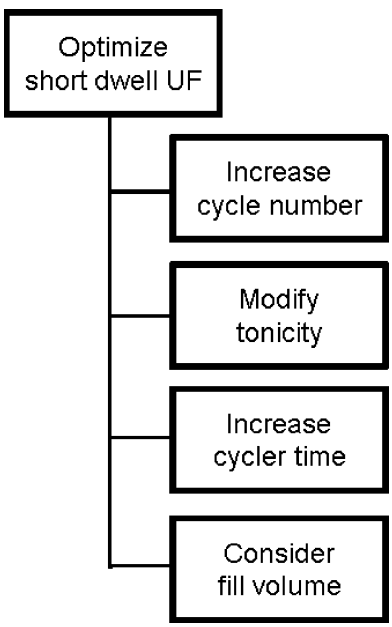

Fig. 12.11 Algorithm for fluid management in patients on PD: Management of the short dwell. UF: ultrafiltration. Modified from Ref. [151] with permission

therapy. For example, equal mixing of a 1.5 and 2.5% dextrose solution can create a 2% dextrose solution. The caloric cost per milliliter of ultrafiltration is lower with the use of higher tonicities of dextrose [151]. An increase in the fill volume helps increase ultrafiltration because of a higher total glucose mass in the peritoneal cavity [185]. However, increasing fill volumes increases IPP and may enhance net fluid absorption [110], though the effects are likely to be modest with short dwell times in APD [151]. An algorithm for fluid management in APD is detailed in Figs 12.10 and 12.11.

Incremental Peritoneal Dialysis

The decision to initiate dialysis was until recently based on the development of uremic symptoms or complications. It is becoming conventional now to start dialysis earlier to have a healthy start and avoid malnutrition and uremic complications. It is suggested that one could initiate dialysis with a "full-dose" prescription, ignoring the residual kidney component, or alternatively, one could "incrementally" increase the dialysis component of solute clearance as RKF decreases, maintaining minimal total solute clearance goals at all times [170].

APD offers an option for incremental peritoneal dialysis. Patients with significant RKF may be initiated on NIPD. With decline in RKF clearances may be augmented by switching to high-dose NIPD or to CCPD. Later, clearances may be improved by combining APD with CAPD (Fig. 12.12) [186]. Theoretically, such an approach could protect the peritoneal membrane from 24-h glucose exposure. Early start of peritoneal dialysis is associated with some risks. These risks include infection and a quicker loss of RKF. There is also the possibility that increasing the length on peritoneal dialysis may contribute to eventual patient "burn out". The reduced interference with daily routine, lower work burden, and fewer complications with APD make this a preferable procedure for early start.

Monitoring of Treatment

Patient compliance with therapy may be monitored by use of removable memory cards, teledialysis, reviewing order histories, and by frequent home visits. Catheter malfunction may be suspected if there are frequent alarms and by observing the fill/drain profiles. Changes in serum creatinine should make one suspect a change in RKF, changes in peritoneal transport characteristics, or noncompliance. Direct measurements of RKF are mandated by guidelines every 2 months and of peritoneal clearances every 4 months [170]. Since APD treatments are intermittent in nature, a fluctuation in plasma concentrations predialysis versus postdialysis may be seen. These differences are more marked for urea than creatinine and postdialysis samples will overestimate Kt/V [187]. To standardize measures of Kt/V, the blood sample should preferably be obtained at a time equidistant from the previous and subsequent nocturnal APD session.

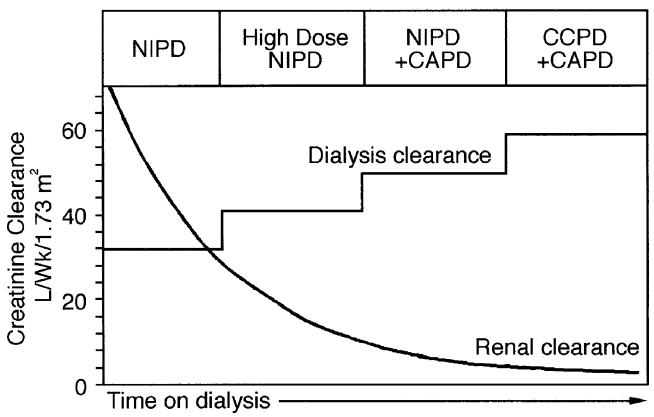

Fig. 12.12 Schematic drawing showing the adaptation of APD to change in residual kidney function. From Ref. [186] with permission

Complications of APD

Qualitatively, the complications of APD are similar to those encountered with CAPD. However, quantitative differences may exist in the incidence of these complications in the two modalities. Here, we will discuss selective complications of APD.

Peritonitis

Although the incidence of peritonitis in patients treated with peritoneal dialysis has decreased during recent years, it remains a major complication and frequent cause of hospitalization and discontinuation of peritoneal dialysis. The incidence of peritonitis in the earlier years of APD was significantly lower than CAPD [26, 188–190]. With the introduction of disconnect systems, the incidence of peritonitis has markedly decreased on CAPD. Some studies continue to demonstrate a benefit of APD over CAPD. In a randomized prospective study, de Fijter and associates [191] observed that peritonitis occurred significantly less often in those patients receiving CCPD than in those on CAPD with Y-connectors (0.51 compared with 0.94 episode per patient-year; $p = 0.03$). The median time to the first episode of peritonitis was 11 months for patients receiving CAPD with Y-connectors compared with 18 months for CCPD patients ($p = 0.06$). Patients on CAPD with Y-connectors developed their second episode of peritonitis in 6 months compared to 25 months for CCPD patients ($p = 0.18$). Rodriguez-Carmona [192] also reported on the superiority of APD over CAPD in regards to peritonitis. The adjusted difference was 0.20 episodes/patient/year.

In contrast, Burkart et al. [193], in another prospective study, found no difference in the incidence of peritonitis between patients on APD (0.58 episode per patient-year) and patients on the Y-set (0.61 episode per patient-year). Their patients using the standard spike system developed peritonitis at a significantly higher rate of 1.62 episodes per patient-year. Williams and co-workers [194] reported the incidence of peritonitis on APD to be similar to CAPD with disconnect systems with one episode occurring every 31 months and 29 months, respectively. The incidence of peritonitis for CAPD without disconnect systems was one in 13 months. Yishak et al. [195] reported peritonitis rates of 0.57 per patient-year and 0.55 per patient-year on APD and CAPD, respectively. A report of the French Peritoneal dialysis registry [8] reported a lower incidence of peritonitis on APD. However, the data is hard to interpret since the patient populations were somewhat different. Patients needing nursing assistance, overall a sicker population, more often received CAPD with nondisconnect systems and a majority of autonomous patients received APD. Oo and colleagues [196] in a recent retrospective analysis of the USRDS database between 1994 and 1997 found CAPD to be associated with a lower risk of development of a first episode of peritonitis after 9 months of peritoneal dialysis therapy as compared to CCPD. Even though this data set did not include information on connectology, it is likely that most patients would have been on a Y-system (with or without a twin-bag).

In studies showing benefit of APD over CAPD, the reduced numbers of connections to, and disconnections from, the abdominal catheter have been thought to be significance [191, 192]. Furthermore, most of these connections in APD occur between two sterile surfaces (a new connection line and a new bag); while in CAPD, most connections are between the new set and a reusable transfer line and peritoneal catheter. Improved patient technique due to performance of all connections in the same environment, less patient fatigue due to performance of fewer connections, and assistance of a helper may help reduce peritonitis rate. Most APD systems now employ flush-before-fill technology, further reducing infection by touch contamination. In addition, peritoneal immune function may be better preserved in patients with dry days in NIPD or having long dwells on CCPD [37, 197].

Patients with peritonitis usually present with cloudy fluid and abdominal pain. A dialysate white blood cell count $>100/mm^3$, with more than 50% polymorphonuclear cells, is supportive of the diagnosis, as is a positive Gram stain. The number of cells in the effluent will depend in part on the length of the dwell. Patients on APD with a day dwell who present during the day generally have cell counts similar to those of CAPD patients and are not difficult to interpret. However, APD patients without a daytime exchange who present with abdominal pain may have no fluid to withdraw. In this case, 1 L of dialysate should be instilled and allowed to dwell for at least 1 h, and then drained and examined for turbidity and sent for cell count, differential, and culture. In equivocal cases, or in patients with systemic and abdominal symptoms in whom dialysate appears to be clear, a second exchange is performed with a dwell of at least 2 h but preferably 3–4 h. On occasions, the initial drain of stagnant fluid present in the abdomen all day in patients with only partial daytime exchanges or dry days will appear cloudy in the absence of peritonitis. The white blood cell count may exceed $100/mm^3$, but

mononuclear cells will predominate. More important, dialysate rapidly clears with the initiation of peritoneal dialysis. Clinical judgment should guide initiation of therapy [198].

For patients on APD who present during their nighttime treatment, the dwell time is much shorter than with CAPD; in this case, the clinician should use the percentage of polymorphonuclear cells rather than the absolute number of white cells to diagnose peritonitis. The normal peritoneum has very few polymorphonuclear cells; therefore, a proportion above 50% is strong evidence of peritonitis, even if the absolute white cell count does not reach 100/mL [198].

The diagnosis of peritonitis in APD may often be delayed in patients using cyclers that dispose of dialysate directly without a drain bag [199]. To avoid those problems, patients should be trained to collect a small amount of the dialysate from the initial drain at the start of the night therapy and inspect it for cloudiness. If abdominal pain is experienced, a manual exchange for inspection and possible cell count with culture is recommended.

The organisms causing peritonitis in APD are similar to CAPD [191, 195, 200]. *Pasteurella multocida* has been identified as the cause of peritonitis in a few patients. This infection is caused by cats biting into the cycler tubing [201].

Intraperitoneal antibiotics, used intermittently or continuously, are preferred to intravenous antibiotics for treatment of peritonitis. Most antibiotics have enhanced absorption during peritonitis. For successful intermittent intraperitoneal therapy, high concentrations of the drug must be achieved in the systemic circulation, of sufficient magnitude that enough drug will diffuse back into the dialysate in subsequent drug-free exchanges [202]. With rapid exchanges in APD, there may be inadequate time to achieve therapeutic intraperitoneal levels with subsequent exchanges using intermittent antibiotics. Little is known about the pharmacokinetics of antibiotics and treatment outcomes in APD. Further, most of the studies performed in APD have been done on uninfected patients with intravenous administration of antibiotic, which makes it hard to extrapolate the data to intraperitoneal treatment of peritonitis [203–205]. The data show the clearance of antibiotics is largely dependent on dialysate flow as well as the RKF [202].

Among the data available, cefazolin, cefepime, and ceftazidime used once daily do not provide an adequate minimum inhibitory concentration of antibiotic during short nighttime cycles for most organisms [206–208]. Similarly, vancomycin in a dose of 15 mg/kg given intravenously also does not provide adequate intraperitoneal levels [205]. Oral ciprofloxacin in a dose of 750 mg twice a day provides dialysate concentrations that exceed the MIC for *Escherichia coli* and *Klebsiella* sp, but below those needed for *Pseudomonas aeruginosa* [209]. In spite of this pharmacokinetic data, clinical studies using intermittent antibiotics on APD have provided cure rates between 73 and 88%, catheter removal rates of 7.5–17.5%, and peritonitis-related deaths of 2–10%, which is not different than CAPD [210].

The International Society of Peritoneal Dialysis in its recommendations for treatment of peritoneal dialysis infections: 2005 Update [198] has suggested that vancomycin, cefazolin, tobramycin, fluconazole, and cefepime may be administered intermittently while continuing APD. The recommended doses are mostly higher than those for CAPD and a minimum 6-h dwell time for the antibiotic containing dialysate is advised. The committee also acknowledged the inadequacy of data backing these recommendations. Given this lack of knowledge, alternative options for treatment are switching patients to CAPD, using longer cycles on APD, or continuous antibiotics. Each institution should consider modifying the guidelines for initial antibiotic therapy based on their data on common organisms and sensitivities. In addition, patients may require adjustment of the APD prescription to account for the increased permeability of the peritoneal membrane during peritonitis.

Catheter Infections (Exit Site and Tunnel)

Catheter-related infections are an important cause of morbidity, peritonitis, and catheter failure. There appears to be little difference in the incidence of catheter-related infections on APD in comparison to CAPD. In data reported by Burkart et al. [193], the incidence of exit-site infections was 0.41 episode per patient-year for APD, 0.32 per patient-year for patients on Y-sets, and 0.62 per patient-year for patients on a standard spike. Statistical significance was only seen for the comparison between Y-set and standard spike ($p = 0.01$). de Fijter et al. [191] and Rodriguez-Carmona et al. [192] reported a similar incidence of exit site infections between APD and CAPD. Holley and coworkers [211], on the other hand, reported a significant decrease of exit-site infections for cycler patients (0.5 episode per patient-year) in contrast to CAPD patients using disconnect systems (0.86 episode per patient-year). Patients on nondisconnect systems developed exit-site infections at an incidence of 1.2 episodes per patient-year. Overall, disconnect systems, including APD, have fewer catheter infections than nondisconnect systems. It may be

postulated that, by disconnecting, the exits are subject to lesser trauma, tension, torque, or pulling [193]. The assessment and management of exit site and tunnel infections in APD is no different from CAPD.

Complications of Increased IPP

Hernias and Dialysate Leaks

The most common anatomic complication of peritoneal dialysis is hernias. The usual sites for these are sites of previous abdominal incisions and the umbilical, inguinal, and pericatheter regions [212]. The incidence of hernias on CAPD ranges between 10 and 25%, while on IPD the incidence is 2–5%; for CCPD the incidence is approximately 9% [213, 214]. The higher pressures in sitting and standing as against in the supine position may be partly responsible for this difference [97]. However, in spite of the fact that IPP rises proportional to the infused volume, there is no consensus between studies whether higher fill volume increases the incidence of hernias and leaks. In a survey of 75 dialysis units, representing 1864 dialysis patients across the United States and Canada, Van Dijk et al. [212] found no association between the volume of dialysate and the time of the largest exchange with the development of hernias. Similarly, Del Paso et al. [215] and Hussain et al. [216] found no association between fill volume and hernias. Furthermore, Durand et al. [217] found no relationship between IPP and mechanical complications. It may be possible that the IPP required to cause hernias are much higher than achieved under usual clinical conditions, and patients who develop hernias have structural weakness of the abdominal wall. Susceptible patients include older multiparous females, patients with autosomal dominant polycystic kidney disease, those with prior hernias or dialysate leaks, and prolonged corticosteroid treatment [212, 215, 218]. Susceptible patients should receive smaller diurnal dwells. Surgery is recommended for most hernias because of the risk of bowel or omental incarceration and strangulation. Post-surgery, once patients return to peritoneal dialysis, low volume and/or supine dialysis should be used.

Dialysate leaks are another frequent complication and occur more often in CAPD than APD. Risk factors for development of leaks are the median insertion of the peritoneal dialysis catheter, increased intra-abdominal pressure, and a weak abdominal wall. Leaks are characterized by dissection of fluid through tissue planes and may or may not be associated with hernias. These may present as abdominal or genital edema, pericatheter pseudohernias, and rarely as a vaginal leak of dialysate. Leaks may be a cause of ultrafiltration failure and weight gain [219]. Fluid leaks may be detected by radionucleotide imaging, MR peritoneography, or by computerized tomography scans with contrast in the dialysate [220]. Sometimes, leaks without associated hernias resolve by utilizing low-volume supine dialysis or a temporary transfer to hemodialysis. Surgical repair may eventually be required.

Respiratory Function

The presence of fluid in the abdomen and elevated IPP impact on pulmonary indices. There is a greater decline in pulmonary indices in the supine position compared to the upright or sitting positions [97]. CAPD patients generally have better pulmonary indices than patients do on APD. A good measure of the tolerance of intraperitoneal volumes is the forced vital capacity (FVC) in the sitting position [97, 180] and supine position [97, 217] (Fig. 12.8). Thieler et al. [221] described that the FVC in the supine position declined by a mean of 3.4% after the infusion of 2 L of dialysate into the peritoneal cavity. Pulmonary indices were not significantly affected by the presence of 2 L of fluid in the sitting or upright positions. In a study by Durand et al. [108], vital capacity decreased linearly by 4.42% per liter of V_{ip} in the supine position. During sleep, the drop in vital capacity is reflected by a reduction in the pulmonary reserve volume. Decreases in vital capacity by 20% or more may affect blood oxygenation. It has to be stressed that some patients may feel discomfort and shortness of breath at lower intraperitoneal volumes, possibly due to the reduced strength of the diaphragm [96, 111]. Caution needs to be exerted in increasing fill volumes on APD in patients with lung disease. The ultimate guide of the appropriate intraperitoneal volume is the subjective assessment of the patient [97, 180].

Hydrothorax

Hydrothorax is another pulmonary complication. Hydrothorax usually develops on the right side. Patients may range from being asymptomatic to having severe respiratory compromise. Most patients developing hydrothorax are females; multi-parity confers an additional risk. Fluid transverses the diaphragm through lymphatics or through defects in the diaphragm [219]. This complication occurs very rarely on NIPD and may be treated by low-volume supine dialysis, pleurodesis, or surgical repair [222].

Back Pain

Back pain is another complication related to increased IPP. The increased IPP can pull lumbar vertebrae into a more lordotic position and increase the stress on the spine. Poor muscle tone, osteoporosis, and degenerative joint disease can worsen the process. The treatment is aimed at reducing IPP by switching to APD, preferably with dry days [214].

Residual Kidney Function

The RKF contributes significantly to the adequacy of dialysis and the excretion of middle and large molecules. Survival on peritoneal dialysis has been linked to the RKF [158, 164]. Various studies have explored the loss of RKF in APD patients. An analysis of the Dialysis Morbidity and Mortality Study (DMMS) found no difference in the decline of RKF between APD and CAPD although ultrafiltration rates were not reported [223]. Hamada et al. [224]. reported better preservation of renal function in APD patients in a small study with a two-year follow-up. A prospective, nonrandomized study of 53 new CAPD and 51 APD patients followed for at least 1 year found a faster rate of loss of RKF in APD patients, despite controlling for PET results. This difference may have been negated by the role of ultrafiltration in determining loss of RKF and may have been influenced by prescription alterations once PET results were known [225]. In a small nonrandomized study of new dialysis patients, Hiroshige et al. [226] found that RKF declined more rapidly in APD patients over a 6-month period. For the eight patients on NIPD, the rate of decline in creatinine clearance was -0.29 mL/min/month and for the four CCPD patients -0.34 mL/min/month. These rates were significantly higher compared to the authors' own CAPD data, as well as the data of others. In another prospective, small nonrandomized trial of 36 consecutive unmatched new PD patients followed over 1 year, there was a faster rate of decline in the APD group. The APD group consisted of both CCPD and NIPD patients without any difference in the rate of loss for each therapy, although the numbers were small [227]. It is suggested that the acute changes in volume status and osmotic load induced at each nightly PD session could potentially accelerate deterioration of RKF.

Technique and Patient Survival in APD

Peritonitis and catheter related infections are the leading cause of technique failure on peritoneal dialysis. Other causes include mechanical catheter problems, inadequate dialysis including ultrafiltration failure, and psychosocial problems. In 1984, Diaz-Buxo et al. [19] had reported the technique survival for CCPD to be 80%, 62%, and 56% at 1, 2, and 3 years, respectively. A more recent study by Mujais et al. [10] examined the profile of PD practice in the United States by following four large inception cohorts of patients starting PD in the years 2000–2003. This study found that transfer to HD was lower in APD than CAPD for any cause of technique failure. This difference was most evident in the first year on PD and tended to disappear during the second year of therapy. Overall technique survival in APD was 81% in the first year and 67%, 55%, and 46% in each of the 3 subsequent years in this study. Patients on CAPD had a significantly higher rate of technique failure in the first 6 months and stabilized thereafter. Overall, technique success was 75% in the first year and 63%, 53%, and 44% in each of the 3 subsequent years for CAPD [10]. Patients treated with APD have a survival advantage over CAPD in the first 6 months of therapy. A younger age, selection bias of patients for APD, or better compliance with therapy may have influenced patient survival on APD in this study. The overall trend is of improving patient outcomes and technique success with time. The European APD Outcome Study was a prospective multicenter study of outcomes on APD in anuric patients. Patient survival was 78% and technique survival 62% and combined patient and technique survival was 49% at 2 years. The predictors of poor survival were age >65 years, malnutrition, diabetic status, and ultrafiltration <750 mL/day [152]. Peritoneal membrane transport had no effect on survival, though the study excluded low transporters [152].

Chapter 13
Peritoneal Dialysis Program Organization and Management

The Nurse's Role

M. Luongo and B. Prowant

Peritoneal dialysis (PD) has been a successful mode of renal replacement therapy with a positive response from patients [1]; however, there has been a progressive decline in patient recruitment for this self-care modality and in the total number of PD patients in the United States [2, 3]. This has contributed to a lack of clinical experience and expertise in PD, and loss of the infrastructure crucial for successful implementation of PD therapy. This is both a cause for concern and a distinct challenge.

As a renal replacement therapy, PD can be individualized for each patient's specific clinical and psychosocial needs [4, 5]. Also, the patient who assumes responsibility for self-care can benefit from the flexibility and freedom that PD offers.

The success of PD as a renal replacement modality in an ever-changing healthcare arena is dependent on the commitment and efforts of all members of the PD healthcare team [6]. This chapter will discuss the development and organization of a PD home program [7, 8] and the nursing roles in providing care to PD patients [9–13].

Structure and Function of a PD Program

Establishing the foundations of the PD program should be the shared responsibility of the medical director and PD nurse manager. Defining each team member's responsibilities and writing the position description is one of the first steps in program development. Clarifying the specifications of the physical environment and ordering the necessary equipment is often the next step [14, 15]. Other critical elements include creating policy and procedures and training protocols, developing quality outcome management strategies, and financial planning [7, 8, 16–18].

The Healthcare Team

The clinical care and support of the self-care PD patient is a team effort. The team is comprised of a central core of healthcare providers and a peripheral group of specialty consultants (Table 13.1) [19–22]. Core members of the PD healthcare team include the nephrologist, access surgeon, PD nurse, advanced practice nurse [22], dietitian, and social worker. Some larger PD programs have successfully integrated a technician role [19, 20]. The core team members collaborate with the patient's primary care physician and other healthcare professionals who contribute to the care of PD patients. It is often the PD nursing staff who coordinate the efforts of the team to provide home care for the PD patient [12, 13].

The Physical Environment

Developing a safe, functional environment for a PD program requires strategic planning. The PD nurse needs to be involved throughout this process to provide the necessary nursing perspective. Table 13.2 lists essential elements of the physical plan for a PD home program [7, 8, 14, 16, 17].

Table 13.1 Healthcare team members

Core PD team members
• Patient
• Nephrologist
• Peritoneal dialysis nurse
• Dietitian
• Social worker
• Renal fellow
• Access surgeon
• Advanced practice nurse
Consulting physicians
• Primary care physician
• Infectious disease specialist
• Diabetologist
• Gerontologist
• Psychologist/psychiatrist
• Hospitalist
• Vascular surgeon
Other care providers
• Transplant team
• Research staff
• Hospital nursing staff
• Extended care facility staff
• Rehabilitation facility staff
• Hemodialysis staff

Table 13.2 Physical requirements for the peritoneal dialysis program

• Waiting room or reception area
• Training room(s)
• Clinic rooms
• Conference room
• Staff office(s)
• Restrooms for patients and staff
• Clean utility room
• Dirty utility room
• Supply storage area
• Secured area for patient records, computerized records, printers, copy and fax machines

Planning should focus first on safety for patients and staff. Hallways and training rooms need to be large enough to accommodate wheelchairs, stretchers, and emergency equipment. Training rooms must be large enough to accommodate the nurse, patient, and family members. A larger room may be constructed for group training.

To prevent falls, the floor covering should not be slick or slippery; it should have some texture to promote safe footing. If part of the unit is carpeted, the carpet fibers should be short to prevent tripping and to allow effective cleaning. Light-colored, washable paint should be used to reduce glare. Large windows will need shades or adjustable blinds to filter sunlight and prevent glare. The training room needs to have a thermostat so the temperature can be adjusted to the comfort level of the individual patient [23].

Table 13.3 outlines equipment required for a PD program. Sturdy furniture should be selected to provide comfortable seating for patients and family members. Wheeled chairs should have locking wheels to prevent falls and to provide secure seating. Each training room must have a table where the patient can sit comfortably to practice dialysis procedures. Additional counter space may be available to organize dialysis supplies and equipment. These surfaces must be constructed of a material that can withstand frequent disinfection with approved cleaning solutions.

Another concern regarding the physical environment is the ability to protect the patient's privacy and confidentiality. Training rooms and clinic rooms need doors rather than just curtains. The PD nurse needs an office or private

Table 13.3 Equipment requirements for the peritoneal dialysis program

- Chairs and table top working areas
- Cabinets for supply storage
- Sinks for hand washing
- Wall-mounted soap dispensers and hand sanitizers
- Portable IV poles or ceiling-mounted hooks for solution bags
- Patient scales
- Scales for weighing dialysis solution bags
- Wall-mounted clocks
- Wall-mounted sphygmomanometer
- Automatic sphygmomanometer
- Dialysis cycler
- Device(s) to heat dialysis solutions
- Refrigerator
- Computers, printers, copy machine, fax machine
- Wheelchair

area to provide patient counseling and to make confidential phone calls. The area where medical records are stored must be able to be locked when not in use. Electronic medical records must be protected with passwords and security screen locks. Fax machines must also be located in a restricted area and a confidentiality statement must be included on the first page of all faxed transmissions that include patient information.

Policy and Procedure Development

Federal regulations mandate that each PD program have a policy and procedure manual. This manual should include all patient care procedures, written patient education materials, position descriptions, and strategies for outcome management. Table 13.4 outlines components of a policy and procedure manual. The initial effort of developing a procedure manual will be outweighed by the long-term benefits.

Policies and procedures should be evidence-based whenever possible. Several evidence-based practice guidelines have been published in recent years [24–26]. These provide detailed information describing which practices and procedures are supported by scientific data, the level of the scientific evidence, and key references. The International Society for Peritoneal Dialysis (ISPD) and national societies have also published guidelines and recommendations for clinical care [27–29]. Reviews of controlled clinical trials [30–32] and best demonstrated practices [33, 34] have also been published.

After the PD program is successfully underway, periodic review and revisions to the policies and procedures are mandated by regulatory guidelines. Typically, the policy and procedure manual is reviewed and revised annually to reflect current practice and to meet regulatory requirements; however, individual sections may require updates between annual reviews.

The medical director and PD nurse manager will also need to develop mechanisms to review clinical outcomes, and note changes in regulatory mandates, insurance parameters, and current standards of care. The review of clinical outcomes may be accomplished through weekly dialysis rounds, monthly summaries of care, an annual report of program outcomes, and the continuous quality improvement program. The clinical outcomes should be compared to regional and national benchmarks [35–39] and recently published data.

Patient and staff education materials are essential for successful home dialysis. Patient education materials are available from equipment and supply manufacturers, others have been published or are available on the internet [40, 41]. Patient education materials should be available in a variety of formats and media [42]: written and illustrated [43], audio [44] and video, “hands-on” [45], and interactive [46]. Besides unit-specific procedures and education materials, patients should be given a list of resources including websites [41]. The nursing staff will also need reference books (e.g., drug manuals, nephrology, dialysis, and nursing textbooks), current journal subscriptions and resource lists including websites.

A copy of the patient’s bill of rights should be included in the patient’s home training manual and posted in the dialysis unit. Some home dialysis units also include a list of patient responsibilities.

Table 13.4 Components of a peritoneal dialysis program policy and procedure manual

- Mission statement
- Goals and objectives
- Role descriptions for the peritoneal dialysis team members
- Description of the CKD patient education program

  - Disaster preparedness
  - Emergent and non emergent hospitalizations
- Samples of all program-specific educational materials
- Procedures for routine monitoring of quality indicators

Patient Safety

All electrical equipment in the PD unit must be checked for electrical hazards, approved for use, and routinely maintained.

Appropriate emergency equipment and medications must be available and all members of the nursing staff will need to maintain certification in cardiopulmonary resuscitation (CPR). Some institutions require that support staff also be certified in CPR. Emergency drills should take place periodically to provide the staff with education and experience in how to function in a life-threatening emergency.

To protect all patients, visitors, and staff, a unit-specific fire plan must be developed. A written fire plan should be posted and emergency contact numbers need to be in view for easy accessibility. All staff must know the location of fire alarms, fire doors, fire extinguishers, and evacuation routes. Periodic fire drills are mandatory.

Infection Control

Practices in the Peritoneal Dialysis Unit

A number of practices recommended to reduce the transmission of disease in hospitals, ambulatory care settings, and hemodialysis units are appropriate of peritoneal dialysis units [47–51]. These are summarized in Table 13.5 and discussed below.

Handwashing

Effective handwashing remains one of the most effective strategies to prevent the transmission of diseases in health care facilities. The Centers for Disease Control and Prevention (CDC) recommends handwashing after removing gloves and between patient contacts [47]. Handwashing procedures must be developed for both the dialysis unit and for the patient in the home environment. Many units promote the use of an antibacterial liquid soap in a pump dispenser in the home when many family members are using the same sink(s) for handwashing. This may prevent sharing of bacteria that might accumulate on bar soap. The current guideline for hand hygiene in healthcare settings reviews studies and provides recommendations to improve hand hygiene practices [52]. This document also summarizes recent studies related to alcohol-based hand rubs. These "waterless" disinfectants have been shown to remove microorganisms effectively and take less time than conventional handwashing [53]. Studies have shown that there is less irritation to hands [53, 54] and increased compliance with hand hygiene among healthcare workers [53, 55].

Although we found no studies specifically related to use of alcohol-based hand cleansers in peritoneal dialysis, these are being used both in the clinics and by patients and partners dialyzing at home. They could be used routinely when PD procedures call for handwashing, instead of soap and water (when hands are not visually soiled). This would eliminate the problem of increased transfer of microorganisms when hands are washed but not thoroughly dried [56]. Waterless cleansers could be also be used when the patient is connected to the cycler and may not be able to reach a sink, and whenever a continuous ambulatory peritoneal dialysis (CAPD) patient is performing procedures in a

Table 13.5 Recommendations to reduce disease transmission [47–51]

Immunizations
• Routine serologic testing for hepatitis B and C
• Vaccination for all patients susceptible for hepatitis B
• Test for anti-HBs 1–2 months after series is complete
• Retest annually and give booster immunization if necessary
Injections
• Use single-use syringes and needles
• Use single-dose medication vials or prefilled syringes whenever possible
• Perform hand hygiene before preparing and administering an injection
• Prepare injections in a designated medication room or area
• Use aseptic technique to prevent contamination of sterile equipment and medications
• Dispose of syringes and needles in an approved container at the point of use
Venipuncture
• Use barriers when drawing blood to prevent blood from contaminating surfaces
• Perform hand hygiene before donning gloves and after removing gloves
Equipment
• Handle equipment that might be contaminated with blood in a way that avoids contact with skin and mucous membranes
• Evaluate equipment and devices for the potential for cross-contamination
• Establish procedures for safe handling and effective cleaning
• Maintain physical separation between clean and contaminated equipment and supplies
Exposure to blood
• Wear gloves for procedures that might involve contact with blood
• Perform hand hygiene after inadvertent blood contamination
Other
• Clean and disinfect training and clinic rooms between patients
• Routine infection surveillance
• Infection control education

location where there is not access to running water. It is also possible that the use of waterless hand cleansers might increase compliance with handwashing by PD home patients.

Immunizations

Pneumococcal pneumonia and influenza vaccines are recommended for patients with chronic illnesses, and the hepatitis B vaccination series is recommended for patients on dialysis therapy [49]. Each dialysis unit should be prepared to provide these immunizations or refer patients to a local health department, if the immunizations are not given in the physician's practice. All immunizations must be documented in the patient's medical record, including the date of immunization, location of injection, drug lot number, and occurrence of any unusual reaction. A copy of the documentation should be given to the patient.

Dialysate Disposal

Another aspect of patient safety is the disposal of infectious waste. The procedures for disposal of peritoneal dialysis effluent will vary depending on the physical layout of the PD unit. Waste maybe disposed in a designated waste sink in the training room or in a central waste disposal area. When transferring dialysate to the central disposal area, it must be handled in a manner that prevents contact with clothing, skin, and mucous membranes. Some units use plastic bags designated for infectious waste for this purpose. The PD nurse must use standard precautions to protect him/herself and other members of the staff when emptying the dialysate bags. A face shield, gloves, and protective gown or apron should be worn when handling the dialysate. A mask might also be worn when handling dialysate from patients with known tuberculosis, as transmission has occurred from inhaling aerosolized mycobacteria [47]. The bags and tubings should be discarded in a designated hazardous waste receptacle. Spills of effluent must be cleaned with an approved bactericidal/virucidal solution.

At home, dialysis patients typically discard dialysate in the toilet or a sink. Patients who use dialysis cyclers with an open drain line should be instructed to ensure that the tip of the drain line is not submerged below the water level in the toilet or drain [47]. Procedures for dialysate disposal at home should include warnings against splashing, instructions regarding how to clean spills, and how to clean the sink or toilet used for dialysate disposal, and appropriate cleaning solutions. If a family member or someone other than the patient is disposing of the dialysate, they should use the protective garb similar to that recommended for the staff.

Quality Improvement Program

The quality improvement program provides data collection, evaluation, and outcome management for an interdisciplinary team effort [57] in promoting excellence of care. In many countries, establishing a quality improvement program is not optional, but is a regulatory requirement. All quality improvement efforts monitor and assess clinical outcomes and make changes in the processes of care with the ultimate goal of providing efficient, effective, and safe patient care, which will result in improved patient outcomes [8, 58].

Table 13.6 provides examples of outcomes that may be monitored in a quality improvement program. At a minimum, PD-related infections [27], catheter survival [59, 60], patient survival, and technique survival (proportion of patients remaining on PD therapy) should be monitored. Data may be collected and analyzed on a monthly, quarterly, or annual basis, depending on the size of the program and the frequency of the outcome. Outcomes can be compared to data from national registries and published reports [35–39]. Review of the literature, particularly abstracts from nursing and multidisciplinary meetings, and networking with other programs are helpful when initiating a quality improvement program in order to obtain ideas about data collection strategies and experiences in making timely changes to improve outcomes.

Each program needs to adopt or develop a system to routinely collect information. Designing a tool to collect the information on a monthly basis is often a simple, effective method of documenting outcomes. This may be a simple tool to manually enter the data or a computer program to collect and analyze the information. Reports can also be generated by the program's Medical Information System (MIS) of computerized patient records. The data collection may be a shared responsibility of all the team members or it may be the sole responsibility of one nurse.

Inherent in the continuous quality improvement (CQI) process is the need for several members of the interdisciplinary team to meet periodically, discuss the outcomes, analyze the contributing factors (root cause analysis), and plan strategies to improve outcomes. Typically, it is a nurse who coordinates the quality team; however, multidisciplinary participation,

Table 13.6 Outcomes for continuous quality improvement projects

- Adequacy of dialysis
- Technique survival (time on peritoneal dialysis)
- Access
  - Catheter demographics
  - Catheter survival
  - Catheter-related infections
    - Exit site infection
    - Tunnel infection
    - Peritonitis
  - Catheter complications
- PD complications
- Hospitalizations for dialysis complications
- Fluid balance and hypertension
- Nutrition
- Metabolic parameters
  - Serum albumin and protein
  - Anemia management
  - Calcium/phosphorus balance
  - Electrolytes
  - Glucose management and control
  - Secondary hyperparathyroidism
- Effectiveness of patient education program
- Psychological adjustment to PD

including that of a committed physician, is critical to its success [57]. The team process facilitates the implementation of changes required to achieve excellent outcomes and promote PD as an effective renal replacement modality.

Another component of quality assessment and improvement is to solicit feedback from the patients regarding the care they receive [1, 61]. Patient satisfaction surveys that guarantee anonymity and are returned to an address or individual separate from the home dialysis program can provide surprisingly candid feedback pointing out problems in delivery and effectiveness of care. It has been suggested that the process of care has a strong impact on retention of chronic PD patients [62], so responding to patients' concerns may improve patient retention.

CQI efforts in PD programs have resulted in increasing the number of patients who choose PD therapy [63–65], reducing infections [66–80] and amputations [81], changing procedures for home care interventions [67, 68, 72–74, 76, 80], and identifying strategies to improve dialysis adequacy [77, 82–84], fluid balance [85], nutrition [86], bone health [87, 88], and anemia [89]. The CQI effort also promotes the development of a team identity and, in some instances, may improve communication and reduce adversarial relationships.

Financial Considerations

Fiscal responsibility is important for the long-term success of the PD program. Prudent use of supplies and medications can be achieved through staff and patient education and an organized approach to inventory levels. Each program will have a unique approach to cost effectiveness based on methods of supply ordering, vendor contracts, and available storage space.

A technical assistant or secretary can be taught to participate in supply inventory, computerized billing, tabulating monthly charges, and staff payrolls, with supervision from the nurse manager. A dialysis technician can also participate in these activities and save personnel costs in large programs [19, 20].

Establishing a good working relationship with the home supply team is vital to insure that the patient has the appropriate home supplies but does not accumulate excess or outdated supplies, thus avoiding waste and expensive emergency deliveries.

The PD nurse may be supported by administrative staff in assessing PD program costs, but must take an active role in this process. Developing an internal communication process for transmitting information regarding patient training days, episodes of care, and billing for supplies and drugs is critical. Networking with the individuals who are responsible for the billing process also contributes to effective billing. Often, the nurse must educate the billing staff regarding aspects of clinical care to help them understand the often-complicated billing process for the home dialysis patient.

Table 13.7 Legal strategies to manage risk

Program is structured to comply with all state and federal regulatory requirements
Clinical care
• Consent for procedure(s) signed by patient or proxy
• Patient rights are posted and a copy given to patients
• Documentation of advance directives
• Physician orders for all treatments
• Patients and families are treated in a professional and caring manner
• Patient privacy and confidentiality are respected and documented
• All patient interactions and interventions are documented
• Patient plan of care signed by patient and team members
• Periodic review of patient's skills and knowledge and retraining if indicated
• Incident or unusual occurrence forms completed as necessary
Staff roles
• Position descriptions for all team members
• Competencies listed for each position
• Competencies are evaluated and documented for each staff member
• Team members must function within defined competencies
• Nurse should not dispense medications for home use

Cost accounting should be done by the PD nurse on a monthly basis so that the acquired revenue can be compared to the program's activities. This can include a record of clinic visits, training sessions, home visits, on-call activity, staff educational sessions, and supplies for the home patient and the dialysis unit. In some instances, the PD nurse is involved in the development of the annual budget. Insights from the budget planning process and monthly cost accounting can be very helpful in understanding the program's financial stability, and increases the nurse's investment in maximizing efficient supply ordering and effective billing [7, 17].

Legal Considerations

PD is a unique specialty within the practice of nephrology medicine and nursing. The PD nurse often functions in an autonomous role while providing quality care for the home dialysis patient. Providing legal protection of both the patient and staff must be a key part of the program's philosophy and policies [90]. The policy and procedure manual must be very specific in delineating the role of each core team member. Job descriptions need to be specific and current. The nurse must be careful not to exceed defined boundaries (e.g., in many countries, only a physician or pharmacist may dispense prescription medications) and must document patient care consistently and objectively.

The healthcare team should not hesitate to obtain professional legal advice for complicated patient situations [90]. Sources of assistance in the hospital setting or large dialysis organizations are the risk management team, designated patient advocates, and the ethics committee [91]. Table 13.7 summarizes strategies to manage legal risks in a home dialysis program.

Education of the Patient with Chronic Kidney Disease

One of the first tiers of education is that which is provided for the patient with chronic kidney disease. This takes place prior to the initiation of renal replacement therapy. The newly diagnosed patient with chronic kidney disease is faced with many life-altering changes that maybe both overwhelming and confusing. Efforts to provide excellent predialysis care include early detection, strategies to slow disease progression, prevention of uremic complications, education regarding therapy options, and the timely start of renal replacement therapy [92–100].

One key to successful predialysis management is the timely referral of the patient to a nephrology practice where a nephrologist or a nurse practitioner can individualize the patient's care and education. The newly diagnosed patient often focuses on the term *end-stage renal disease* and can become frightened and discouraged, so identification and regard for the patient's fears and anxieties must be foremost in the minds of the care providers. It is important to establish an atmosphere of trust.

Early interventions include nutritional counseling, hypertension education, and medication reviews. The patient may initially obtain the most information and education from the dietitian and the nephrology practice nurses; however, in some nephrology practices, specific education strategies and programs are in place that require participation of the PD nurse, hemodialysis nurse, social worker and transplant team. This allows the patient to meet and develop an early relationship with members of the renal replacement therapy team [1]. Other programs refer patients to predialysis education programs or dialysis education activities based exclusively in the home dialysis program [6].

Utilizing an integrated care approach to support the patient in choosing the right modality at the right time in the course of chronic kidney disease (CKD) is the responsibility of the both the nephrology and dialysis teams [101–103]. Timely education and decisions about dialysis modality also support PD, because often the CKD patient who develops uremia and starts hemodialysis emergently does not have the opportunity to then change to PD due to logistical barriers [5, 6, 104].

Providing predialysis education helps the patient understand the disease process, monitor and control hypertension, medications, strategies to preserve residual renal function, and renal replacement therapies. It should also create a supportive environment that allows the patient to ask questions and voice concerns. The patient then has the necessary information to make an informed choice of the mode of renal replacement therapy [5, 6, 101–103]. This early relationship and patient education may also help to promote adherence and the development of self-care management skills.

Renal replacement therapy options must be carefully presented without bias. All CKD patients should have the benefit of education about PD, hemodialysis, and transplant candidacy. Although PD is primarily a self-care therapy, patients who are not physically or mentally able to assume the responsibility for dialysis have done PD successfully with the assistance of family members, friends, or contracted care providers. Predialysis education can be accomplished by a variety of methods, but should be based on principles of adult education [105–110], with a chronic disease focus [111]. Individual counseling is appropriate for all patients, but group classes may also be helpful for the patient and family members, and classes utilize staff time more efficiently. For the patient who is unusually anxious, it is often helpful to provide an opportunity to meet with an established dialysis patient. The questions and information sharing are based on actual personal experience. These encounters are often rewarding and may be valuable for all prospective dialysis patients [112].

Participation in predialysis education is a valuable opportunity for the PD nurse and other PD team members. Their participation in early intervention and early education can contribute to recruitment of prospective PD patients. Key to retaining the interest of patients in PD is periodic follow-up and response to the patient's questions and concerns. The PD nurse must also communicate with the referring primary care physician and nephrologist.

Interviewing Prospective PD Patients

The interview process provides an opportunity to share information with the patient and family members about PD while establishing a relationship the prospective home dialysis patient. The interview may be part of the predialysis education program or take place later, after the patient has chosen PD. Knowledge of dialysis modalities and participation in the decision about type of renal replacement therapy promote the development of a sense of control early in the patient's dialysis experience. The patient learns to actively participate in his care. This can help to control fear, reduce anxiety and establish self-care skills. Developing this confidence may also promote adherence to the plan of care [113–115].

To prepare for the interview, the PD nurse should review the patient's medical history and prior experience with health care. Goals should be set for the interview and shared with the patient and family. Careful regard for cultural diversity and the patient's religious beliefs can aid in individualizing the process [112, 116, 117]. The patient with a language barrier must have the services of an interpreter. Whenever possible, this interpreter should not be a family member or friend so that unintentional bias or misinterpretation does not occur [116, 117].

The nurse must be competent in physical assessment, nursing diagnosis, and adult education and have good communication skills. Knowledge of chronic kidney disease management and renal replacement therapy options are also prerequisites. Utilizing this knowledge, the nurse then needs to individualize the information for each prospective patient. A successful interview will also depend on the nurse's compassion, understanding, and self-confidence [118, 119].

The physical environment is also important for a successful interview experience. The ideal setting would provide adequate lighting, a comfortable temperature, and comfortable seating for the patient and family in an environment that is free from distractions. Information should be directed to the patient with the family as the support system. The

nurse must also be a good listener and be ready to answer questions and validate the patient's fears and anxieties. The chronically ill patient will fatigue easily and the nurse must adjust the length of the interview based on the patient's tolerance. Allowing the patient to take a break and have refreshments may be helpful. Some patients may need a return appointment to complete the interview or to have time for questions and answers.

If the prospective patient has not had the opportunity to meet with a successful PD patient, this may be helpful. Asking questions of a fellow patient may not only provide information, but meeting a confident and successful PD patient may diminish stress and foster a positive approach to assuming self-responsibility [118].

Table 13.8 provides a sample outline for an initial interview. The nurse must be careful to select content that is important at the time of the interview. It may not be feasible to either obtain or offer as much information as desired, so it is important to individualize the interview. Using a written tool to collect information is recommended, and a documentation tool that follows the unit-specific interview outline can be developed.

There are additional issues related to interviewing the hospitalized patient. This patient is often sicker and under more environmental stress, and may need to make a more immediate decision about modality selection. Lack of privacy, lack of sleep, noise, and frequent interruptions can make the interview process challenging. If the PD nurse must interview the hospitalized patient, it is important to work with the hospital nursing staff to schedule an opportune time. Patients who are acutely ill and/or frankly uremic often must rely on family and significant others in making decisions, so they should be included whenever possible. The interview will need to be succinct and organized. Concise documentation of the content presented and the patient's response must be in placed in the hospital record to communicate with other healthcare providers [118].

Patients may also choose to transfer to PD later in the course of renal replacement therapy. The established hemodialysis patient may decide to switch to PD due to lifestyle issues, dissatisfaction with hemodialysis, or clinical complications of hemodialysis. The patient with recurrent problems with vascular access may need to change to PD in order to survive. Also the patient with a failed transplant may choose to resume dialysis as a home PD patient.

Table 13.8 Interview outline for prospective peritoneal dialysis patients

Patient information

- Employed/student/retired/disabled
- Family and community support
- Hobbies/interests
- Access to transportation
- Travel

Assessment of language and education

- Language
- Level of formal education
- Reading level
- Previous chronic kidney disease education

Review of health status

- Primary diagnosis
- Co-morbidities
- Prior experience with renal replacement therapies
- Prior experience with self-care

Assessment of physical limitations

- Sight
- Hearing
- Impaired ambulation
- Tactile impairment
- Hand strength
- Limitations in activities of daily living

Assessment of home environment

- Type of home; utilities
- Other individuals sharing home
- Appropriate area for dialysis procedures
- Space for supply storage
- Pets in household

PD Access

Effective management of the PD access is essential for successful PD. This includes catheter selection, preoperative, perioperative, and postoperative routines, chronic catheter care, and analysis of outcomes. The PD nurse will need to fulfill the roles of educator, coordinator and evaluator in establishing a PD access program with positive catheter outcomes [120, 121].

The first step is to identify and communicate with the team members who participate in access management. This includes the nephrologists, surgeons, operating room staff, recovery room staff, and the hospital unit staff. It may also include the interventional radiology staff and individuals who purchase supplies. The PD nurse may need to meet with each member individually or in small groups to achieve a collaborative approach to access management. Follow-up may be done by telephone and email. In some programs, an access coordinator or nurse may be designated to manage the scheduling of both hemodialysis vascular access and PD catheter placement and interventional procedures.

The group must choose the catheter(s) that will be utilized by the program. There is a variety of catheters to choose from: single or double cuffed, straight or coiled, presternal, and catheters with or without a swan neck configuration [122–124]. Implantation techniques vary and may include surgical dissection, laparoscopic placement, and burying the external segment for future externalization of the catheter [123, 125, 126]. The choices should be based on research of the available catheters, the current data in the literature, and the surgeon(s)' and program's experience.

The nephrologist or nurse practitioner will make the initial referral for PD and catheter placement, and will be responsible for the short- and long-term management of the patient's care. The surgeon will evaluate the patient for catheter placement, implant the catheter, and provide surgical follow-up. In some programs, the surgeon may also be involved in long-term outcome management by reviewing catheter outcomes data or participating in quality meetings. If catheters are routinely placed in an interventional radiology setting, the radiologist or interventional nephrologist would be part of the quality team.

Table 13.9 PD catheter management routines [60, 121, 122, 124, 127–130]

Preoperative routine

- Patient selects peritoneal dialysis as renal replacement therapy
- Patient referred by nephrologist for catheter placement
- Peritoneal dialysis nurse educates patient and family about catheter placement routines and initial catheter care
- Patient is evaluated by surgeon; catheter exit site evaluated in both upright and supine positions
- Proposed catheter insertion and exit sites are marked
- Culture nares (if done at this unit)
- Consent for procedure is obtained
- Bowel , bladder, and skin preparation
- Patient reports to either hospital pre operative admission area, to transient outpatient area or other designated location on day of catheter placement

Perioperative routine

- If catheter is placed by surgical dissection or by laparoscopy, the patient will be cared for by the operating room team during the procedure
- Antibiotics are given before the start of the procedure
- Catheter patency is tested by infusing and draining
- Catheter is capped or appropriate tubing or transfer set is attached
- Dressings are applied to incision site and exit site per program protocol
- Catheter is secured to prevent traction at the exit site
- Surgeon will recommend when the catheter can be first used for dialysis exchanges

Postoperative routine

- Patient will be monitored either in a recovery room or in a transient care setting
- Pain control is provided
- Surgeon will determine if patient may return home or will be admitted for overnight observation
- Peritoneal dialysis nurse may flush catheter either in the hospital or transient care setting or arrange for clinic follow-up in 24 to 48 h
- Initial dressing per program policy may be removed either by surgeon, peritoneal dialysis nurse, or designee
- Prophylactic antibiotics (systemic and/or local) continued per unit protocol
- Patient is provided with written instructions for catheter care, bowel regimen, pain medication prescription, and follow-up appointment
- Emergency telephone numbers are provided and reviewed
- Follow-up appointments are arranged with the peritoneal dialysis outpatient program

Table 13.10 Components of catheter evaluation at routine clinic visits

- Inspect catheter and adaptor for cracks, splitting and leaks
- Inspect catheter exit site for dialysate leak and signs of exit site infection
- Inspect the abdominal wall for evidence of subcutaneous leak and hernias
- Monitor the flow of effluent during infusion and drain
- Monitor effluent for color, clarity, and the presence of fibrin
- Observe the patient for unusual pain or discomfort
- Periodic review of home exit site care procedures

The PD team needs to identify the responsibilities of each unit or staff member (e.g., the operating room nurses often participate in testing catheter patency, capping the catheter, and placing the surgical dressings), develop written protocols for catheter care procedures, provide initial staff education, and identify resources for these care providers. Outlines of preoperative, perioperative, and postoperative routines are listed in Table 13.9 [60, 121, 122, 124, 127–130].

Each program must develop specific procedures for maintaining catheter patency, including nonheparin alternatives. There must also be protocols for catheter obstruction [131], daily exit site care, and strategies to prevent infection. Also, effective procedures for catheter "break-in" help to maintain patency, facilitate wound healing, and prevent early leaks [132].

Long-term management of PD catheters is a crucial to insuring the patient's longevity on PD. Early identification of catheter complications [133] and catheter-related infections and prompt intervention are critical to catheter survival. All team members must agree on and follow exit site procedures so that the patient has the benefit of consistent care. A routine catheter and exit site assessment should be part of each clinic visit and hospital admission. Table 13.10 summarizes elements of catheter assessment. Catheter-related queries can also be incorporated when assessing the PD patient by phone.

A quality program for PD catheter outcomes helps to insure consistent monitoring and evaluation of access management. The nurse acting as a facilitator can utilize the documentation from routine catheter and exit site assessments to effectively track catheter-related problems and infections.

The PD nurse must also monitor the literature for evidence-based practices for exit site and catheter care and benchmarks for catheter outcomes [24, 59, 60].

PD Patient Education and Training for Home Dialysis

The foundation of a successful PD program is the provision of effective home dialysis training [134–137]. PD nurses often do not have formal training in education theories, methods, and strategies [138–141]. To successfully develop a program and successfully teach patients, the nurse must acquire this knowledge and related skills. Attending a formal education course or seminars, networking with colleagues, and developing a relationship with a mentor can prove to be excellent sources of information [139]. Each nurse must then take responsibility to periodically enrich his/her knowledge of the adult learning principles. Regional or national conferences offer opportunities for learning, networking, and informal sharing of experiences. An important investment for any dialysis unit is the purchase of adult education texts and resources [105–110]. Also, nephrology nursing textbooks include chapters on patient education [142, 143].

Although there may be generic learning objectives (Table 13.11) and a recommended list of content (Table 13.12), the educational program for each patient must be individualized. The cultural and religious background of the patient must be regarded when individualizing the patient education plan [116, 144, 145]. Patients who speak a different language should have the benefit of an interpreter who can translate the information in an unbiased manner. Utilizing an interpreter will lengthen the training sessions or increase the number of sessions. In general, the length of the training session is determined by the patient's degree of uremic symptoms, endurance, and attention span. Transportation requirements may also affect the scheduling and length of the session.

The patient and family must be included in scheduling sessions, deciding who will attend with the patient and arranging transportation. The patient should be the focus of each patient education session with the family member(s) providing support. When family members are training as dialysis partners or to provide back-up support, they will almost always have mastered the content by the time the CKD patient has; however, they will need to practice the procedures. Documentation should include verification that each individual who will be performing dialysis procedures has participated in the training and identify which procedures they can safely perform.

Table 13.11 Objectives for the peritoneal dialysis instructor

The PD instructor will:

- Provide an environment for effective learning
- Present an overview of the PD course
- Prepare learners for what they will learn and how both the learner and instructor will know that learning has occurred
- Apply concepts of adult learning
- Restrict educational content to three or four messages per hour
- Use pairs to help learners differentiate between symptoms and concepts
- Help the learner problem solve by defining problems and listing possible solutions
- Recognize the learner's need to repeat new information in order to move it from short- to long-term memory
- Recognize that repetition is an important method of reinforcing learning
- Recognize that information memorized is easiest to forget
- Use questions to evaluate the learning process and guide the learner
- Evaluate the effectiveness of learning by tracking outcomes
- Understand that retraining or additional education may be required over time

In teaching procedures the instructor will:

- Understand the difference between learning motor skills and procedures
- Not teach theory during motor skill learning
- Demonstrate steps of procedures with consistency
- Prevent the learner from practicing procedures until all steps have been learned in order
- Supervise the practice of procedures until all steps have been mastered
- Encourage and support the learner through repetition and verbal clues
- Provide immediate feedback during practice

Source: Adapted from [138] with permission.

Table 13.12 Suggested content for the PD home training education program

- Review of normal kidney function
- How peritoneal dialysis works
- Principles of aseptic technique
- Preparation of home environment for peritoneal dialysis
- Handwashing technique
- Utilization of waterless hand sanitizer
- Preparation of exchange area
- Organization of supplies
- How to do CAPD exchange
- Problem solving with exchange procedure
- How to set up and program automatic cycler
- Problem solving with cycler/APD procedures
- Addition of medications to PD solution bags
- Warming of dialysis solutions
- Appropriate use of face mask
- Documentation on home record sheets
- Monitoring of weight, blood pressure, and heart rate
- Principles of fluid balance
- Recognition of hypovolemia and hypervolemia
- Guidelines for managing fluid balance
- Exit site care
  - Routine exit site care
  - Use of antibiotic cream/ointment at exit site
  - Recognition of signs/symptoms of exit site infection
  - Care of the infected exit site
- Methods of securing catheter
- Recognitions of signs/symptoms of peritonitis
- Specific instructions related to PD complications:
  - Obstruction to flow of dialysis solutions
  - Change in dialysate color

Table 13.12 (continued)

- Fibrin formation
- Utilization of heparin or non heparin alternatives
- Accidental disconnections
- Traumatic injury to catheter or exit site
- Reporting falls or accidents with suspected abdominal trauma

- Guidelines for utilization of different dextrose concentrations
- Development of individualized daily dialysis prescription
- Daily hygiene routine including showering and frequent handwashing
- Review of medications
- Sexuality and reproductive concerns
- How to contact nephrologist and peritoneal dialysis nurse
- Seeking emergency assistance
- Description of elective or emergent hospitalizations
- PET and adequacy monitoring procedures
- Storage and ordering of supplies
- Review of travel procedures
- Outline of follow-up appointments

The PD unit is typically the site for training; however, in special circumstances, the training may occur in a hospital, rehabilitation setting, or even in the patient's home [146–148]. A few programs have routinely trained patients in their homes; others have limited training in the home to patients with special needs. The patient who is unusually anxious, disabled, or dependent on others for care may benefit from exclusive training in the home [149]. Patient education outside of the dialysis unit typically requires more nursing time, so is costly [149]. Regardless of the site, it is essential to maintain a quiet environment with few interruptions.

Patients may be taught in a small group for at least part of their training. There is no evidence that this method is more or less effective than individual teaching sessions. Some patients find group training supportive; however, others find it too distracting.

Sample content for a PD education program is listed in Table 13.12. This is not all-inclusive, but provides a basic framework. The PD nurse will need to individualize the content for each patient and determine what should be accomplished in each session. Clear, consistent instructions are particularly important when teaching procedures and may foster patient adherence.

The number of training sessions will vary depending on the patient's learning needs and ability to learn; however, the number of patient education days or sessions may be limited by the reimbursement structure, and the nurse must be aware of the financial implications. One study found that older patients and those with more co-morbidity required more training sessions [150].

Patient education needs to be well-documented [151]. Although checklists are useful tools during the patient education process, most regulatory agencies do not consider a checklist alone to provide adequate documentation. A written narrative indicating not only what topics have been covered, but the patient's response may be required. This might include a description of the patient's ability to grasp concepts, remember sequences, perform procedures, and problem solve. Written quizzes or tests may be included as documentation of learning [152].

The patient preparing for home dialysis should also have sessions with both the dietitian and social worker. The dietitian will perform an initial assessment, outline both short- and long-term plans for adequate nutritional intake, and teach the patient and family about the dietary recommendations. Dietary counseling will need to be provided on a regular basis to help the patient maintain an adequate protein intake, control total caloric intake, and avoid excessive intake of phosphorus, sodium, and potassium [7, 153].

The social worker also performs an initial assessment and may assist the patient with community resources, billing issues, supplemental insurance, housing, and transportation issues [154]. The social worker may also help the patient to cope with CKD and dialysis therapy by discussing the patient's fears, anxieties, coping strategies, and support systems. Unusually anxious patients and those with mental health diagnoses will need more intensive psychosocial or psychiatric support during the initial training period or even throughout the course of home dialysis.

The learning process continues after the patient is dialyzing successfully at home [155]; therefore, patient education is never completed, but is a continual process of reinforcement and evaluation of the patient's adaptation and changing learning needs. Some programs have a formal continuing education program, which provides a review and updates for established home dialysis patients [156]. Others have a monthly education topic that is presented at routine clinic visits. Still others provide information on clinic bulletin boards or in newsletters.

Home Visits

Visiting PD patients in their homes may be done at the time the patient completes home training, after the patient is established at home, when dialysis-related problems occur (e.g., repeated infections, problems with fluid balance), or for follow-up of ongoing problems [157–159]. In some programs the home visit is an essential step in initiating PD at home. When the initial home visit is made at the completion of home training or shortly thereafter, it gives the nurse another chance to evaluation evaluate what the patient has learned and the readiness of the patient and family to assume the responsibility for home dialysis.

If necessary, additional education can be provided during the home visit. The home visit provides a critical opportunity to evaluate the patient's environment: where PD will take place, how supplies are stored, facilities for showering or bathing and handwashing, and the safety of the physical environment. The nurse can also observe the patient performing dialysis procedures and interacting with family members and others. Also, in the safety of his or her home, the patient may voice concerns, anxieties, or questions that were not discussed in the dialysis unit. Table 13.13 is a sample checklist for documentation of home visit activities and assessments.

Reinforcement of previous training and additional training of family members may also be accomplished at this visit. Other home health providers may also want to be included at this visit not only to acquire education but also to network with the home PD nurse.

The home visit can enhance the relationship between the nurse and patient, fostering a mutual respect. In response to a patient satisfaction questionnaire, both patients and caregivers responded that they valued home visits [160].

Table 13.13 Home visit assessments and documentation

Physical environment:
____home _____apartment _____nursing home
____shelter _____other
Bathroom facility _____private _____shared

Inspection of environment:

- Cleanliness _____hand soap/sanitizer available
  _____sink/water for hand washing
  _____overall cleanliness of home
- Supplies _____safely stored
  _____missing supplies
  _____inventory list
  _____appropriate quantity
- Medications _____safely stored
  _____refrigerated if needed
  _____location of syringes

Pets

- Type and number of pets
- Are pets restricted from the exchange area?

Designated area for exchanges:

- Are supplies organized for this area?
- Can patient safely do the exchange?
- Can the patient perform handwashing in this area?

Family involvement:

- Who are the significant others in the home setting?
- Are there small children in the home?
- Which family members participate in PD?
- If patient not able to do self-dialysis, who is the dialysis caregiver?
- Does the patient have a health care/medical proxy?
- Who is the emergency contact?

Note date of next supply order and delivery

Schedule follow-up appointments

The limitations of the home visit must be addressed as well. Home visits are time consuming and costly. There may be neighborhoods and physical environments that are not safe for visiting care providers. Also, patients may decline to participate in this activity.

The home visit may need to be repeated if the nurse suspects changes in the home environment that may contribute to increased incidence of infections, patterns of nonadherence, or changes in the family support system.

Observations of the home environment must all be documented in the patient's medical record [157–159]. A documentation tool that follows the unit-specific home visit outline could be developed (Table 13.13).

Long-Term Management

After training has been completed and home dialysis has successfully been initiated, there must be an organized approach to providing long-term nursing care. This includes routine clinic visits, additional visits for problems, telephone follow-up, periodic retraining, and coordination of care with other providers. Table 13.14 summarizes elements of follow-up care for home dialysis patients.

Routine Clinic Visits

Routine clinic visits (e.g., at monthly intervals) provide an opportunity for the team to evaluate the patient's clinical status and adjustment to home dialysis. Ideally, the patient is seen by the PD nurse and the nephrologist together; however, in some programs, the visit with the nephrologist takes place at a separate location. Also, the social worker and dietitian see the patient during clinic visits, either routinely, at intervals as indicated by regulations, or when there is a need or patient request. Elements of the clinic visit are summarized in Table 13.15, and include a physical assessment, review of the current dialysis regimen and medication prescriptions, evaluation of adherence, answering patient questions, providing encouragement and support to the patient and family, and outlining changes in interventions to improve care. All prescription changes and recommended interventions should be documented in the patient's medical record, and the patient should receive a written copy of the team's recommendations [105, 112, 161].

Detecting nonadherence to the plan of care in the home peritoneal dialysis setting is a complex process [113]. The patient is not routinely assessed or observed in the home environment. Unexplained clinical changes in serum chemistries, hemodynamic instability, signs and symptoms of uremia, repetitive infections, and frequent appointment cancellations may be indicators of nonadherence.

Compliance with home peritoneal dialysis has been studied by repeated inventories of home dialysis supplies [162, 163] and by reviewing treatment data recorded by dialysis cycler software [164, 165]. The studies that inventoried home dialysis supplies, one in the United States [162] and one in Brazil [163], found similar rates of compliance with dialysis exchanges: 74 and 70%, respectively. The U.S. study found that noncompliant patients had significantly more peritonitis and hospital admissions, significantly lower weekly Kt/Vs, and were significantly more likely to transfer to hemodialysis [162]. The Brazilian study also found that noncompliant patients had lower weekly Kt/Vs; however, the peritonitis rates were similar between compliant and noncompliant patients [163]. The studies of compliance as recorded by cycler software show relatively few missed treatments, but also measured compliance by the volume of dialysis solution delivered [165] and the total dialysis time [164]. One of these studies found that patient education improved compliance [165]; however, compliance may also have improved in this group because they knew compliance was being monitored.

Establishing a realistic home dialysis regimen that reflects the patient's culture, lifestyle, and psychosocial needs, and providing individualized support may also enhance adherence to the dialysis prescription. This continuum of education and support is essential to foster adherence, not only to the dialysis regimen, but to medications, and to diet and fluid restrictions. Finally, promoting patient adherence to the plan of care is the responsibility of all participating healthcare providers.

The patient who has difficulty adhering to the plan of care or who is experiencing clinical complications may benefit from more frequent visits. One group found that when patients were included in the discussion regarding dialysis prescriptions, they were more adherent to dietary salt and fluid restrictions and had better fluid balance [166].

13.14 Nursing care activities for PD home patients

Establish care plan including nursing diagnoses and associated short- and long-term goals

- Care plan is updated quarterly by the peritoneal dialysis nurse, nephrologist, social worker, and dietitian.
- Document follow-up of home dialysis patient in the clinic visit and telephone consultation notes.
- Recently hospitalized patients will have a discharge summary of care in the medical record coupled with a plan to resume home dialysis care.

Clinical management parameters for home peritoneal dialysis care include

- Hemodynamic stability
  - Assess fluid and electrolyte balance
  - Monitor blood pressure and review blood pressure control
  - Review antihypertensive medications
  - Adjust dialysis regimen as necessary
- Anemia therapy
  - Therapy with erythrocyte stimulating agents (ESAs) is initiated and monitored with appropriate patient education
  - Oral iron supplements and intravenous iron therapy, as indicated
  - Obtain and monitor associated laboratory tests
  - Obtain appropriate insurance authorizations
- Calcium and phosphorus balance; secondary hyperparathyroidism
  - Coordinate nutritional counseling
  - Monitor and adjust phosphorus binders and should be vitamin D therapy
  - Obtain and monitor associated laboratory tests
- Nutrition counseling
  - Coordinate periodic nutritional counseling for patient and family
  - Nursing support for the individualized nutritional plan
  - Refer for resources for nutritional supplements, if needed
  - Obtain and monitor associated laboratory tests
- Catheter management
  - Assess catheter and exit site
  - Review procedures for exit site care
  - Local care interventions when indicated
  - Prescribe/provide antibiotics, when necessary
  - Monitor catheter function
- Home peritoneal dialysis management
  - Monitor patient (and partner's) adjustment to self-care and home dialysis
  - Measure adequacy of dialysis per program policy
  - Explain laboratory and adequacy of dialysis test results to patient
  - Explain need for prescription changes and new dialysis orders
  - Provide option of home visit, if indicated
  - Provide periodic retraining, if indicated
- Development of patient competence and self-responsibility
  - Use team problem solving approach
  - Incorporate patient into decision making
  - Provide time for patient to discuss individual issues with team
  - Individualize patient care and support
  - Offer patient positive feedback on a routine basis
  - Evaluate patient adherence and strategies for accountability
  - Refer for psychological or psychiatric support when indicated
- Transplant evaluation
  - Support transplant education
  - Encourage/refer for transplant evaluation
  - Obtain blood samples for routine screening
  - Encourage patient-to-patient networking
  - Support development of self-care management behaviors
  - Document patient's adherence to self-care management

Table 13.15 Components of clinic visit assessment

Review current dialysis prescription and routine
Reinforce any changes in dialysis prescription
Inspect and evaluation catheter and exit site
Vital signs (including supine and upright blood pressure measurements), and weight
Assess fluid balance
Review prescribed and over-the-counter medications
Assessments including: • Cardiovascular system • Pulmonary system • Gastrointestinal system • Central nervous system • Skin integrity • Mobility/physical limitations • Social support system • Psychological adjustment • Any infections and treatment
Review patient's home records • Dialysis • Fluid balance • Blood glucose control
Review laboratory results
Query regarding any hospitalizations and results of visits to other healthcare providers since last clinic visit
Update nursing diagnoses and care plan as indicated
Schedule follow-up appointment(s)

Communication Between Visits

An important part of follow-up management is communicating with the patient between visits, by telephone, mail, or email. Some programs specify an interval for routine telephone calls for established PD patients (e.g., weekly or once between clinic visits). The frequency and length of these communications also depend on individual circumstances. More frequent communication and more intensive support are required for new PD patients. Communication between clinic visits may also be indicated when a patient has several co-morbid conditions or is acutely ill, when there are problems with adherence to the dialysis routine, and when there are laboratory results that require adjustments in medications or dialysis prescription. Telephone conversations also provide time for the nurse answer questions, provide instructions (e.g., for adequacy collections), and clarify future appointments. Communications between clinic visits a can strengthen the bond between nurse and patient and may help to prevent patient isolation and burnout.

The health assessment and plan of care need to be periodically updated. In some programs or states, monthly or quarterly care plans are mandated.

It is important to engender an atmosphere of trust and security. Developing a supportive environment encourages patients to be honest and open in their communications, to give accurate information about self-care activities, and to voice their questions and fears. Using several avenues of communication with both patients and families encourages active participation. Individual discussion, group meetings, follow-up phone calls, letters, posters, handouts, newsletters, and email are all effective methods of communication.

Retraining

Annual or more frequent retraining sessions are used to reinforce correct dialysis procedures and technique or to introduce new dialysis systems or procedures. Annual retraining can be incorporated into a monthly clinic visit or can be done with a group of patients in classes or a day-long PD patient education seminar. Topics that are frequently covered include review of dialysis procedures, introduction of a new system for CAPD exchanges or a new cycling device, addition of medications to the dialysis solution, strategies to prevent infection, maintaining good fluid balance, recognition of signs and symptoms of infection, basic problem solving, exit site and catheter care, and assessment of the

catheter exit site. Time can also be designated to review how to contact the PD nurse and/or nephrologist for questions, problems, or emergencies, and how to prepare for an elective or emergent hospitalization. Obviously, this list is not all inclusive, but it addresses elements that are critical to safe and effective home dialysis. If a retraining visit is scheduled to address a specific problem, the objectives and strategies for the retraining session will have to be individualized.

Methods of retraining include formal and informal presentations, written handouts, demonstrations, skits, and videos. Methods of assessment include verbal review, quizzes or having the patient fill out a written questionnaire [103, 105, 138, 167]. It is also critical to allow sufficient time for patient and family questions. If the review is done as a class or education day, there should be time for patients to meet and talk with one another. Also, a patient or patients may participate in the presentations. Patients can share helpful hints and strategies for long-term success on home dialysis [168]. As with other types of follow-up care, retraining can contribute to enhanced adherence, and help to prevent burnout.

This time also provides an opportunity to ask the patient and family for suggestions regarding improvement of services and the plan of care. The patient who experiences frequent infections or is having difficulty adhering to home procedures may need frequent retraining that should be focused on the individual patient needs.

Providing On-Call Coverage

In many programs the PD nurse provides "on-call" coverage. Providing this coverage reduces unnecessary emergency department visits and hospitalization admissions, and ensures a channel of communication for the patient on a 24-h basis. This support service is both emotionally reassuring and clinically correct for the home PD patient.

Depending on the particular program's policies, the "on-call" role may vary. The nurse may provide telephone consultation on a 24-h basis to answer patient's questions, assist with problem solving, and offer clinical direction and support. In other situations the nurse is also the provider who triages the patient's care by directing the patient to a physician or emergency department for appropriate care. The most common problem necessitating emergency department visits is peritonitis [169]. In some programs, for a dialysis-related complication such as peritonitis, the PD nurse may also meet the patient at the emergency department to facilitate care.

Other healthcare providers who may be involved in "on-call" coverage include nephrologists, clinical nephrology fellows, interns, and residents. Nurse practitioners and hemodialysis nurses may provide on-call services to PD patients. Standing medical orders and specific policies and protocols to manage clinical problems help to ensure that the care provided is safe and appropriate.

The Hospitalized PD Patient

The role of the home PD nurse in providing care or consultation for the hospitalized patient will vary with each program [170, 171]. The PD program that is either hospital based or hospital affiliated may routinely require direct involvement of the PD nurse. The outpatient PD nurse may provide periodic inservice education for hospital nurses and be responsible for written protocols and guidelines. The PD nurse would be available to direct clinical care of the PD patient in both acute and non acute care units. In other programs, the PD nurse may perform CAPD procedures or set up the cycler and initiate PD. Communication and consistency are vital when providing the direction necessary for safe patient care.

The PD nurse who is not involved in hospital consultation can still participate in providing support for the hospitalized patient. Educating the patient about how to prepare for an elective hospitalization can be incorporated into the initial training for home dialysis. Providing written transfer information for the hospital unit can be critical in assisting the hospital staff to safely provide PD (Table 13.16) [170]. Telephone calls to the patient's hospital unit and primary nurse can be a successful method of clinical support.

Anticipating the patient's needs for an elective admission is another nursing responsibility. Preparing the patient and family for the routine of hospital care can diminish the stress associated with any hospital admission.

When the patient is admitted to a hospital that is not affiliated with a PD program, discussing the patient's dialysis-related needs with the hospital's admitting service and the department of nursing can only help to make the experience safer.

Common issues the PD nurse encounters during hospitalizations are the need for appropriate supplies, identifying who will be responsible for the dialysis exchanges, problem solving with exchanges, prevention of infection, identification of dialysis-related complications, and documentation of the patient's dialysis routine and clinical outcomes. The

Table 13.16 Hospital transfer information for the PD patient

Pertinent medical history/reason for admission
Medication allergies
Other allergies, e.g., latex
Medication list
Peritoneal dialysis
○ Description of any dialysis-related problems
○ Type of catheter
○ Most recent exit site assessment
○ Membrane classification, e.g., PET results
○ Current dialysis prescription
○ Type of PD system or cycler used at home
○ Whether patient requires a partner to do dialysis
○ Most recent dialysis adequacy results
○ Target weight
○ Blood pressure range
○ Specific issues related to home dialysis that may affect discharge

PD nurse may also assist the staff nurses with accurate documentation of fluid balance, the infusion and draining of exchanges and consistent daily weights. Hospital nurses who are inexperienced with PD and CKD particularly need the support of the home PD nurse.

Often, attending physicians or hospitalist physicians are not familiar with the patient's dialysis routine and prescription. Providing a checklist or sample dialysis prescriptions can often improve the appropriateness of the dialysis prescription and diminish the anxiety of the physician who is not familiar with PD. A sample checklist of components of the PD prescription for the hospitalized patient is shown in Table 13.17.

Discharge planning needs to be coordinated between the hospital staff and the PD nurse. The discharge summary of care must be provided to the home dialysis program so that home care can be resumed safely. The list of discharge medications needs to be reviewed carefully by the PD nurse for new medications, intentional changes to the dialysis orders and accidental omissions.

The PD nurse should educate the patient to always call the home dialysis program the day before (or the day of) discharge to arrange for the next outpatient appointment, clarify the current home dialysis prescription, and determine if any additional supplies need to be ordered . In some instances, a visiting nurse may be utilized for nondialysis support. The visiting nurse may not be familiar with PD and may need education about the patient's home dialysis responsibilities.

PD in Long-Term Care Facilities

After a hospitalization or due to other clinical and psychosocial circumstances, the PD patient may not be able to perform home dialysis unassisted. The patient may then need either short-term or long-term care in order to continue PD safely and consistently. Or a rehabilitation facility may provide a bridge before to discharge to the home. If the patient requires rehabilitation, the PD nurse will need to network with the hospital case manager and staff of the rehabilitation facility to ensure that the rehabilitation staff can perform dialysis safely. The rehabilitation nursing staff will need educational programs, written procedures, and protocols to provide PD care and contact information for the PD unit or primary nurse. Weekly or more frequent communication with the rehabilitation facility will provide an opportunity to follow the patient's clinical course and also to consult with the facility staff regarding the PD. Consistent communication is a key to provision of safe dialysis in a rehabilitation facility and also fosters successful discharge planning and transition back to self-care at home.

PD can be provided in the long-term care facility or nursing home as well [172, 173]. The patient may be admitted for a short-term transitional period after hospitalization or may need long-term care. Prior to the patient's admission to the nursing home, the nurse may do preliminary visit to the facility to meet the nursing director, schedule PD education classes for the staff, and to assess the environment for cleanliness and room for supply storage. The nurse will need to provide educational programs, written protocols, and procedures. Specific physician orders for dialysis must be provided and periodically reviewed. Finally, depending upon the state or federal policies and the payers, the administrators of the PD program and the nursing home must develop a written financial contract and clarify billing procedures.

Table 13.17 Dialysis prescription checklist for the hospitalized PD patient

Fill volume

- 500–1,000 mL (new catheter, initial therapy)
- 2,000–3,000 mL (maintenance therapy)
- 3,500 mL or greater (for unusual circumstances)

Exchanges

- Frequency will depend on PET results
- CAPD: 4–5 exchanges per 24 h
- APD: 5–8 exchanges per 24 h (combination of APD cycles, last fill, daytime exchanges)

Dextrose concentration

- 1.5%
- 2.5%
- 4.25%

Icodextrin 7.5% (used for selected patients)

- CAPD: overnight exchange or longest dwell
- APD: longest daytime dwell
- Glucose monitor per manufacturer's recommended list

Heparin

- CAPD: 1,000–2,000 units per 2- or 2.5-L bag
- APD: 2,000–3,000 units per 5- or 6-L bag
- For heparin allergy, heparin alternatives, or tissue plasminogen activator (tPA)

Chronic exit site care

- Daily inspection of site for erythema, exudate, leakage
- Daily cleansing of site
- Application of antibiotic ointments to site if indicated
- Catheter must be secured firmly with tape
- Culture exudate for suspected infection

Antibiotics

- Per current ISPD recommendations and guidelines available at www.ispd.org
- Route may be either intravenous or intraperitoneal
- Dosing may be in each solution bag or in the longest daily dwell

Insulin

- Either subcutaneous or intraperitoneal
- IP should be added immediately before exchange
- Monitor serum blood glucose

Potassium

- Safest route is oral
- May be added to intravenous solutions
- May be added to dialysis solution bag, if necessary

Specimens for suspected peritonitis

- Cell count
- Culture and sensitivity
- Gram stain
- Fungal culture

The monthly clinic visit may be accomplished by transporting the patient to the PD unit or in some situations the PD nurse and nephrologist may elect to visit the patient in the nursing home. This allows for evaluation of the patient's clinical needs and also provides an opportunity to observe the nursing home setting. Care provided by the PD nursing staff must be carefully documented in the patient's medical record in the PD program on a consistent basis.

The PD nurse should also communicate with the family about their perception of the nursing home's ability to safely manage their family member's care.

Modality Transfers

Hemodialysis patients may decide to change their dialysis modality to PD. Unfortunately many patients begin hemodialysis before they are informed about renal replacement options. Some of these patients decide to change modalities when better informed [174, 175]. A hemodialysis patient may also select PD to assume more responsibility for self-care. Hemodialysis patients with vascular access complications may switch to PD due to lack of available access. Often, these patients may have had many attempts to create a vascular access, and a long history of access complications, infections, and hospitalizations. These patients may not have initially selected PD because of reluctance to manage self-care, but now must depend on PD to survive. Such patients are often discouraged, anxious, and without residual renal function. Managing these patients presents a distinct challenge to the entire PD team. Because they have minimal or no residual renal function and often have a history of infection and chronic inflammation, they must be followed closely.

The patient who has a failed kidney transplant may select PD as the modality of choice. This patient may have experienced a very difficult clinical course of rejection episodes, infection, and hospitalizations compounded by disappointment and depression. This patient will also be a challenge to the team due to both the emotional experience of transplant loss and the effects of chronic immunosuppression. The PD nurse will need to pay particularly careful attention to educating the patient about infection prevention.

Assessment and Classification of the Peritoneal Membrane

The policies of the program should include a specific plan for obtaining the first assessment of the dialysis membrane. This will provide information about the patient's individual membrane characteristics that will allow for accurate prescription planning. Recommended assessments include the peritoneal equilibration test (PET), standard peritoneal permeability analysis (SPA), and the peritoneal dialysis capacity test (PDC) [26]. This section focuses on the PET, as it is most widely used. The standardized PET consists of a single 4-h exchange with dialysate samples at 0, 2, and 4 h and a blood sample at 2 h [176–178]. Abbreviated procedures have also been described [179, 180].

It is recommended that the initial PET be scheduled at least 4 weeks after catheter placement and the start of PD. The PD nurse must provide the patient with both verbal and written instructions outlining how to prepare for the test. As the day for the test approaches, it is suggested that the nurse call the patient to review the instructions. On the day of the test, if the nurse suspects that the patient has not complied with the instructions, the PET should then be rescheduled in order to prevent erroneous data and subsequent conclusions. Detailed descriptions of the PET procedure have been previously published [181, 182]. Common errors include inadequate drainage of the prior long-dwell exchange or of the PET exchange; inadequate mixing of dialysate; samples not drawn at the appropriate times; dialysate samples are mixed up and incorrectly labeled; or the final sample is diluted with fresh dialysis solution. If there are problems with the PET or results that are not consistent with the clinical picture, the evaluation can be repeated in the clinic. Each sample should be labeled when drawn (errors can occur with prelabeled tubes), and all samples should be run at the same time.

Indications for repeating the PET are unexplained clinical changes, suspected nonadherence with dialysis, suspected changes in the peritoneal membrane or membrane failure, or if there is an apparent change in membrane function due to infections or surgical procedures. Some programs may choose to repeat the PET at standard intervals, but there is no conclusive evidence that this is necessary.

PD Adequacy

Provision of adequate dialysis is part of the foundation to achieving a successful PD program. The PD program must have policies and procedures to direct an organized approach to the assessment of dialysis adequacy, and to intervene with appropriate dialysis prescription adjustments. Typically, the PD nurse and the medical director collaborate to develop dialysis adequacy policies, procedures, and data collection tools. Careful review of the current evidence-based practice guidelines [24–26] is necessary to determine the standard of practice and set the program's adequacy goals. In some countries, regulatory agencies mandate evaluation of dialysis adequacy at specified intervals to insure the delivery of safe patient care.

Differentiating between the concepts of adequate dialysis and optimal dialysis is important when establishing program policies. Adequate dialysis is defined as the dose of dialysis associated with an acceptable morbidity and mortality. Optimal dialysis is defined as the dose of dialysis associated with no further improvement in symptoms and survival [183, 184].

One typical practice is to schedule the first adequacy testing with the initial PET. An alternate approach is to perform both the first PET and initial adequacy testing during training. Adequacy testing may be repeated according to practice guideline recommendations or specific program policy. Clinical reasons for repeating adequacy testing include diminished residual renal function, symptoms of uremia, evaluation of patient adherence to dialysis prescription, and validation of the effectiveness of major prescription changes [26, 178, 185–188].

Dialysis adequacy testing should always be accompanied by a careful clinical assessment of the patient. An individual who is adequately dialyzed will look well, be free of uremic symptoms, maintain appropriate physical activity, have adequate nutrition, and report a generalized sense of well being [183]. In contrast, the patient who is inadequately dialyzed will have uremic symptoms and difficulties with fluid balance and blood pressure control. Inadequately dialyzed patients may also be malnourished and anemic, and are more likely to have neuropathies and sleep disturbances [183, 187]. Eventually, patients who are not well dialyzed will have an increased incidence of cardiovascular events, hospital admissions, and deaths [189, 190].

Risk factors for inadequate dialysis include an inappropriate or inadequate dialysis prescription, loss of residual renal function, large body surface area, low membrane transport characteristics, poor tolerance of large exchange volumes, a pattern of noncompliance, and patient resistance to prescription changes [187, 188, 191].

Urea kinetic modeling of peritoneal dialysis [192] requires a 24-h collection of urine and dialysate. The adequacy assessment should be done when the patient is clinically stable, does not have an infection, and is in good fluid balance. Patients must receive specific written instructions, verbal explanations, and appropriate reminders to complete the adequacy study. Patients should also be interviewed when they bring in the collections to determine if the samples were collected and labeled appropriately. PD adequacy assessment collection procedures are outlined in Table 13.18 [182, 193, 194].

If working in a hospital-based or independent facility, the PD nurse may need to communicate with laboratory personnel to explain the purpose of adequacy testing and the collection procedures and to agree upon sample size, containers. and labeling.

Common problems with the PD adequacy assessment include patient errors in collection (incomplete drain, including too few or too many exchanges, inaccurate volume measurement), mislabeling of specimens, laboratory errors, and calculation errors. Dialysate collections with either too many or too few exchanges will yield erroneous results and cannot be used. Also, if the patient does not save all urine, or saves urine at a different time than the dialysis, the results will not be accurate. The PD nurse and the laboratory must follow specific written procedures to collect and label samples correctly and analyze the results accurately [181, 186].

The laboratory results may be reported as raw data or may be returned with adequacy calculations. If raw data is reported, the PD nurse may perform the adequacy calculations manually, or enter them into a computer program, which will automatically calculate the adequacy results.

The adequacy results can then facilitate prescription adjustments [4, 183, 184, 187, 188]. Prescriptions that are individualized in respect to the patient's membrane characteristics will be most effective [183, 195]. The patient with low transport rates will benefit from longer dwell times and larger exchange volumes. The patient with average and high average transport rates may need additional exchanges and larger exchange volumes. The patient with a high transport rate will need rapid cycles with an automatic cycler with one or more daytime exchanges [196]. The patient who is experiencing a decline in residual renal function may need adequacy monitoring and prescription adjustments more frequently to avoid inadequate dialysis.

All adequacy assessments and prescription changes need to be carefully documented in the patient's medical record. These data can then utilized by the quality management program focusing on the provision and documentation of adequate dialysis.

In summary, maintaining adequacy is dependent on the information that the membrane characterization and adequacy studies offer. This allows the PD nurse and team to make thoughtful and accurate dialysis prescriptions [178, 183, 188]. Careful explanation to the patient coupled with a positive supportive approach can foster the patient's cooperation with prescription changes and overall adherence [186].

Prevention of Infection

Another cornerstone of successful PD therapy is the prevention and treatment of infections. The PD nurse must be expert in educating the patient about safe home procedures, identification of infections, and the importance of adherence to procedures [184]. The nurse also must be aware of the most current infection guidelines and recommendations concerning the catheter exit site and peritonitis [27, 197–200].

Table 13.18 PD adequacy assessment collection procedures

CAPD batch method

- Collect all drain bags for 24 h
- Weigh/measure effluent to determine 24-h total volume
- Combine all drained effluent in one large container
- Mix well
- Take sample for urea, creatinine

CAPD aliquot method

- Collect all drain bags for 24 h
- Weigh/measure effluent bags individually and calculate total volume, for example:
  #1 2,700 mL
  #2 2,600 mL
  #3 2,750 mL
  #4 2,850 mL
  total 24-h volume: 10,900 mL
- Take 0.1% sample from each bag (the volume of the bag is recorded in mL, and the decimal point is moved three places to the left); for example, 0.1% of 2,700 mL is 2.7
- Combine all samples and send to laboratory for urea and creatinine

APD batch method

- Instruct patient to collect 24-h dialysate in drain bag
- Instruct patient to save drain bag and note treatment data from the APD machine (nighttime prescription volume, initial drain, and UF)
- Patient may bring entire drain bag or instruct patient to mix dialysate and take a sample from the drain bag
- Calculate 24 h drain volume
- Take an appropriate sample and send to laboratory for urea and creatinine

APD aliquot method

- Instruct patient to collect 24-h dialysate in drain bag
- Instruct patient to save the drain bag from the daytime exchange
- Instruct patient to bring 200 cc from the APD drain bag and the entire manual drain bag to the unit
- Instruct patient to note treatment date from APD machine (night time prescription volume, initial drain, and UF)
- Calculate 24 h drain volume from APD and manual exchange
- Agitate drained effluent in bag to mix well
- Take 0.1% sample from APD drain bag; for example, if total APD drain volume is 11,400 mL, 0.1% is 11.4 mL
- For the manual exchange, weigh/measure the dialysate volume
- Take 0.1% sample; for example, if bag volume is 2,600 mL, 0.1% is 2.6 mL
- Add the two samples together in one container and mix well
- Take an appropriate sample and send to the laboratory for creatinine and urea

Source: Adapted from [182] with permission.

The primary goal of exit site care is to prevent infection [27, 132, 201]. Chronic exit site infections lead to prolonged use of antibiotics, disruption in adequate nutrition, and possible catheter removal. A recent study by Hall and colleagues found that the use of a structured education program based on principles of adult learning resulted in improved exit site conditions [137]. The written procedures must be clear, concise, and reinforced at each clinic visit. The nurse must be careful to assess the exit site at each clinic visit, and if an infection is suspected, treatment must start immediately to prevent a tunnel infection that usually leads to catheter loss [202]. There are situations that predispose the patient to early exit site infections. These include *Staphylococcus aureus* nasal carriage, sutures at the exit site, excessive manipulation of a newly implanted catheter, early colonization of the exit site, malnutrition, and diabetes [132, 204]. High-risk patients must be identified and their exit sites must be consistently and carefully assessed [203, 204].

There is a variety of protocols for exit site care [205–208] and currently most recommendations are opinion- rather than evidence-based [27, 132]. However, there is general consensus about many aspects of exit site care [205–208]. The initial dressing(s) should be changed by the PD nurse or designee. The use of aseptic technique, gloves, and masks are commonly noted. Careful hand washing is mandated along with securing the catheter with tape or immobilization devices to prevent traction and disruption of the exit site and tunnel. Effective cleaning of the site can be accomplished with normal saline, hypertonic saline, dermal wound cleansers, or mild soap and water. Hydrogen peroxide and iodine preparations should not be used in the healing wound tissue but could be used on the surrounding skin. Patients are taught to sponge bathe until the site heals, then they can shower. The healing exit site should not be submerged in bath

water. This prevents contamination with water-borne organisms and maceration of the healing tissue in the sinus track [132]. Dressings should be of absorbent material.

Some programs will have the patient remove the dressing once the site is healed or only wear a loosely applied dressing as a means of mechanical protection for the site. Antibiotic creams and ointments may be prescribed for exit site care as well. The most commonly used agent is mupirocin applied in a thin smear to the site daily or less frequently [209]. Recently gentamicin cream has been used with reported success [210].

Treatment of an exit site infection must be prompt and thorough. Erythema, tenderness at the site, and the presence of exudates all indicate the presence of infection [27, 132, 202–204, 209, 210]. The exudate should be cultured when present, because cultures of the exit site and sinus track may grow resident flora, rather than the infecting microorganism. Exuberant granulation tissues should be cauterized with silver nitrate sticks. Local care may include the application of wet saline dressings to the exit site daily or more frequently, cleansing with a mild cleansing agent, and carefully securing the catheter with nonirritating tape [132, 201, 202, 205]. The ISPD has published guidelines for treatment of exit site infections [27] and these are also available online at www.ispd.org. The usual course of antibiotic therapy is a minimum of 2 weeks. Infections that do not resolve, or that recur, and fungal infections will need a longer course of treatment. Inadequately or ineffectively treated exit site infections may progress to tunnel infections, which are often chronic and may result in peritonitis, catheter loss and transfer to hemodialysis [27, 202].

Each program must develop as specific set of policies and procedures to prevent, identify, and treat peritonitis. These must be periodically reviewed with the team to assure awareness of and support for the policies. Effective patient education must be a part of peritonitis prevention and management. The success of patient education will depend on the education of the PD nurse. The nurse must know how peritonitis is defined (Table 13.19) and the routes by which it can be acquired (Table 13.20) [27, 211]. Most nurses will have completed a basic microbiology course, but the PD nurse must assume responsibility for the specific knowledge needed to classify causative organisms, understand antibiotic treatment, and provide appropriate follow-up. The PD nurse must be familiar with the latest protocols and guidelines (from the ISPD, current literature and from national and regional conferences). Protocols can be obtained from the ISPD website. Networking with colleagues can also help with anecdotal experiences. The medical director must support the PD staff in assessment of infected patients, provision of peritonitis treatment and follow-up.

Identifying the risk factors for peritonitis can guide the nurse in the routine monthly clinic assessment. These include chronic exit site infection, tunnel infection, nasal carriage of *S. aureus*, bacteremia, immunosuppression, history of hemodialysis access sepsis, poor adherence to dialysis procedures, and invasive procedures not covered with prophylactic antibiotics (e.g., dental work, colonoscopy, and biopsy). CAPD systems that require spiking bags are associated with higher peritonitis rates than double-bag systems.

The presentation of peritonitis is noted by cloudy fluid, tenderness of abdominal wall, pain, fever, chills, diarrhea, nausea, and vomiting. Collecting the specimens is very important to identify the organism in a timely way. Each program must have a specific strategy for specimen collection, laboratory cooperation, and retrieval of results.

Table 13.19 ISPD peritonitis definitions [27]

Peritonitis – inflammation of the peritoneum
Infectious peritonitis – inflammation of the peritoneum due to microorganisms
Refractory peritonitis – symptoms persist after 5 days of treatment
Relapsing peritonitis – infection recurs within 4 weeks of therapy completion with same organism
Recurrent peritonitis – infection that recurs within 4 weeks of therapy completion with a different organism
Re-infection peritonitis – infection that occurs more than 4 weeks after therapy completion with the same organism
Nosocomial peritonitis – infection that occurs during a patient hospitalization

Table 13.20 Routes of contamination responsible for peritonitis [27, 211]

Transluminal – contamination of the closed system
Periluminal – along the outer surface of the catheter
Hematogenous – blood-borne organisms
Transmural – migration of organisms from the bowel
Ascending – from the female reproductive tract

Table 13.21 Determining the time at risk for infection

Time at risk (in days) =
patients on PD for entire month × # days in month
Plus
days of PD for new patients who trained, transferred in or returned post-transplant
Plus
days on PD for patients who discontinued PD due to transplant, transfer or death
Total days at risk ÷ number of days in month = months at risk
Months at risk ÷ 12 = years at risk
Number of events ÷ years at risk = rate per year
To determine the interval of months between episodes:
Months at risk ÷ episodes
Months between episodes ÷ 12 = rate per year

Source: Modified from [58] with permission.

Part of the initial training time must be devoted to the prevention and treatment of infection. The PD nurse must work very closely with each patient to assess individual risk factors, personal hygiene, procedure technique and potential for adherence. The patient should be provided with instructions for accidental contamination and also what to do if symptoms of peritonitis occur. Infection prevention must be reviewed periodically, at the home visit, at a monthly clinic visit or during retraining. The patient's vision and fine motor control should be periodically evaluated. Multiple infections or suspected changes in the home environment may prompt an additional home visit [159].

Once the diagnosis of peritonitis is made, the nurse must insure that the specimens are collected correctly and antibiotic treatment is started. Antibiotics may be given by the intravenous, intraperitoneal or oral route. The current ISPD guidelines and recommendations provide extensive information for antibiotic treatment [27]. The patient may come to the clinic to receive treatment, but is typically taught to self-administer at home. Fluid balance and protein intake will need to be carefully monitored during this period of acute inflammation. If the patient is too ill to manage safely at home, hospitalization may be necessary.

It is important to discuss with the patient what may have contributed to the development of peritonitis, but at the same time it is important not to blame the patient. Supporting the patient during the infection is crucial to promote future adherence and to alleviate the patient of guilt and uncertainty [112, 113].

The evaluation of peritonitis must be part of the quality management program. Each infection must be documented along with the results of treatment. The PD nursing staff must participate in quality projects related to infection and are often responsible for determining the program's rates of exit site infection and peritonitis. Table 13.21 outlines one method of determining time at risk for infections [58], one of the steps in determining infection rates. This infection documentation should be done monthly and then collated yearly. The data and analysis is necessary to evaluate the program's management of infection.

Special Considerations

Employment

Working, either full time or part time, is important for many PD patients. Some patients choose PD therapy because it provides the flexibility of scheduling that enables them to continue working. Also, the sense of accomplishment and purpose, and the income attained by working contribute to the well being of the home dialysis patient. Vocational counseling by the social worker or by a specialized counselor can be helpful to the patient seeking employment.

For the patient who is already employed, the PD nurse and patient can adjust the home dialysis schedule to accommodate the work schedule. Flexibility and creative planning may be necessary. Rearranging supply deliveries, clinic visits, and timing of exchanges may help the patient to sustain employment and to also be adherent with the dialysis schedule. If the patient is able to do an exchange in the workplace, the PD nurse may, at the patient's request, make a visit the workplace to inspect the environment where the PD exchange will take place and offer suggestions and support to the patient. Also, if the patient requests, letters may be sent to the employer to describe the dialysis regimen and provide education for the employer. The PD nurse should monitor the patient's adjustment to work, ability to do dialysis safely in the work setting, and to maintain an acceptable dialysis routine [8].

Exercise

Routine exercise is important to maintain cardiovascular health. The nephrologist and PD nurse must assess the patient's capacity for exercise and make recommendations regarding how to exercise safely. In all cases, the exercise program must be individualized. Care must be taken not to put pressure or traction on the PD catheter. It is important that the integrity of a healed tunnel remain intact in order to prevent exit site infection and dialysate leaks. Low impact exercises that avoid high intraabdominal pressure, such as walking and the use of a treadmill device at low speed and minimal platform elevation, or riding an exercise bicycle with minimal resistance [212–214] are safe for the majority of PD patients. Sports that involve physical contact, jumping, and weight lifting are riskier and need to be carefully evaluated. In all instances, the nephrologist must be involved in this assessment and the plan for the patient needs to be documented.

Warming Dialysis Solutions

Dialysis solutions should be protected against extremely hot temperatures during shipping and storage. High temperatures cause the glucose to break down, forming glucose degradation products (GDPs). The level of cytotoxic GDPs can double within a few hours; however, the concentration of GDPs gradually returns to normal when the dialysis solution temperature is lowered, and returns to baseline within 40 days [215].

Dialysis solutions should be warmed to body temperature shortly before use. Most manufacturers recommend using dry heat with temperature regulation to provide a safe heating mechanism for the home PD patient. Often a heating pad device is used; this is included in the initial home supply shipment. Other commercially available devices that employ dry, temperature-regulated heat (e.g., a heating cabinet or incubator) may be used in the dialysis unit or purchased by patients. Home patients have warmed bags by placing them in the sunshine or on a home heating vent or radiator. Regardless of the warming mechanism, the temperature of the solution should be approximately 37°C, and the bags should feel tepid to the touch. Heating solution bags in warm water is not recommended due to the potential exposure to water-borne organisms. If necessary, a dialysis solution bag that is at room temperature can be infused slowly to avoid excessive abdominal cramping.

Microwaving PD solution bags is controversial. Microwave devices may heat solutions unevenly, creating hot spots that may not be noticeable to the touch. This then exposes the patient to the risk of thermal burns. Also, due to differences in wattage and efficiency, different microwave ovens will require different time settings to achieve the same final temperature. Although microwaving PD solutions does not alter the pH or chemistries of the solution [216, 217], it is less clear whether microwaving PD solution bags causes leaching of plasticizers and chemicals into the dialysis solution.

Although manufacturers may not recommend microwaving their PD solutions, this has been widely practiced. Each program must make an informed decision whether it will allow microwave warming of PD solutions. Specific policies and procedures for microwaving PD solutions must be developed. Overheating of solutions can be avoided by measuring the warming time required for each size bag to reach 37°C in each microwave used to warm solutions. Inverting the heated bag several times will mix the solution and help to dissipate hot spots [177, 216].

Swimming

There are a number of anecdotal opinions regarding the risks and benefits of swimming for PD patients; however, many agree that swimming is an acceptable form of exercise for the PD patient. The patient with an exit site that has not healed or is infected should avoid swimming until healing has occurred [8, 201, 214]. The patient who has a healed exit site may swim but will need to protect and care for the exit site per program procedures. There are a variety of recommendations to consider. Some programs advocate covering the exit site and catheter with occlusive dressings while swimming, and then performing exit site care immediately after swimming. Others recommend changing into a dry bathing suit or clothing after swimming to prevent prolonged moisture at the exit site. There is more consensus that swimming in lakes and ponds poses the greatest risk for infection due to stagnant water with high bacteria counts. There is also general consensus that swimming in clean, chlorinated pools poses the least risk, and that the risks associated with swimming in ocean waters depends on the proximity of the beach to sewage outlets and highly populated areas [8, 214].

Table 13.22 Checklist for patient traveling on peritoneal dialysis

Travel details
Destination
Travel dates
Mode of transportation
Type of lodging
Back-up PD unit
-Unit name
-Individual contact name
-Contact information
-Billing policy
-Required diagnostic tests
-Required medical records
Shipping of dialysis supplies
Patient education
Letter of medical necessity
Supplies and equipment to carry on
Medications
Diabetic supplies
Performing dialysis procedures while traveling
Traveling with a cycler
Disposal of dialysate
Contacting the back-up unit
Paying for dialysis expenses while traveling
Tips for international travel

Travel

PD patients may travel for pleasure or business; regional, national, and international travel can all be accomplished while performing PD safely; however, the dialysis unit must assist the patient in preparing for dialysis while traveling [218–226]. A detailed resource for both the nurse and PD patient is the "PD Tool Box" [220]. Information abstracted from this reference is included in Table 13.22.

When making travel plans, the patient needs to inform the PD nurse of the destination, and dates of departure and return. A dialysis unit at the patient's point of destination must be identified as an emergency contact for short trips; however, the designated unit may assume the role of the primary dialysis unit during a prolonged stay.

The patient should travel with letters of medical necessity, a description of medical supplies, a list of medications, copies of the current information from the medical record (similar to the information for hospital admission, Table 13.16), and the telephone numbers of emergency contacts and the destination dialysis unit.

Often, dialysis supplies are delivered to the travel destination. Arrangements with the home dialysis supplier must be made well in advance to prevent disruption of service and additional charges. All administrative and financial details must be reconciled before the patient arrives at his destination. Dialysis services provided in other countries may not be covered by health insurances and may require private payment by the patient.

If the patient is traveling to a remote area and is not able to reach a dialysis unit in a reasonable amount of time, a supply of antibiotics may be given to the patient to self administer in an emergency situation.

Disaster Preparation

Recently, we have witnessed natural disasters that have included hurricanes, tornados, earthquakes, tsunamis, fires, and extreme temperature changes. Political and religious tensions have resulted in conflicts and terrorist attacks. These events have raised awareness of the potential for future disasters and the necessity of disaster planning. The PD nurse must help the patient and family prepare to continue dialysis during a disaster, when there may be disruption in communications and dialysis-related services [227–229], but must do so without unnecessarily alarming them.

Patients who use a dialysis cycler should be taught to use manual systems in case of power outages, or should have a back-up generator to provide temporary power. Home dialysis patients should have a minimum of 2 weeks of PD

supplies and all medications. Waterless hand sanitizers should be kept on hand in case of contaminated water supply. Patients should also be encouraged to have several days of food and bottled water on hand in case of interruption in basic services. Each patient should have a current medication list, a medical alert bracelet, and a plan of how to communicate with the home dialysis unit [230].

A discussion about how long the patient can survive without dialysis may also be necessary along with an emergency diet list and strategy for fluid management. In a prolonged or widespread disaster, the patient may need to seek treatment at a distant dialysis unit or hospital. Each patient should have a list of emergency phone numbers and a list of alternative dialysis units and hospitals. Patients may be referred to the National Kidney Foundation, the regional ESRD Networks, and the Centers for Disease Control and Prevention for additional brochures and dialysis preparedness information [231–233].

Roles of the PD Nurse

The success of individual PD patients, the success of dialysis programs, and the success of PD as a renal replacement modality all depend on contributions of the PD nurse. The combination of roles of the PD nurse is perhaps among the most unique in the profession of nursing. The PD nurse is influential in providing home dialysis care and is often viewed as the team leader for this modality [12, 13]. Balancing nursing autonomy with the multidisciplinary team effort required can provide both professional and personal satisfaction. To achieve this, the PD nurse must integrate a number of varied roles on a daily basis. Each of these roles is important for successful outcomes.

The first role is that of an educator. Providing consistent and creative patient education is the foundation of a successful PD program [8, 142, 234]. Although healthcare professionals do not necessarily receive formal courses in adult education, it is imperative that the PD nurse acquire the knowledge and skills necessary to teach patients and families. This knowledge may come from formal education courses, continuing education, review of the education literature, and information from other colleagues and through anecdotal experiences [138, 139]. Critical content includes principles and theories of education, the characteristics of the adult learner, and teaching methods [112]. The nurse is also responsible for acquiring or developing patient educational materials and establishment of a specific home training plan. These must then be individualized for each patient with chronic kidney disease who chooses PD therapy.

Although educating patients and families is the primary goal of the PD nurse, educating other healthcare providers is also essential. The nurse will often be responsible for educating others regarding specifics of PD. The target audience may include physicians, renal fellows, nephrology and non-nephrology nurses, advanced practice nurses, dialysis technicians, dietitians, social workers, administrators, and allied healthcare personnel (e.g., secretaries, laboratory technicians, insurance representatives) [138, 234–236]. In providing education to other healthcare professionals and support staff, the PD nurse promotes self-care while also promoting PD as a renal replacement therapy.

The PD nurse is also a learner. Acquisition of information about chronic kidney disease, diabetes mellitus, gerontology, peritoneal dialysis, infections, cardiovascular disease, research findings, practice guidelines, and new regulations is a continual process, which is critical both to develop individual expertise and remain clinically competent.

The next role that the PD nurse must fulfill is that of a clinical care coordinator. The patient and PD nurse work together at the central focus of the home care team [1, 12, 13]. The nurse often coordinates the care provided by the nephrologist(s), social worker, dietitian, access surgeon, transplant team, and other caregivers (Table 13.1). Furthermore, the nurse ensures that appropriate communication is established with the primary care physician, nurse practitioner, and specialty consultants. Functioning as a care coordinator requires persistent attention to detail and maintaining consistent channels of communication. The result of this care coordination is the provision of efficient, safe, and competent patient care with smooth transitions between care settings [237].

The PD nurse also has a strong clinical role, starting with the responsibility for developing safe and effective policies and procedures both for the dialysis clinic and self-care at home. The nurse must have clinical assessment skills, clinical expertise, and critical thinking ability [238] to make accurate nursing diagnoses and identify appropriate nursing interventions for complications of chronic kidney disease, PD, cardiovascular disease, diabetes mellitus, and vascular disease. Also, the application of self-care management principles, fostering adherence, and identifying psychosocial needs [239, 240] are part of the clinician role [113, 134]. Finally, the clinical role includes measurement and documentation of short- and long-term outcomes. These data can be compared against regional and national standards and benchmarks to determine the quality of care [35–39, 241]. They can also be used for specific continuous quality improvement projects.

The PD nurse may also participate in clinical research. Most often nurses assist in identifying eligible patients, and with recruitment and data collection. As PD nurses becomes more experienced with and educated in clinical research techniques, they often assume more responsibilities and may participate in clinical trials and multicenter studies [238]. Eventually, some nurses go on to assume lead roles as research investigators. Nurses should also utilize clinical research findings, developing an evidence-based practice whenever possible.

Mentoring is also a role that the PD nurse must fulfill. It is critical to guide new and less experienced nephrology nurses to encourage professional development [242].

Finally, the PD nurse is a leader [242, 243]. To become a respected professional and leader, there must be a balance among the various roles. A leadership job title does not need to be assigned for the nurse to be respected as a leader. The truly professional PD nurse accepts the autonomy the role provides, but at the same time respects the boundaries of the nursing roles and practices accordingly [244–246]. Daily clinical practice requires competency, commitment and integrity. This commitment fosters a sense of trust that patients recognize and respect. And it is this trust contributes to the unique bond between the PD nurse and patient [112]. The patients recognize that the nurse is a leader who provides not only expert clinical care but also compassionate support. Nephrologists recognize the PD nurse as a collaborative partner in providing safe home dialysis care and value the commitment to pursuing standards of excellence [7, 10, 12, 13, 247–249].

Fulfilling these roles depends on the level of competency the PD nurse achieves. It is crucial for the nurse to broaden his/her scope of knowledge. Understanding the literature, networking with expert colleagues, and attending conferences and national meetings are all part of becoming a competent professional. Joining professional organizations and participating in committees and projects enlarges the nurse's professional experience. In turn, this professional enrichment enhances clinical care [249].

Conclusion

In conclusion, to successfully fulfill these roles, the PD nurse requires a broad knowledge base, many skills, and a measure of courage. The nurse must be willing to function autonomously, take risks, balance multiple challenges, and promote and accept change. Above all, the nurse must have the commitment and courage to champion the PD program.

Chapter 14
Peritoneal Dialysis Access and Exit-Site Care Including Surgical Aspects

P. Kathuria, Z.J. Twardowski, and W.K. Nichols

The key to a successful peritoneal dialysis program is a permanent and safe access to the peritoneal cavity. The catheter should provide optimal and consistent hydraulic function and form a stable interface with the body. A well-healed peritoneal dialysis catheter prevents the periluminal migration of bacteria and leakage of dialysate.

Peritoneal access is an important key point in technique survival. Catheter-related problems and infections cause up to 20% of patients to transfer permanently to hemodialysis; many more require temporary periods on hemodialysis [1]. With the reduction in peritonitis rates, catheter-related complications during peritoneal dialysis have become a major concern.

The history of peritoneal access, different peritoneal dialysis catheters, surgical insertion techniques, infections, and mechanical problems are addressed in this chapter.

Glossary

The terminology pertinent to the currently used peritoneal catheters is reviewed here [2]. After implantation the typical double-cuff catheter has three segments (Fig. 14.1): *intraperitoneal,* located intraperitoneally; *intramural,* contained within the abdominal wall tunnel; and *external,* situated outside of the skin exit. The *peritoneal catheter tunnel* is the passageway through the abdominal wall within which the peritoneal catheter is contained. A properly implanted double-cuff peritoneal catheter creates a tunnel with a short sinus tract, a shallow peritoneal recess, and a 5–7 cm long tunnel proper, which consists of tissue ingrown into the cuffs and a fibrous sheath covering the inter-cuff tunnel segment. A longer tunnel proper (20–50 cm) is typical for the presternal catheter [3]. Figure 14.2 depicts tissue structures in relation to cuff position in healed tunnels. After implantation of a single, deep cuff catheter, the tunnel is composed of three parts: 1) a sinus tract located between the skin exit and the cuff; 2) a peritoneal tunnel recess, which is a peritoneal pocket covered with the mesothelium from the internal tunnel exit to the collagen-mesothelial interface at the cuff; and 3) a tunnel proper, comprising the tissue ingrown into the cuff. Another type of single-cuff catheter is provided only with a superficial cuff, has a short sinus tract, but a long peritoneal recess.

Historical Perspective

Both biologic and technologic evolutions reveal puzzling similarities. A structure of a new species is taken from the existing forms; new technological solutions develop from existing forms as well. In the early years of peritoneal dialysis, there was no specific device for peritoneal dialysis; rather, the devices used in medicine, general surgery, and urology were adapted [4]. A species or technology not adjusted to the environment or requirements is eliminated and is preserved in fossils or museums of technology.

In the older literature three terms were used for the infusion of fluid to and drainage from the peritoneal cavity: peritoneal lavage (from Latin *lavare* = to wash), irrigation, (from Latin *irrigare* = to water), and dialysis (from Greek *dialusis* = to separate). The terms *lavage* and *irrigation*, used frequently in the English literature in the 1930 s, 1940 s, and 1950 s, came from surgical practice of cleaning the peritoneum. *Peritoneal dialysis* indicates removal of toxins from the blood through the peritoneal membrane, and this term was commonly used in German literature in the 1920 s and 1930 s. Since the 1960s, it has been used almost exclusively for the process of toxin removal from the blood through the peritoneal membrane.

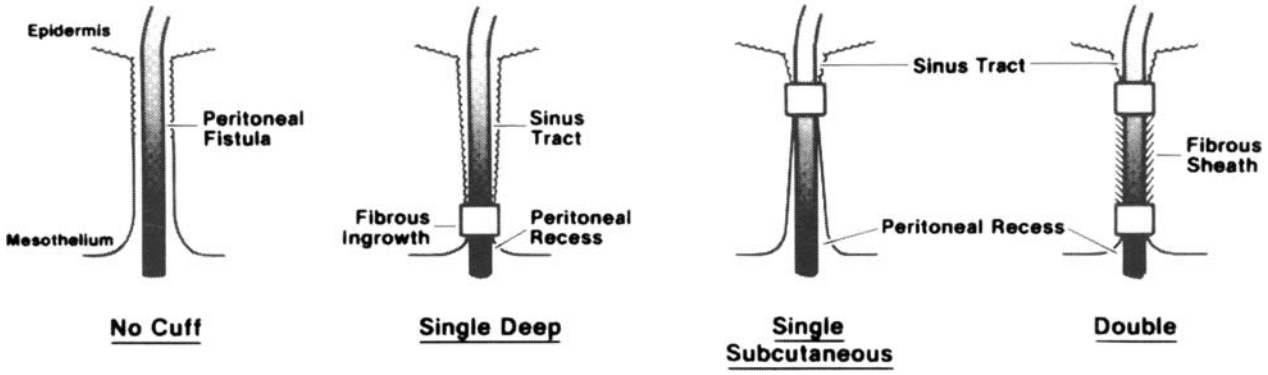

Fig. 14.2 Tissue structures in relation to cuff position in healed tunnels. In catheters without cuffs, a peritoneal fistula is formed. A single deep cuff creates a shallow peritoneal recess and a deep sinus tract predisposing to exit infection. A single subcutaneous cuff generates a shallow sinus tract and a deep peritoneal recess predisposing to pseudohernia. Properly positioned two cuffs limit the depth of both structures

In 1923, Ganter [5] reported his experience in animals and two patients. He used metal needles commonly used at that time for abdominal and pleural punctures. In patients, he did not drain the fluid as he did in guinea pigs, so it was not dialysis as we understand it now; however, there was some dialysis into the saline solution. Two years later at the meeting of the Polish Society of Biology, Landsberg and Gnoinski [6] presented the results of experiments in rabbits. After puncture of the peritoneal cavity with a trocar[1] in the epigastric region the peritoneum was filled with 1 L of Ringer's solution. After 15–30 min of equilibration, the peritoneum was drained through a puncture in the lower region. Because there was some dwell of the dialysis solution, their method should be called intermittent flow peritoneal dialysis in spite of the fact that two trocars were used. Rosenak and Siwon performed several experiments on continuous dialysis in nephrectomized dogs in 1926 [7]. They inserted two glass cannulas through laparotomy. The inflow cannula tip was placed below the liver, the outflow in the Douglas cavity. Simple glass tubes, used in early experiments, were frequently obstructed, so they decided to provide "cannulas with flask shape, multi-perforated, sprinkling can rose-like tips." If the cannula became obstructed despite this modification, they performed omentectomy before inserting new cannulas. One year later, Heusser and Werder carried out experiments on continuous flow peritoneal dialysis similar to those of Rosenak and Siwon. The inflow cannula was similar to theirs, but for outflow they used a rubber drain with multiple side perforations with the tip inserted into the small pelvis. "The omentum was creased with multiple sutures through the lower abdominal wound so that it could not block the openings in the drain tube" [8]. They speculated that the similar technique could be used in patients, and indeed they used it in three cases.

The first continuous flow peritoneal dialyses in humans with acute renal failure caused by poisoning with mercury bichloride were performed in two patients by Balázs and Rosenak in 1934 [9]. For peritoneal access they used glass cannulas distended globularly at the tip and having multiple holes (similar to those used previously by Rosenak and Siwon [7]) or cannulas made of fine wire. The inflow cannula was introduced between the liver and the diaphragm, the outflow cannula was inserted into the Douglas cavity. Both cannulas were introduced by laparotomy under local and light ethyl chlorine anesthesia. In the first patient the continuous dialysis lasted ½ h and 12 L of 4.2% glucose were used, in the second patient 19 L of 0.8% saline were used during 1½ h of continuous dialysis. Both patients died.

The first case of a patient who survived after peritoneal lavage for the treatment was reported by Wear et al. [10]. "A standard gall bladder trochar was introduced in the upper abdomen. The trochar introduced into the lower abdomen was modified by placing numerous small holes in the distal third to avoid occlusion of a single opening by the omentum and intestine. From an insulated reservoir the fluid was introduced into upper cannula. The lower cannula was attached to rubber tubing which hung dependent to a bottle on the floor and acted as syphon." The

[1] From French *trois* (three) + *carre* (side) = three-sided point, a sharp pointed instrument equipped with a cannula, used to puncture the wall of a body cavity and withdraw fluids.

authors used the procedure in five cases, but only one patient survived; it was unclear whether the patient was saved by peritoneal dialysis.

The first intermittent peritoneal dialyses in humans were performed by Rhoads in 1936 and 1937 [11]. In two patients thought to have acute renal failure, peritoneal lavage was performed. The fluid was introduced into the peritoneal cavity through a cannula introduced into the peritoneal cavity under local anesthesia. "Nine liters of fluid were introduced in 6 installments and a total of 6 ½ liters recovered." Temporary improvement in the patients' condition was noted; both patients ultimately died and autopsies revealed chronic glomerulonephritis. The author did not provide a detailed description of the cannula.

No papers on peritoneal lavage, irrigation, or dialysis appeared during the time of Word War II, but the number of renal failure cases after war trauma must have accelerated research on renal replacement therapies and numerous papers on these topics were published in the second half on the 1940s [4].

Abbott and Shea carried out several experiments on dogs to evaluate the methods of peritoneal lavage and desirable solutions. As a result of these experiments, they determined that for removal of dialyzable substances the use of intermittent injection and withdrawal of solution is more efficient than continuous flow lavage, and that the solution should have a chemical composition similar to that of interstitial fluid and should be made slightly hypertonic by the addition of small amounts of dextrose or gelatin or pectin. They performed a limited number of treatments in humans and concluded "that the withdrawal of the fluid could be best accomplished by the use of trochar or insertion of a rubber catheter, since the insertion of a needle does not, as a rule, permit a complete recovery of the injected fluid" [12].

Seligman, Frank, and Fine performed a series of experiments on nephrectomized dogs to determine suitable peritoneal access, optimal flow of continuous flow peritoneal irrigation, and proper irrigation fluid. The access was a mushroom-tip[2] type catheter inserted through an incision or a whistle-tip[3] type inserted using a trocar. Both types had added perforations. Mushroom-type catheters drained more effectively than the whistle-tip type catheters. "To help maintain patency of the irrigating catheters in long term experiments, omentectomy was performed . . . at the time of nephrectomy" [13]. The same group of authors reported the use of this method for treatment of four patients [14]. In all cases, a continuous flow method was used. Initially, the inlet tube was a catheter or a perforated small stainless steel tube. The outlet tube was a whistle-tip type catheter. In later cases, they used two mushroom catheters for inflow and outflow and ultimately they used a mushroom catheter for inflow and a stainless steel surgical drain tube for outflow (Fig. 14.3). The tubes were inserted through surgical incisions and held in place with subcutaneous staysutures. As prophylaxis against peritoneal contamination they incorporated a Mandler (Berkefeld) filter between the solution reservoir and a glass U-tube submerged in a water bath (40–45°C) and connected to the inflow tube. One patient with acute renal failure due to "parenchymatous injury to the kidneys from sulfathiazole administration" was also reported separately in more detail [15]. The mushroom catheter and the sump drain[4] were used in this case. During 7 days of peritoneal irrigation, solution flow ranged from 13 to 35 mL/min and urea peritoneal clearance ranged from 8.4 to 21.0 mL/min. The patient ultimately recovered kidney function. Although in the discussion the authors stated that "[w]e cannot state with finality that the patient would have died without peritoneal irrigation," the severity of the case, 15 days of oliguria/anuria, and improvement during peritoneal lavage seem to justify the assumption that *this was the first patient who survived because of peritoneal dialysis*. Weiss and Mills followed the experience of Frank, Seligman, and Fine using a mushroom catheter for fluid inflow and sump drain for outflow. To improve drainage the sump drain was inserted very low, just above the Poupart's ligament and passed down to the pelvis [16]. Reid, Penfold, and Jones referred to the Frank, Seligman, and Fine paper, but implemented a different technique. They used a Foley[5] catheter for infusion into the peritoneal cavity of twice-normal saline. They drained the fluid through the same catheter after the patient complained of abdominal distension and pain and the appearance of "obvious ascites." The infusion and drainage of fluid continued the following days, but they had difficulty with drainage through the catheter and a considerable amount of fluid leaked around the catheter [17]. Although they used a single catheter and drained the

[2] Mushroom or umbrella catheter, a self-retaining bladder catheter, was invented by de Pezzer in 19th century. It had no terminal opening, only lateral openings.

[3] Whistle-tip catheter = urethral catheter with a terminal opening as well as a lateral one.

[4] Sump drains were double-lumen tubes that allowed air to enter the drained area through the smaller lumen and displace the fluid into the larger lumen. The air sucked back through the larger tube helped to maintain its patency and prevented high negative pressure with consequent suction of adjacent structures into the openings of the large tube. They were used in general surgery and gynecology and in the intraperitoneal space for evacuation of fluid from the peritoneal cavity. The external tubes of sump drains were usually made of a network of stainless steel or brass cords; the internal tubes were solid cannulas.

[5] In 1929, Frederick E.B. Foley (1891–1966) developed a catheter for drainage of urine and retained in the bladder by the distensible balloon.

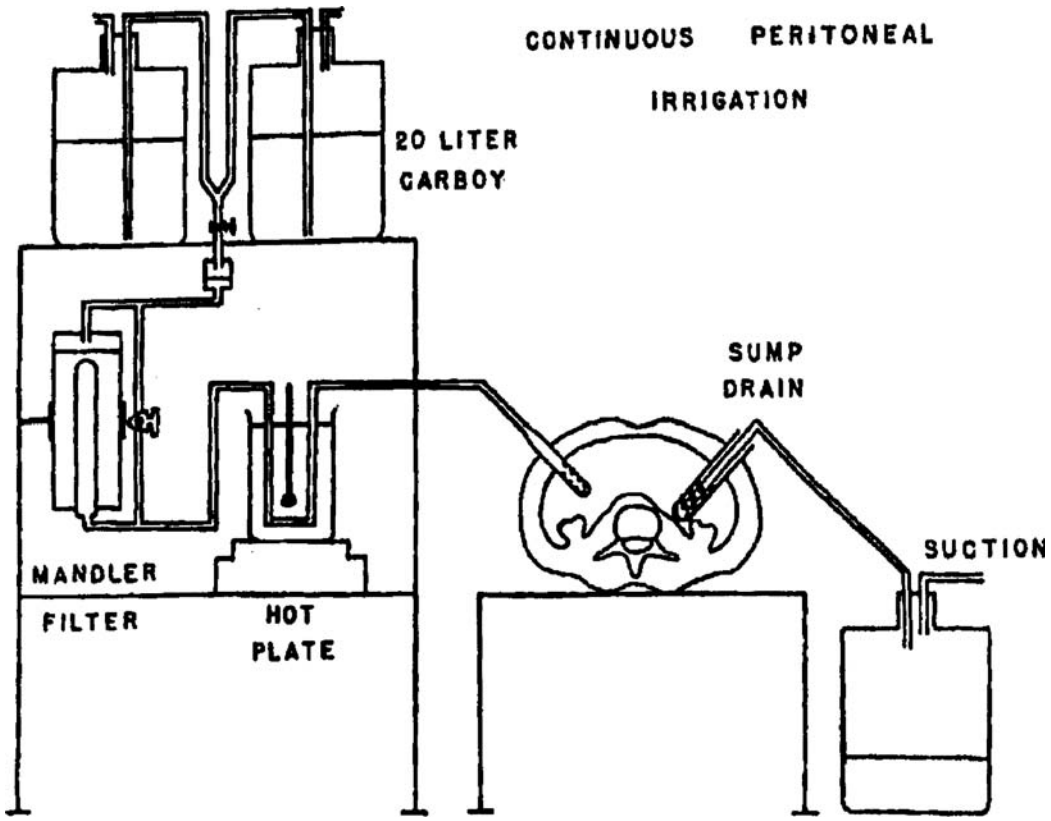

Fig. 14.3 Continuous peritoneal irrigation. A = 20 L carboy, B = Mandler filter, C = hot plate, D = rubber inflow catheter, E = sump drain, F = suction. Modified from [14]

fluid intermittently, the flow method was partly continuous because of constant leakage of fluid around the catheter. Ultimately, the patient recovered.

In 1947 and 1948 numerous papers appeared in the medical literature describing results with peritoneal irrigation [4]. The method of Frank, Seligman, and Fine was generally followed. The major problems encountered by clinicians treating patients with peritoneal irrigation were related to peritoneal access. Rosenak and Oppenheimer [18] listed the five most troublesome complications of peritoneal drains used for fluid outflow: "(1) Rigidity of the tube with resulting pressure on the intestines, (2) Constant suction of contaminated air into the peritoneal cavity, (3) Occasional plugging of the small openings, (4) Leakage of lavage fluid into the dressing, which is a potential source of infection and which make exact determination of nitrogen output difficult, (5) Difficulties of proper fixation of the tube on the abdominal wall." It may be added that fluid leakage made fluid balance very imprecise and resulted in extra nursing work. For the first time they developed a drain specifically for peritoneal dialysis. This was a modified sump drain. Made of stainless steel, the tube provided a rigid extra-abdominal portion, but flexible intraperitoneal portion made of a spiral, stainless steel spring wire with a rounded tip. An adjustable plate was screwed to the outer portion of the steel tube and served for fixation to the abdominal wall by means of adhesive plaster. Compared to the sump drain, the access introduced two important improvements: a flexible tube made of spiral wire instead of rigid pipe and the plate for fixation to the abdominal wall. A second version of the Rosenak-Oppenheimer access was described by Odel et al. [19]. The improved version had two accesses, one for inflow and one for outflow (Fig. 14.4). They were identical, except that the intra-abdominal part of the inflow tube was shorter that that of the outflow tube. The intra-abdominal portion of each tube was made of tightly coiled stainless steel with a rounded tip. Compared to the previous version with a rigid inner tube, in the new version both inflow and outflow accesses had an inner tube made of flexible rubber in the intra-abdominal portion.

In December 1948, Ferris and Odel published their experience with the Rosenak-Oppenheimer access [20]. They used it in only one case, and "found the inflow tube to be entirely satisfactory." However, they experienced considerable difficulty in fluid outflow, because the flexible steel spring appeared to be wound too tightly. They were also concerned with the foreign body reaction to metal and rubber tubes. Accordingly, they improved the Rosenak-Oppenheimer access by changing the intra-abdominal portion of the outer tube (Fig. 14.5). Instead of the spring

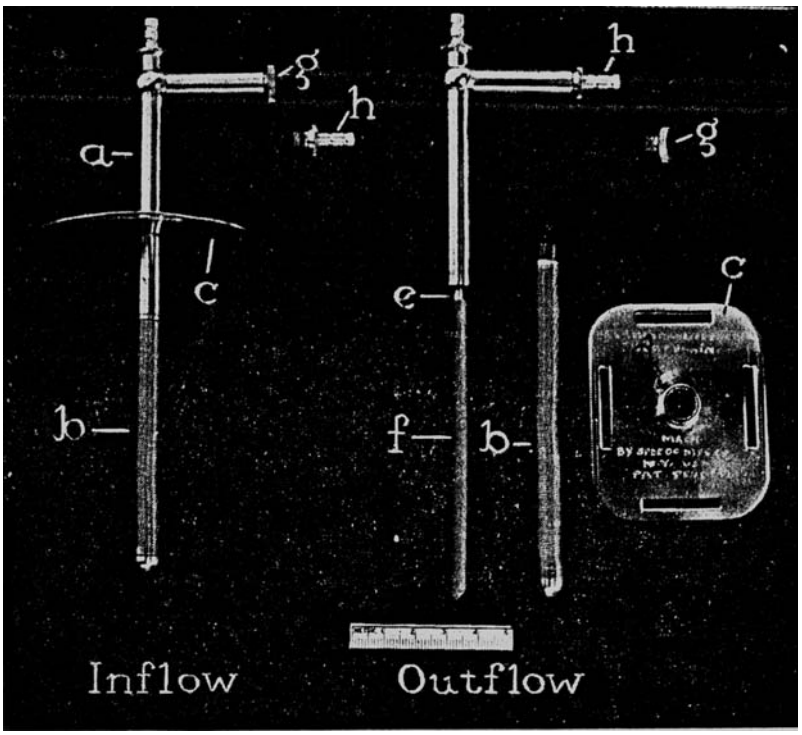

Fig. 14.4 Rosenak-Oppenheimer peritoneal tubes. Fig. 14.5 Ferris and Odel tubes for peritoneal lavage. The assembled tubes are on the left. The short tube on the left is the inflow tube. The outflow tube on the right is disassembled to show the component parts. A = rigid extra-abdominal, b = polyvinyl intra-abdominal outer tube, c = malleable metal flange, d = thumbscrew, e = rigid inner portion, f = polyvinyl inner portion, g = metal plug, h = adapter, i = inflow bendaloy, j = outflow bendaloy. Modified from [20]

coil they used a polyvinyl tube with multiple perforations. This tubing was "sweated" into the stainless steel portion of the tube with acetone. The tips of the tubes were provided with plugs consisting of bendaloy[6] completely encased in the polyvinyl. The tubes were weighted with these plugs to insure they would hang dependently in the peritoneal cavity. This was particularly important for the outflow tube to keep the tip in the true pelvis, the place of a fluid reservoir. The intra-abdominal portion of the inner tube was also made of polyvinyl. The extra-abdominal part of the catheters remained essentially unchanged, with the exception of the plate (flange). They cut a slot in the flange so that it could be slipped on the tube after implantation, when proper position of the flange could be determined. Ferris and Odel introduced two important ideas in their access: 1) use of plastic (polyvinyl) for the intra-abdominal segment of the access, and 2) use of weights to keep the tip of the tubing in the true pelvis. Both ideas were emulated later by other inventors.

In 1948, Frank et al. reported further experience with peritoneal irrigation based on 14 additional patients in renal failure [21]. The peritoneal access was markedly modified (Fig. 14.6). Only a sump drain was used for inflow and outflow. The external part of the drain was made of glass closed with a rubber stopper, and contained a side arm for fluid inflow and air inlet. This glass portion was connected through an external flexible rubber tube to a stainless steel tip. An internal flexible rubber tube of a smaller diameter than the external was inserted through the rubber stopper up to the stainless steel tip and connected to the suction line. For the insertion of the sump drain, two incisions were made. The upper incision through the skin to the fascia was made beneath the costal margin; the lower incision entering the peritoneum was made in the lower abdomen on the opposite side. A subcutaneous tunnel connecting these two incisions was made; the metal end of the flexible sump drain was inserted through the upper incision, passed along the tunnel, and inserted into the peritoneal cavity through the lower incision. Thus, for the first time, a long subcutaneous tunnel was created for the peritoneal access. "The patient lies semi-erect so the fluid in the pelvis remains below the upper incision. Thus no contact by possible ebb flow can be made between the fluid and the skin of the abdominal wall." The authors used intermittent or continuous flow technique. For continuous flow technique they used "a small rubber inflow catheter" and a sump drain for outflow. The intermittent flow technique was accomplished with a new catheter by alternating inflow and suction (Fig. 14.7). In intermittent flow peritoneal dialysis, various volumes (500–2,000 mL) were introduced as determined by patients' tolerance, allowed to remain for 15 min to 3 h, after which the fluid was aspirated. Any air entering the system was bubbled through an alkaline solution of parachlorophenol and cresol. Peritonitis episodes were frequent, but edema was not a problem in most patients because hypertonic solutions were used. They cautioned against using too concentrated solutions. In one patient, "a solution of 5% gelatin and 2.5% glucose withdrew fluid so rapidly as to produce shock. Moreover, the hypertonicity may be responsible for the peritoneal irritation and by increasing it still further infection may be even more likely" [21].

A major advance was the introduction of less rigid materials by French physicians in 1949 [22]. They designed polyvinyl tubes, 25–30 cm long, with diameters of 2–3 mm. The terminal 15 cm of the tubes had lateral openings, all 2 or 3 mm. The tubes were introduced into the abdominal wall with the help of trocars. After local anesthesia, the trocar with pointed mandrel was introduced into the peritoneal cavity, then the pointed mandrel was replaced with a blunt rod and the trocar was advanced deeper without the risk of peritoneal trauma. Finally, the rod was removed and the polyvinyl tube was introduced through the trocar sheath. After infusion of 3–4 L of solution, the outflow tube was inserted on the opposite side of the abdomen with the same technique. The authors were very satisfied with the performance of the polyvinyl tubes.

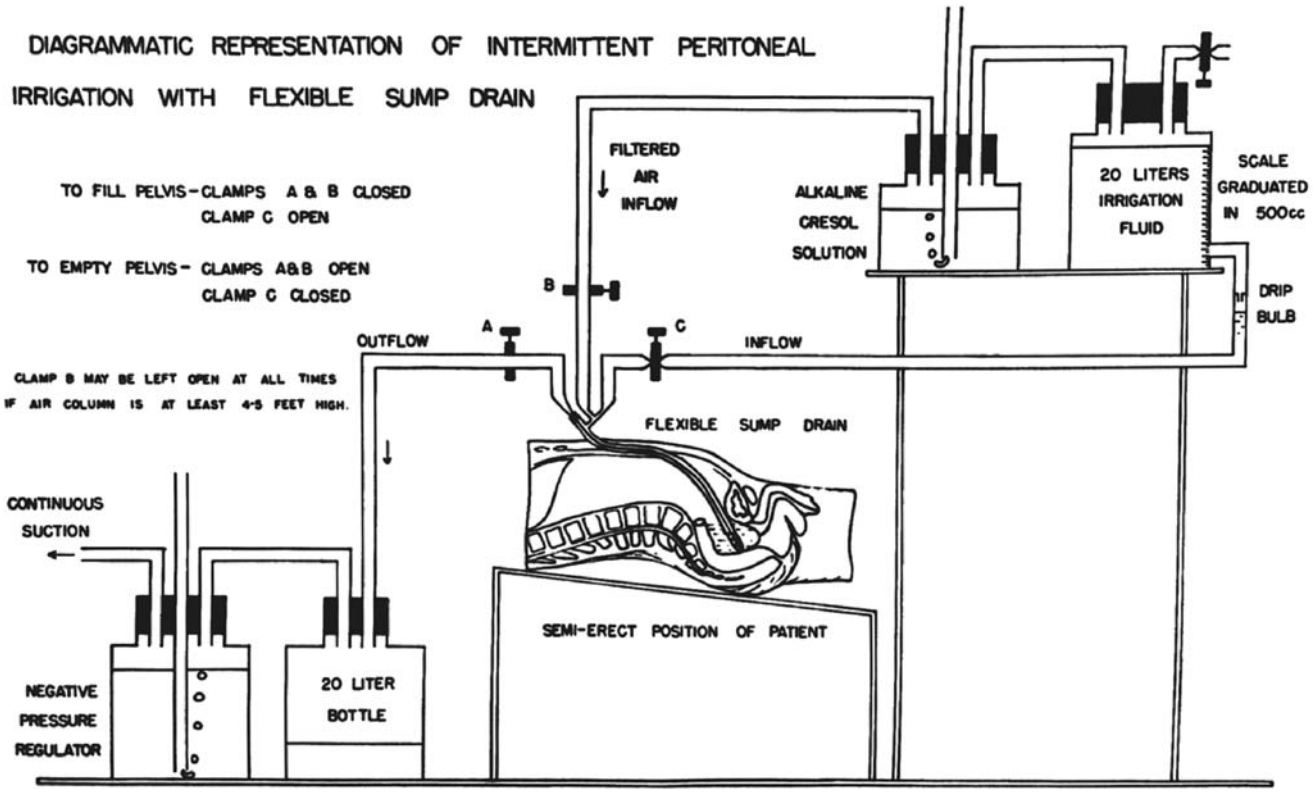

Fig. 14.7 Diagrammatic representation of intermittent peritoneal irrigation with flexible sump drain. Note: to fill pelvis – clamps A & B closed, clamp C open; to empty pelvis – clamps A & B opened, clamp C closed; clamp B might be left open at all times if air column was at least 4–5 feet high. Modified from [21]

Rapid progress in peritoneal dialysis was made in the 1950 s. Grollman et al. [23, 24] reported their experience with intermittent[7] peritoneal lavage in nephrectomized dogs and in five patients. In dog experiments, 1 L of peritoneal fluid was infused into the peritoneal cavity through a needle. After a variable dwell time the fluid was siphoned off through the same size needle, followed by refilling. The exchanges were usually done twice daily in the morning and late afternoon. The technique was modified for patients. The fluid was infused into and drained from the peritoneal cavity through a single polyethylene tube placed through the anterior abdominal wall. "A trocar was inserted as in the routine removal of ascites fluid, the stylet replaced with the polyethylene plastic tube, and the trocar[8] removed." The lavage lasted between 16 and 48 h. According to their experience, "The intermittent procedure just described avoids the complex apparatus, multiple incisions and constant attention necessary when one utilizes a constant perfusion technique. It is, nevertheless, almost equally effective as a means of replacing renal excretory function since ... it requires several hours for equilibrium to be established between fluid in the peritoneum and the blood. A continuous lavage tends, moreover, to result in the channeling of the perfusion fluid and hence may actually prove less efficient..." [23].

The next major progress was made in the late 1950 s when Maxwell et al. reported their experience with 76 peritoneal dialyses [25]. Seemingly minor improvements in the technique provided major improvements in results. The catheter was introduced with a technique similar to that of Grollman et al. [23], but the semirigid catheter was made of nylon[9]

[7] There has been some confusion regarding the terms *intermittent* and *continuous* peritoneal dialysis. Some authors applied the term *continuous* if the lavage was carried on for several days without interruption, and the term *intermittent* if the lavage was interrupted for a night or a day or two [21]. Others applied the term *continuous* if peritoneal fluid flowed continuously between the inflow and outflow accesses. In this terminology, intermittent lavage was carried with only one access and the flow was interrupted [2]. Grollman and his colleagues used the term *intermittent* in the latter meaning, but they performed continuous lavage in the other understanding of this word. To avoid confusion, there was a proposal to use the term *continuous peritoneal dialysis regimen* for dialysis carried out day and night 7 days per week without interruption and *continuous flow peritoneal dialysis technique* for the other meaning of this word.

[8] Here, by trocar, the authors understood the sheath or cannula of the trocar,

[9] Nylon is made of repeating units with amide linkages between them. Hence, it is frequently referred to as a polyamide. Various forms of nylon with various properties are available.

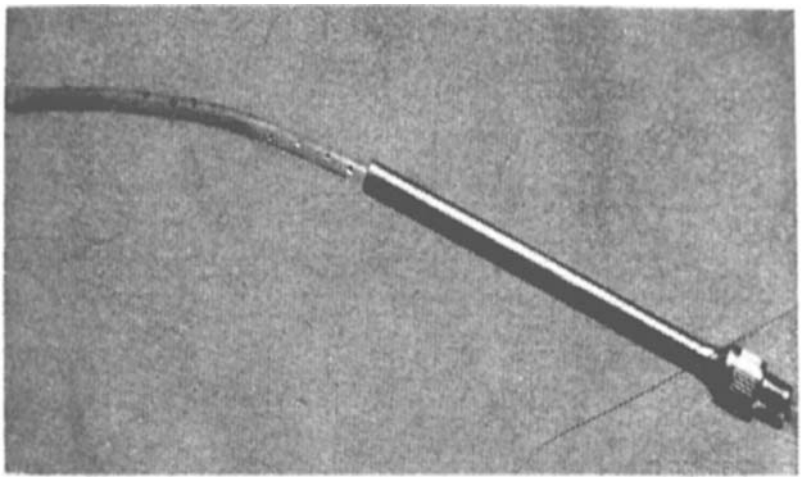

Fig. 14.8 Maxwell's trocar and permanently curved nylon (polyamide) catheter with rounded tip and multiple small perforations at the distal end. Reprinted with permission from [25]. Copyright © 1959, *American Medical Association*. All rights reserved

instead of polyethylene, had rounded tip, and had numerous very tiny perforations (80 holes of 0.02 inch[10] diameter) instead of larger openings at the distal 3 inches (Fig. 14.8). The authors believed that the use of nonirritating plastic prevented omentum and intestines from clinging to the catheter, and that the small diameter of perforations prevented particles of omental fat from plugging the catheter. They used a 17F Duke trocar set for insertion of the catheter.

At the same time, Doolan and co-workers [26] developed a polyvinyl catheter with multiple ridges to prevent omental wrapping. Both catheters were inserted into the peritoneal cavity with the help of a paracentesis trocar. Smooth, plastic materials were much less irritating to the peritoneum than previously used glass, rubber, or steel, thereby omental occlusion became less frequent. The drainage of fluid from the peritoneal cavity was markedly improved, but leakage and pericatheter infections continued to plague the access.

In the early 1960 s, various conduits, buttons, and prostheses were developed to facilitate repeated entrance to the peritoneal cavity. These devices never gained popularity as major complications, particularly peritonitis and adhesion formation leading to technical difficulties, were not eliminated [4]. Disappointed with these poor results, Boen and his collaborators developed the repeated puncture method and published their experience in 1964 [27]. The semirigid catheter was inserted through the 14F trocar described by McDonald [28]. The catheter was removed after each dialysis. Intermittent peritoneal dialysis was carried out once weekly for 14–24 h with 3 L of fluid per hour with the use of cycling machine.

Although McDonald's thin-walled 14F trocar significantly decreased the incidence of pericatheter leaks and bleeding, common with previously used 17F trocars, these were not eliminated. To circumvent these problems, Weston and Roberts invented a stylet catheter, which was inserted without a trocar [29]. A sharp stainless steel stylet ("three-sided trocar point") inserted through the nylon catheter was used to penetrate the abdominal wall (Fig. 14.9). As a result, the abdominal opening fitted snugly around the catheter, thereby preventing leakage. Only local anesthesia was used for catheter insertion. Before catheter insertion the abdomen was filled with dialysis solution via a 14 or 15 gauge needle inserted through the *linea alba* below the umbilicus. Then a small incision was made in the skin, the catheter with the stylet was pierced through the abdominal wall, then the stylet was withdrawn, the catheter advanced to the right or left pelvic gutter, and dialysis was started with 2 L exchanges. After dialysis the catheter was usually removed. This type of catheter is still being used for acute renal failure.

A major step forward in creating a permanent peritoneal access was made in 1964. Gutch [30] noticed lower protein losses with silicon rubber catheters as compared to those with polyvinyl ones, which suggested less irritation of the peritoneum with a new material. About the same time, Palmer, with the help of Wayne Quinton, already successful in manufacturing silicon rubber shunts for hemodialysis, developed a catheter which is a prototype of currently used coiled catheters [31]. The catheter was made of silicon rubber, the intraperitoneal end was coiled and had numerous perforations extending 23 cm from the tip, a long subcutaneous tunnel was supposed to hinder periluminal infection (Fig. 14.10). To impede further infection and leakage, a tri-flanged step was created for securing the catheter in the deep abdominal fascia.

In 1965, Henry Tenckhoff, at the University of Washington, was beginning to treat patients on chronic peritoneal dialysis [32]. After initial few dialysis in the hospital, the patients would be trained for home dialysis. On the weekends,

[10] 0.02 inch = 0.0508 mm

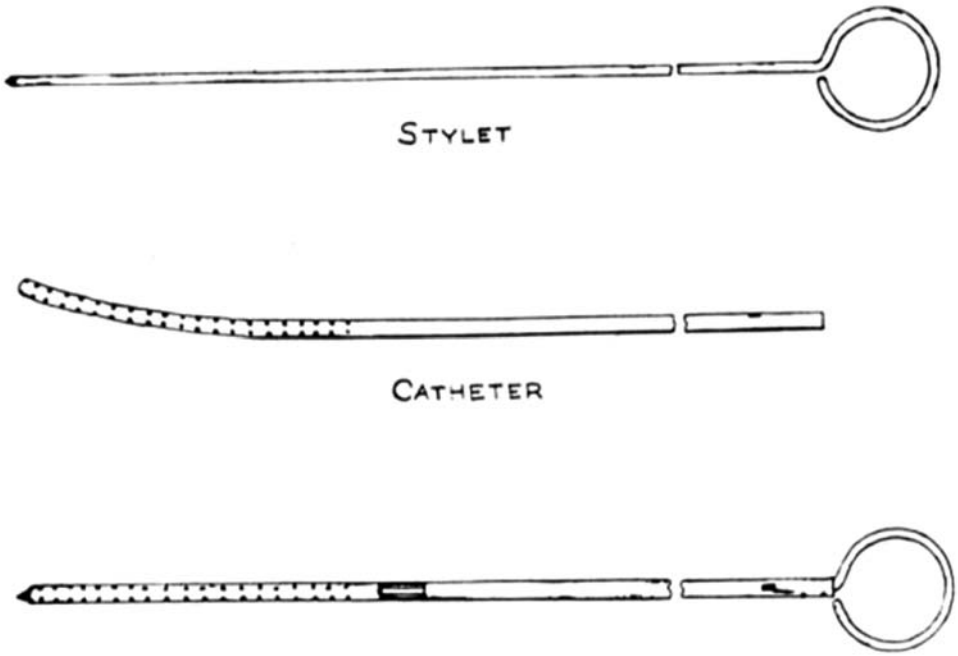

Fig. 14.9 Weston and Roberts' stylet catheter. Modified from [29]

Tenckhoff would go to patient's home, insert the catheter, and begin dialysis. After the appropriate time on dialysis, the patient would remove the catheter and cover the exit wound with a dressing. Although the method was successful in Tenckhoff's hands, the technique was cumbersome, and Tenckhoff recognized its limitations.

In 1968, McDonald and co-workers [33] developed an external seal composed of polyester (Dacron®) sleeve and polytetrafluoroethylene (Teflon®) skirt. Tissue ingrowth into these elements created a firm external seal to prevent leakage and microorganism migration. No subcutaneous tunnel was created; the catheter was inserted straight through the abdominal wall. This catheter never gained popularity, as at the same time Tenckhoff and Schechter published the results of their studies on a new catheter, which provided results superior to any other catheter designed so far [34]. Their catheter (Fig. 14.11) was an improved version of the Palmer catheter. An intra-abdominal flange was replaced by a Dacron® cuff, a subcutaneous tunnel was shortened, and the second, external cuff was used to decrease the length of the catheter sinus tract. Ultimately, the coiled intraperitoneal portion was replaced by a straight segment resembling the Gutch catheter. Intraperitoneal segment was kept open ended and the size of the side holes was optimized to 0.5 mm to prevent tissue suction. A shorter subcutaneous tunnel and straight intraperitoneal segment facilitated catheter implantation at the bedside with the aid of a specially designed trocar (Fig. 14.12). To avoid excessive bleeding the catheter was inserted through the midline. The Tenckhoff catheter has become the gold standard of peritoneal access. Even today, 40 years later, the Tenckhoff catheter in its original form is the most widely used catheter type. Some of the original recommendations for catheter insertion, such as an arcuate subcutaneous tunnel with downward directions of both intraperitoneal and external exits, are still considered very important elements of catheter implantation.

The most common complications of the Tenckhoff catheter included exit/tunnel infection, external cuff extrusion, obstruction (which was usually a sequel of catheter tip migration out of the true pelvis with subsequent omental wrapping or tip entrapment in peritoneal adhesions), dialysate leaks, recurrent peritonitis, and infusion or pressure pain. Numerous devices were tried to improve the results achieved with Tenckhoff catheter – most of them unsuccessfully as this catheter is still preferred by most nephrologists for treatment with peritoneal dialysis.

To prevent exit infection, a subcutaneous catheter was developed by the Stephen et al. [35]. The catheter had two tubes in the peritoneal cavity, and a subcutaneous container. The container was to be punctured for each dialysis. This device was used for continuous flow peritoneal dialysis. To decrease peritonitis episodes, Gotloib et al. [36] developed a prosthesis, which consisted of a Teflon® tube with internal diameter similar to the external diameter of the peritoneal catheter. The head of the tube was funnel shaped to simplify insertion of the catheter. The prosthesis was implanted surgically with the head located in the subcutaneous tissue and the tube penetrating through the parietal peritoneum. After a week, dialysis was started. The skin over the prosthesis head was pierced with a stylet and then the catheter

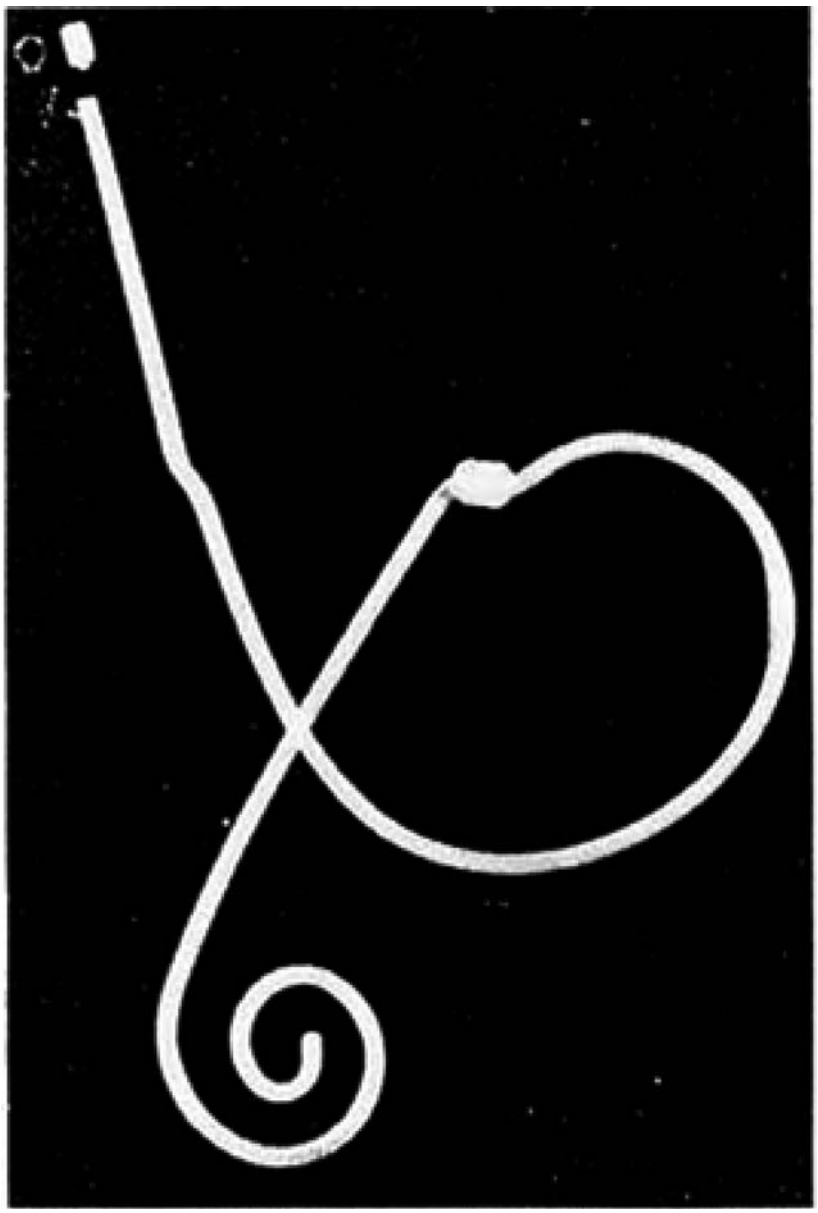

Fig. 14.10 Palmer and Quinton's silicone rubber catheter with triflange step (A) and coiled tip (B). Modified from Palmer, Quinton, and Gray [31]

introduced into the prosthesis, the stylet removed, and the catheter advanced to the pelvic gutter. The catheter was removed after each dialysis. Yet another approach to decrease exit-site infection rates was to position the subcutaneous cuff at the skin level [37]. The catheter tubing was made of Silastic to which was attached a transcutaneous segment with a flange and cuff of expanded polytetrafluoroethylene (PTFE). The flange was located subdermally and the collar protruded through the skin. The cuff was placed perpendicularly through the subcutaneous tissue without a lateral tunnel. Unfortunately, contrary to expectations, such a position tends to increase infection rates [38].

To decrease catheter migration and omental wrapping the intraperitoneal segment of the catheter was provided with a saline inflatable balloon [39] or discs [40]. Valli et al. [41] revived an idea of bulbous distension of glass cannula [7, 9], but, instead of glass, a stiffened silicone rubber with a balloon surrounding the catheter tip was used. In an improved version, the preballoon segment of the intraperitoneal portion of the catheter was eliminated and the balloon was attached to the abdominal wall to avoid migration. The internal segment in the balloon was eliminated; the tube ended at the balloon, which was smaller than in the previous version. Thus, the improved catheter (Valli-2) in its concept was very close to those of mushroom or column disc catheters, but with better material and smaller and more numerous holes [42]. This balloon cannot migrate but still may be obstructed by bowel or omentum. Thornhill et al.

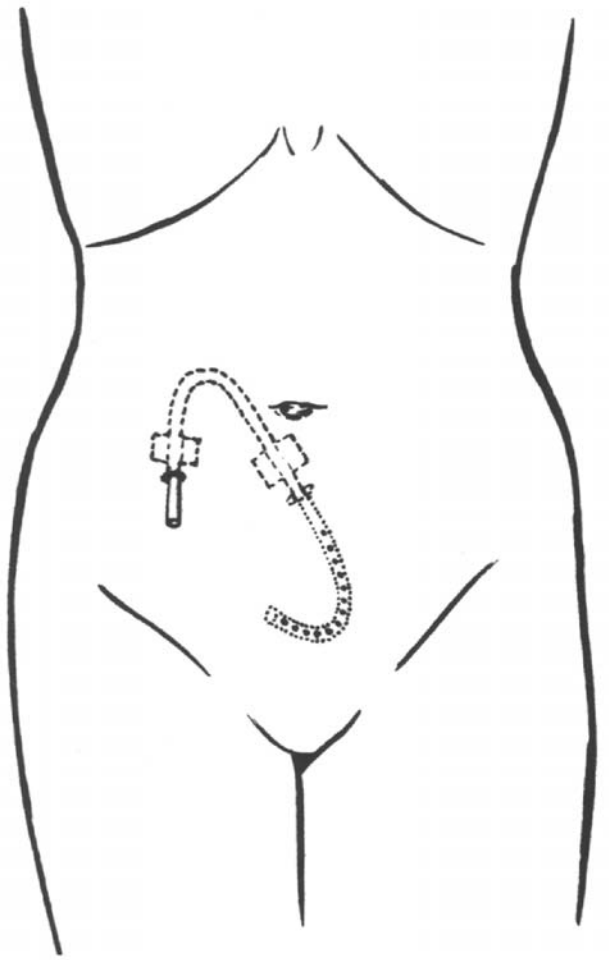

Fig. 14.11 Properly implanted Tenckhoff and Schechter silicone rubber catheter with two cuffs. Modified from [34]

[43] returned to the concept of implanting a mushroom-like structure just below the peritoneum in the left lower abdominal quadrant. However, unlike the de Pezzer rubber catheter, the head of their catheter was made of two parallel discs of silicone elastomer separated by short pillars and anchored to the abdominal wall by a Dacron® felt sleeve. They believed that the column disc catheter would perform better than the mushroom catheter used in the 1940 s and even better than the Tenckhoff catheter. Unfortunately, this was not the case. Compared to the Tenckhoff catheter the rate of catheter obstruction was higher and the catheter survival was markedly lower in the subsequent clinical study [44]. The use of this catheter gradually ceased. In 1993, Ash and Janle [45] changed the intraperitoneal segment of the catheter from the column disc to a longitudinal tube with 1-mm wide "flutes" or grooves on the surface. The intraperitoneal segment lay against the parietal peritoneum and was connected perpendicularly to a transabdominal tube, thus creating a "T"-shaped catheter. The catheter cannot migrate, but still may be obstructed by bowels, adhesions, or omentum. Another approach was undertaken by Chiaramonte et al. [46, 47]. Because the best position of the catheter tip for dialysate outflow is in the true pelvis, they decided to shorten the catheter and implant it very low, just a few centimeters above the symphysis pubis. Such a catheter had a limited capability to migrate outside of the true pelvis and the omental wrapping was less likely as in the majority of people the omentum does not reach below the pelvic brim. This was a return to the old idea of locating an outflow peritoneal access very low, in the Douglas cavity, where conditions for fluid drainage were the best. The insertion point was either on the *linea alba* or McBurney point, 3–4 cm over the pubis. According to the authors, the catheter obstruction rate was very low, other complications were not worse than with the Tenckhoff catheter, with the exception of pericatheter leaks, which were significantly higher. This was related to the low insertion site of the catheter, near the pubis, where intraabdominal pressure in the upright position is higher compared to that of the insertion site of the Tenckhoff catheter near the navel. To keep the catheter tip in the true pelvis, Di Paolo et al. [48] returned to the idea of Ferris and Odel [20] of adding weights into the catheter tips. Instead of bendaloy they incorporated a 12-g tungsten weight at the silicone rubber catheter tip.

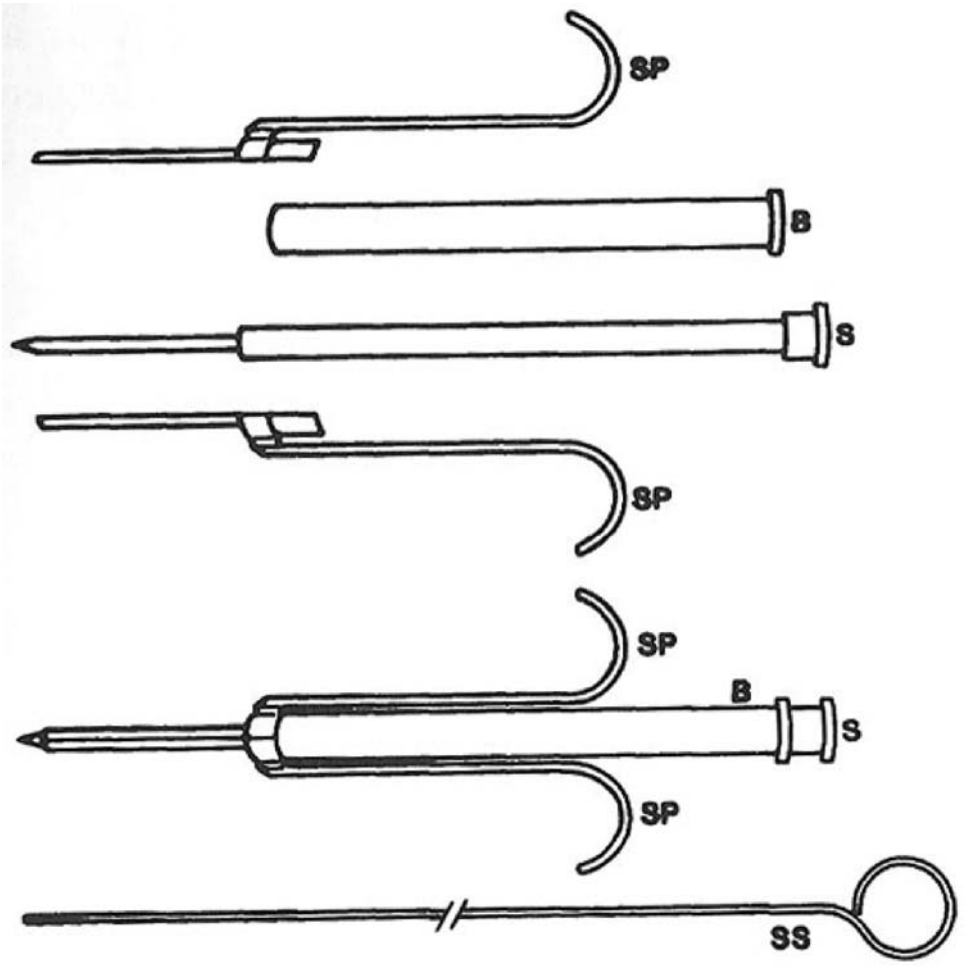

Fig. 14.12 Tenckhoff trocar – assembled (above) and disassembled (below). SP – side pieces; S – pointed stylet; B – barrel; SS – stiffening stilette

Early peritoneal accesses were plagued by pericatheter leaks. The Tenckhoff catheter with Dacron® cuffs drastically decreased this complication in supine peritoneal dialysis. The introduction of ambulatory peritoneal dialysis once again increased the frequency of pericatheter leaks because of increased intraabdominal pressure in the upright position. To prevent this complication, a new catheter was designed. The catheter, dubbed the Toronto Western Hospital Type 2 (TWH-2), was made of silicone rubber tubing and was provided with two cuffs, similar to the Tenckhoff catheter, and two silicone rubber discs to curtail catheter migration; however, it had new features. The catheter was provided with a polyester disc (flange) at the base of the deep cuff and a silicone rubber ring (or bead) situated close to the flange that provided a groove in which a purse string suture could tie the peritoneum tightly [49]. These innovations by themselves did not decrease leakages, so the authors signaled that they started a modified implantation technique. Instead of implantation through the *linea alba*, the catheter was inserted though the rectus muscle.

Several catheters have been developed in recent years aimed at eliminating or decreasing multiple complications of Tenckhoff catheters. Twardowski et al. [50] designed silicone rubber "swan-neck" catheters that are permanently bent between two cuffs. These catheters may be implanted in an arcuate tunnel with their shape undistorted. A similar principle was applied by Cruz to polyurethane catheters (Fig. 14.13) [51]. In 1992, Twardowski et al. [3, 52] described a new catheter that had an exit site on the chest instead of the abdomen (Fig. 14.14). Moncrief et al. [53] described a modified swan-neck catheter with an elongated external cuff. They also substantially changed technique of catheter insertion by keeping the external part under the skin until the ingrowth of the tissue into the cuff is strong. Only after several weeks (three to six or more) is the external part exteriorized.

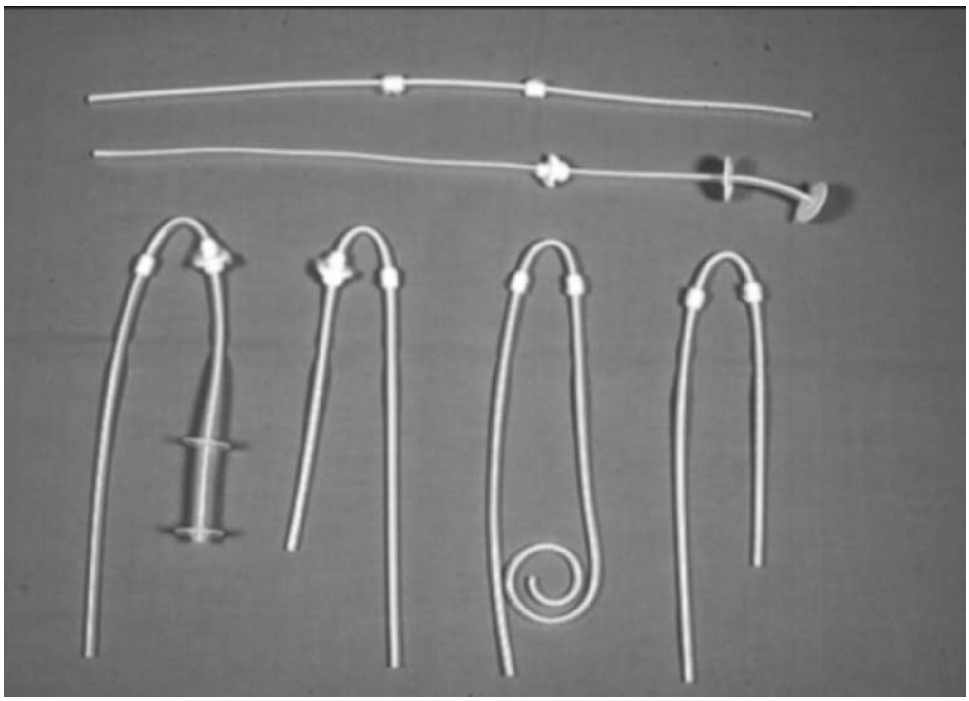

Fig. 14.13 Tenckhoff, Toronto Western Hospital (TWH) catheters and various swan-neck catheters. All swan-neck catheters have two cuffs and bent intramural segment. Swan-neck Missouri catheters have a slanted flange and bead at the deep cuff

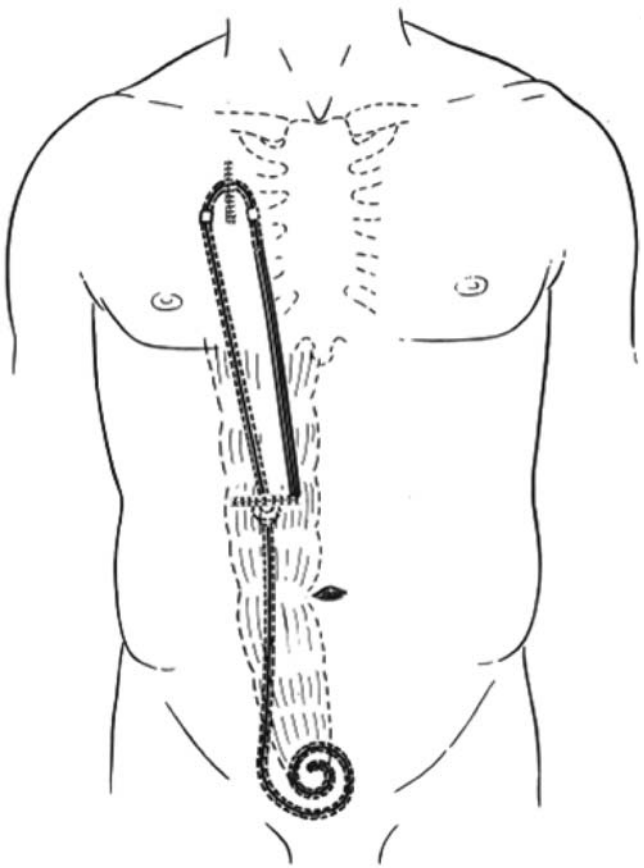

Fig. 14.14 Swan-neck presternal catheter after implantation. The deep cuff with flange and bead is shown in the rectus muscle; the titanium connector is 2–3 inches (5–7.5 cm) above the deep cuff. The middle and superficial cuffs are in the parasternal area, and the exit is 3 cm below the external cuff. Modified from [52]

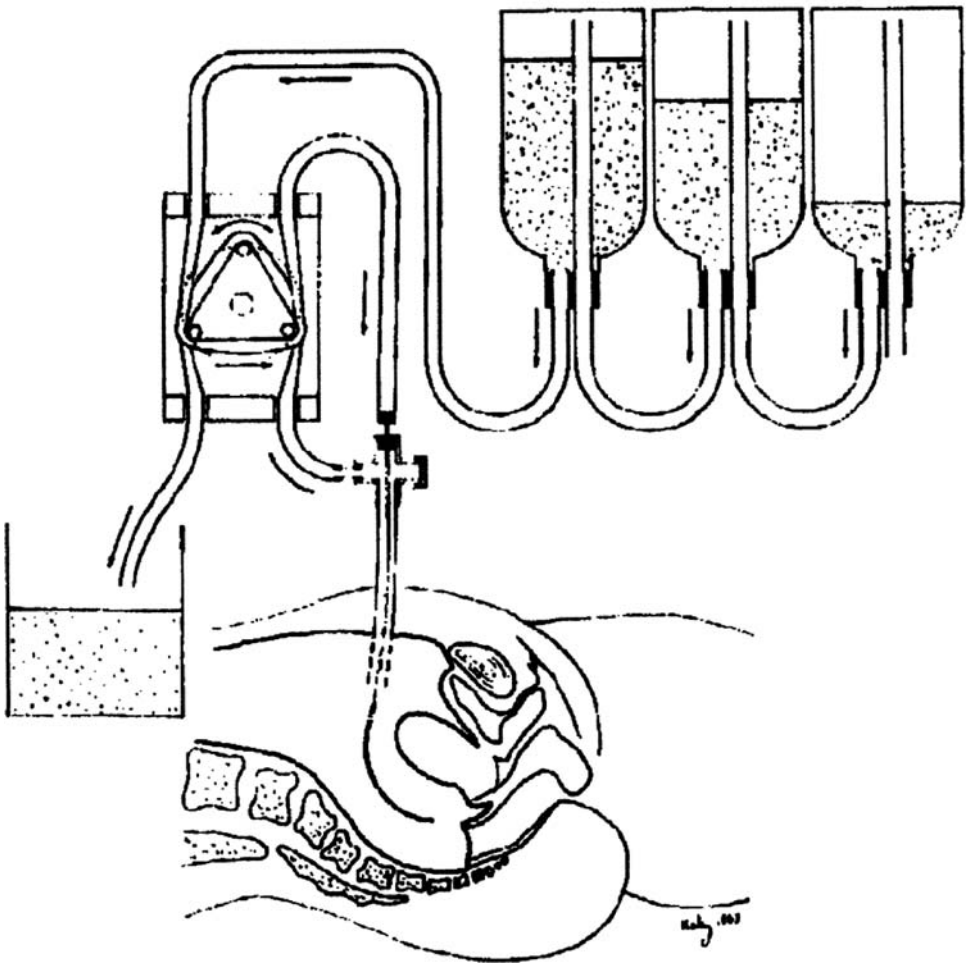

Fig. 14.15 Automatic continuous flow peritoneal dialysis of Lange, Treser, and Mangalat. A = inflow. B = outflow. Modified from [55]

Continuous flow peritoneal dialysis, introduced in animals in 1926 by Rosenak and Siwon [7] and in humans by Balázs and Rosenak in 1934 [9], was used concomitantly with intermittent flow peritoneal dialysis until the late 1960 s (Fig. 14.15). High fluid flows were used with either two catheters [22, 54] or double-lumen catheters. One double-lumen catheter was developed by Lange et al. [55]. The catheter (Fig. 14.16) was composed of a short nylon catheter of 15 cm length with an outer diameter of 4.7 mm and inner diameter of 4 mm and numerous perforations in the distal 3 cm. The catheter was introduced into the peritoneal cavity with a trocar under local anesthesia; the trocar was removed and the catheter was attached to a four-way connector and 2,000 mL of solution was infused to the peritoneal cavity. Immediately thereafter, a stiff nylon catheter, 37 cm long, with an outer diameter of 2.2 mm and inner diameter of 1.4 mm was introduced to the pelvic gutter through the lumen of the large catheter. The internal catheter was tightly sealed in the opening of the cross and connected to the inflow tubing. The fluid inflow was through the inner catheter to the pelvic gutter and drainage was through the large catheter with openings below the parietal peritoneum of the anterior abdominal wall. Stephen et al. [35] used their subcutaneous catheter for recirculating peritoneal dialysis, which was an offshoot of continuous flow peritoneal dialysis.

The technique of continuous flow peritoneal dialysis was abandoned after the advent of continuous ambulatory peritoneal dialysis regimen in the late 1970 s as it was associated with technical difficulties due to catheter obstruction, abdominal pain related to high flow, and less then expected dialysis efficiency because of fluid channeling [56]. There is a renewed interest in continuous flow peritoneal dialysis, as it is believed that new peritoneal accesses may make this modality successful. One of these catheters, a fluted double-lumen catheter, has been recently described by Diaz-Buxo from Fresenius Medical Care North America, Lexington, Maryland, USA [57, 58]. Within the abdominal wall, this catheter consists of two tubes using a novel configuration, where one slightly oval-shaped tube embeds within the other crescent-shaped tube. Externally, the tubes are separate. Intraperitoneally, the tubes are also separated, with each tube terminating with a fluted section. The internal part of this double-lumen catheter is similar to the T-fluted catheter with

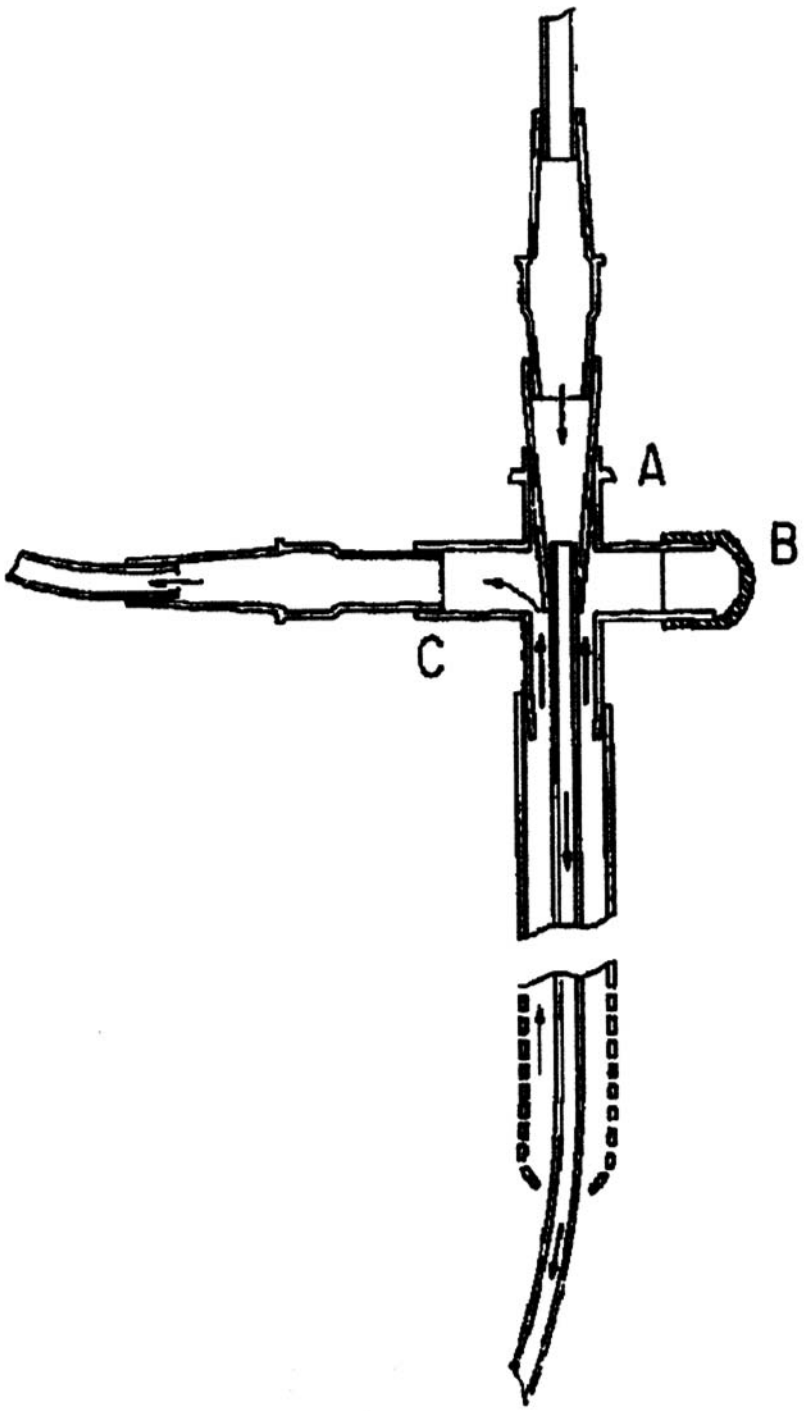

Fig. 14.16 Lange, Treser, and Mangalat's double-lumen catheter for continuous flow peritoneal dialysis. Modified from [55]

the exception that the latter is a single-lumen catheter. Another catheter, a double-lumen catheter with diffuser, has been recently developed by Ronco et al. [59]. The intraperitoneal segment of the outflow tubing has a coiled design. The intraperitoneal segment of the inflow tubing is a short, thin-walled, silicone rubber, round, tapered diffuser with multiple side holes, which allow the inflowing dialysis solution to be dispersed just below the parietal peritoneum, far away from the outflow tubing tip. This design is a reversal of the catheter of Lange et al. [55], where inflow was to the pelvic gutter and drainage through the large catheter with openings below the parietal peritoneum of the anterior abdominal wall.

In agreement with the general pattern of biological and technological evolution, the first peritoneal accesses were devices that had been used in other fields of medicine or surgery. Gradually, the accesses were designed specifically for

peritoneal dialysis. Most of the designs improved the performance of peritoneal accesses, although some led nowhere and were abandoned. The major breakthrough came in the 1960 s with the invention of the Tenckhoff catheter.

Technological evolution never ends. Multiple attempts are being made to eliminate remaining complications of the Tenckhoff catheter, such as exit/tunnel infection, external cuff extrusion, migration leading to obstruction, dialysate leaks, recurrent peritonitis, and infusion or pressure pain. New designs combine the best features of the previous catheters or incorporate a new element. Not all attempts are successful, but many are. The swan-neck catheters with the permanent bend of the silicone rubber in the intratunnel segment have been among the most successful. Consecutive gradual improvement leading to the classic Tenckhoff catheter and subsequent modification of the Tenckhoff catheter are summarized in Table 14.1.

Other innovations have included surface modification of catheters to reduce infections. Silver, because of its antimicrobial activity, has been studied extensively. Surface coating of catheters using ion-beam-assisted deposition

Table 14.1 Development of new features in peritoneal accesses for dialysis in humans

1st Author	Year	Ref.	Fig.	Main new feature(s)	Prior similar concept(s) [ref.]

Twardowski	1985	[50]	12	Permanent bend of intercuff segment	Permanent bend was a new idea
Twardowski	1992	[3]	12	Exit on the chest, long tunnel, three cuffs	Exit on the chest and three cuffs were new ideas. Frank et al. [21] and Palmer et al. [31] designed long tunnels
Di Paolo	1996	[48]	12	Tungsten weight at the catheter tip	Bendaloy weight at the tip (Ferris and Odel [20])

of silver was shown to be effective in reducing infections in our initial animal studies [60, 61], but such catheters have not been studied in human subjects. Another technology to treat catheters is by silver ion beam implantation therapy, wherein the silver ions penetrate the catheter to a depth of 200–300 nm. In a study of 67 such silver-treated catheters and 72 controls, no differences in exit-site infections or peritonitis were noted [62]. The failure to reduce infections may be secondary to the low surface availability of silver. Further, the lack of effect on peritonitis may be secondary to the lack of silver in the internal lumina by this technology. An alternative is to impregnate the catheter matrix with silver. The distribution of submicron silver evenly through the matrix creates a larger antimicrobially active surface than can be created by surface coating [63]. The silver ions are released from the matrix into the unstirred water layer of the surface and are available to interact with the free sulfhydryl groups of bacterial enzyme systems [63]. In vitro studies have demonstrated the antimicrobial activity of these silver-impregnated catheters against coagulase-negative staphylococci (CNS), *Staphylococcus aureus, Enterococcus faecalis, Escherichia coli, Pseudomonas aeruginosa,* and *Candida albicans* [64]. While no studies have been done with silver-impregnated peritoneal dialysis catheters, clinical tests with silver-impregnated vascular catheters have not consistently shown favorable results [65, 66].

A preliminary evaluation of a silver ring device mounted on a catheter showed significant reductions in exit-site infections in a population with a very high exit-site infection rate [67]. A subsequent randomized study showed this device to be ineffective in reducing catheter-related infections. The rate of catheter explantation was similar in the study and control group. Displacement of the silver ring into the tunnel track contributed to infections and catheter loss in almost 6% of the patients [68]. The authors postulated that the piston movement of the catheter may have prevented the ring from being in constant contact with the skin.

Early exit site colonization is associated with higher catheter loss [69]. This has led to studies with antibiotic coated catheters. In-vitro studies show that antimicrobial impregnated catheters loose their efficacy with time [70] but at least theoretically, these catheters would be effective at the most crucial time post-implantation. Clinical studies have shown that intravenous catheters impregnated with chlorhexidine and silver sulfadiazine or minocycline and rifampin are effective in reducing bacterial colonization of catheters with the data being somewhat controversial on reduction of catheter related blood stream infections [71, 72]. Antimicrobial impregnated peritoneal catheters have been studied in rats [73, 74]. In one study, after implantation, the exit sites of both control and impregnated catheters were inoculated with S. *aureus*. All of the control catheters developed colonization at the exit-site and intra-peritoneally seven days post-implantation. In the impregnated catheters, none had intra-peritoneal colonization while12.5% had colonization of the exit-site [73]. In another animal study, Trooskin and colleagues [74], peritoneal dialysis catheters with anionic antibiotic bonded to cationic surfactants, were found to be more resistant to colonization after exit site and intraluminal bacterial challenges. In a prospective randomized study of 86 patients, catheters which were bonded with cefoxitin were unable to show decrease in exit-site infections and peritonitis when compared with the control group [75]. Further refinement of this technique may make this approach effective in the future.

Favorable experience gained with alumina ceramic in orthopedic surgery, otorhinolaryngology, and dentistry inspired Amano et al. [76] to use alumina ceramic for a peritoneal catheter. In this catheter the part of the tubing designated to be contained within the sinus tract is replaced by a rigid alumina ceramic connector. Dog experiments with this material revealed only minimal skin down growth. Preliminary human experience was encouraging [76], but no long-term results have yet been published.

This chapter will describe in detail some of those catheters that are in current use, their insertion technique, postimplantation care, and long-term results. New, emerging techniques will be briefly reviewed.

Currently Used Chronic Peritoneal Catheters

The chronic peritoneal catheter is composed of an intraperitoneal and extraperitoneal portion. The latter comprises a tunnel within the body wall (intramural) and an external (outside the exit site) portion. The intraperitoneal and extraperitoneal portions differ in various catheters and there are many combinations of those. Figure 14.17 shows combinations of intraperitoneal and extraperitoneal designs of currently available chronic peritoneal catheters.

A survey conducted at the Annual Dialysis Conference in 2005 looked at the choice of peritoneal dialysis catheters and implantation techniques over the preceding year [77]. Worldwide, the Tenckhoff catheter was the most popular, used in 65% of patients, followed by the swan-neck catheter in 26% patients. The swan-neck catheter was used in 36% of patients in the United States and 49% in Europe. In this survey, no usage of the swan-neck catheter was reported from Canada, where almost three quarters of the catheters were Tenckhoff and the rest Toronto Western Hospital catheters. Mexico and Central America exclusively used Tenckhoff catheters. Over 90% of the catheters had two cuffs and 68% had coiled intraperitoneal sections. Surgical implantation was used for 72% of patients and 16% were peritoneoscopically placed [77].

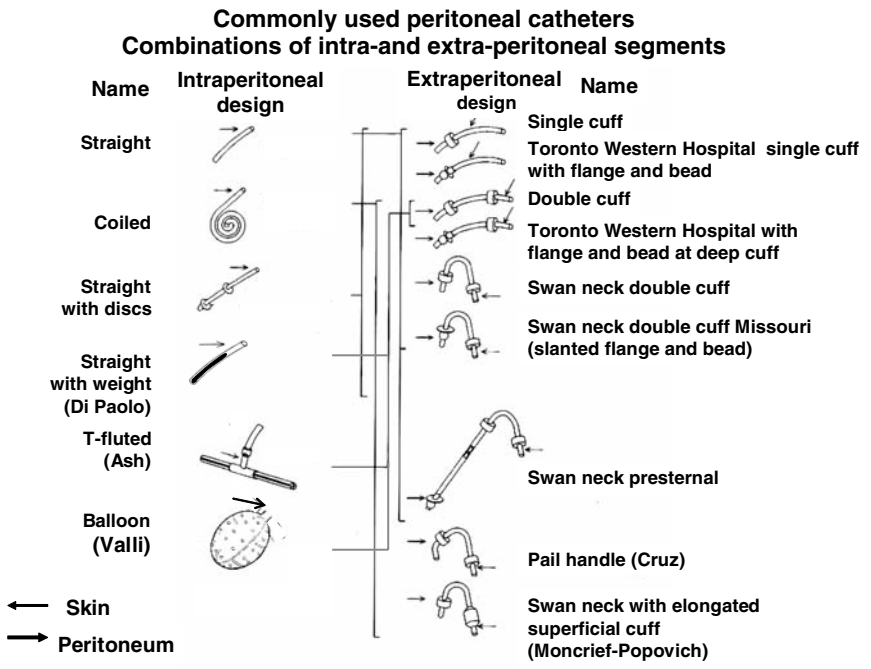

Fig. 14.17 Currently available chronic peritoneal catheters showing combinations of intraperitoneal and extraperitoneal designs. Modified and updated from [129]

Among the pediatric population in this survey, the Tenckhoff catheter was predominant (59%), with swan-neck catheters being used in 41% of patients. In Mexico and Asia the Tenckhoff catheter was used exclusively in children. The majority of the catheters were implanted surgically in this population as well [77]. A survey in 1994 had shown an increase in utilization of swan-neck catheters in the Unites States [78] and it now appears that Europe is following the trend. The swan-neck catheters are associated with fewer episodes of early outflow track obstruction and catheter migration but have not been shown to decrease peritonitis [1, 79]. The use of swan-neck catheters is recommended preferentially by the International Society of Peritoneal Dialysis [1]. The most commonly used catheters are described in detail below.

Straight and Coiled Tenckhoff Catheters

The catheter consists of silicone rubber tubing with a 2.6 mm internal diameter and a 5 mm external diameter (Figs 14.1 and 14.13). The catheter is provided with one or two polyester (Dacron®), 1-cm-long cuffs. The overall length of the adult straight double-cuff catheter is about 40 cm. The lengths of segments are as follows: intraperitoneal, about 15 cm; intercuff, 5–7 cm (intramural); external, 16 cm. The intraperitoneal segment has an open end and multiple 0.5-mm perforations at a distance of 11 cm from the tip. The coiled Tenckhoff catheter differs from the straight in having a coiled, 18.5-cm-long perforated intraperitoneal end. As mentioned above, the coiled catheter reduces inflow infusion "jet effect" and pressure discomfort. All Tenckhoff catheters are provided with a barium-impregnated radiopaque stripe to assist in radiological visualization of the catheter.

Swan-Neck Catheters

The swan-neck catheter is the second most commonly used catheter at present. Its design is based on a retrospective analysis of complication rates with Tenckhoff and Toronto Western Hospital catheters. This analysis showed that the lowest complication rates were with double-cuff catheters implanted through the belly of the rectus muscle and with both internal and skin exits of the tunnel directed downwards; however, the resulting arcuate tunnel led to frequent

Table 14.2 Swan-neck catheter features preventing complications

Exit/tunnel infection	Downward exit, double cuff, short sinus
External cuff extrusion	Permanent bend between cuffs
Intraperitoneal tip migration	Downward intraperitoneal entrance
Pericatheter leak	Insertion through the rectus muscle
Peritonitis	Decreased tunnel infections
Infusion/pressure pain	Coiled intraperitoneal tip

external cuff extrusion [50]. Swan-neck catheters feature a *permanent bend* between cuffs (Table 14.2) [80]. The catheter was dubbed "swan-neck" because of its shape. As a result of this design, catheters can be placed in an arcuate tunnel in an unstressed condition with both external and internal segments of the tunnel directed downwards. A downward-directed exit, two intramural cuffs, and an optimal sinus length reduce exit/tunnel infection rates. A *permanent bend* between cuffs eliminates the silastic resilience force or the "shape memory," which tends to extrude the external cuff. A downward-directed peritoneal entrance tends to keep the tip in the true pelvis, reducing its migration. Insertion through the rectus muscle decreases pericatheter leaks by promoting fibrous ingrowth into the Dacron® cuff. Lower exit/tunnel infection rates curtail peritonitis episodes. Finally, swan-neck catheters with a coiled intraperitoneal segment minimize infusion and pressure pain.

Swan-neck prototypes (Fig. 14.18) were designed in 1985 and were used briefly between August 1985 and April 1986. These catheters were made with 80° of arc angle and were inserted in a reversed U-shape tunnel with the incision at the top of the tunnel [81]. Only 27 of these catheters were inserted because we noted a tendency to cuff extrusions, which we considered a risk for exit infections [82]. Further observations confirmed our predictions. Cuff extrusion occurred in nine catheters and led to exit infections and finally to catheter removal. Initial excellent results with these catheters because of elimination of leaks and malfunctions were obviated later by high infection rates. Cuff extrusions resulted from resilience forces pushing on the external cuff due to an insufficient bend of the catheter and too long a distance between cuffs. We considered these catheters as suboptimal and discontinued their use in April 1986 [82, 83]. Based on this unfavorable observation the catheters were modified; the new catheters, swan-neck 2 and 3 catheters, had straight intraperitoneal segments. A major improvement was in the inter-cuff shape; the distance between cuffs was shortened from 8.5 to 5 cm in swan-neck 2 and to 3 cm in swan-neck 3 catheters and the bend was increased from 80° to 170–180° arc angle. The catheters were provided with short or long intraperitoneal segments, selected according to patient size and insertion site, to secure the catheter-tip position in the true pelvis [82, 84]. Because in several patients infusion pain occurred due to a "jet effect" and/or tip pressure on the peritoneum, we modified the intraperitoneal segment of the catheters, replacing a straight segment with a coiled one (swan-neck coiled). These catheters were introduced in January 1990 and within a month swan-neck straight catheters were phased out [83].

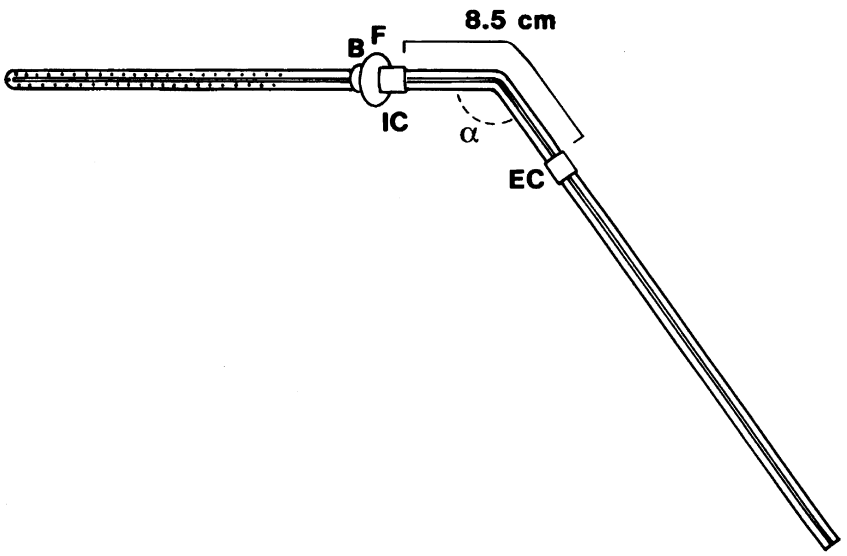

Fig. 14.18 Swan-neck Missouri prototype catheter. Arc angle = 180° – α = 80°. Cuff extrusions were common with these catheters because of insufficient bend and too long a distance between cuffs. We consider these catheters as suboptimal and we have not used them since April 1986

Swan-Neck Tenckhoff Straight and Coiled Catheters

The Tenckhoff type of the swan-neck peritoneal dialysis catheter is provided with two Dacron® cuffs. It differs from the double-cuff Tenckhoff catheter only by being permanently bent between cuffs. This type of catheter may be inserted at the bedside and does not require surgical insertion; however, a subcutaneous pocket and tunnel has to be created in the same way as for other swan-neck catheters. The intraperitoneal segment of the swan-neck coiled catheter is identical to that of the Tenckhoff coiled catheter [84]. All swan-neck catheters are manufactured by Covidien (Mansfield, MA 02048, USA).

Swan-Neck Missouri Straight Catheter

The swan-neck Missouri abdominal catheter has a flange and bead circumferentially surrounding the catheter just below the internal cuff; the flange and bead are slanted approximately 45° relative to the axis of the catheter. The catheters for left and right abdominal tunnels are mirror-images of each other. A swan-neck abdominal Missouri 2 abdominal catheter with a 5-cm inter-cuff distance is used in average to obese people (Fig. 14.19). A swan-neck abdominal Missouri 3 abdominal catheter with a 3-cm inter-cuff distance is used in lean to average persons [84].

Swan-Neck Missouri Coiled Catheter

The intraperitoneal segment in all swan-neck coiled catheters is 34 cm from the bead to the tip of the coil. Swan-neck abdominal Missouri 2 coiled abdominal catheters with the 5-cm inter-cuff distance (Fig. 14.19) are used in average to obese people. Swan-neck abdominal Missouri 3 coiled catheters with 3-cm inter-cuff distance are used in lean to average persons. The catheters for left and right tunnels are mirror-images of each other [84]. The overall survival values of straight and coiled swan-neck Missouri abdominal catheters are not significantly different, but none of the

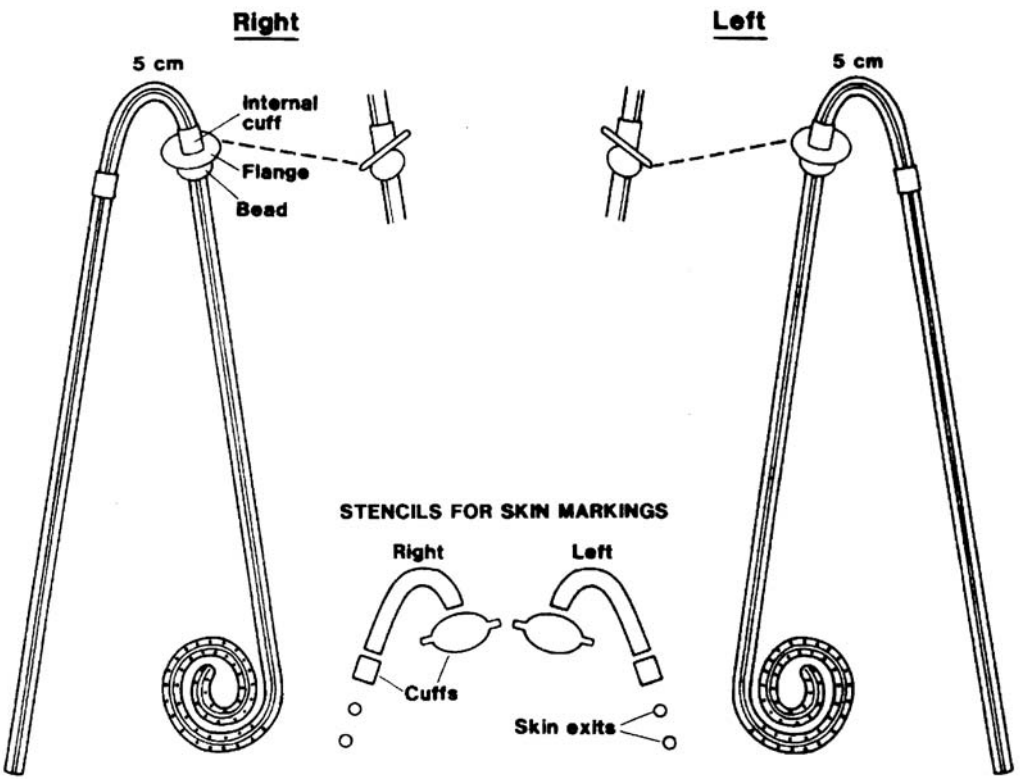

Fig. 14.19 Swan-neck Missouri 2 coiled (curled) catheters and stencils. Swan-neck Missouri 2 catheters have 5-cm intercuff distance and intraperitoneal length of 32 cm from the bead to the tip. The flange and bead are slanted approximately 45° relative to the tubing axis. The catheters for left and right tunnels are mirror-images of each other. The stencil follows exactly the shape of the intramural segment. The stencil can be flipped to be used for right or left catheter. The holes for exit-site markings are located 2 and 3 cm from the cuff. A 3-cm mark is used for average or obese persons, a 2-cm mark is suitable for lean or average persons

patients experienced infusion or pressure pain with coiled catheters, whereas this complication occurred in several patients who had catheters with straight intraperitoneal segments [83]. Swan-neck catheters are also available in smaller sizes for children and infants.

Swan-Neck Presternal Catheter

Potential advantages of exit location in the chest instead of in the abdomen are shown in Table 14.3. The chest is a sturdy structure with minimal wall motion; the catheter exit located on the chest wall is subjected to minimal movements, decreasing chances of trauma and contamination. Also, in patients with abdominal ostomies and in children with diapers, a chest exit location reduces the chances of contamination. Moreover, a loose garment is usually worn on the chest and there is thus less pressure on the exit. Surgical experience indicates that wounds heal better after thoracic surgery than after abdominal surgery; this may, in part, be related to less chest mobility. Obese patients have higher exit-site infection rates and a tendency to poor wound healing, particularly after abdominal surgery. The subcutaneous fat layer is much thinner on the chest than on the abdomen. If fat thickness *per se* is responsible for quality of healing and susceptibility to infection then chest location may be preferred for obese patients. All these favorable factors, together with easy exit-site care using a magnifying mirror, significantly reduce exit-site infections. The location of the exit site on the chest is particularly advantageous in small children because of the greater distance from diapers and is subjected to fewer traumas during crawling/creeping. The catheter is also advantageous for psychosocial reasons. A chest exit location allows a tub bath without the risk of exit contamination. Although the exit site can be located in the presternal or parasternal area we will usually refer to this catheter as presternal for simplicity. However, implantation directly over the sternum should be avoided to prevent catheter damage during median sternotomies used for cardiac surgery. A long catheter tunnel, combined with three cuffs, may curtail pericatheter bacterial penetration into the peritoneal cavity, thus reducing the incidence of peritonitis [3, 84, 85].

To accommodate these principles we modified the swan-neck peritoneal catheter to have an exit on the chest but preserving all advantages of the swan-neck abdominal Missouri coiled catheters, minimizing catheter obstruction, cuff extrusion, pericatheter dialysate leak, and infusion pain. A major difference from the swan-neck abdominal Missouri catheter is in the length of the subcutaneous tunnel. The catheter (Fig. 14.20) is composed of two silicone rubber tubes, which are cut to an appropriate length and connected end to end at the time of implantation [84, 85]. Figure 14.14 shows the catheter in relation to the torso after implantation. The implanted lower (abdominal) tube constitutes the intraperitoneal catheter segment and a part of the intramural segment. The upper or chest portion of the tube constitutes the remaining part of the intramural segment and the external catheter segment. The lower tube is identical to the swan-neck abdominal Missouri catheter, with the exception that it is not bent and does not have a second cuff. The proximal end of the lower tube is straight and with a redundant length to be trimmed to the patient's size at the time of implantation. A titanium connector, provided in a package, is to be used to connect the two components at the time of implantation.

Table 14.3 Potential advantages of the swan-neck presternal catheter compared to the swan-neck Missouri catheter

Attribute	Advantage	Explanation
Exit on the chest	Decreased risk of exit infection	Good immobilization
		Good wound healing
		Loose garment/less pressure
		Easy exit-site care
		Less fat thickness
		Far from ostomies*
		Far from wet diapers**
		Less trauma with creeping**
	Psychosocial	Better body image for some patients
		Easy exit-site care
		May take tub bath without risk of exit contamination
Three cuffs	Decreased risk of peritonitis	Strong (triple) barrier
		Long tunnel, long distance for bacterial penetration

*In patients with ostomies.
**In small children

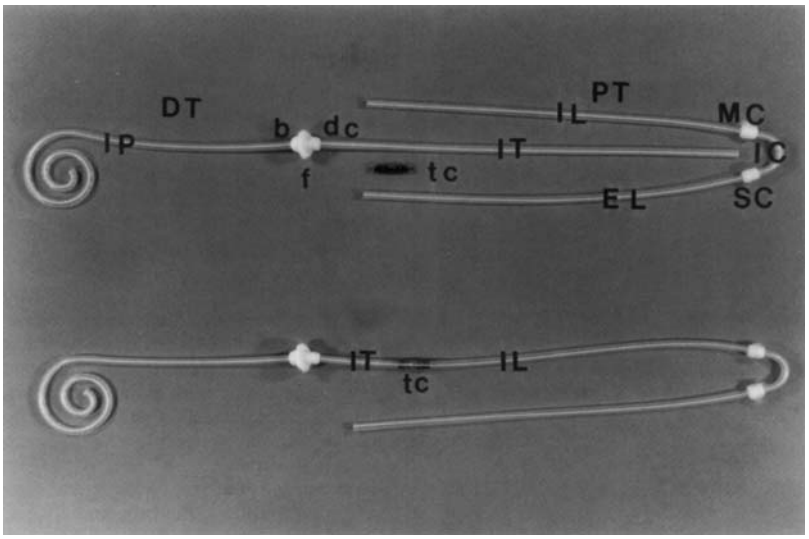

Fig. 14.20 Swan-neck presternal catheter: two tubes of the swan-neck presternal peritoneal catheter before (top) and after (bottom) connection. Both tubes and bead are made of silicone rubber moulded in the shapes as shown. A flange and all cuffs are made of woven polyester fibers. Proximal (upper, chest) tube (PT) consists of an intra-tunnel limb (IL), medial (center) cuff (MC), inter-cuff segment (IC), superficial cuff (SC), and external limb (EL); 1–2 cm of the external limb adjacent to the superficial cuff is intended to be in the sinus tract of the tunnel (from the cuff to the exit). Distal (abdominal, lower) tube (DT) consists of an intra-tunnel segment (IT), deep (distal, preperitoneal) cuff (dc), flange (f), bead (b), and intraperitoneal segment (IP). After implantation (bottom), the intra-tunnel limb (IL) of the chest tube and the intra-tunnel segment (IT) of the abdominal tube are trimmed to the size of the tunnel and coupled with titanium connector (tc)

The upper tube carries two porous Dacron® cuffs, a superficial and middle or central cuff, spaced 5 cm apart. The tube between the cuffs has a permanently bent section defining an arc angle of 180°. The distal lumen of the upper tube communicates with the proximal lumen of the lower tube through the titanium connector. The tubing grip of the titanium connector is so strong that the two parts of the catheter, especially after connection reinforcement with monofilament or braided suture, in practice cannot separate spontaneously in the tunnel [86]. The swan-neck presternal catheter is available for children and infants [87]. Tubing diameter is smaller for pediatric patients.

Moncrief–Popovich Catheter

This catheter is a modified swan-neck Tenckhoff coiled catheter (Fig. 14.17) with a longer subcutaneous cuff (2.5 cm instead of 1 cm). This catheter is most commonly used in conjunction with the Moncrief–Popovich implantation technique (see below).

Radiopaque Stripe

The slanted flange and bead, and bent tunnel segment, require that the swan-neck abdominal Missouri abdominal and Toronto catheters for right and left tunnels be mirror-images of each other. To facilitate recognition of right and left Toronto and Missouri catheters, each catheter has a radiopaque stripe in front of the catheter (Fig. 14.19). In a swan-neck presternal catheter the stripe also facilitates proper alignment of the lower and upper tubes. The stripe is also useful during insertion and postimplantation care, facilitating recognition of catheter twisting. Because of this last feature Tenckhoff-type catheters are also provided with the stripe. Right and left swan-neck Tenckhoff catheters differ only with respect to the position of the stripe. Unlike swan-neck Toronto and Missouri catheters, with the slanted flange, the swan-neck Tenckhoff catheter may be implanted on either side. In this case the stripe may be positioned in the back of the catheter. Nevertheless, to retain uniformity of the stripe position anterior it is recommended that swan-neck Tenckhoff catheters be inserted with the corresponding tunnel direction (right tunnel with right catheter, left tunnel with left catheter).

Other Catheters

Catheters used in small numbers, such as recently designed catheters with one-center experience (T-fluted [45], self-locating [48]) and those used in smaller numbers (Cruz [51, 88], Toronto Western Hospital [40], Life-cath or Column disc [43], Valli [41, 42] and Gore-Tex [38] catheters), will not be described in detail. Readers are referred to the original publications.

Accessories for Implantation of Catheters

Stencils

Stencils have been developed for skin markings to facilitate creation of proper tunnels for swan-neck catheters [84]. Stencils are for swan-neck abdominal Missouri 2 (Fig. 14.19), swan-neck abdominal Missouri 3, and swan-neck abdominal Tenckhoff catheters. The stencils follow exactly the shape of the intramural segments of the catheters and the catheter tunnels must follow the shape of the catheters exactly as designed to maximize the advantages of this design. The stencils can be flipped to be used for right or left catheters. The holes for exit-site markings are located 2 and 3 cm from the superficial cuff. A 3-cm mark is used for average or obese persons; a 2-cm mark is suitable for lean or average persons. Stencils for swan-neck Tenckhoff catheters also reflect precisely the shape of their intramural segments.

Stiffening Stylet

A 62-cm-long stiffening catheter guide is used to facilitate catheter insertion into the true pelvis. During insertion, approximately 1 cm of catheter is left beyond the tip of the catheter guide to protect the intestine. The catheter resumes its natural coiled shape after the stylet is removed [84].

Tunneling Devices

Tenckhoff Trochar

Tenckhoff developed a special trochar for bedside insertion of cuffed catheters into the peritoneal cavity (Fig. 14.12). The trochar (available from Covidien, Mansfield, MA 02048, USA) consists of a sharp, stainless-steel stylet; a solid, wide, open-ended barrel; and two side-pieces with handles [89].

Scanlan Tunneler/Bard Tunneler

A Scanlan (Scanlan International, St. Paul, Minnesota, USA) or Bard tunneler (Bard Peripheral Vascular Division, Inc., Tempe, Arizona, USA) is used during swan-neck presternal catheter implantation to create a tunnel extending from the abdominal wall incision to the presternal or parasternal area. A tunneler that will accommodate vascular grafts up to 8 mm is suitable for presternal catheter implantation. The tunneler, developed for tunneling vascular grafts, consists of an outer sheath with a blunt tip, and a stiff rod with handle. The stiff metal rod serves to stiffen the tunneler as it is pushed through the subcutaneous tissue and a spring clamp or suture hole at the tip is used to grasp or attach the upper tubing and pull it through the sheath [90].

Exit Trochar

The catheter tunnel extending from the superficial cuff to the skin exit should have a diameter close to that of catheter tubing. Thus, the last portion of the tunnel (from external cuff to the exit) should be made with a piercing trochar, e.g., the Faller trochar (Covidien, Mansfield, MA 02048, USA) or a 3/16 inch (4.76 mm, F15) trochar designed for the Hemovac system (Zimmer Mfg. Co., St. Louis, Missouri, USA) or the trochar from a 19 Blake drain (Ethicon Inc. a Johnson & Johnson Company, Somerville, New Jersey, USA) of external diameter similar to that of the catheter tubing [84, 90].

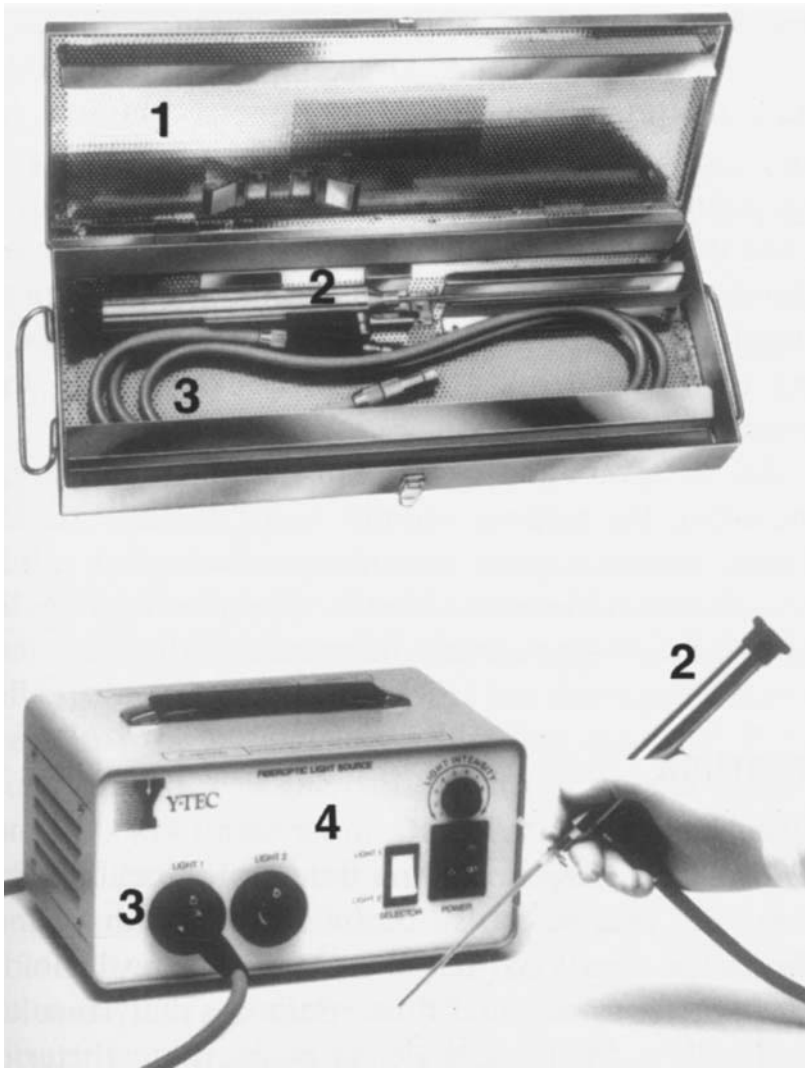

Fig. 14.21 Components for the peritoneoscopic catheter insertion. Above: the sterilization tray (1); the Y-TEC® scope (2); and the light guide (3). Below is the Y-TEC® light source (4), with the scope (2), and light guide (3)

Peritoneoscopic Equipment

The basic equipment (Fig. 14.21) required for peritoneoscopic insertion (manufactured and distributed by Medigroup, North Aurora, Illinois, USA) includes a 2.2-mm diameter, 15-cm long Y-TEC peritoneoscope with a 2.5-mm steel cannula with internal trochar and a spiral-wound Quill catheter guide surrounding the cannula [91, 92].

Seldinger (Guidewire) with Peel-Away Sheath Equipment

The essential instruments (Fig. 14.22) for this technique include a guide needle, attached to a syringe, a Seldinger guidewire, and a tapered dilator with surrounding scored peel-away sheath [93–96]. The necessary equipment and videos can be obtained through Cook Critical Care, Division of Cook Inc., Bloomington, Indiana, USA.

Titanium Connectors, Tyton Ties, and a Tension Tool

After implantation, the catheter must be connected to the peritoneal dialysis set. A titanium connector serves this purpose. A single-piece connector shown in Fig. 14.23 is simply inserted into the end of the external catheter tubing.

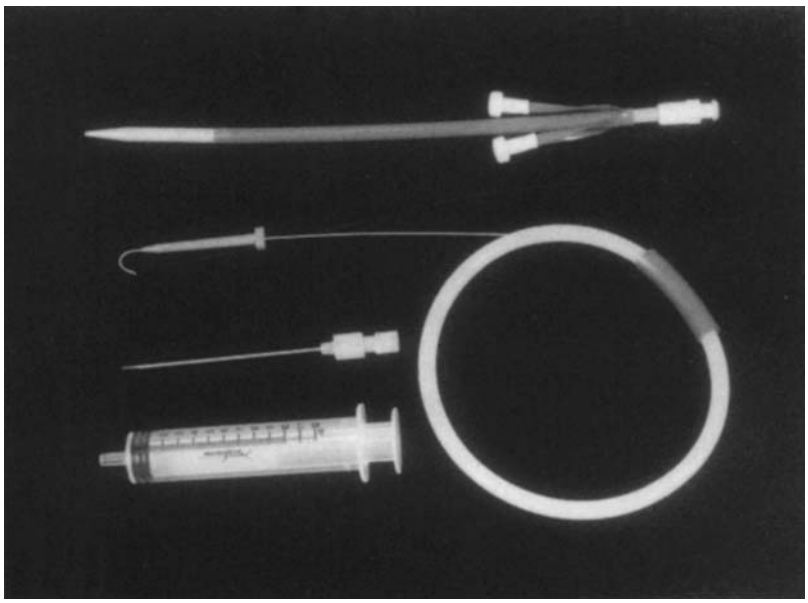

Fig. 14.22 Equipment for guidewire insertion method. From the top: peel-away sheath with dilator, guidewire, needle, and syringe

The external part is equipped with a female Luer lock adapter and sealing cap. The intracatheter adaptor is barbed and its external diameter is slightly larger than the internal diameter of the tubing to avoid accidental disconnection; however, this titanium connector has been associated with numerous instances of spontaneous separations. Tyton ties and a tension tool (Tyton Corporation, Milwaukee, Wisconsin, USA) routinely used to secure bundles of electrical wirings, and available in department stores, may be used to prevent disconnection of the titanium adaptor from the tubing. A 4-inch (100-mm) tie is placed around the distal end of the catheter over the adapter. Care is taken to place the tie in the groove between adapter ridges and not over a ridge. Then the tie is tightened with the tension tool that also trims the excess length. The locking segment is located at the stripe, which will be positioned at the front of the patient (Fig. 14.23). This keeps the added bulk away from the patient [84, 97, 98].

A recently introduced two-piece adapter (Baxter Healthcare Corporation, Deerfield, Illinois, USA), shown in Fig. 14.24, is very safe and no instances of accidental connector disengagements have been reported. The only disadvantage of this design is the substantially higher price.

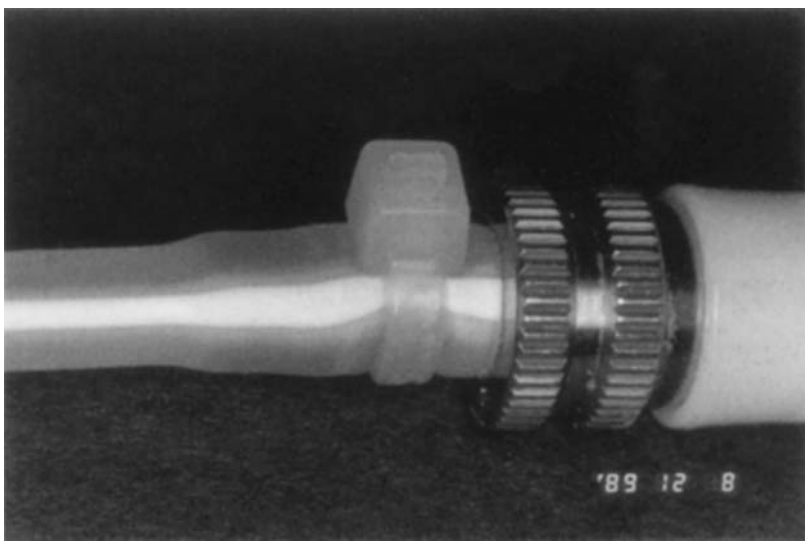

Fig. 14.23 A single-piece titanium adaptor with a barbed connector in the catheter tubing and a male Luer lock connector attached to the female connector of the extension tube. The nylon tie is in place over the catheter/barbed connector junction. The locking segment is over the stripe and will be away from the patient's skin

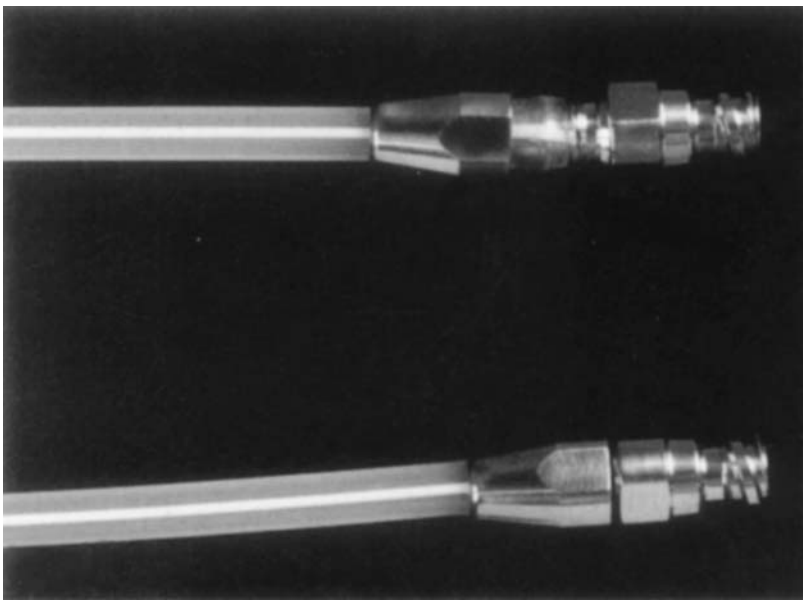

Fig. 14.24 A two-piece adapter (locking titanium adapter – Baxter) with two parts disengaged (upper), with adaptor inserted into the external end of the catheter and after the two pieces are screwed together and tightened (lower)

Insertion of Rigid Catheters

Rigid Catheters for Acute Dialysis

The two most widely used rigid catheters in North America are the Stylocath (Abbott Laboratories, North Chicago, Illinois, USA) and the Trocath (Baxter Healthcare Corporation, Deerfield, Illinois, USA).

Preinsertion Patient Assessment and Preparation

When the need to start peritoneal dialysis is urgent, one may elect to access the peritoneal cavity through a rigid catheter. This catheter can be inserted at the bedside, with minimal preparation. Equipment required for paracentesis is all that is needed.

Bedside insertion *should not* be offered to patients who are extremely obese, or have had previous abdominal surgery, since abdominal adhesions increase the risk of unintentional viscus perforation. In addition, this approach should only be done in children by an experienced pediatric nephrologist or a nephrologist with a pediatrician in attendance. If a nephrologist places the catheter a surgeon should be on stand-by, in case of complications. The patient should receive preoperative sedation and have nothing to eat or drink at least 12 h prior to the procedure.

All observers and persons in the immediate area, including the patient, should wear surgical masks. Those patients who experience discomfort while completely supine should raise their heads slightly. In conscious patients it may be useful to familiarize them with the Valsalva maneuver. The operator and assistant(s) should "scrub, gown and glove." A "circulating" nurse should be present to assist.

Insertion Technique

Using sterile precautions, a small stab wound (2–3 mm) is made in the midline under local anesthesia, 2–3 cm below the umbilicus. The stab wound should be small so that the abdominal wall holds the catheter firmly and thus minimizes dialysis solution leak. With the stylet in place, the catheter is introduced through the abdominal wall by a short thrust, or preferably with a rotary motion. The operator will recognize the loss of resistance as a "pop" as soon as the peritoneal cavity is entered. While the catheter is being thrust through the abdominal wall its tip is directed towards the coccyx. Because successful perforation of the abdominal wall for introduction of the catheter requires a sensitive "feel" for the pressure applied, prior infusion of 2–3 L of dialysate will distend the abdomen, which in turn will facilitate this maneuver. Some infuse 2 L of dialysis fluid via a small-gauge needle prior to stylet puncture. A cooperative patient can also assist successful perforation by voluntarily tightening the abdominal musculature.

Once the peritoneal cavity has been entered the stylet is withdrawn a few centimeters and the catheter is advanced deep into the pelvis. If the operator encounters resistance while the catheter is being advanced, or if the patient

complains of pain, the advance in this direction should be stopped and another direction tried. If this is still not possible, the operator may infuse 2–3 L of dialysis solution into the peritoneal cavity if this has not been done. This can be via the catheter if the holes in the distal end are within the abdominal cavity. This infusion accomplishes two important objectives: first, it facilitates recognition of the "true" intraperitoneal space; second, dialysis solution in the peritoneal cavity reduces the likelihood of viscus perforation by moving the intra-abdominal contents away from the advancing catheter.

After one or two good in-and-out exchanges, the catheter is firmly secured to the skin with the aid of a metal disc.

Complications

Table 14.4 shows complications of rigid catheter insertion. After catheter implantation, bloody effluent appears after the first exchange in approximately 30% of cases [99, 100]. This bleeding (usually minor) comes from the small vessels in the abdominal wall. After three or four exchanges, bleeding usually stops, unless the procedure has damaged a major vessel or the patient has a bleeding disorder. Pressure applied over the catheter insertion site usually controls minor bleeding. If the bleeding is copious it may obstruct the catheter; in this event it, is a common practice to add 1,000 units of heparin to each liter of dialysate to minimize the risk of obstruction. Intraperitoneal heparin is not absorbed in sufficient quantities to influence systemic coagulation.

Dialysis solution leak is encountered in 14–36% of patients after rigid catheter insertion [99–101]. Frequent manipulation of the catheter to improve drainage increases the risk of dialysis solution leak from the catheter-exit site. Such leaks may also occur when the catheter is not properly secured to the skin. The risk of external leak is higher in elderly or debilitated patients who have lax abdominal walls. The presence of a large intra-abdominal mass, such as a polycystic kidney, may raise the intra-abdominal pressure to high levels and promote dialysis solution leak around the catheter after the standard 2-L volume has been instilled.

Fluid may extravasate into the abdominal wall, particularly in patients who have had a previous abdominal operation or multiple catheter insertions. This complication usually results from tears in the peritoneum or represents an infusion of dialysate into the "potential" space between the layers of abdominal wall. Uncommonly, dialysis fluid may enter the pleural cavity [101–109]. In such cases, peritoneal dialysis is usually discontinued and the patients are switched to hemodialysis. Acute hydrothorax results from either a traumatic or a congenital defect in the diaphragm.

Inadequate drainage is frequent during initial dialysis, and may be due to one or more of the following factors: loss of siphon effect, one-way obstruction, and/or incorrect placement of the catheter. One-way (outflow) catheter obstruction may have multiple causes. Fibrin or blood clots may be trapped in the catheter and block the terminal holes, especially when dialysis is complicated by major hemorrhage or peritonitis. Poor outflow may also reflect extrinsic pressure on the catheter from adjacent organs such as a sigmoid colon full of feces or a distended bladder. Omental wrapping is likely if the catheter is misplaced into the upper abdomen.

Occasionally, accidental penetration of the extraperitoneal space by the catheter may cause poor drainage. In such a situation, continued infusion produces further dissection, and the fluid may become trapped and is no longer available for drainage. Loculation of fluid, another cause of poor drainage, is encountered in patients who have had previous intra-abdominal operations or peritonitis. Such loculation, caused by adhesions, not only diminishes the surface area available for dialysis but may seriously reduce ultrafiltration capacity. The incidence of this complication is low, varying between 0.5 and 1.3% [110–118]. Abdominal distension and even respiratory compromise may develop in some patients with inadequate drainage.

Poor ultrafiltration may leave the patient hypervolemic and on occasions rapid hypertonic exchanges can cause excessive fluid removal leading to hypovolemia and hypotension. Rapid exchanges may also be complicated by sodium sieving leading to hypernatremia [100, 115, 119]. Acute peritoneal dialysis may be complicated by significant protein losses in dialysate ranging from 10 to 20 g/day [118–120].

Table 14.4 Complications of rigid catheter insertion

Bleeding
Dialysis solution leak
Poor drainage
Extraperitoneal space penetration
Viscus perforation
Peritonitis
Abdominal pain
Loss of rigid catheter in the peritoneum

Perforation or laceration of internal organs during bedside insertion of a catheter has been frequently reported. Lacerated or perforated organs include the bowel, bladder, liver, a polycystic kidney, aorta, mesenteric artery, and hernia sac [100, 112, 114, 121–123]. Abdominal distension due to paralytic ileus or bowel obstruction may predispose the patient to bowel perforation. Those who are unconscious, cachectic, or heavily sedated are also at high risk. Clinical evidence of bowel perforation includes sudden, sharp, or severe abdominal pain followed by watery diarrhea, and poor drainage of dialysis solution, which may be cloudy, foul smelling, or mixed with fecal material. Such a situation requires prompt removal of the catheter, and allowing the perforation to seal off completely in about 12–24 h. An exploratory laparotomy may be necessary and surgical consultation should be obtained.

Abdominal pain may be encountered in as many as 56–75% of patients with the first use of the catheter [100, 110, 118]. There are many causes of abdominal pain, but catheter-related pain occurs when it impinges on any of the viscera. Pain may occur during inflow and outflow of dialysis solution and also when the solution is dwelling. Inflow pain is often related to the acidity of the solution, its temperature, the jet effect from a straight catheter, or distension of tissues around the catheter. These complications can be dealt by adding sodium bicarbonate (5-25 mEq/L), warming the solution or adjusting the infusion rate [119]. Outflow pain is due to entrapment of omentum in the catheter during the siphoning action of fluid drainage. Constant pain during dialysis indicates pressure effects on intra-abdominal organs and often produces continuous rectal or low-back pain. This complaint calls for an adjustment in catheter position.

The incidence of peritonitis, when the stylet catheter is used, increase with time the catheter is left in the abdomen [124]. Phu et al [125] studied veno-venous hemofiltration and acute peritoneal dialysis with a rigid catheter for infection-associated acute renal failure. He reported an incidence of 42% of cloudy dialysate with only one patient having confirmed peritonitis. Chitalia et al [120] reported 5 episodes of peritonitis among 87 patients treated for hypercatabolic acute renal failure with either continuous equilibrating peritoneal dialysis or tidal peritoneal dialysis with the abdomen accessed with a stylet catheter.

Loss of a part or the entire rigid catheter has been reported following its manipulation with the trochar in place [113, 114, 126–128]. The distal end of the catheter may be amputated after intra-abdominal kinking of the catheter, followed by manipulation. However, the presence of broken catheters within the abdominal cavity may not cause symptoms or ill-effects. During laparoscopy, broken catheters have been found lying freely in the peritoneal cavity without causing a peritoneal reaction, or have been found walled off by mesentery without an inflammatory reaction. On routine postmortem examination, Stein [128] discovered such a catheter in a patient who had previous peritoneal dialysis. Exploration to retrieve the catheter maybe unnecessary because laparotomy may be more hazardous than leaving the catheter in a severely ill patient. Laparoscopic retrieval may be considered and likely will be tolerated in almost all patients. The incidence of catheter loss into the peritoneal cavity has been greatly reduced since the introduction of a design which incorporates a metal disc with a central hole; this not only allows the catheter to pass through the abdominal wall but also holds the catheter snugly to the skin of the abdominal wall.

Insertion of Soft Catheters

Because of the high frequency of dialysis solution leak, and poor drainage necessitating frequent catheter manipulation and resultant peritonitis with the use of rigid catheters, some centers prefer to insert a single- or double-cuff Tenckhoff catheter for treatment of acute renal failure. Tenckhoff recommended use of a single-cuff catheter for acute cases [1]. For treatment of chronic kidney disease, only soft catheters are used.

Patient Preparation

Acute Dialysis

Patient assessment and preparation before soft catheter implantation for treatment of acute renal failure is the same as that before rigid catheter insertion.

Chronic Dialysis

Patient preparation before catheter implantation for treatment of chronic kidney disease is more elaborate [1, 84, 97, 129, 130]. Immediately prior to surgery, chest and/or abdominal hair should be removed with an electric clipper. Prophylactic antibiotics prior to implantation are recommended.

Abdominal Exit

The belt line of a patient is identified, preferably in the sitting or standing position, with slacks or pants as usually worn [1, 129]. Depending on the size and shape of the abdomen, presence of previous scars, right- or left-handedness, and patient's preference, the tunnel is marked using the stencil (available with swan-neck catheters) in such a way that the exit hole would be created at least 2 cm from the belt line. Skin markings may be made with any good surgical marker.

Women usually wear a belt above the umbilicus; hence stencils are often marked below the belt line in female patients. The catheter should not be subjected to excessive motion with patient activities, and there should not be pressure on the tunnel when the patient bends forward. In obese people, with pendulous abdomens, it is mandatory to insert the catheter above the skin-fold so they can see the exit for its care. Men usually prefer a belt line below the umbilicus and there may not be enough space below the belt line; therefore a stencil is generally marked above the belt line in male patients. The label of the chosen catheter type is written on the belly of the patient. A band with the catheter label is also attached to the patient's left wrist.

Enemas are no longer recommended. Instead, the patient should take a shower if able. Skin markings may require remarking if they become faint after a shower. Antibiotic prophylaxis prior to catheter insertion is recommended and is discussed in a subsequent section of this chapter.

Presternal Exit

Depending on the size of the patient, the abdominal cuff and flange location is marked over the rectus muscle [90]. To secure the catheter-tip position in the true pelvis, but without an excessive pressure on the pelvic peritoneum, the position of the cuff should be above or at the level of the umbilicus in all persons. To determine a preferred position of the deep cuff, a coiled catheter tip is placed on the pubic bone and the cuff position is marked. On the chest, a superficial cuff is marked at the second or third intercostal spaces and the exit 3 cm from the cuff in the presternal or parasternal area. It is preferable not to cross the midline in patients likely to have heart surgery. Care is taken to avoid an exit site too close to bra lines in females. Prophylactic antibiotics, shower, and bowel prep are used in the same way as for abdominal exit.

Catheter Preparation

Immediately before implantation, the catheter is removed from the sterile peel pack and immersed in sterile saline. The porous Dacron® cuffs and Dacron® flange are gently squeezed under saline to remove air [84, 90, 131]. Thoroughly wetted cuffs provide markedly better tissue ingrowth compared to unwetted, air-containing cuffs [84, 90].

Implantation Method

Blind (Tenckhoff Trochar)

At the bedside, a sterile procedure must be strictly followed while inserting the catheter. A 2–3 cm incision is made in the skin at the insertion site (e.g., the midline 2 cm inferior to the umbilicus). This places the site of entry at the linea alba, a point of minimal vascularity and tissue resistance [92]. The lateral margins of either rectus muscle are alternative sites because they are also relatively avascular. It should be remembered that the placement through the belly of the rectus muscle using blind insertion may cause injury to the inferior or superior epigastric artery.

Through the skin incision the wound is deepened to the linea alba with blunt dissection using a curved hemostat. At this time, an "anchoring" suture is inserted in the fascia. The peritoneal cavity is entered with a "priming needle" (a "catheter over a needle," venicath-type needle, or a stylet peritoneal catheter) into the superior aspect of the wound and through the linea alba. One must take care to ensure "intraperitoneal" placement of all hole outlets of the priming device. If the parietal peritoneal membrane is separated from the preperitoneal tissue this will result in "preperitoneal" infusion of dialysis fluid and make impossible any further intraperitoneal infusion of dialysis fluid by this method. Furthermore, the expansion of the preperitoneal "pocket" is extremely painful. When dialysis solution infusion produces pain, the operator should suspect preperitoneal instillation; however, the heavily sedated or anesthetized patient may not be able to voice an objection. At this time poor dialysis solution inflow may also indicate that hole outlets are lodged in a preperitoneal position, although one might also anticipate a moderate restriction of flow in any case, given the relatively small lumen of the access catheter.

Following sterile connection of the administration tubing to the priming device, 2–3 L of dialysis solution are infused into the peritoneal cavity, until the patient feels distended. While dialysate is being instilled to the desired volume, the Tenckhoff catheter should be "prepared" by wetting it with a small volume of normal saline. Air from the cuffs is removed by squeezing. A wetted stiffening stylet is inserted into the catheter, thus straightening and "stiffening" it to permit introduction of the catheter into the Tenckhoff trochar, and beyond it into its correct intra-abdominal position.

It is useful to predilate the linea alba with a smaller trochar or dilator rather than a needle, thereby facilitating introduction of the larger Tenckhoff trochar. With firm but gentle pressure, and a twisting action, the trochar with its pointed stylet in place (Fig. 14.12) is pushed into the peritoneal cavity via the small perforation. Immediately after the resistance ceases (indicating entrance into the peritoneal cavity), the obturator is removed. The true intraperitoneal placement should be recognized by the "welling-up" of dialysis solution into the barrel of the trochar. If the operator has instilled enough dialysis solution during the priming procedure, he/she should insert the trochar until its wider portion comes to rest on the linea alba. This portion should not enter the peritoneal cavity, thus keeping the perforation at the desired diameter. This larger barrel is designed not only to accept the Tenckhoff catheter, but it also allows for the passage of the Dacron® cuffs.

The catheter is threaded on a stiffening stylet. About 1 cm of catheter is left beyond the tip of the stylet to protect the intestine. Proper placement of the catheter in the pelvis will greatly facilitate siphon drainage. During this phase of insertion, certain details, although they may seem trivial, if not attended to with care may produce unfavorable results. For example, as the catheter is introduced into the trochar on its way to the abdominal cavity, the tip should be passed smoothly beyond the trochar. Careful, gentle, and angular movement of the trochar and stiffened catheter (adjusting its intra-abdominal position and relationship to abdominal contents) may be needed to achieve easy passage of the catheter deep into pelvis.

Once the catheter has completed its "internal" course, the detachable trochar barrel should be removed, leaving the split side-pieces *in situ* for easier manipulation until the final positioning is satisfactory. At this point the stiffening stylet should be removed while the operator holds the catheter firmly in place. Once the desired depth of placement is achieved, the remaining catheter is "fed" into the peritoneal cavity while slowly withdrawing the stiffening stylet until the preperitoneal (inner or deep) Dacron® cuff comes to rest on the linea alba. Then the trochar is separated into its two longitudinal sections and withdrawn, leaving the catheter cuff in proper position. The ideal location for the internal cuff is at the preperitoneal level. However, if the catheter is intended for a short-term use until the patient recovers from an acute renal failure event, the location of deep cuff at the preperitoneal level is not as critical as in the case of long-term use. The Dacron® cuff must not be left positioned in the peritoneal cavity.

Catheter patency is tested in the same manner described in the surgical procedure. When the function is deemed satisfactory the catheter is secured in place to the linea alba with an anchoring suture before preparing for the creation of the subcutaneous tunnel towards the proposed exit site.

After choosing the catheter exit site, a stab wound (not an incision) is made using a blade, taking care to penetrate only the skin. The opening should be just the size of the catheter. Choose a site that will permit the creation of a tunnel of an appropriate length and shape of the catheter. A subcutaneous tunnel is created using a malleable uterine sound or the Faller trochar, being careful to manipulate the catheter gently. For the swan-neck Tenckhoff catheter, the tunnel must follow the skin marking made prior to the insertion. The outer cuff should be positioned approximately 2 cm from the skin exit. The recommended method for tunnel creation for the swan-neck Tenckhoff catheter is to make a superior subcutaneous pocket as described for surgical insertion (see below) and penetrate the exit with the piercing trochar. No sutures are used at the exit site. The titanium connector is then inserted into the end of the catheter. The skin of the insertion wound is sutured, and appropriate surgical dressings applied. Dressings are applied for at least 1 week while leaving an accessible length of catheter to permit the catheter to be handled without disturbing the dressings.

Peritoneoscopic

The use of peritoneoscopy for peritoneal catheter placement was developed by Ash at Lafayette, Indiana [92, 132, 133]. Tenckhoff and swan-neck Tenckhoff (straight and coiled) catheters may be implanted with this technique. Like blind insertion, it is performed through a single abdominal puncture. No fluid is instilled before insertion of the cannula and the trochar into the abdomen (through the medial or lateral border of the rectus). The trochar is removed, and the scope is inserted through the cannula. After assuring the intraperitoneal location by observing motion of glistening surfaces, the scope is removed and 600 cm^3 of air placed in the peritoneal cavity with the patient in the Trendelenburg position. The scope is reinserted and, during continuous observation, scope, Quill, and cannula are advanced into the clearest space and most open direction between the parietal and visceral peritoneum. Following this, the scope and

cannula are removed and the Quill catheter guide is left in place. The next step in the procedure involves the dilation of the Quill and musculature to approximately 0.5 cm. This is large enough to allow the catheter to be easily inserted through the rectus muscle and for the cuff to be advanced into the muscle. The catheter follows the path previously viewed by the peritoneoscope as directed by the Quill guide. As long as the Quill guide stays in position the catheter will advance into the desired place. The catheter is advanced on a stylet and is actually "dilating" its way until the cuff arrives and stops at the muscular layer. Placing the cuff in the musculature can be accomplished using a pair of hemostats advancing the cuff within the Quill guide. Thereafter, the Quill guide is removed, hydraulic function of the catheter checked, the tunnel made subcutaneously using a trochar, and the catheter brought out through the exit site – similar to the surgical insertion technique.

Excellent results with this technique were reported by its originator. Copley et al. [133] have reported their 1,183 patient-months experience with 135 double-cuff swan-neck coiled catheters inserted peritoneoscopically over a 40-month period. Complications were few and the overall 40-month survival probability was 62%. Nine catheters were removed because of obstruction and 16 for catheter-related infections.

Seldinger (Guidewire) and Peel-Away Sheath

This technique may be used for insertion of straight and coiled Tenckhoff catheters as well as of swan-neck Tenckhoff straight and coiled catheters. The preinsertion patient preparation is similar to the preparation described for rigid catheter insertion. The procedure may be done with [96] or without [93, 94, 134] prefilling the abdomen with dialysis solution. Prefilling of the abdomen is accomplished through a temporary peritoneal catheter.

In the "dry" method a 2-cm incision is made and the "dry" abdomen is entered with an 18-gauge needle (e.g., the Verres needle as used for laparoscopy). A guidewire is passed through the needle and the needle is withdrawn. The introducer (dilator) with sheath is passed over the guidewire. After the dilator-sheath is inserted, the dilator is removed, leaving the sheath in place. The Tenckhoff or swan-neck Tenckhoff catheter, stiffened by a partially inserted blunt stiffening stylet, is then directed down into the sheath [96]. The catheter may also be introduced without the stiff stylet [78, 134]. As the cuff advances, the sheath is split by pulling tabs on its opposing sides. Splitting the sheath allows the cuff to advance to a position within the abdominal wall. By further splitting and retraction, the sheath is removed from its position around the catheter. A subcutaneous tunnel is then created as in surgical placement. With this technique, the incidence of early leak is very low. However, the risk of viscus perforation and improper placement of catheter are the drawbacks of this technique.

Surgical (by Dissection)

Surgeons perform majority of catheter implantations; and 72% of catheter implantations are performed by surgical dissection [77]. Dissective placement is mandatory for catheters with stabilizing devices (e.g., flanges) at the parietal surfaces (Toronto Western Hospital, swan-neck Missouri abdominal, and swan-neck presternal). The paramedian approach through the rectus muscle, currently used in our center, will be described [84].

The surgical placement can be done either using a general anesthetic or using conscious sedation and local anesthesia. The decision depends on both surgeon and patient preference and somewhat on accepted local practice. Because of the long tunnel for the presternal catheter, our practice has been to use a general anesthetic to ensure patient comfort.

The surgical preparation of the abdominal wall consists of a scrub with Betadine soap, pat-drying, and painting with Betadine paint solution. Alternatively, DuraPrep, an iodine containing preparation, can also be used. It aids in adhering the sterile transparent surgical drape. In patients with iodine sensitivity, an alternative prep should be used. Skin markings are often very faint after surgical preparation and require remarking with a sterile surgical pen. Finally, the abdomen is covered with a sterile, iodine impregnated transparent surgical drape. The skin and surrounding tissues of the incision sites and tunnel are anesthetized with 1% lidocaine or 0.25% Marcaine (bupivicaine).

A 3–4 cm transverse incision is made through the skin and the subcutaneous tissue. Perfect hemostasis, preferably using electrocautery, is mandatory. The anterior rectus sheath is exposed and may be infiltrated with 1% lidocaine. A transverse incision is made in the anterior rectus sheath (Fig. 14.25). The rectus muscle fibers are separated bluntly in the direction of the fibers down to the posterior rectus sheath. Self-retaining retractors are helpful to hold muscle fibers away from the operative field. The sheath posterior rectus peritoneum may be infiltrated with 1% lidocaine. A 5-mm incision, reaching the peritoneal cavity, is made with a scalpel and stretched slightly (Fig. 14.26). The edges are grasped and elevated creating a pneumoperitoneum. A purse-string nonabsorbable suture of 2-O monofilament is then placed through in the posterior rectus sheath, transversalis fascia, and the peritoneum under direct vision.

The catheter is threaded on a long, blunt stiffening catheter guide. About 1 cm of catheter is left beyond the tip of the stylet to protect the intestine. The edges of the opening are lifted. The catheter is inserted through the opening and

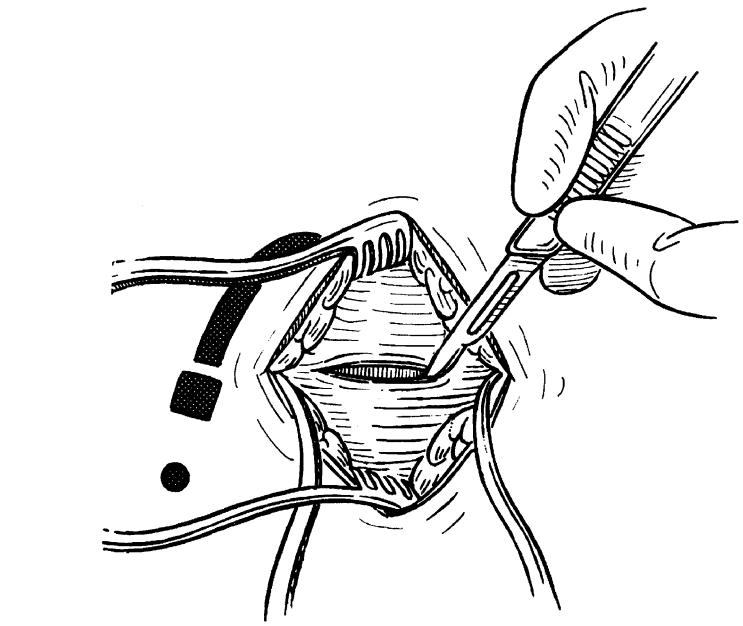

Fig. 14.25 An incision through the anterior rectus sheath

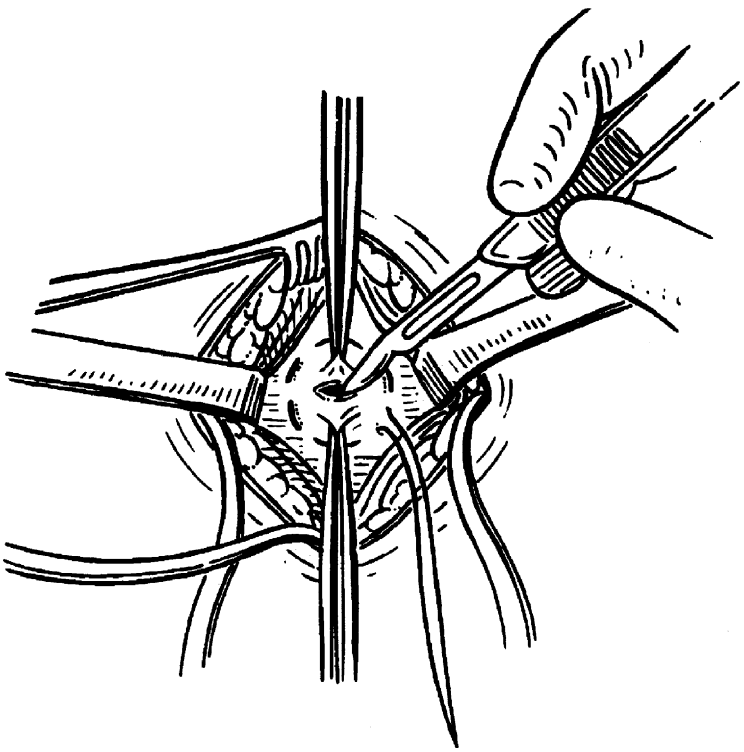

Fig. 14.26 The posterior rectus sheath has been exposed, a purse-string suture has been made, and a 5-mm incision reaching the peritoneal cavity is being created with a scalpel

introduced into the opposite deep pelvis if there is no resistance. If awake, the patient may feel some pressure on the bladder or rectum. When the catheter with catheter guide is about half to three-quarters inserted, the catheter guide is removed and the catheter continues to be directed into the pelvis.

Using a combination of retraction on the peritoneal edge and pushing, the bead is introduced into the peritoneal cavity. The flange is placed flat on the posterior rectus sheath and the purse-string suture is tied securely between the bead and the flange (Fig. 14.27). The stripe must be positioned anteriorly and the flange is anchored with at least two 2-O monofilament, nonabsorbable sutures into the posterior rectus sheath at the 6 and 12 o'clock positions (Fig. 14.28). The self-retaining retractors are removed and the deep or internal cuff is buried among the muscle fibers. A small stab wound is made in the anterior rectus sheath above the transverse incision. The catheter is grasped with a right-angled hemostat and pulled through the stab incision (Fig. 14.29). The stripe is positioned anteriorly. The

remaining procedure differs for the swan-neck abdominal Missouri and the swan-neck presternal catheter. The relationship of the catheter to the tissue structures of the abdominal wall is shown in Fig. 14.30.

Swan-Neck Abdominal Missouri

A superior subcutaneous pocket is made to the level of skin marking to accommodate the bent portion of the catheter and the external cuff (Fig. 14.31). The catheter tunnel extending from the cuff to the skin exit should have a diameter close to that of catheter tubing. Thus, the last portion of the tunnel (from external cuff to the exit) should be made with a piercing trochar, e.g., the Faller trochar (Covidien, Mansfield, MA 02048, USA) or a 3/16-inch (4.76 mm, F15) trochar for Hemovac system (Zimmer Mfg. Co., St. Louis, Missouri, USA) or the trochar for a 19 Blake drain (Ethicon, A Johnson & Johnson Company, Somerville, New Jersey) with an external diameter similar to that of the catheter tubing [84, 90, 97, 135]. A trochar is attached and carefully passed through the pocket and the external exit indicated by the stencil mark (Fig. 14.32). The bent portion of the catheter is positioned carefully in the subcutaneous pocket. Care is taken to keep the stripe facing frontward. The external cuff is positioned 2–3 cm from the skin exit. *No sutures are placed at the exit site to secure the catheter*. A titanium adapter is attached to the catheter and an extension tube is connected to the adapter [84]. A 1-L bag of sterile saline or dialysis solution containing 1,000 units of heparin is spiked via the extension tubing and the solution is infused. The fluid should all run in 5 min. The wound is checked for

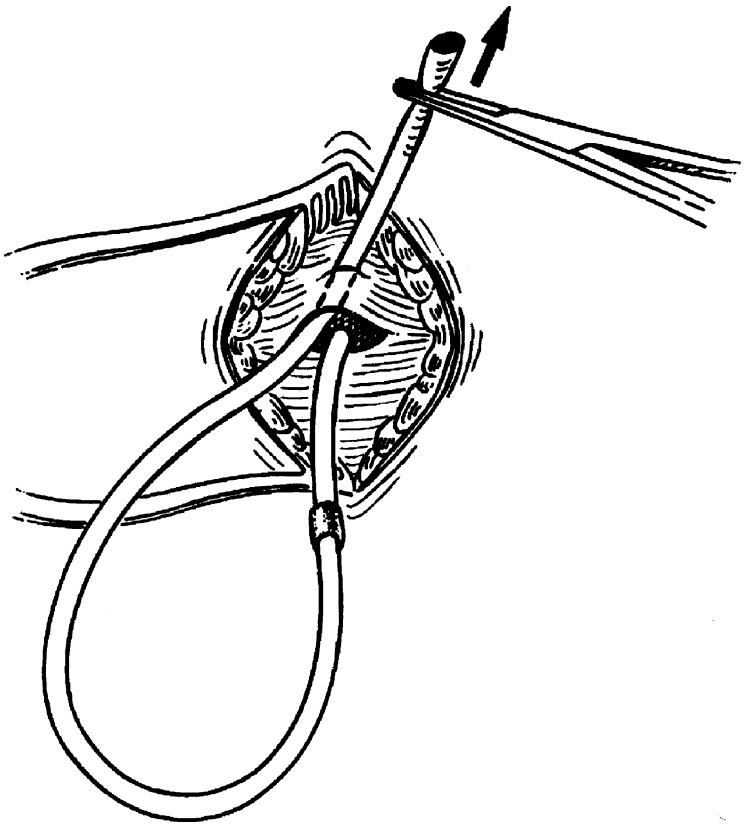

Fig. 14.29 The catheter is passed through the incision centered above the transverse incision

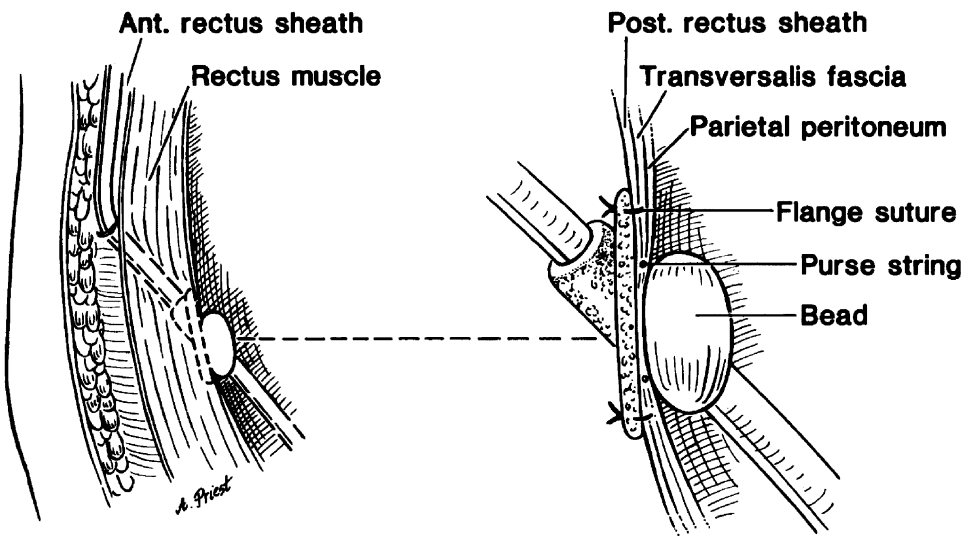

Fig. 14.30 The relationship of the catheter to the tissue structures of the abdominal wall. The bead is in the peritoneal cavity, the flange is flat on the posterior rectus sheath, the purse-string is between the bead and the flange, the deep cuff is in the rectus muscle

leaks and inspected for hemostasis. The transverse incision in the anterior rectus sheath is closed with a 2-O monofilament nonabsorbable suture. After infusing the dialysis fluid, the bag should be lowered to the floor and at least 200 mL of solution should drain within 1 min. If good flow is obtained the wound is irrigated and the skin incision is closed with absorbable subcutaneous and subcuticular sutures. The catheter is never sutured at the exit site. The position of the catheter is confirmed while still in the operating room on an abdominal X-ray. The incision is covered with Steri-strips, several layers of high-absorbency gauze dressings, and secured with Tegaderm®, which also immobilizes the catheter. The dressing is to be left in place for a week. In cases with bleeding, fever, or large drainage from the incision or exit the dressing should be changed earlier.

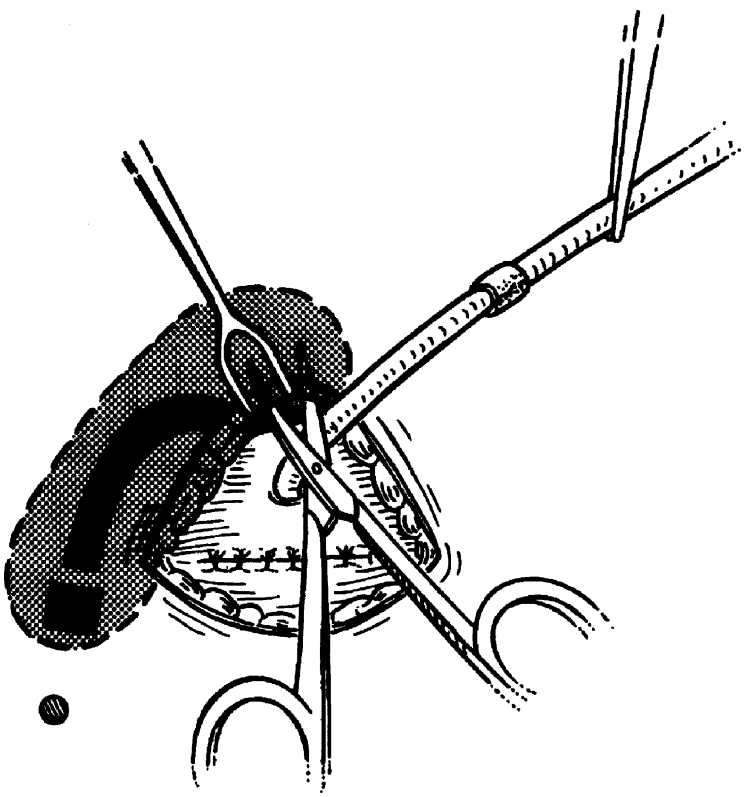

Fig. 14.31 A subcutaneous pocket is made to the level of skin marking to accommodate the bent portion of the catheter and the external cuff

Swan-Neck Presternal

A vertical 3–4 cm incision is made in the parasternal area (Fig. 14.33) at the level of the second and third rib at the stencil site [90]. Using a combination of sharp and blunt dissection, a superior subcutaneous pocket is made on both sides of the incision to accommodate the bent section of the upper (chest) tube of the catheter. The pocket is dissected enough to accommodate the middle and superficial cuffs (Fig. 14.34). Careful hemostasis is essential.

A Scanlan or Bard tunneler is used to create a tunnel extending from the abdominal incision to the presternal or parasternal area to permit joining the upper and lower tube. The tunneler, developed for tunneling vascular grafts, consists of an outside disposable or reusable sheath, blunt tip, and an inner rod with a handle at one end and a spring clamp or suture hole at the other. The metal rod serves to stiffen the tunneler as it is pushed through the subcutaneous tissue and the spring clamp or suture hole is used to secure the catheter and pull it through the sheath. Keeping the stripe in front as a guide, the abdominal end of the presternal portion of the catheter is pulled caudally through the sheath, and the sheath is removed by pulling in the caudal direction (Fig. 14.35).

The middle cuff of the upper catheter is carefully placed on the stencil mark. When the catheter is appropriately positioned the lengths of the two parts of the catheter are measured and the catheters are trimmed to an appropriate length. Sufficient length on each portion should be left to facilitate connection. A titanium connector is inserted into the presternal end and then the connector is inserted into the abdominal end of the catheter. The stripes on both tubes are positioned facing up. A 1-O Ethibond® tie is now placed and tied on both tubes over the appropriate groove of the titanium connector. The two sutures are tied together (Fig. 14.36) and the titanium connector is positioned in the subcutaneous tissue approximately 5–8 cm superior to the abdominal incision.

A trochar of the same size as the catheter tubing is attached and carefully passed through the pocket and the external exit site indicated by the stencil mark (Fig. 14.37). The stripe should be facing front. The trochar is disconnected. The bent portion of the catheter is carefully positioned in the subcutaneous pocket. The titanium Luer lock connector is attached. No sutures are placed at the exit site to secure the catheter. One liter of normal saline is infused through the infusion set and drained immediately. Outflow should be approximately 200 mL in 1 min. The wounds are checked for leaks, irrigated, and inspected for hemostasis. The transverse incision in the anterior rectus sheath is closed with a 2-O monofilament nonabsorbable suture. Skin incisions are again inspected for hemostasis. Any bleeding vessels are controlled with electrocautery and the incisions are closed with absorbable subcutaneous and subcuticular sutures. The operative site is covered with several layers of high-absorbency gauze dressings and secured with Tegaderm®, which also immobilizes the catheter. The dressing is to be left in place for a week.

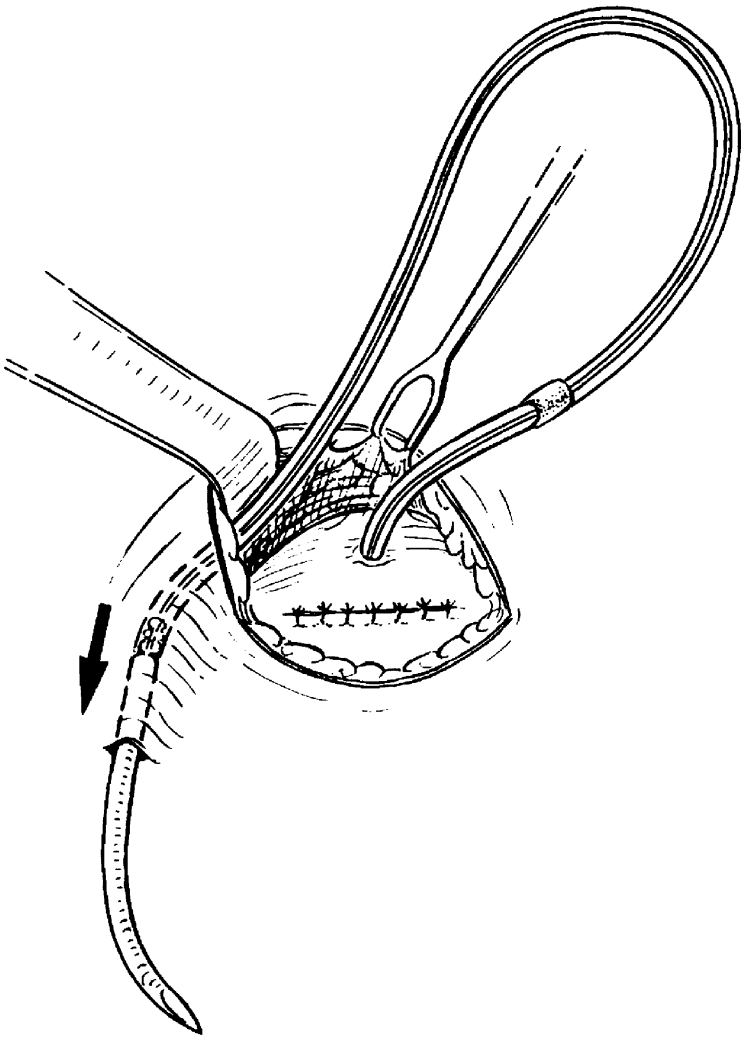

Fig. 14.32 A trochar is attached and passed through the pocket and the external exit indicated by the stencil mark. The piercing trochar is the same diameter as the tubing

Tenckhoff

This technique is similar to that of the swan-neck Missouri abdominal catheter; however, because there is no inter-cuff bend, the anterior stripe position is not essential and the subcutaneous pocket is not needed. Instead a straight upward or laterally curved tunnel is made with the help of a piercing trochar. The subcutaneous cuff is positioned 2–3 cm from the exit. As there is no flange, the deep cuff is positioned longitudinally, parallel to the rectus muscle fibers, on the posterior rectus fascia.

Swan-Neck Tenckhoff

A combination of techniques for the Tenckhoff and swan-neck Missouri abdominal catheters is used. The deep (inner cuff) is positioned longitudinally on the posterior rectus sheath with the stripe facing front. As explained earlier, in an earlier section entitled "Radiopaque Stripe," if the left catheter is used for the right tunnel and vice-versa, the stripe must be positioned posteriorly. The subcutaneous pocket is made in the same way as with swan-neck Missouri catheter.

Moncrief–Popovich Technique

This is an operative technique characterized by subcutaneous embedding of the external limb of the dialysis catheter at the time of implantation. The buried catheter is exteriorized after 3–5 weeks or when indicated to initiate dialysis [53]. This technique has been characterized as the "AV fistula of peritoneal dialysis" [136]. The advance placement of the catheter and the subcutaneous placement allow it to heal in a sterile environment. When exteriorized, patency is easily

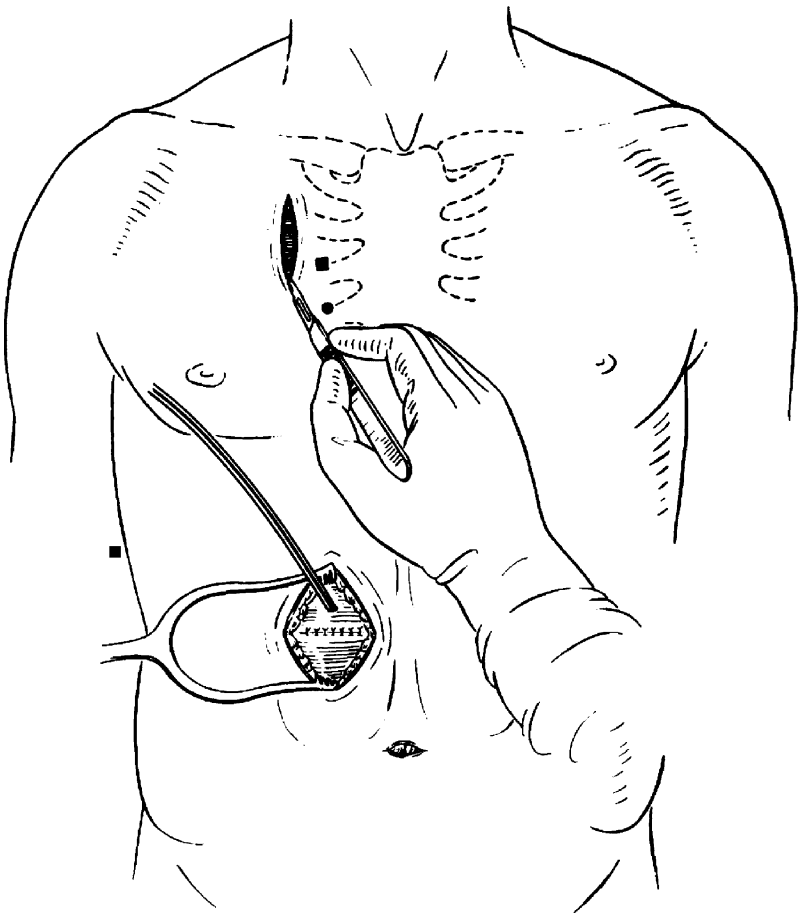

Fig. 14.33 Vertical incision in the parasternal area

established by irrigation or occasional use of a thrombolytic and only an occasional catheter needs surgical intervention [137]. Using swan-neck catheters with this technique, Moncrief and co-workers [53, 138] reported a significant reduction in pericatheter infections, exit-site infections and peritonitis but others have found no difference in peritonitis rate [139]. Some authors have noted an increase in perioperative complications such as seromas and subcutaneous hematomas [140]. A video [141] demonstrating the technique is available from the Austin Biomedical Research Institute, Austin, Texas, USA.

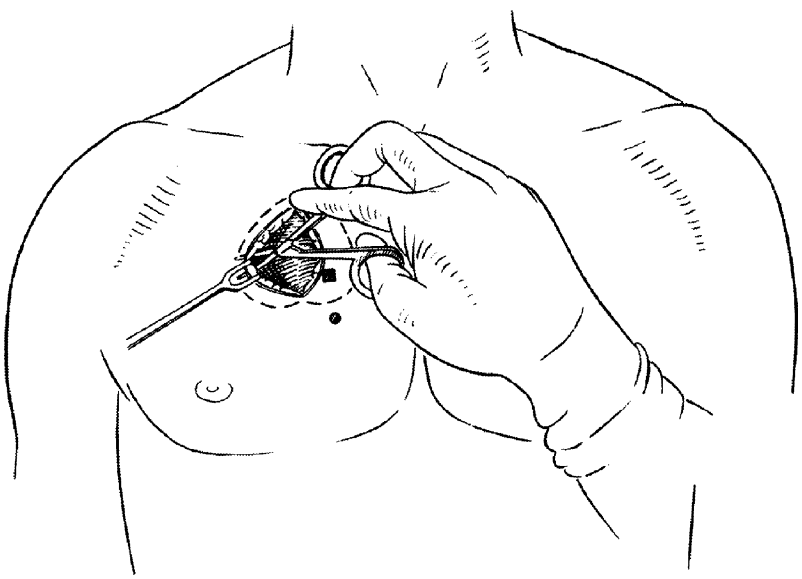

Fig. 14.34 Two small subcutaneous pockets are made on both sides of the chest incision to accommodate the bent section of the upper tube of the catheter

Laparoscopic Technique

Since the early 1990 s, there has been a significant change in the surgical approach to the abdomen. Starting in the early 1990 s laparoscopic approaches for all varieties of abdominal conditions began to replace traditional techniques. Naturally, these minimally invasive techniques were applied to placement of abdominal catheters. For almost two decades there has been a significant and increasing number of publications showing the efficacy and utility of using minimally invasive techniques for placing continuous ambulatory peritoneal dialysis catheters and managing their complications [142–153].

Nijhuis et al. [153] and Crabtree [154] have described a laparoscopic technique using a two-puncture technique for the placement of a continuous ambulatory peritoneal dialysis catheter. A pneumoperitoneum is created using a combination 4.5 mm trochar/Veress needle introduced into the contralateral upper abdominal quadrant. Crabtree and Fishman [154] use nitrous oxide to create a pneumoperitoneum allowing the procedure to be done under local anesthetic. A 3.5-mm zero-degree laparoscope is inserted through this trochar and an abdominal exploration is carried out. A 1.5–2 cm long incision is made in a perimedian site on the ipsilateral side of the abdomen. The subcutaneous tissues are dissected and the anterior rectus sheath is transversely incised. Using blunt dissection a pathway is created between and beneath the muscle. A 10-mm trochar is passed under visual control above the transversalis fascia and peritoneum. The trochar is then introduced into the abdominal cavity under direct vision and the peritoneal catheter is positioned in the pouch of Douglas. The cannula is removed and the catheter withdrawn so that the deep cuff is situated within the rectus muscle. The incisions are closed in standard fashion. This technique allows visual control and correct placement of the catheter in the pelvis. By placing the catheter in this fashion the authors have reduced their catheter-related problems and established a functioning catheter in about three-quarters of the cases.

The laparoscope can also be used for other purposes in patients on chronic peritoneal dialysis [155–159]. Specifically, catheter malposition and intra-abdominal adhesions are two conditions in which the laparoscope may be of considerable help. Entry to the abdominal cavity is established by direct cut down or Veress needle puncture in one of the upper abdominal quadrants. If an open technique is used, a purse-string suture is placed in the peritoneum and posterior fascia so that a snug fit around the trochar will be obtained. The trochar is inserted under direct vision with both techniques and a pneumoperitoneum is created by connecting to a CO_2 source. If the Veress needle approach is

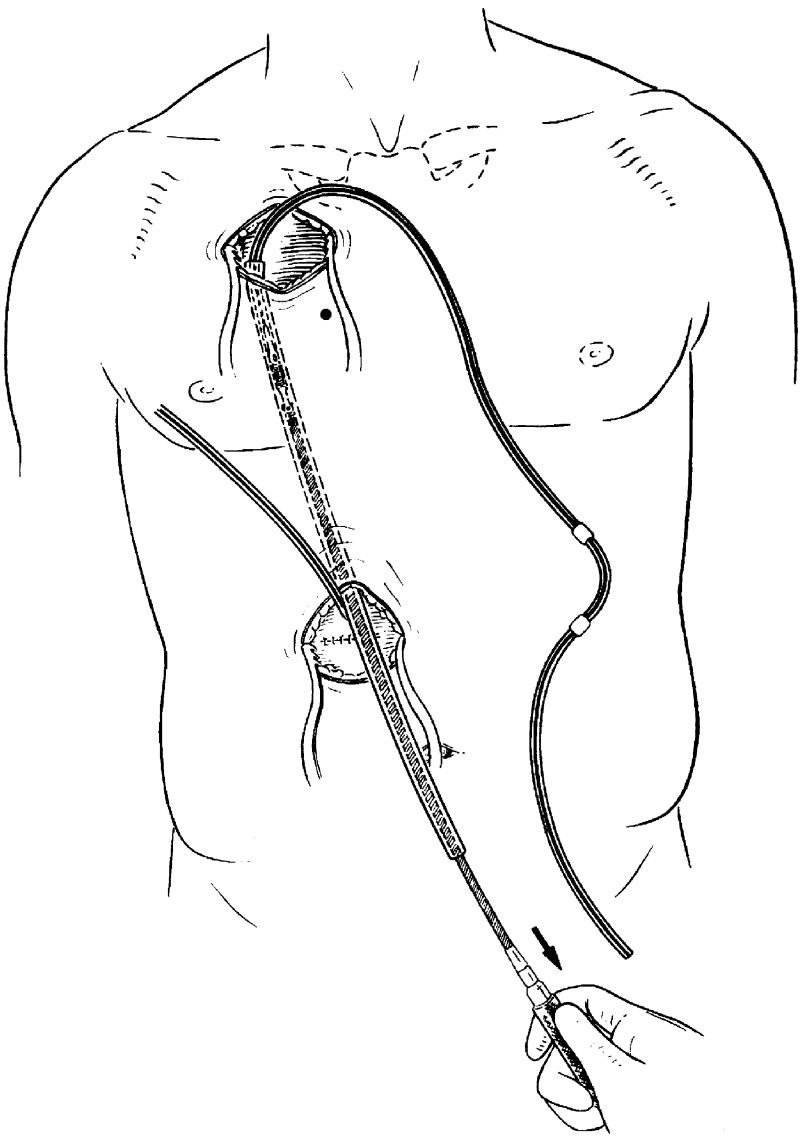

Fig. 14.36 Both parts of the catheter are tied over the titanium connector and the catheter is pulled cephalad

chosen, a pneumoperitoneum is first created then entry to the abdomen is made under direct vision using a Visiport Plus (Tyco Healthcare Norwalk, Connecticut, USA). Visual inspection will then demonstrate the problem of either adhesions and/or catheter malposition. Clinical judgment is used to place a second port, which is done under direct vision. Using grasping forceps or an electrocautery hook or scissors, the catheter can be repositioned, or the adhesions may be taken down. These techniques are of great help in salvaging an otherwise unworkable catheter.

Immediate and Early Postoperative Care

In the operating room, the position of the catheter is checked by a plain X-ray of the abdomen. Absence of catheter kink in the tunnel and the catheter-tip location in the true pelvis usually predict excellent catheter function. A liter of saline should be instilled in the peritoneal cavity and drained to confirm function prior to closing the incisions. Appropriate dressing of the exit site is placed in the operating room.

Postoperatively, we recommend performing exchanges until the dialysate return is clear. These may be done manually or using a cycler. One thousand units of heparin are added to each liter of dialysis solution. One-half or 1-L volumes of dialysis solutions are used for these exchanges. In spite of clear dialysate in the first postimplantation washout, the dialysate is usually blood-tinged in these exchanges. Once the dialysate returned is clear, the catheter is capped until peritoneal dialysis is initiated. There is no consensus whether a peritoneal washing should be performed

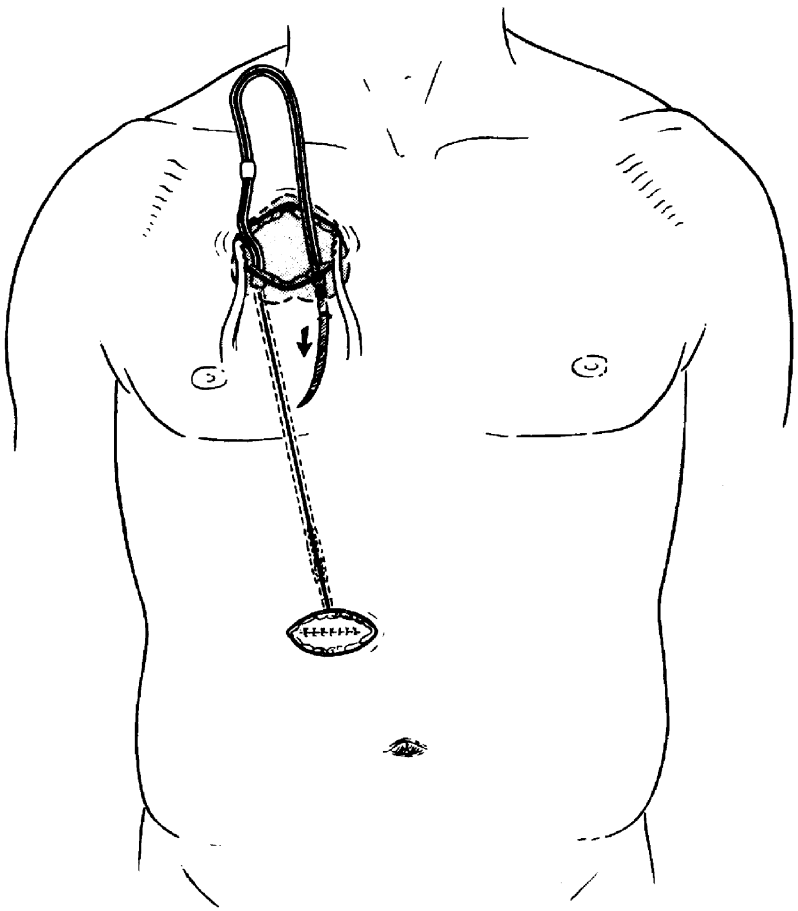

Fig. 14.37 A trochar of the same size as the catheter tubing is attached and carefully passed through the pocket, and the external exit is indicated by the stencil mark

once a week during the break-in period. The Moncrief technique of catheter implantation, leaving the external catheter buried until later exteriorization has not shown an increased rate of catheter obstruction.

Peritoneal dialysis should preferably be delayed for 2 weeks after implantation to allow for good healing and to prevent leaks [160]. If dialysis is required immediately, the options are to perform hemodialysis in the interim or to use low volume exchanges on peritoneal dialysis in the supine position. We do not commence peritoneal dialysis in the vertical position sooner than 14 days post implantation; thus, continuous ambulatory peritoneal dialysis (CAPD) or a last bag continuous cycling peritoneal dialysis (CCPD) are not used for 14 days.

Factors Influencing Catheter Complications

The common complications of peritoneal dialysis catheters include exit/tunnel infection; external cuff extrusion; obstruction, which is usually a sequel of catheter-tip migration out of the true pelvis with subsequent omental wrapping or tip entrapment in peritoneal adhesions; dialysate leaks; peritonitis; and infusion or pressure pain (Table 14.5). This section of the chapter will describe factors that influence these complications. A video illustrating these factors is available [97].

Table 14.5 Catheter-related common complications

Exit/tunnel infection	Pericatheter leak
External cuff extrusion	Peritonitis
Catheter obstruction	Infusion or pressure pain

Tissue Reaction to a Foreign Body Penetrating Skin

The tissue reaction begins immediately after a break in the integument occurs. Bleeding from capillaries and body fluids forms a coagulum of a hydrophilic fibrin–fibronectin gel and cellular debris. Various cytokines coordinate the subsequent entry of inflammatory cells and fibroblasts and the formation of new blood vessels [161]. Polymorphonuclear leukocytes phagocytose local bacteria and, together with the coagulum, form a scab. The polyester cuff also fills with clotted blood. Gradually, neutrophils, macrophages, fibroblasts, and new capillaries penetrate between the polyester fibers. Macrophages coalesce into giant cells and completely or partially surround the polyester fibers. Fibroblasts produce collagen fibers, which intertwine with the polyester fibers. The formation of the strong fibrous tissue is completed after approximately 6 weeks. Healing of the sinus starts beneath the scab with the production of granulation tissue composed of new vessels and fibroblasts. A mature granulation tissue is formed when neutrophils are replaced with mononuclear leukocytes, and fibroblasts lay down collagen fibers. Upon this tissue, there is a peripheral ingrowth of new epidermal cells.

Epidermal cells spread over the granulation tissue beneath the scab. Based on animal experiments it has been widely accepted that epithelial cells spread over granulation tissue until they meet epithelial cells from the opposite "shore" or until they encounter dense collagen fibers [162–171]. Winter [165] postulated that, in naturally occurring percutaneous organs such as teeth, the inhibition of epithelial migration is achieved by a periodontal membrane, which consists of bundles of collagen fibers embedded in the cementum of the tooth. In his view, other situations in which epidermal cell migration is inhibited include macroporous implants and skin autographs. Finally, he theorized that the basement membrane, a collagenous structure, also inhibits basal cell invasion of the dermis. The hypothesis that collagen fibers play a paramount role in inhibiting epithelial cell spreading led to the development of several devices of porous material to encourage dermal ingrowth and to prevent epithelialization of the tunnel ("marsupialization") [131, 167, 171, 172]. It has been suggested that the epithelium adjacent to a silicone catheter tends to migrate towards and beyond the subcutaneous cuff, creating a sinus between the tubing and the skin that is prone to bacterial colonization with subsequent infection [163].

The development of an epithelialized tract is well supported in animal models [60, 167, 170, 172] and in our previous reviews we cited these data as relevant in human peritoneal catheter sinus tracts [135, 173, 174]. However; our observations of catheter tunnels removed from patients showed that in almost all human peritoneal catheter tunnels the epithelium does not reach to the cuff, but stops a few millimeters from the exit in the sinus tract [175]. These observations lead us to believe that granulation tissue *per se* can also inhibit epidermal cell spreading. This observation also has an important influence on catheter design and implantation, particularly the material for the superficial cuff and its distance from the exit.

In humans, unlike experimental animals, the spreading of epidermis is slow. This discrepancy should not be surprising because the epidermal turnover rate in such animals is about six to seven times faster than in humans [176]. We found that in fast-healing catheter exits in humans the epidermis starts entering into the sinus after 2–3 weeks; in slow-healing exits the epidermis starts entering into the sinus after 4–6 weeks [69]. The healing process is complete after about 4–8 weeks, when the epidermis covers approximately half of a visible sinus tract with the remaining half covered with granulation tissue [69].

Tunnel Morphology after Healing Process Is Completed

A detailed description of peritoneal catheter tunnel morphology has been published elsewhere [175]. A well-healed tunnel of a double-cuff swan-neck Missouri catheter removed electively (Fig. 14.38) showed four segments: tissue ingrown to the flange and internal cuff, tissue surrounding the inter-cuff segment, tissue ingrown into the external cuff and the sinus tract. The most external part (0.5–1 cm) of the sinus tract and the skin surrounding the skin exit of the tunnel constitute the exit site. In the majority of humans the epidermal cells penetrate only a few millimeters from the skin exit and may reach the cuff located less than 15 mm from the exit [175, 177]. Although unusual, a single instance of keratinized epithelium penetration all the way to a cuff located 45 mm from the exit has been reported [178]. Close to the exit, the surface of the sinus tract is covered with wrinkled epidermis, containing all layers of epidermis including a horny layer. Deeper in the sinus, the epidermis loses the horny layer and becomes similar to the mucosal epithelium; hence the surface becomes glistening and white. The rest of the sinus tract is covered with the granulation tissue that is yellowish in appearance. A thick layer of collagen fibers surrounds the sinus. The granulation tissue contains numerous multinucleated giant cells, capillaries, cellular infiltrate composed mostly of mononuclear cells, and scant collagen fibers. The collagen fibers do not attach to the smooth surface of the silicone rubber, the material from which most peritoneal dialysis catheters are made.

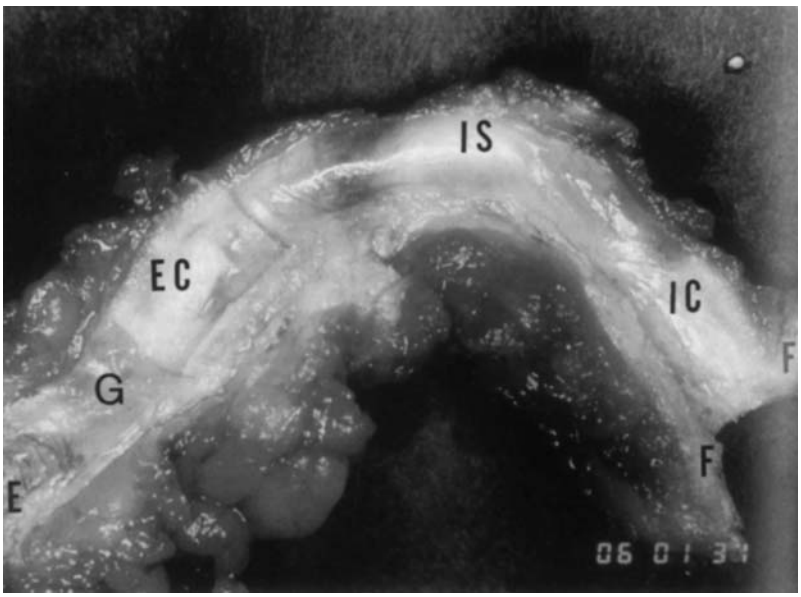

Fig. 14.38 A well-healed tunnel of a double-cuff swan neck Missouri catheter removed electively. From the left: E, epithelium; G, Granulation tissue; EC, external cuff; IS, intercuff segment; IC, internal cuff; F, flange

The junction between the granulation tissue in the sinus and the cuff is well defined. The cuff is surrounded by a dense fibrous capsule that contains numerous capillaries. About 80% of the polyester fibers are surrounded completely or partially by multinucleated giant cells. Spaces between the polyester fibers are filled with mature collagen and fibroblasts. No neutrophils are seen in an uninfected cuff.

The junction between the cuff and the inter-cuff segment shows a smooth surface without granulation tissue. The glistening, shiny inter-cuff tunnel segment resembles a tendon sheath and contains numerous micropits. The absence of any cellular reaction indicates that bacteria do not reach to this part of the tunnel. The surface is covered with an amorphous, mucinous substance on top of a modified layer of fibroblasts forming pseudo-synovium. There are no giant cells in this segment because silicone rubber *per se* does not induce giant cell formation.

The transition between the inter-cuff segment and the deep cuff is abrupt due to change from an avascular, acellular, fibrous sheath to a highly vascular and cellular tissue ingrown into the cuff. If the deep cuff is implanted into the muscle, the fibrous capsule surrounding the cuff and the cuff tissue itself are highly vascularized, otherwise the tissue ingrown into the cuff is similar to that of the external cuff.

Factors Influencing Healing and Early Infection

The most important factors influencing healing process and early infections are (Table 14.6) tissue perfusion, mechanical factors, sinus bacterial colonization, epithelialization, local cleansing agents, exit direction, and systemic factors.

Tissue Perfusion

The coagulum and necrotic tissue are gradually removed from the tunnel. Part of the necrotic tissue is absorbed and part is drained out of the tunnel. The tunnel should not be too tight with reference to the catheter circumference, so as to allow free drainage of necrotic tissue and to prevent tissue edema; both these factors decrease local perfusion and oxygen tension [179], which are critical for the wound-healing process. On the other hand, too large an incision prolongs healing by the shear volume of repair needed and the movement of loose tubing in the tunnel [180].

Table 14.6 Factors influencing healing process and infection

Tissue perfusion	Cleansing agents
Mechanical factors	Exit direction
Microorganisms	Systemic factors
Epithelialization	

Mechanical Factors

Mechanical stress slows the healing process [163]; thus the catheter should be relatively tightly anchored in the tunnel and also well immobilized outside the tunnel, especially during the break-in period [137]. Frequent dressing changes involve catheter manipulation, and hence should be avoided during the healing period. Constricting sutures at the exit site may cause pressure necrosis with skin sloughing, and facilitate bacterial penetration into the tissue; they must not be used [137].

Microorganisms

The presence of microorganisms in the wound is the major cause of impaired healing [181]. Bacterial counts exceeding 10^5 organisms per gram of tissue are associated with poor wound healing. Beta-hemolytic streptococci may affect healing regardless of the bacterial count in the wound [182]. Bacteria prolong inflammation and interfere with epithelialization, collagen deposition, and wound contraction [181]. Endotoxins produced by the bacteria stimulate release of collagenase, which contributes to collagen degradation and destruction of surrounding tissues [181]. Wound contamination by bacteria in association with hypoxia potentially suppresses macrophage-regulated fibroblast proliferation [183].

Maintaining sterility of the exit and sinus in the initial healing period is of utmost importance. Antibiotic penetration into the coagulum is poor; therefore, antibiotics should be present in sufficient concentration in blood and tissue fluids before the coagulum is formed. This may be achieved if antibiotics are given prior to implantation and is evidenced by several studies and a meta-analysis documenting preoperative intravenous prophylaxis reduce early peritonitis but not exit-site/tunnel infection [184].

Epithelialization

Epidermal cells grow over the granulation tissue beneath the scab. If the scab is forcibly removed during cleansing, the epidermal layer is broken, thus prolonging the process of epidermization. Sinus epithelialization is supported by sterile and undisturbed conditions at the exit. Again, frequent dressing changes facilitate exit contamination; on the other hand, liquid serous or sanguineous exudate at the exit promotes bacterial growth. Therefore, the exit should be kept dry, but dressing changes should not be too frequent.

Cleansing Agents

The objective of wound cleansing is to remove the organic and inorganic debris and to create conditions optimal for wound healing. Cleansing agents should not only decrease the number of bacteria, but also be harmless to the body defenses. Strong oxidants such as povidone-iodine and hydrogen peroxide are cytotoxic to mammalian cells [185, 186] and may impair angiogenesis [187]. It is prudent to apply such antiseptics only to the intact skin surrounding the wound or granulation tissue and avoid the sinus track [188]. Nonionic, amphophilic, nontoxic surfactants, widely used in burn wound care, facilitate necrotic tissue removal without jeopardizing body defense mechanisms [185, 189]. These include agents such as 20% Poloxamer 188 (Shur-Clens®; Calgon Vestal Laboratories, St. Louis, Missouri, USA) and Puriclens® (Care-Tech Laboratories, Inc, St. Louis, Missouri, USA), which are innocuous, yet excellent in cleansing the exit from contaminants.

Exit Direction

Exit direction is also important. Immediate postimplantation drainage of necrotic tissue is facilitated by gravity when the exit is directed downwards.

Systemic Factors

During the healing process, part of the granulation tissue is gradually resorbed and replaced by fibrous tissue. The fibrous tissue and part of the granulation tissue is covered with the epidermis [175]. Impaired nutrition, diabetes mellitus, uremia, hypothyroidism, obesity, chemotherapy, and corticosteroids are factors known to decrease wound healing by impeding the process of fibrosis [181]. It is prudent to avoid permanent catheter implantation while the patient is severely uremic, malnourished, or taking glucocorticoids.

Factors Influencing Infection of Healed Catheter Tunnel

Design of the catheter and its location in the created tunnel influences exit and/or tunnel infection. Other factors that may influence infection rate include bacterial colonization of the sinus, *S. aureus* nasal carriage status, catheter skin exit direction, sinus tract length, number off cuffs, and materials for the external cuff and the tubing in the sinus (Table 14.7).

Table 14.7 Factors influencing infection of healed catheter tunnel

Bacterial colonization of the sinus
Staphylococcus aureus nasal carriage
Catheter skin-exit direction
Sinus tract length
Number of cuffs
External cuff material and tubing in the sinus

Bacterial Colonization of the Sinus

Almost all healed catheter sinuses are colonized by bacteria [190]. It has been well documented in the surgical literature that wound infection is the result of imbalance between the host defense and bacteria [182]. The number of bacteria as a critical factor in wound infection was already recognized in World War I [191]. Elek [192] demonstrated that it requires 7.5×10^6 staphylococcal organisms to produce a pustule in normal human skin but the number of bacteria necessary to cause infection was reduced 10,000-fold in the presence of a single suture. Bacterial virulence is also important; *S. aureus* or *P. aeruginosa* are more likely to induce an inflammatory response than is *Staphylococcus epidermidis*.

It appears that there is a constant interaction between the colonizing bacteria and the body defense mechanisms at the sinus tract. The part of the sinus tract covered with epidermis seems to respond to bacteria in the same way as the rest of the body integument but the part covered with granulation tissue appears to respond by constant exudation of serum with white blood cells to suppress bacterial proliferation and curb their penetration deeper into the sinus. If the number of bacteria increase, then the amount of exudate increases and granulation tissue proliferates and becomes more vascularized. The number of bacteria entering deeper into the sinus depends on the number and species of bacteria at the exit site, exit direction, as well as sinus tract length, the latter an important contributing factor in the amplitude of catheter movement in the sinus. Optimum defense mechanisms, after the sinus is healed, are observed best in undamaged epidermis and granulation tissue; trauma to these structures may tilt the balance in favor of microorganisms and allow their rapid multiplication.

Nasal Carriage of S. *aureus*

The nose of patients on peritoneal dialysis is colonized by a variety of microorganisms including *S. aureus*, coagulase-negative *Staphylococcus*, and Gram-negative organisms [193]. While no association has been found between nasal colonization by coagulase-negative *Staphylococcus* and Gram-negative bacteria and peritoneal dialysis infections [193, 194], there is a strong association between *S. aureus* nasal carriage and catheter infections.

S. aureus principally resides in the anterior nares (vestibulum nasi or "nose picking area") [195]. There is strong correlation between the nasal and hand carriage of *S. aureus*. In the study by Boelaert et al. [196], 15 of 20 hemodialysis patients who carried *S. aureus* in their nares also carried the organism on their hands, but only two of 20 patients who did not carry *S. aureus* in their nares carried *S. aureus* on their hands ($p < 0.001$). Eighty-seven percent of patients who carried *S. aureus* in their nares and on their hands carried the same strain at both sites. Thus, it is likely that bacteria are carried from the nares to the vicinity of the catheter exit on hands.

Cross-sectional studies have established that approximately 50% of dialysis patients are nasal carriers of *S. aureus* [197, 198]. Nasal carriers are categorized into three groups based on longitudinal studies: persistent, intermittent, and noncarriage. Persistent carriers are usually colonized by a single strain of *S. aureus* over long durations of time, while intermittent carriers may carry different strains over time [195]. The load of *S. aureus* in the anterior nares of persistent carriers is higher resulting in increased dispersal and risk for infections [199]. In a study with median follow-up of 33 months, persistent nasal carriers had three times the number of peritoneal dialysis related infections than intermittent carriers and noncarriers, with majority of the isolated *S. aureus* being identical to the nasal isolates [200]. Luzar et al. [197] in a multicenter study reported on the increased incidence of exit-site infections in nasal carriers of *S. aureus*; in 85% of these infections the strain from the nares and the strain causing the infection were similar in phage type and antibiotic profile. The risks of staphylococcal catheter-related infections are higher in nasal carriers with diabetes mellitus or those who are immunosuppressed [201].

A few studies have failed to find an association between *Staphylococcus* carriage and *Staphylococcus* catheter-related infections [202, 203]; however, the overwhelming evidence does support this association. Furthermore, several studies have documented the benefits of treating the nasal colonization of *S. aureus* [204–208] and are discussed in a subsequent section of this chapter.

Catheter Skin-Exit Direction

The original recommendation of a downward-pointing exit came from Tenckhoff and Schechter [34]. A retrospective analysis from the University of Missouri found that compared to upward-directed exits, the exits directed downwards tended to be infected less frequently and, once infected, were significantly less resistant to treatment [50]. Several other authors have demonstrated superiority of downward directed exit sites in both pediatric and adult populations [209–211]. This should not be surprising since upward-directed tunnels facilitate exit contamination by gravity-aided flow of sweat, water, and dirt (Fig. 14.39). Once the exit is infected, it is resistant to treatment because of poor external drainage; rather, the pus tends to penetrate deeper into the tunnel. In addition, downward drainage of necrotic tissue immediately postimplantation is easier than drainage against gravity.

The advantage of caudal exit direction in preventing and treating infections has support in several other clinical conditions. Periodontitis, which may be considered as a naturally occurring "foreign" body exit-site infection, most frequently effects the lower incisors ("exits" directed upwards) [212]. The influence of exit position on the frequency and tenacity of paranasal sinus infections was postulated by Zuckerkandl in the nineteenth century. The relatively frequent infections of the maxillary sinus are believed to be due to unfavorable positions for discharge because the *ostium maxillare* (in the upright position of the body) is located at the highest point of the cavity; the cavity must be completely filled with secretions before the discharge may escape [213]. All of the other cavities are more favorably constructed for drainage and less likely to be infected [213]. The use of downward directed tunnels have been demonstrated to be effective in reducing exit-site infections in chemotherapy catheters and pediatric hemodialysis tunnels [214, 215].

Lateral pointing exit sites may be necessary in some individuals due to body habitus. In a retrospective study, downward and lateral catheter tunnel-track and exit site produced equivalent outcomes for infectious and mechanical complications [216].

Swan-Neck Catheters

Based on the observations that downward-exiting catheters are less likely do develop infections, Twardowski et al. developed the permanently bent swan-neck catheter with an inverted U-shaped arc between the deep and superficial cuffs. The U-shaped, arcuate bend allows the catheter to exit the skin pointing downward and the intraperitoneal segment is also directed downward to the pelvis [50]. The preformed shape promotes pelvic orientation by eliminating

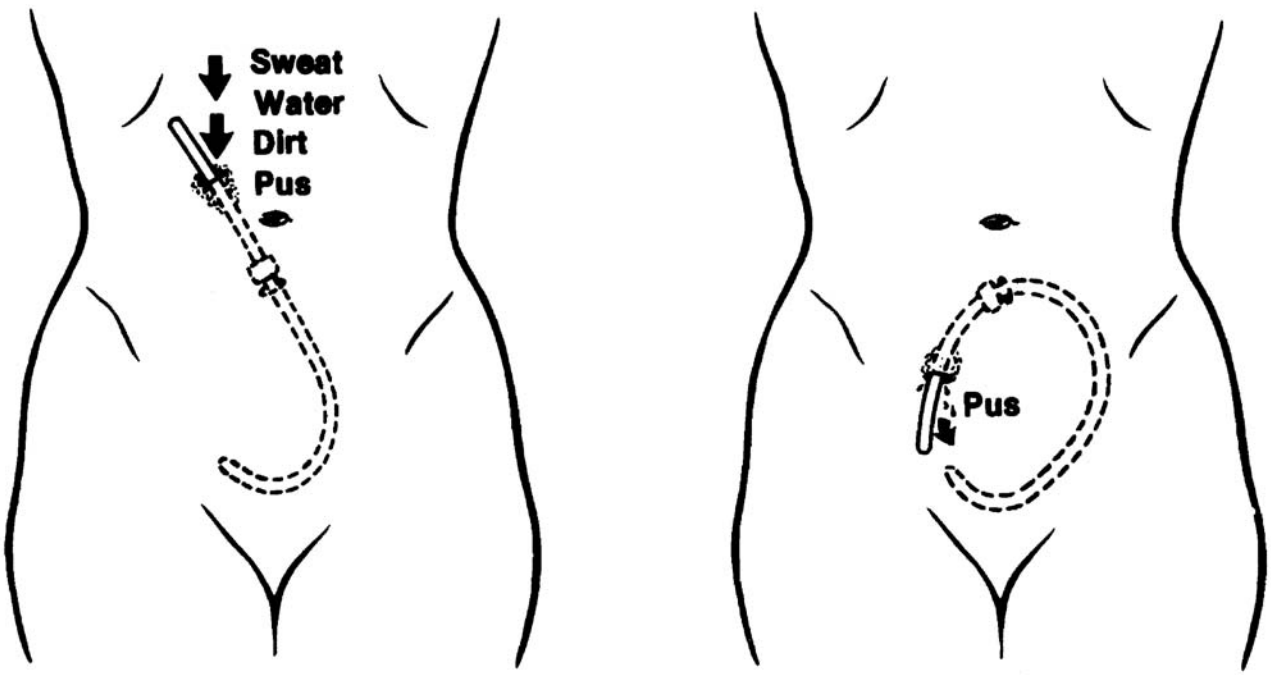

Fig. 14.39 *Left*: exit easily contaminated with down-flowing sweat, water, and dirt; difficult pus drainage prolongs treatment. *Right*: good pus drainage facilitates recovery. Reproduced from [50] with permission

shape memory effects. The surgical insertion of swan-neck catheters requires greater planning and technical skill for creating an appropriate tunnel than a straight catheter [1]. The data from Twardowski et al. [83], Lye et al. [217], and others has shown reduced exit-site infections with swan-neck catheters while others such as Hwang and Huang [218] and Eklund et al. [219, 220] demonstrated no benefit in the incidence of exit-site infections. These swan-neck catheters offer benefits in a lower incidence of cuff migration [79] and less frequent drainage related issues [79, 217, 220, 221].

Sinus Tract Length

The epidermis covering the sinus tract undergoes a turnover probably similar to the normal epidermis with cell maturation and desquamation; granulation tissue produces exudate. All these contents, if not expelled, create a favorable milieu for bacterial growth. With a long sinus tract the chances of infection are higher [162–164]; therefore, the sinus tract should be as short as possible. Tenckhoff recommended that "the subcutaneous Dacron®; felt cuff should be located immediately beneath the skin exit" [89]. Such a localization of the cuff, however, predisposes to its extrusion. Indeed, in some centers the rate of extrusion reached 100% [222]. In other centers the rate, although lower, was high enough to question the wisdom of using the superficial cuff at all. The most recent recommendation is to place the subcutaneous cuff at least 2–3 cm from the exit site [223].

Number and Location of Cuffs

There are three basic shapes and designs for the Dacron® cuffs: a single cuff around the catheter, usually placed in the rectus muscle but sometimes on the outer surface of the rectus; dual cuffs around the catheter, one in the rectus sheath and the other in the subcutaneous tissue; and a disc-and-ball deep cuff, with the parietal peritoneum sewn between the Dacron® disc and the silicone ball (Toronto-Western and Missouri catheters) [224]. The presternal catheters have three Dacron® cuffs: The upper tube carries two cuffs, a superficial and a middle or central spaced 5 cm apart, and a single deep cuff incorporated on the abdominal tube.

Single external-cuff catheters were used by Tenckhoff for treatment of acute renal failure. This type of catheter used in patients undergoing chronic intermittent peritoneal dialysis yielded similar results to those of the double-cuff catheter; however, with continuous ambulatory peritoneal dialysis, double-cuff catheter survival was better than of these catheters [225]. The complications of catheters with a solitary external cuff include the development of pseudohernias due to high intra-abdominal pressure from the constant presence of fluid in the peritoneal cavity. The use of such catheters has been abandoned.

Another type of single-cuff catheter has only a deep cuff. This type of catheter has been used because of problems with external-cuff extrusion and the questionable value of the external cuff. Earlier studies found such single-cuff catheters to be associated with a shorter time to first peritonitis episode and shorter survival times than the double-cuff catheters [211, 226–229]. However, the matter is not settled as a randomized controlled trial of 60 patients compared single- versus double-cuff catheters and found no differences in peritonitis, exit-site infections, and catheter survival [230].

Material for the External Cuff and Tubing in the Sinus

Peritoneal dialysis catheters are manufactured using highly biocompatible polymers, which minimize the foreign body reaction and enhancing device longevity. A thin fibrous capsule usually develops around the catheter but does not adhere to the catheter. Consequently, a potential space exists between the catheter and the fibrous layer that allows movement of the catheter and permits infection to spread from the exit site to the peritoneal cavity. Fabric cuffs are used to provide anchorage to the catheter [231]. The external cuff, if used, may play a role in preventing the spread of epidermal cells into the sinus track. As an example of perfect arrangement the anatomy of the tooth/gingival interface is cited [171]. The periodontal ligament attaches to the cementum, creating an extremely strong bond. The cementum is composed of hydroxyapatite crystals, collagen fibers, proteoglycans, and mucopolysaccharides [232]. Such a living material is unlikely to be used for the external cuff.

The traditional cuffs are made of polyester fiber (Dacron®). Soon after implantation, there is an acute inflammatory reaction characterized by the accumulation of polymorphonuclear cells and activated macrophages and eventually develop into foreign body giant cells. Later, fibroblasts and blood vessels grow into the cuff. In mature uninfected cuffs, histopathology reveals giant multinucleated cells, sparse mononuclear cells, and collagen fibers intertwined with the polyester fibers. A fibrous capsule surrounds the cuff. The tissue ingrown into the cuff *per se*

does not seem to constitute a critical barrier for infection spreading [175]. It seems that the basic beneficial role of the external cuff in infection prevention is by anchoring of the catheter resulting in restriction of its piston-like movements, thus decreasing transport of bacteria into the sinus. Favorable results with a "wing" instead of cuff appear to give clinical support to this hypothesis [233]. This "wing," however, does not seem to anchor the catheter as well as the cuff. Cuffs made of titanium fiber mesh have been evaluated in animal models and appear more biocompatible and integrate more favorably in the surrounding tissue [234].

Bioactive coating of catheters may be an alternative to cuffs. In animal studies, a bioactive glass-ceramic coating of silicone catheters was successful in inducing tissue adhesion of silicon catheters by promoting adhesion and cell proliferation [231]. In another animal study, a biocompatible silicone material with micropores was used as a cuff. The micropores facilitated ingrowth of blood vessels and loose collagen and cellular matrix, improving biointegration and decreasing exit-site infections. However, further studies and human data are needed to accept a substitute for polyester fabric (Dacron® velour) as a material for the external cuff.

In animal studies, it has been demonstrated that polyurethane intravenous catheters are less prone to infections than silastic intravenous catheters [235]. This may be related to differences in surface irregularities effecting microbial adherence. No studies have addressed differences in exit-site infection between polyurethane and silicon rubber peritoneal dialysis catheters in a direct comparative study. The incidence of exit-site infections with the Cruz dialysis catheter, which is made from polyurethane, are no different than reported in literature for silicone catheters [236, 237]. However polyurethane catheters are less biostable and the Dacron® cuff is more likely to separate from the catheter [238].

Exit Sites: Classification and Care

Exit-Site Appearance Post Implantation

Unless a large hematoma in the wound is present, all exits look the same a week after implantation [69]. The exit is painless or minimally tender with light pink color of less than 13 mm in diameter from border to border (including the width of the catheter). Blood clot or serosanguineous drainage is visible in the sinus. No epidermis is visible in the sinus and the sinus lining is white and plain. Signs of good healing include a decrease in color saturation and diameter around the exit, change of drainage to serous, decreased drainage amount, decreased tenderness, and progression of epidermis into the sinus. An increase in color, diameter, or saturation around the exit; change of drainage to yellow; change of granulation tissue color to mottled, pink or red; or change of granulation tissue texture into slightly exuberant or exuberant are signs of poor healing.

Our exit-site study [69, 239] revealed four types of healing exits: 1) Fast-healing exits had no drainage or minimal moisture deep inside by the third week; epidermis started to enter into the sinus within 2–3 weeks, progressed steadily, and covered at least half the visible sinus tract 4–6 weeks after implantation. 2) In slow-healing exits without infection, epidermis started to enter into the sinus after 3 weeks or progressed slowly and did not cover half the visible sinus by 5 weeks; the sinus might have had serous or serosanguineous, but never purulent, drainage persistent up to 4 weeks. 3) Healing interrupted by infection initially looked identical to the fast-healing exit, but within 6 weeks the epidermis had not progressed, or had regressed, granulation tissue became soft or frankly fleshy; drainage increased and/or became purulent. 4) In slow-healing exits due to early infection, granulation tissue became soft or fleshy and/or drainage became purulent by 2–3 weeks; sinus epidermization was delayed or progressed slowly, only after infection was appropriately treated.

Classification of Exit-Site Appearance

Attempts to classify exit appearance into two categories (infected and not infected) are difficult, if not impossible, because infected and uninfected exit appearances overlap. This overlap is due to the peculiarity of tissue reaction to the foreign body penetrating the skin, and stems from the delicate balance between bacteria in the sinus and host defenses as described above. The presence of a small amount of exudate causing crust formation does not indicate infection, but if the bacterial attack is more severe, or the host defenses are weakened, then the amount of exudate increases; granulation tissue proliferates, becomes more vascularized, epithelium regresses, and signs of infection become obvious. Low-grade exit infection may abate without systemic antibiotics.

We have performed extensive evaluation of exit-site characteristics [69, 190]. From the 565 evaluations of 61 healed exit-sites in 56 patients evolved a new classification [240]. The classification is based on the cardinal signs of inflammation as proposed by Aulus Cornelius Celsus in his treatise, *De Medicina*, written in the first century AD. These are well known: *calor* (heat), *rubor* (redness), *turgor* (swelling), and *dolor* (pain). Additional features, specific for an exit of any skin-penetrating foreign body, are drainage, regression of epidermis, and exuberance (profuse overgrowth) of granulation tissue ("proud flesh"). Granulation tissue is defined as exuberant if it is significantly elevated above the epidermis level. Scabs and crust do not indicate infection. Culture results did not influence exit classification. Positive cultures in exits not inflamed indicate colonization, not infection. Cultures were commonly negative from infected exits on antibiotic therapy. However, inflammation in almost all cases is caused by infection, regardless of culture results. Inflammatory responses to tubing itself or local irritants are rare.

Improvement or deterioration of inflammation is associated with respective decreases or increases of pain, induration, drainage, and/or exuberant granulation tissue, and/or regression or progression of epithelium in the sinus. Increased lightness (pink, pale pink) or darkness (deep black, brown) and decrease in color diameter indicate improvement, increase in red color saturation and diameter indicate deterioration. Ultimately, a new classification with five distinct categories of exit appearances has been established: acute infection, chronic infection, equivocal, good, and perfect. Two special categories are included: external cuff infection and traumatized exit. Trauma may result in various appearances. Cuff infection may not be associated with exit infection. Detailed descriptions of the various exit appearances illustrated by over 200 color photographs have already been published [69, 190, 239–241]. The characteristics for each category of catheter exit site are summarized in Table 14.8.

Acute Catheter Exit-Site Infection

This involves purulent and/or bloody drainage from the exit-site, spontaneous or after pressure on the sinus, and/or swelling; and/or erythema with diameter 13 mm or more from border to border; and regression of epithelium in the sinus. Acute catheter inflammation lasts less than 4 weeks and may be accompanied by pain, exuberant granulation tissue around the exit or in the sinus, and the presence of a scab or crust.

The common pathogens are *S. aureus* and *P. aeruginosa* [242–245]. Other organisms causing exit-site infection are coagulase-negative *Staphylococcus*, diphtheroids, anaerobes, streptococci, legionella, and fungi. Exit-site culture may be negative in patients receiving antibiotics.

Chronic Catheter Exit-Site Infection

These are characterized by purulent and/or bloody drainage from the exit-site, spontaneous or after pressure on the sinus; and/or exuberant granulation tissue around the exit and/or in the sinus; and regression of epithelium in the sinus. Chronic infection persists for more than 4 weeks and crust or scab is frequently present. Swelling, erythema, and/or pain indicate exacerbation. Exit culture may be negative in patients receiving antibiotics.

Equivocally Infected Catheter Exit Site

There is purulent and/or bloody drainage, which cannot be expressed outside the sinus, accompanied by the regression of epithelium, and occurrence of slightly exuberant granulation tissue around the exit and/or in the sinus. Erythema with a diameter less than 13 mm from border to border may be present, but pain, swelling, and external drainage are absent. Exit culture may be negative in patients receiving antibiotics.

Good Catheter Exit

Exit color is natural, pale pink, purplish, or dark and there is no purulent or bloody drainage. Clear or thick exudate may be visible in the sinus. Mature epithelium covers only part of the sinus; the rest is covered by fragile epithelium or plain granulation tissue. Pain, swelling, and erythema are absent. Positive peri-exit smear culture, if present, indicates colonization not infection.

Perfect Catheter Exit

This is at least 6 months old with its entire visible length of sinus tract covered with the keratinized (mature) epithelium. Exit color is natural or dark and there is no drainage. A small, easily detachable crust may be present in the sinus or around the exit. Positive peri-exit smear culture, if present, indicates colonization not infection.

Table 14.8 Characteristics of each category of exit-site appearance

	Perfect	Good	Equivocal	Acute infection <4 weeks	Chronic infection >4 weeks	Cuff infection without exit infection
Exit						
Pain/ tenderness	None	None	None	May be present	Only if exacerbation	May be present over cuff
Colour	Natural, pale pink or dark	Natural, pale pink, purplish or dark, bright pink <13 mm	Bright pink or red <13 mm	Bright pink or red >13 mm	Bright pink or red >13 mm only if exacerbation	Natural, pale pink, purplish or dark, bright pink <13 mm
Crust	None or small, easily detached or specks of crust on dressing	None or small, easily detached or specks of crust on dressing	Present, may be large and difficult to detach	Present	Present, may be difficult to detach	Typically absent
Scab	None	None	None	May be present	May be present	Absent
Drainage	None	None	None even with pressure on sinus; dried exudate on dressing	Purulent or bloody, spontaneous or after pressure on sinus; wet exudate on dressing	Purulent or bloody, wet exudate on dressing	Chronic or intermittent; purulent, bloody, tenacious or "gluey"
Swelling	None	None	None	May be present	Occurs only if exacerbation	Cuff induration may be felt on palpation; negative ultrasound does not rule out the diagnosis
Granulation tissue	None	None	Plain or slightly exuberant	Slightly exuberant or "proud flesh" may be present	"Proud flesh" or slightly exuberant typically visible	None
Sinus						
Epithelium	Strong, mature; covers visible sinus	Strong, mature at rim; fragile or mucosal deeper	Absent or covers part of sinus	Absent or covers part of sinus	Absent or covers only part of sinus	Covers most or all of sinus; may be macerated
Granulation tissue	None	Plain beyond epithelium	Slightly exuberant	Slightly exuberant or "proud flesh"	"Proud flesh" or slightly exuberant	None or exuberant deep in sinus
Drainage	None or barely visible; clear or thick	None or barely visible clear or thick	Purulent or bloody, sometimes clear	Purulent or bloody	Purulent or bloody	Purulent, bloody, gluey; may be seen only after pressure on cuff; clot or dried blood in sinus

Trauma may result in pain, bleeding, scab, and deterioration of exit appearance. Exit appearance depends on intensity of trauma and time of evaluation. Reprinted from [241] with permission

External Cuff Infection Without Exit Infection

There is intermittent or chronic, purulent, bloody, or gooey drainage, spontaneous or after pressure on the cuff, and induration of the tissue around the cuff. Exuberant granulation tissue may be seen deep in the sinus; sinus epithelium may be macerated. Exit site may look normal on external examination. Ultrasound may show fluid collection around the cuff, but negative ultrasound does not rule out cuff infection. Exit culture may be negative in patients receiving antibiotics.

Traumatized Exit

Features of traumatized exit depend on the intensity of trauma and the time interval until examination. Common features of trauma are pain, bleeding, scab, and deterioration of exit appearance (e.g., perfect exit transforms to good or equivocal or acutely infected).

Alternative Exit-Site Classification Systems

Several alternative classification of exit sites have been proposed [246–248]. The scoring system by Schaefer et al. [246] is based on an Exit-Site Score (ESS, 0–10). The parameters include the presence of an erythema (0, none; 1, <0.5 cm; 2, >0.5 cm), a crust (0, none; 1, <0.5 cm; 2, >0.5 cm), tenderness (0, none; 1, moderate; 2, severe), swelling (0, none; 1, moderate; 2, severe), and discharge (0, none; 1, clear; 2, purulent). The exit site is considered infected if the total score exceeds 4 or greater. Purulent drainage alone is sufficient to indicate infection [246] . This system has been validated only in children.

Exit-Site Care

Early Care

Early colonization of the exit was the most significant factor in determining the healing pattern; the later the colonization, the better healing [69]. Positive culture from either sinus washout or peri-exit smear 1 week after implantation was associated with early exit infection, a higher peritonitis rate, and a high probability of catheter loss due to an exit/tunnel infection, and higher peritonitis rate; however, the time to the first peritonitis episode was not shorter than in the groups with later exit colonization [69].

The goal of early care is to delay bacterial colonization and to minimize trauma to the exit site. After implantation, the exit site should be covered with sterile gauze and occlusive dressings must be avoided. Gauze dressings can wick away drainage from the exit and keep the exit site dry. It is generally agreed that postoperative dressing changes should be restricted to specially trained staff [249]. Dressings should not be changed frequently unless there is evidence of bleeding or significant drainage [250]. Our usual practice is to change dressings every week for the first 2 weeks. Once the exit is colonized, by week 3 in the majority of cases [69], more frequent dressing changes are indicated, because the major rationale for infrequent dressing changes, avoidance of exit colonization, no longer exists. Moreover, more frequent cleansing of the exit will decrease the number of bacteria at the exit. Aseptic technique, including both masking and wearing sterile gloves, should be used for postoperative dressing changes. Nonionic surfactant such as 20% poloxamer 188 (Shur-Clens®) is used to help gauze removal if it is attached to the scab. If the scab is forcibly removed, the epidermal layer is broken, a new scab has to be made, and the epidermization is prolonged. Care is taken to avoid catheter pulling or twisting. The exit sites may be cleaned with normal saline, nonionic surfactant, hydrogen peroxide, or povidone-iodine. Povidone-iodine and hydrogen peroxide are cytotoxic and should be kept out of the exit-site sinus. After cleansing, the exit site should be patted dry with sterile gauze, covered with several layers of gauze dressings, and secured with air-permeable tape.

The exit and visible sinus should be evaluated for quality of healing at each dressing change throughout the 6-week healing period. If healing does not progress, if there are signs of deterioration or infection, the exit is probably already colonized [69]. A clinical culture of the exudate should be taken, and an appropriate systemic antibiotic should be given.

It is recommended that patients do not shower or take tub baths post-catheter implantation, to avoid colonization with waterborne organisms, and to prevent skin maceration. Once more frequent dressing changes are started (after approximately 2 weeks), the patient may take a shower, but only before the dressing change, otherwise he/she must take sponge baths and avoid exit wetting.

Protecting the catheter from mechanical stress is extremely important, especially during break-in. Catheters should be anchored in such a way that the patient's movements are only minimally transmitted to the exit. Although a variety of devices are available to immobilize the dialysis catheter, these devices have not been shown to be any more effective than tape and dressings in preventing infections [251]. The method of catheter immobilization should be individualized, depending on exit location and shape of the abdomen.

Chronic Exit-Site Care

Local Care

The components of chronic exit-site care include assessment and cleansing of the exit-site, immobilization of the catheter and protection of the exit site from trauma. Chronic exit-site care is the responsibility of the patient or the caregiver along with close attention by the physician and nurses on office visits.

Frequent, preferably daily, exit site care is optimal. Cleansing of the exit site is essential to reduce resident bacteria. The exit site is first washed with antibacterial soap and water or with a nonionic surfactant such as 20% poloxamer 188 (Shur-Clens®). Povidone-iodine, chlorhexidine, and Amuchina may be used as disinfectants in routine exit-site care. These agents should not be allowed into the exit-site sinus. After cleansing, the exit has to be patted dry with sterile gauze.

The results of a prospective study by our group indicate that cleaning with soap and water is the least expensive and tends to prevent infections better than povidone-iodine painting and hydrogen peroxide cleaning [252]. Others have found povidone-iodine to be superior to nondisinfectant soap [253].

Amuchina is an electrolytic chloroxidizing solution containing sodium hypochlorite. Amuchina exerts bactericidal, viricidal, and fungicidal effects on a variety of pathogens through generation of hypochlorous acid. Amuchina 10% (ExSept plus) and Amuchina 5% (ExSept) have been found to be as effective as povidone-iodine 10% in preventing exit-site infections [254]. In an open-label, single-center prospective pediatric study, Amuchina 50% was compared to amuchina 3%. The rates of exit-site infections were similar in both groups. Amuchina 3% is the most cost effective option compared to Amuchina 50%, povidone iodine 10% or chlorhexidine 4% [255]. Amuchina may occasionally cause scab formation and exit-site irritation [254].

A dressing cover for 6–12 months after implantation is recommended. Continued use of dressings is indicated for infected exit sites or likely to be contaminated. Patients should avoid submersion in water, particularly in a Jacuzzi, hot tub, or public pool, unless watertight exit protection can be implemented. The surrounding skin is coated with a skin protector and secured with Tegaderm®. Prolonged submersion in water containing high concentrations of bacteria frequently leads to severe infection with consequent loss of catheter. Swimming in the ocean, and well-sterilized private pools, is less dangerous. Exit care must be performed immediately after a shower or water submersion, with particular attention to obtaining a well-dried exit. Patients with the swan-neck presternal catheter may take a hot tub bath without exit-site submersion. Because of this feature this catheter was dubbed the "bath-tub" catheter [3].

Antibiotic Prophylaxis

Exit-site infections are commonly caused by *S. aureus* and *P. aeruginosa* [242–245]. Mupirocin is a carboxylic acid that inhibits bacterial protein synthesis by binding isoleucine t-RNA synthetase and is active against staphylococci and streptococci but not enterococci or Gram negatives [256]. Data supports the use of mupirocin at the exit site to decrease exit-site infections and peritonitis by *S. aureus* [207, 257–260]. The usual recommendation is to apply mupirocin daily after cleansing. Once-weekly application of mupirocin to the exit site has also been shown to be effective in decreasing exit-site infections and peritonitis episodes comparable to those obtained with daily application [261, 262].

Alternative to mupirocin, gentamicin cream [263] and ciprofloxacin otologic solution [237] are effective in reducing the incidence of *S. aureus* as well as Gram-negative exit-site infections. Bernardini et al. randomized 133 individuals to exit-site mupirocin or gentamicin cream [263]. Catheter infection rates were 0.23/yr with gentamicin cream versus 0.54/yr with mupirocin ($p = 0.005$). *S. aureus* exit-site infections were infrequent in both groups (0.06 and 0.08/yr; $p = 0.44$). While there were no pseudomonal exit-site infections in the gentamicin group, there were 0.11 episodes per patient year in the mupirocin arm. Peritonitis rates were 35% lower in the gentamicin arm, with a striking decrease in Gram-negative peritonitis. Montenegro et al. randomized 164 individuals to exit-site care with soap and water only versus exit-site care with soap and water plus application of 1 mg ciprofloxacin (0.5 mL otologic solution) [237]. Ciprofloxacin reduced exit-site infections to 0.06 episodes per patient-year of exposure in contrast to 0.41 episodes in the control group ($p = 0.001$). *S. aureus* infections were significantly reduced and none of the treated patients developed pseudomonal exit-site infections.

Table 14.9 Antibiotic protocol options for preventing exit-site infections

1. Exit-site mupirocin:
a. Daily after cleansing in all patients
b. Daily after cleansing in carriers only
c. In response to a positive exit-site culture for *Staphylococcus aureus* denoting carriage
2. Intranasal mupirocin twice per day for 5–7 days:
a. Every month, once patient identified as a nasal carrier
b. Only in response to positive nose culture
3. Exit-site gentamicin cream daily in all patients after cleansing

Source: Reproduced with permission from [223]

The nasal carriage of *S. aureus* is also a risk factor in peritoneal dialysis–related infections [197, 200, 204, 205]. The treatment of *S. aureus* nasal carriage with intranasal mupirocin twice a day for 5–7 days has been shown to decrease the incidence of *S. aureus* exit-site infections [204–206], and in some studies peritonitis and catheter loss [205, 206]. On meta-analysis, intranasal mupirocin was found to have no benefit on decreasing peritonitis rates and catheter loss [264]. Periodic retreatment is frequently necessary because of a high recolonization rate [204–206]. This may be done routinely at monthly intervals or based on periodic screening. Since the strains of *Staphylococcus* colonizing the exit site may be different from the nose [265], exit-site prophylaxis may be the preferred option and is more convenient. An alternative to intranasal mupirocin is the use of oral rifampin in a dose of 600 mg/day for 5 days every 3 months to reduce *S. aureus* exit-site infections [207, 208]. In a randomized study, mupirocin and rifampin were equally effective in reducing *S. aureus* peritonitis and catheter loss, however, rifampin was often poorly tolerated [207]. In a meta-analysis of studies on prophylaxis against *S. aureus*-related infections in patients on dialysis, resistance to rifampin ranged from 0 to 18.2% and the drug had to be discontinued in 6.6% of patients due to toxicities [266]. The overall benefit of mupirocin prophylaxis (nasal and exit-site) were evaluated in another meta-analysis; there was a highly significant relative risk reduction of 37% for all *S. aureus* infections, 34% for peritonitis, and 38% for exit-site infections [267].

There are few side-effects associated with the mupirocin, mainly nasal irritation and discharge for the nasal route [204]. Exit-site mupirocin ointment can structurally damage polyurethane and should be avoided with these catheters [268]. An increasing prevalence of mupirocin resistance is being reported [269, 270]. Perez-Fontan has reported that high-level resistance to mupirocin (defined as an MIC $\geq$512 μg/mL) increased from nonexistent in the period 1990–1996 to 12.4% in 1999–2000. He also noted that the accumulated incidence of *S. aureus* exit-site infection in the period 1997–2000 was 32.3% in patients colonized by mupirocin-resistant *S. aureus* as compared with 14.5% in those colonized by mupirocin-sensitive *S. aureus* ($p = 0.03$), suggesting a substantial impact of the development of resistance [269]. In these reports, none of the isolates were methicillin-resistant [269, 270] nor are there reports of development of cross-resistance [271]. Prolonged usage and multiple intermittent courses of mupirocin appear to be the factors most frequently associated with the development of mupirocin resistance [271]. However, one study that examined mupirocin resistance over a 7-year period reported no increased prevalence in mupirocin resistance over this time period [272]. Programs should perform periodic surveillance to detect the emergence of resistant strains.

The International Society of Peritoneal Dialysis recommendations on antibiotic protocols for preventing exit-site infections are reproduced in Table 14.9 [223].

Early Complications Related to Peritoneal Access

Early complications post-soft catheter insertion are similar to those after implantation of the rigid catheter, but their frequency is lower, particularly with surgical, peritoneoscopic, or laparoscopic insertion. Blood-tinged dialysate is common postimplantation but severe bleeding occurs very rarely with surgical insertion. Dialysate leaks are unlikely if ambulatory peritoneal dialysis is postponed for at least 10 days after implantation [273]. This complication is particularly rare with the Toronto Western Hospital, swan-neck Missouri abdominal, swan-neck presternal, and Lifecath® column disc catheters. Early leak is usually external and may be confused with serous drainage from the exit. A diagnosis of a leak is supported by a higher glucose concentration in the drainage compared to the simultaneously measured blood glucose concentration.

Poor dialysate return is usually due to catheter obstruction if loss of siphon or tubing occlusion is ruled out. The most common reason of catheter obstruction is occlusion of the tip by bowel and/or bladder or intraluminal formation

Table 14.10 Early catheter obstruction

Cause	Prevention/treatment
Occlusion by bowel	Laxatives
Occlusion by bladder	Empty bladder
Clot	Rinse out blood, heparin, urokinase, dislodge
Omental wrap	Partial omentectomy
Multiple adhesions	Adhesiolysis
Kink in the tunnel	Surgical correction

of clot (Table 14.10). Emptying the bladder and using laxatives may restore catheter function if there is obstruction by bladder or bowel. Clot may be prevented by rinsing out blood from the peritoneal cavity and using heparin or can be dislodged by forceful injection through the tubing into the peritoneal cavity or pulling by suction using a syringe filled with heparinized saline. If these maneuvers are unsuccessful the catheter may be filled with urokinase (Abbokinase) 5,000 IU, diluted in normal saline. Thrombolytics like tissue plasminogen activator and urokinase may open the obstruction in 10–15% of cases [274–277]. Using high pressure during fluid infusion, Hashimoto et al. [278] were able to open six catheters occluded by clots. Catheter kinking in the tunnel is usually associated with two-way obstruction, is recognizable on abdominal X-ray in two views, and requires surgical correction as soon as diagnosis is made. If the catheter is not kinked, but does not function for 2 weeks, omental wrapping or multiple adhesions are most likely and omentectomy or adhesiolysis using laparoscopy may be required.

A reversed one-way peritoneal catheter obstruction, in which the fluid can be drained but the next infusion cannot be performed, is extremely rare. In one such case, the catheter tip was obstructed with a clot which caused inflow obstruction. The catheter tip was obstructed with a clot, which caused inflow obstruction. This clot was removed by suction with a syringe. We speculated that the clot was firmly anchored in the catheter tip, and that only a few proximal side-holes were open. The outflow was not obstructed because the catheter tip must have been located in a large pocket of free peritoneal space. The clot behaved like an accordion. During drainage the clot became stretched and narrowed (like an accordion bellow in extension) and fluid was able to flow through some of the side-holes. During infusion the clot buckled up and widened (like a compressed accordion bellow), completely occluding the central lumen and side-holes [279].

Another reason for obstruction may be catheter adherence to the peritoneum. This complication was found in children who have undergone partial omentectomy at the time of insertion of a single-cuff, straight Tenckhoff catheter. Relocation of such catheters may be attempted with a so-called "whiplash" technique [280]. After localization of the catheter adherence site, using a strict sterile technique, a blunted steel trochar is inserted into the catheter and gently advanced until the trochar tip is 5–7 cm proximal to the tip of the catheter. Using a deep cuff as a fulcrum, and using short and rapid whiplash motions, the catheter is then freed from the adherence point. The catheter tip is then, under fluoroscopy, relocated to a new site. A modification of this method using a pliable copper thread was successfully used in adults [281]. A catheter that has migrated to the upper abdomen may be relocated using a guidewire [282–284]. Although these methods may obviate the need for surgery, they are not without risk. The guidewire may break during manipulations, may perforate the catheter, and may lead to recurrent peritonitis.

Catheter migration out of the true pelvis is seen frequently on abdominal X-rays done for various reasons in patients with functioning catheters. While about 20% of X-rays showed the catheter tip translocated to the upper abdomen, only 20% of these translocated catheters (4% of the total) were obstructed or malfunctioning. The remaining functioning malpositioned catheters were either permanently translocated or repositioned spontaneously to the true pelvis. About 3% of catheters in our series were obstructed with the tip in the true pelvis [285].

While the great majority of malpositioned catheters are not obstructed, a catheter with its tip in the upper abdomen is still about six times more likely to be obstructed than a normally positioned catheter. The migration of the catheter tip may, however, be the result of the obstruction rather than its cause; omentum entangling the catheter tip may be responsible for its translocation.

Repositioning of the internal catheter segment is best done surgically using a laparoscopic method (see above). In our experience, if this method fails to restore catheter function because the peritoneum is not usable for peritoneal dialysis because of massive adhesions, catheter relocation or replacement in such a situation is worthless. The patient must be transferred to hemodialysis.

Viscus perforation is unlikely with surgical catheter insertion. Early peritonitis with a soft catheter is half of that reported with a rigid catheter, even in treatment of acute renal failure [126]. Abdominal pain is more likely with straight catheters due to "jet effect" and tip pressure, as discussed in the section on infusion/pressure pain.

Late Complications Related to Peritoneal Access

Factors influencing catheter complications have been discussed earlier. Complications are not randomly distributed throughout the life of the catheter. Whereas leaks and catheter malfunction occur shortly after catheter implantation, infectious complications lead to catheter failure later.

Exit-Site Infections

The use of a classification system facilitates early diagnosis of exit problems, and treatment can be more specific. Exit-site care and treatment for each appearance category are summarized in Table 14.11.

Table 14.11 Exit-site treatment and care for each category of exit-site appearance

	Equivocal infection	Acute infection	Chronic infection	Cuff infection
Evaluation	Culture and sensitivities on peri-exit smear; Gram stain	Culture and sensitivities on exudate; Gram stain	Culture and sensitivities on exudate; Gram stain	Palpation of cuff and tunnel; culture and sensitivities and Gram stain of exudate (spontaneous or after pressure on cuff); ultrasound of cuff/tunnel
Initial therapy	Cauterize slightly exuberant granulation tissue. Topical mupirocin. Exit care daily; clean with mild disinfectant soap; do not use strong oxidants on granulation tissue; use a sterile absorbent dressing.	Cauterize slightly exuberant and exuberant granulation tissue. First-generation cephalosporin for Gram-positive organisms; quinolone for Gram-negative organisms; vancomycin for methicillin-resistant *S. aureus*. Exit care daily or b.i.d.; clean with mild disinfectant liquid soap or nonionic surfactant agent; do not use strong oxidants on granulation tissue; use a sterile, absorbent dressing.	Cauterize slightly exuberant and exuberant granulation tissue. First-generation cephalosporin for Gram-positive organisms; quinolone for Gram-negative organisms; vancomycin for methicillin-resistant *S. aureus*. Exit care daily or b.i.d.; clean with mild disinfectant liquid soap or nonionic surfactant agent; do not use strong oxidants on granulation tissue; use a sterile, absorbent dressing.	Cauterize proud flesh. Initial antibiotic therapy based on Gram stain results.
48 h	Change to Neosporin, gentamicin, or chloramphenicol ointment if Gram-negative organisms on culture.	Adjust therapy according to culture and sensitivities.	Adjust therapy according to culture and sensitivities.	Adjust antibiotic according to culture and sensitivities.
Follow-up	If no improvement in 2 weeks, change to systemic antibiotic based on initial culture and sensitivities. Continue therapy 7 days past achieving a good appearance.	Evaluate weekly; reculture if no improvement. Continue to treat for 7 days after achieving a good appearance.	Evaluate every 2 weeks; reculture every 2 weeks if no improvement on appropriate therapy. Add synergistic drug or change antibiotic according to culture and sensitivities. If infection recurs repeatedly after achieving a good appearance: (a) consider chronic antibiotic suppression; (b) if no improvement after a month of treatment, suspect cuff infection and treat as such. If accompanying peritonitis, remove catheter.	Re-evaluate every 2 weeks; reculture monthly. If no remission: (a) consider cuff shaving; (b) consider catheter replacement. If accompanying peritonitis, remove catheter.

Acute Exit-Site Infection

A culture of exit-site exudate or, if there is swelling/erythema without expressible exudate, a smear culture of the skin surrounding the exit should be taken as soon as a clinical diagnosis of an acute exit-site infection is made. Recommendations for the care of infected exit-sites are based on sound surgical practices and anecdotal experiences. Increasing the frequency of dressing changes to once or twice a day helps the healing process, especially in those with copious drainage. Nonirritating solutions (e.g., nonionic surfactant) are preferred cleansers to remove drainage and reduce the number of microorganisms. An infected exit should be covered with a sterile nonocclusive dressing to absorb drainage, protect against trauma, and shield against superinfection.

An attempt may be made to treat early infections with erythema and no drainage with topical treatments. These treatments include application of soaks to the exit twice to four times daily, as well as the application of dry heat. Soaking solutions include normal saline, hypertonic saline, sodium hypochlorite, dilute hydrogen peroxide, povidone-iodine, and 70% alcohol [223, 249, 286, 287]. Local applications of povidone-iodine ointment, mupirocin, and Neosporin® cream, ointment, or ophthalmic solutions have been recommended [223]. Topical antibiotics are of limited value in treating acute or chronic infection with copious drainage because of the inability to achieve sufficiently high local concentrations [288]; however, topical antibiotics are helpful once drainage diminishes.

Depending on the clinical appearance, empiric antibiotic therapy may be initiated immediately or delayed until the results of the culture are available. Prior cultures or the Gram stain may guide initial therapy. Gram-positive organisms are treated with an oral penicillinase-resistant penicillin, cephalexin, or sulfamethoxazole trimethoprim. In slowly resolving or particularly severe-appearing *S. aureus* exit-site infection, rifampin 600 mg daily is added. Oral antibiotics are equally effective as intraperitoneal antibiotics for most ESI with the exception of methicillin-resistant *S. aureus* [223]. Vancomycin should be avoided in the routine treatment of Gram-positive exit-site infection and tunnel infections to prevent emergence of resistance. Gram-negative organisms may be treated with oral quinolones such as ciprofloxacin. The presence of *P. aeruginosa* should prompt the use of two antibiotics with different mechanisms of action such as ciprofloxacin and ceftazidime or an aminoglycoside. These infections are often refractory to treatment and have frequent relapses [223, 289]. Very often *Pseudomonas* exit-site infections resolve only after catheter removal. Antibiotic therapy should be continued until the exit site appears entirely normal, with a minimum of 2 weeks of therapy.

Exuberant granulation tissue (proud flesh) is cauterized with a silver nitrate stick, a procedure widely used in surgical practice, veterinary and human [288, 290]. No more than one or two applications are necessary in most patients with acute infection. This procedure speeds up the healing process and facilitates epithelialization. Cauterization should be restricted to granulation tissue only, and accidental touching of the adjacent epithelium should be avoided. Use of a magnifying glass aids in precise cauterization. This can be done safely by a physician or nurse [291].

Catheter immobilization is a sound practice providing protection against accidental trauma. Trauma leads to bleeding, and blood is a good medium for facilitating growth of microorganisms. Catheter immobilization should be continued or implemented during the acute infection stage.

An ultrasound of the exit site is indicated to evaluate for presence of tunnel and cuff involvement if the infection fails to respond to 2 weeks of appropriate antibiotics. Since patients with *S. aureus* and *Pseudomonas* sp. exit-site infections have a high incidence of cuff and tunnel involvement, an ultrasound examination when the cultures are reported should be a consideration. Another indication for ultrasound is the presence of simultaneous exit-site infection and peritonitis [292].

Most acute infections respond favorably to therapy. An exit-site with an acute infection in association with proud flesh and bleeding requires prolonged antibiotic therapy. Association with a positive nasal culture had no influence on the outcome. Conditions that delay healing or make therapy ineffective are cuff and/or tunnel infection, infection due to a resistant organism or a virulent pathogen, and patient noncompliance [223, 293]. Recurrent infections that progress to chronic infection and/or cuff infection are associated with a poor prognosis. Catheter removal is indicated when acute exit-site infection leads to tunnel infection and peritonitis. Management of cuff infection is discussed later in this section.

Chronically Infected Exit Site

The work-up leading to the proper diagnosis of a chronically infected exit site is similar to that performed to diagnose acute infection. These infections are hard to treat. Once the culture and antibiotic sensitivity results are available, an appropriate antibiotic should be started. A combination of synergistic antibiotics is preferred to a single agent, to avoid emergence of resistant organisms, since the therapy is given over a prolonged period. In chronic infection, the bacterial flora or the antibiotic sensitivity may change during the course of treatment. Therefore, an unresponsive exit site may

have to be cultured repeatedly for timely diagnosis. The response to treatment is usually slow. An ultrasound of the catheter tunnel may be indicated to evaluate for cuff infection. The features of the chronic infection change very slowly to those of an equivocal exit and then eventually to those of a good exit site.

The antibiotic therapy and local care of the exit site are continued until the desired features of a good exit are achieved. In some cases, exit features change to equivocal and remain as such for a long time. In such instances, the systemic antibiotic is discontinued and replaced with a topical antibiotic. Chronic infection requires repeated cauterization of exuberant granulation tissue. Typically, weekly cauterization for several weeks is necessary. The cauterization is continued as long as the proud flesh persists. The cauterization will discolor the proud flesh from red to gray. Some cases of chronic infection may require long-term (many months) suppressive doses of a systemic antibiotic. Typically, these cases show reinfection on discontinuing the systemic antibiotic. It is likely that such cases represent undiagnosed cuff infection. Chronic exit-site infections may require catheter removal.

Local care is similar to that used in treating acute infection. After achieving the features of an equivocal exit, the frequency of local care may be reduced to once a day.

Equivocal Exit

The equivocal exit site is a subclinical form of infection. If left untreated, most equivocal exits will progress to acute infection. Therefore, aggressive management of equivocal exits assumes great importance. Aggressive local care with a topical antibiotic may cure most equivocal exit sites. Exits with external, slightly exuberant granulation tissue, which usually progress to acute infection, require systemic antibiotics. Cauterization of the slightly exuberant granulation tissue in the sinus may be necessary.

An acute infection may acquire equivocal features during the recovery phase. Such an exit site warrants less aggressive therapy compared to one with acute infection; the key to therapy being daily local care while systemic antibiotics may be discontinued.

Local therapy with topical antibiotics is the mainstay of treatment for an equivocal exit site. A topical antibiotic is chosen based on the exit swab culture results. The topical antibiotics that we have successfully used include mupirocin, Neosporin®, gentamicin, chloramphenicol, and tobramycin. This effectiveness is due to the absence of copious drainage from the sinus tract. Systemic antibiotic may be used in cases unresponsive to topical therapy. Response to therapy is usually excellent, with cure occurring in almost all instances.

Good and Perfect Exit

The care of these exit sites has been discussed earlier in this section. Catheter immobilization, protection from trauma, use of liquid soap and water for daily care, and use of Shur-Clens® to remove large, irritating crust are appropriate measures to prevent infection. In our experience, a perfect exit is unlikely to become infected unless severely traumatized or grossly contaminated after submersion in water loaded with bacteria.

Traumatized Exit

Bleeding is a common squeal of trauma. Extravasated blood is a good medium for bacterial growth. Bacteria that have colonized the exit multiply rapidly in the presence of decomposing blood and infect the disrupted tissue. Infection may occur as early as 24–48 h after trauma. The prompt administration of an antibiotic, chosen based on the history of skin colonization, may prevent acute infection. In the absence of the information about previous skin colonies, an antimicrobial agent sensitive to Gram-positive organisms, such as a cephalosporin or a quinolone, may be chosen. Therapy may have to be continued for about 7 days after achieving a good appearance. Aggressive treatment is necessary in every instance of trauma reported by the patient. Local care requires gentle cleansing of all blood from the exit site.

External Cuff Infection with or Without Exit Infection

Ultrasound examination of the tunnel is a valuable tool in the diagnosis of cuff infection. While positive findings with ultrasound examination help to establish a diagnosis of tunnel infection, a negative examination does not rule out the existence of an infection [294]. Cuff infection responds to therapy slowly, if at all, and a complete cure is unlikely. A sonolucent zone around the external cuff 1-mm thick following a course of antibiotic treatment and involvement of the proximal cuff are associated with poor outcomes [295]. Vychytil has suggested that in *S. aureus* tunnel infections, if sequential ultrasounds done every 2 weeks do not show a 30% decrease in the hypoechoic area around the cuff, the catheter should be removed [292].

Local care has to be given aggressively. Among the surgical options is catheter removal with simultaneous or delayed catheter replacement [296, 297]. Deroofing of the sinus tract and external cuff shaving [298–301] and replacement of the external tubing segment by catheter splicing [302–304] are other surgical options. The latter two options allow for the continuation of peritoneal dialysis without the need to switch to hemodialysis. In our experience cuff shaving prolonged catheter life for approximately 6–12 months [291]. These temporary measures may be suitable for patients who are expected to stay on therapy for a short period, e.g., patients awaiting transplant; however, cuff infection is a strong indicator for catheter removal in long-term peritoneal dialysis patients. Anecdotal reports suggest that cuff shaving may provide better results in presternal catheters [305]. This may be related to the presence of three cuffs and a long tunnel in the presternal catheter. Shaving of the subcutaneous cuff leaves two cuffs as a double barrier against peri-luminal bacterial penetration.

Peritonitis

Peritonitis on peritoneal dialysis usually develops because of touch contamination or pericatheter spread of bacteria. Touch contamination causes peritonitis by skin commensals such as coagulase-negative *Staphylococcus*, Corynebacterium, diptheroids, and occasionally Gram-negative organisms [193, 306, 307]. Exit-site and tunnel infections are associated with a pericatheter spread of infection [308]. In a trial examining the risk factors for peritonitis, the development of an exit-site infection doubled the risk of subsequent peritonitis [309]. The organisms commonly associated with such infections are *S. aureus* and *P. aeruginosa* [242–245]. Occasional patients develop peritonitis due to hematogenous seeding, bowel perforations or gynecological spread of organisms. Bowel trauma is a known catheter complication [310].

Tunnel infections often require removal of the catheter without which the patient may suffer from recurrent or relapsing peritonitis from the same organism. Even with exit-site infections, occult tunnel infections may be present may cause a high failure rate to therapy. Another cause of recurrent or relapsing peritonitis is the development of bacterial biofilm layers on the catheter. Bacterial biofilms are microbial colonies enclosed in a self-produced polymeric matrix and adherent to the catheter. *S. aureus* and coagulase-negative *Staphylococcus* are the most common organisms forming biofilms. Bacteria in the biofilm are in a sessile form and are intermittently shed in a planktonic form, which can be pathogenic. Biofilm infections are often slow to produce symptoms. Mature biofilms develop resistance to antibiotics, phagocytes, and biocides [311]. The poor penetration of antibiotics into the biofilm may explain antibiotic resistance. Alternatively, the bacteria may enter into a nongrowing state or a spore-like state in which they are protected from killing [312, 313]. Relapsing peritonitis has also been reported due to colonization of presternal catheter at the site of titanium connector. In this case, a removal of the chest segment of the catheter resulted in resolution of relapsing peritonitis [314].

Infusion or Pressure Pain

Some patients may experience pain with infusion of dialysate. This pain may be due to the acidic pH (pH 5.2–5.5), hyperosmolality, or temperature of conventional dialysate [315]. Localized pain may result from irritation from the catheter tip as it rests against the pelvic wall or intra-abdominal organs [316]. The jet effect of rapidly flowing dialysis solutions may also cause abdominal pain. In some rare instances, compartmentalization from adhesion formation around the catheter may cause severe abdominal pain [317].

Coiled catheters are less likely to induce abdominal pain than straight catheters because more of the solution flows shower-like through side-holes, with only part of it through the main lumen that is not in direct contact with the peritoneal membrane. Moreover, the poking force of the coiled catheter is smaller than that of the straight one because the coiled intraperitoneal segment is more flexible. Finally, the larger contact area of the coiled catheter with the parietal peritoneum further reduces the pressure compared to the straight catheter tip.

In the majority of cases, the pain is transient and disappears within a few weeks. Assessment of the catheter by routine radiographs, contrast catheterograms, or CT-peritoneography may be indicated. Table 14.12 shows the maneuvers, which may be used to alleviate the pain. Decreased infusion rate is frequently helpful. If pain occurs only at the beginning of inflow and the end of outflow, incomplete drainage and/or tidal mode for nightly peritoneal dialysis may be successful. Alkalization of conventional dialysate with sodium bicarbonate or use of local anesthetics is sometimes effective, but at the potential cost of increased peritonitis and therapy burden. The use of bicarbonate and bicarbonate/lactate solutions having a physiological pH has been shown to reduce infusion pain [315]. If all these maneuvers are ineffective, the catheter has to be replaced. The replacement catheter should be a coiled one and the catheter should be implanted in such a way that no undue pressure is exerted at the tip.

Table 14.12 Maneuvers to alleviate infusion pain

Slower infusion rate
Incomplete drainage
Tidal mode for nightly peritoneal dialysis
Solution alkalization (sodium bicarbonate: 2–5 mEq/L)
Bicarbonate or bicarbonate/lactate peritoneal dialysis solutions
1% lidocaine – 2.5 mL/L (50 mg/exchange)
Catheter replacement

External Cuff Extrusion

A cuff positioned close to the exit site predisposes it to extrusion. There are at least two forces favoring cuff extrusion (Table 14.13): 1) the pushing force of catheter resilience and 2) pulling and tugging on the catheter. The tendency of a straight catheter implanted in an arcuate tunnel to straighten, due to resilience, plays the most important role in cuff extrusion (Fig. 14.40). Manipulation of the catheter with frequent CAPD exchanges also contributes to this complication. There is also a possibility that high hydrostatic pressure in the abdomen with the constant presence of fluid in the peritoneal cavity, while the patient is ambulatory, also tends to extrude the external cuff.

The external cuff should be implanted approximately 2–3 cm beneath the skin as a compromise between the need of a short sinus tract to prevent infections but not so short as to favor cuff extrusions [1, 223]. Also, resilience forces should be eliminated by creating the tunnel in a shape similar to the shape of the catheter. Tugging on the catheter should be avoided. It is extremely important to avoid resilience forces pushing on the cuff if implanting it

Table 14.13 Causes of cuff extrusion

Catheter resilience
Pulling and tugging
Intra-abdominal pressure?

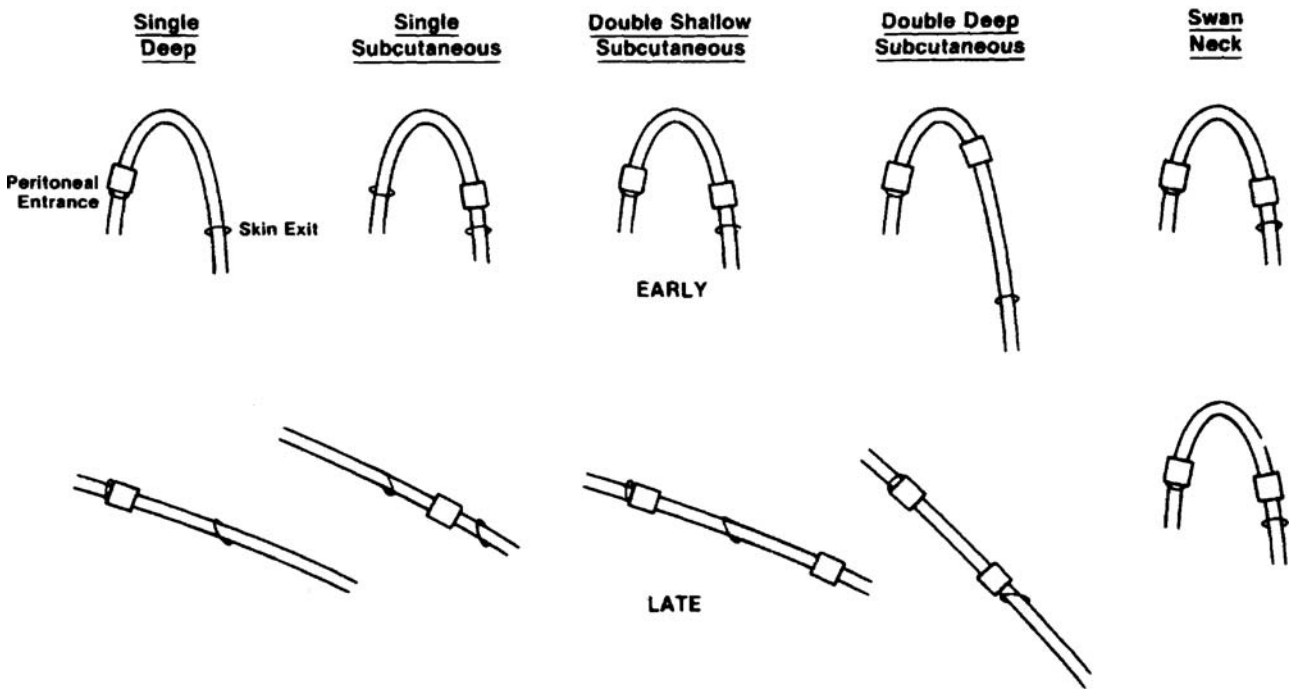

Fig. 14.40 Straight and swan-neck catheters in arcuate tunnels. Upper panel shows catheter configuration immediately after implantation, lower panel portrays catheter shape several months later. Straight catheters forced into arcuate tunnels gradually assume natural, straight configuration. Single-cuff catheters do not extrude cuffs. With long distance between cuffs and shallow subcutaneous tunnel, the external cuff extrusion is inevitable (center), whereas short distance between cuffs and deep position of the subcutaneous cuff precludes its extrusion. Swan-neck catheter maintains its shape

relatively close to the skin exit. The catheter should not be implanted in a site with subcutaneous edema, to avoid cuff extrusion once the edema is resolved. We also recommend a 2-week period of wound healing occur before beginning dialysis training. This helps to seal and anchor the Dacron® cuffs by tissue ingrowth.

If the cuff is not infected it is left alone; however, the cuff usually becomes infected during this process and requires systemic antibiotics or even surgical intervention. If there is no peritonitis and no deep cuff infection then the catheter may be saved, at least for some time, by shaving off the infected superficial cuff [298, 301]. Infection is another cause of cuff extrusion. In this instance the cuff becomes infected while still in the sinus, and is extruded by tissue retraction around the cuff. Two such extrusions were observed with swan-neck Missouri abdominal catheters [83]. We also observed a patient who traumatized her presternal catheter and developed a superficial and mid-cuff infection leading to a tunnel infection. The tunnel was opened and drained and the catheter was shortened to a "one cuff" (deep) catheter which continued to function years after the drainage procedure.

Catheter Obstruction

"Capture" of the catheter by active omentum may cause outflow obstruction. Obstruction from this cause, in the absence of peritonitis, when it occurs is usually a postoperative event (related to a new catheter). We have never seen an obstruction (in the absence of peritonitis) due to omental "capture" as a late event. We believe that Silastic® is more prone to attract omentum very early. In due course of time, with or without use, a proteinaceous (not bacterial) biofilm catheter coating may make the Silastic® less "foreign" to omental tissue. Slow drainage due to catheter translocation, obstruction by bowel, or fibrin clot formation occurs from time to time in some patients. Laxatives and/or addition of heparin 500 U/L of dialysis solution are usually successful in restoring good catheter function. Some patients have permanently translocated catheter out of the true pelvis. If the catheter functions (even with slower drainage), we do not attempt to reposition the catheter. If catheter does not function after implementing simple maneuvers, more aggressive measures, similar to those described in the section on early soft catheter complications should be tried (see above).

An unusual cause of Cruz catheter blockage, which occurred 4 weeks after initiation of dialysis as a result of the tip wrapping by a fallopian tube, has been reported [318]. The fimbriae of the oviduct penetrated through the side-holes of the catheter and occluded the central lumen. Catheter function was restored surgically. A high dialysate flow and bigger side-holes of the polyurethane device (the Cruz® catheter) as compared to silicone rubber catheters might have contributed to this complication.

Catheter-Tip Migration

One- or two-way catheter obstruction is usually the result of catheter wrapping by the omentum. The best condition for dialysate drainage is created with the catheter tip in the true pelvis because, in the majority of people, the omentum does not reach to the true pelvis. Tenckhoff recommended a caudal direction of the intraperitoneal catheter segment to prevent catheter tip migration out of the true pelvis [89]. If the exit site is directed caudally and a straight tunnel points cephalad the catheter *must* have an intraperitoneal bend to place the tip near the true pelvis, and the tip can easily translocate out of the true pelvis due to the silastic "shape memory." The internal cuff operates like a fulcrum on which resilience forces flip the catheter tip into the upper abdomen (Fig. 14.41). If the tip translocates to the left upper abdomen the peristalsis of the descending colon may restore proper position of the tip; however, a tip translocated to the right upper abdomen usually does not return to the proper position because the forces of both catheter resilience and ascending colon peristalsis push the tip upwards. In support of this hypothesis are observations that, when a catheter is implanted with a straight subcutaneous tunnel, with the external exit directed downwards and the intraperitoneal entrance directed upwards, even if the catheter tip is placed into the true pelvis during insertion, it migrates out to the upper abdomen significantly more frequently compared to the opposite tunnel direction [80, 319]. Our experience indicates that the dominant factor in catheter-tip position is the resilience force of the catheter. To avoid the unfavorable influence of resilience forces on the intra-abdominal catheter segment, the catheter needs to be molded in the shape in which it is to be implanted in the tunnel.

The problem of tip migration was approached differently by Oreopoulos et al. [40], who provided the intraperitoneal segment of the catheter with two silicone discs. Once the catheter is in the true pelvis, these discs hinder translocation of the catheter tip. Recently, Di Paolo et al. [48] provided the catheter tip with a small, tungsten weight incorporated into the silicone rubber to prevent catheter migration out of the true pelvis. The migration rate of these

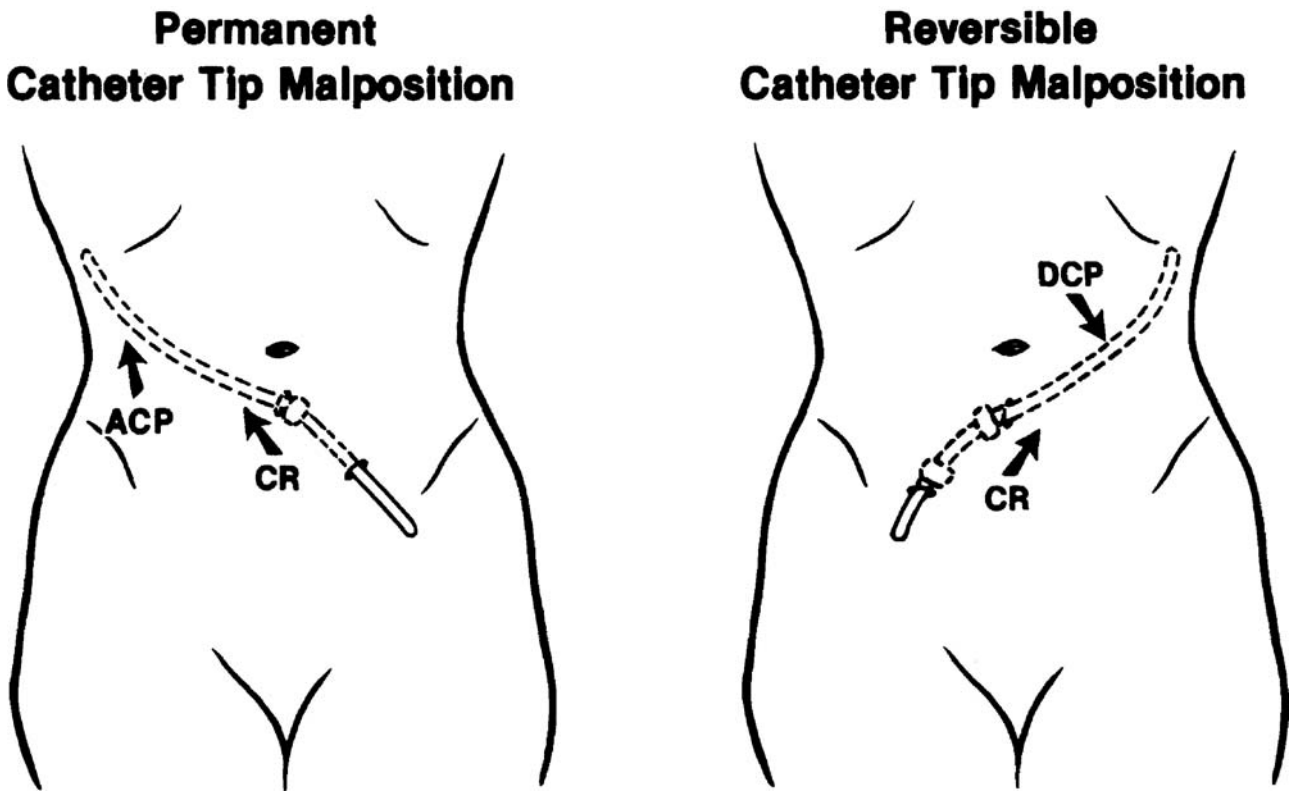

Fig. 14.41 Straight catheter insertion: catheter tip migration out of true pelvis with external exit directed downwards and intraperitoneal entrance directed upwards pointing either to liver or spleen. Note the tendency of catheter to assume its original shape. ACP = ascending colon peristalsis; DCP = descending colon peristalsis; CR = catheter resilience

catheters (no dislocation in 32 catheters over 468 patient-months) was significantly lower than Tenckhoff catheters (nine dislocations in 26 catheters over 415 patient-months). No detrimental effects of these weights were reported. The migration rate of Tenckhoff catheters was unusually high in this study. Catheters with a coiled intraperitoneal segment have more intraperitoneal mass and like the weighted tip catheters appear less likely to migrate out of the pelvis.

Pericatheter Leak

To avoid excessive bleeding, the catheters have frequently been inserted through the midline. In patients treated by intermittent peritoneal dialysis, dialysate leaks are rare because the intra-abdominal pressure is low in the supine position. In CAPD patients, pericatheter leaks are more frequent due to the continuous presence of dialysate in the upright position where the intra-abdominal pressure is higher. Insertion of the deep cuff into the belly of the rectus muscle, as recommended by Helfrich et al. [320], markedly reduces chances of pericatheter leak because of tissue ingrowth from the rectus muscle.

Dialysis solution leaks may occur months or even years after starting CAPD. Management of late leak is similar to that described for early leak. However, most cases of late leak are refractory to conservative therapy and require surgical repair. As discussed earlier, pericatheter leaks are more likely with the midline catheter insertion than with the insertion through the rectus muscle [80, 320]. Similar to the acute leak, this complication is rarely seen with the catheters provided with a bead and polyester flange at the deep cuff (Toronto Western Hospital, swan-neck Missouri abdominal, swan-neck presternal).

Contrary to the early leaks, which are usually external, the late leaks infiltrate the abdominal wall (Table 14.14). The acute leak causes a sudden drop of ultrafiltration and usually occurs after a sudden increase in intra-abdominal pressure (heavy lifting, coughing, or straining). The leak may be mild and intermittent. Such a leak may be difficult to localize. Immediately after leak occurrence the patient may be in good fluid balance without edema of lower

Table 14.14 Late dialysate leak

Acute	Chronic
After heavy lifting, coughing, or straining	Usually a sequela of acute leak
Sudden drop of ultrafiltration	Poor ultrafiltration
May be mild and intermittent	Fluid overload
Abdominal wall edema	Localized abdominal edema
Peau d'orange	Usually without thigh edema
Spongy feeling	

extremities. Abdominal wall edema reveals a dimpling of the skin that gives it the appearance of the skin of an orange *(peau d'orange)* and spongy feeling on palpation. Chronic leak is usually a sequel of an acute leak but may occur gradually. The patient is usually fluid overloaded due to poor ultrafiltration. A repeated peritoneal equilibration test shows unchanged solute transport characteristics but drain volume is lower [321]. Various radiologic procedures to diagnose leaks are discussed below.

Unusual Complications

Organ Erosion

Peritoneal dialysis catheters may cause hemoperitoneum by causing minor tears of the omental vessels [322]. Occasionally, a peritoneal catheter has been reported to have eroded into the mesenteric vessels leading to hemoperitoneum [323]. Peritoneal catheters may cause damage of the internal organs leading to intra-abdominal bleeding [324, 325]. Peritoneal lacerations from a catheter may lead to genital edema or other internal leaks [326]. Erosion into the small intestine, colon, and rectum are also reported on occasion [310, 327–332]. There are reports of transvaginal leak of peritoneal fluid caused by erosion of the vaginal vault by the peritoneal catheter [333, 334].

These complications are mostly described with the straight Tenckhoff catheter and the Toronto Western Hospital catheter [310, 327–331]. Though less common, such complications are also reported with coiled catheters [332]. It is thought that pressure exerted by "soft" but resilient tubing with a pointed tubing end of the straight Tenckhoff catheter or the relatively sharp silastic discs of the Toronto Western Hospital catheter leads to organ or bowel erosion. In most instances, the catheters had not been used for 1–12 weeks before the complication was diagnosed [327, 329–331]. In a dry abdomen, the peritoneum and the bowel are free to rub against the catheter leading to organ erosion.

Mechanical Accidents

Scissors or sharp objects may accidentally cut the external segment of the peritoneal dialysis catheter. Natural wear of catheters after prolonged use, repeated use of clamps, and exposure to certain disinfectants may also cause the catheter to be damaged [335]. Catheters will not self-seal if punctured and such instances may occur during implantation procedure and shaving of the cuff.

To avoid system contamination the patients are instructed to clamp the catheter immediately and cover the area with sterile gauze. If the damage is close to the adaptor, sectioning the damaged segment and inserting another adaptor is a simple procedure. If the damage leaves the catheter too short and there is at least 15 mm of tubing from the exit site, then the catheter may be saved by using the using the peritoneal catheter Peri-Patch® repair kit (Covidien, Mansfield, MA 02048 USA).

The Peri-Patch® repair kit contains a silicone rubber catheter extension with a double-barbed connector inserted in one end and a beta-cap adapter. While repairing the catheter, a sterile procedure must be strictly followed. The operator should "scrub, mask, and glove." A "circulating" nurse should be present to assist. The operating field has to be well protected with sterile towels; the catheter should be wrapped with Betadine®-soaked gauze for 5 min. The catheter is transversely cut with a sterile blade proximal to the damaged site. The catheter clamp is released and the catheter is squeezed with fingers. The patient is asked to strain, to allow dialysate flow from the peritoneal cavity. The flowing dialysate will flush any contaminant. While the fluid is still flowing, the barbed Teflon® tubing of the repair kit is inserted into the catheter as far as possible. Then the silicone rubber tubing of the repair kit is clamped to stop dialysate flow. The connection is dried with gauze. A mould is positioned over the connection and filled with sterile silicone glue. The extension tubing is connected to the catheter in the usual way. The glue cures for 72 h.

Antibiotic prophylaxis for reducing risk of peritonitis should be administered. Using this method we have been able to extend the life of seven peritoneal catheters by a mean of 26 months (range 1–87 months) [335].

Material Breakdown and Catheter Fracture

Functional integrity of the peritoneal catheter is paramount for a successful long-term peritoneal dialysis program. The age of the catheter, the material of the catheter, physical trauma, exposure to chemicals, and oxidants are crucial factors.

Dialysis catheters are made with either silicon rubber or polyurethane. While both these materials are biocompatible, each offers unique characteristics. Silicon rubber catheters cause minimal trauma to surrounding tissues and minimal leeching of plasticizers. Polyurethane has a greater strength and allows catheters to be made with thinner walls and larger lumina [336].

The polyurethane catheters are susceptible to organic solvents and plasticizers [336]. Organic solvents such as alcohol, acetone, isopropyl alcohol, dipropylene glycol methyl ether, deobase (kerosene), and benzene are found in adhesives, adhesive removers, and disinfectants. Plasticizers such as polyethylene glycol are found in ointment bases such as that of mupirocin and naturally in cholesterol and skin oils. The organic solvents can solubilize the polyurethane or cause reversible swelling of the catheter which eventually leads to surface cracking and splitting. Plasticizing agents get absorbed onto the catheters and cause softening or plasticization of the catheters [336]. These changes cause a decrease in tensile strength and lower the yield point. Caution must be exerted to avoid exposure of polyurethane catheters to these solvents and plasticizers. Mupirocin cream instead of ointment should be used in prophylaxis of exit-site infections [268, 337]. Silicon catheters are more resistant to hydrolysis due to their highly cross-linked polymer structure. However, silicone rubber catheters are more likely to be damaged by Betadine® and develop cracks or become brittle [338].

There are reports that inclusion of barium sulfate throughout the entire catheter to render it radiopaque could make the catheter brittle [338]. Currently, the catheters contain only a stripe of barium sulfate and seem to be less prone to this mode of failure.

Implanted peritoneal dialysis catheters are also subjected to mechanical trauma and biodegradation. Silicon catheters usually develop surface erosions with time, largely as a consequence of dynamic mechanical stress. In contrast, polyurethane catheters develop deep fissures and cracks that are likely caused by a combination of macrophage and leukocyte oxidation, environmental stress cracking, and mineralization [339–342].

Allergic Reactions

Among the differential diagnosis of cloudy bags is peritoneal fluid eosinophilia. This condition is diagnosed when eosinophils constitute greater than 10% of the total peritoneal fluid white blood cell count and the eosinophil count exceeds 100 cells per cubic milliliter of peritoneal effluent.

In many cases the peritoneal fluid eosinophilia occurs early after the initiation of PD and is felt to represent a reaction to the plasticizers in the PD catheter or plastic dialysate bags [343, 344]. Other causes include introduction of air or blood into the peritoneum [345], bacterial peritonitis [346], and reactions to icodextrin [347, 348] and dialysate additives. Prior reports put the incidence between 5–61%, but the incidence has significantly receded in recent years due to improvement in the quality of peritoneal dialysis materials. In most cases the eosinophilia resolves without treatment [343, 349, 350]. Coating of the catheter with proteinaceous biofilm may decrease its ability to cause an allergic reaction. Persistent cases may respond to steroids or a mast-cell-stabilizing antihistamine [351–354].

Allergic eosinophilic dermatitis due to silicone rubber is also reported [355]. Topical therapy with steroids or antihistamines may help in some patients.

Radiologic Imaging in Diagnosis of Complications

Peritoneal dialysis catheters contain radiopaque materials that allow the catheter position to be determined by simple abdominal radiographs. The catheter tip should lie deep in the Pouch of Douglas. Plain radiographs also provide information on constipation and ileus, which may impact catheter performance. Contrast catheterograms performed by injecting iodinated contrast material through the PD catheter may be useful in identifying catheter obstructions, kinks, and adhesions around the catheter.

Fig. 14.42 In a CAPD patient a small area of swelling around the umbilicus occurred after lifting a 100 lb weight. CT scan of the abdomen after infusion of 2 L of contrasted dialysate shows a small amount of extravasated contrast containing dialysate in the umbilical area (white arrow)

While plain computerized tomography scans of the abdomen are useful in diagnosis of some complications, these have been replaced by CT-peritoneography. One hundred to 300 mL of iodinated contrast is added to 1,000–2,000 mL of peritoneal dialysate and instilled into the abdomen [356–358]. After instillation of this solution, the patient is encouraged to roll on his or her sides or to walk or perform other activities that may increase the intra-abdominal pressure. An option to increase intra-abdominal pressure is to increase the instilled volume of dialysate by 500 mL over the usual fill volume. A CT scan is performed approximately 2 h later. This procedure allows for the diagnosis of leaks, hernias, adhesions, and chronic peritoneal sclerosis and may identify etiologies of recurrent or relapsing peritonitis. An example of a leak in the periumbilical area without relation to the catheter is shown in Figs 14.42 and 14.43. A leak around the Tenckhoff catheter implanted through the midline is shown in Fig. 14.44.

An alternative to CT-peritoneography is MRI-peritoneography [359–361]. While the MR scans are usually performed using gadolinium-based dye added to dialysate, saline or the dialysate itself can provide a hyper intense

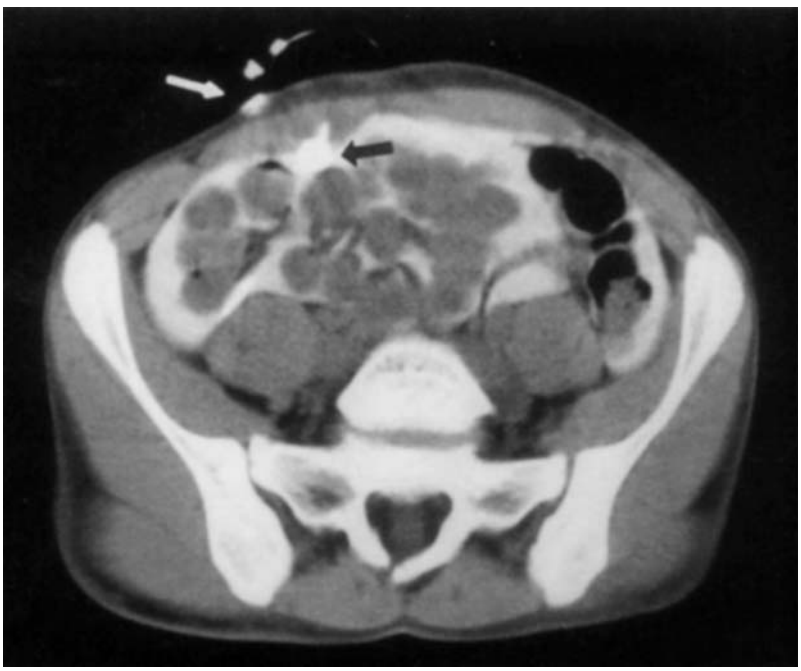

Fig. 14.43 Swan-neck Missouri catheter entering the peritoneal cavity in the vicinity of the extravasated fluid. The intraperitoneal bead (black arrow) and intramural segment leaving the subcutaneous tunnel (white arrow) are clearly recognizable. No extravasated fluid is seen around the catheter entrance into the peritoneum. Pericatheter leak is ruled out

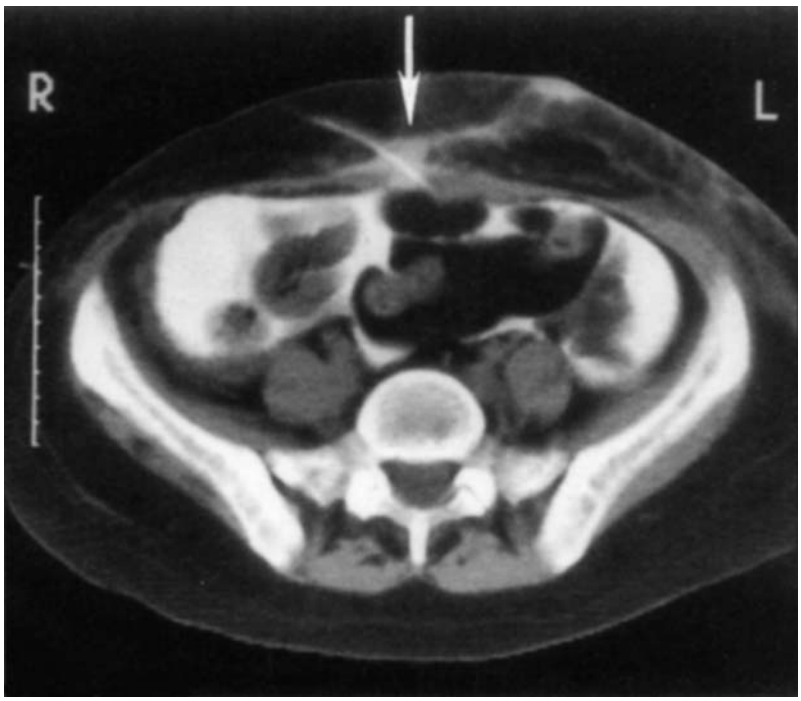

Fig. 14.44 Contrast-enhanced dialysate extravasating around the Tenckhoff catheter (arrow) implanted through the midline

image on T2 imaging due to the electrolyte content of the solution [360]. A potential risk of nephrogenic systemic fibrosis has been described with the intravenous administration of gadolinium in patients with kidney disease [362] but not with intraperitoneal administration so far. A retroperitoneal leak is demonstrated in Fig. 14.45.

Peritoneal scintigraphy is performed by adding 2–5 millicuries of technetium 99 m isotope to a bag of peritoneal dialysis solution [363, 365]. Multiple views in anterior-posterior, lateral, and oblique projections are taken to diagnose leaks and hernias. After completion of the procedure, the dialysate along with the instilled isotope is drained limiting the dose of radiation exposure [365]. Delayed scans are recommended in initially negative studies to diagnose small leaks [364].

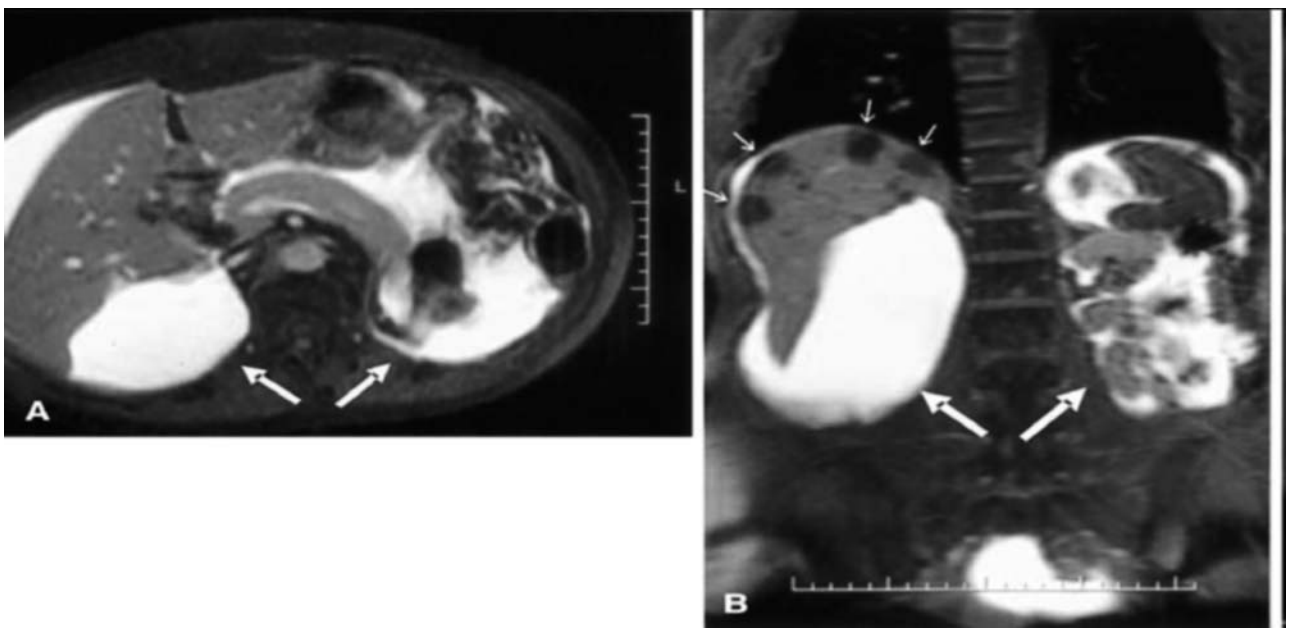

Fig. 14.45 Retroperitoneal fluid leak. (a) axial and (b) coronal T1-weighted images demonstrate retroperitoneal fluid leak (large arrows) in a patient who had bilateral nephrectomy secondary to polycystic kidney disease. Note multiple liver cysts (small arrows). With permission from Springer Science and Business Media [361]

An ultrasound is a good modality to assess the catheter tunnel. High resolution images can be obtained with a high frequency transducer. The intraperitoneal catheter is hard to visualize with ultrasound but Doppler interrogation while injecting saline may reveal the tip [292, 366, 367]. Due to the echogenicity of the catheter wall, acoustic shadows may hide fluid collections unless the tunnel is carefully examined from different angles. The ultrasound is an excellent modality to diagnose catheter tunnel and cuff infections [292, 367]. The normal catheter tunnel has a low-echo circumferential rim around the catheter and the cuff is seen as a cotton-like isoechoic area [366]. Tunnel infections cause a widening and loss of clarity of the circumferential area around the catheter. Abscesses may also be diagnosed on ultrasound and appear larger areas of decreased echotexture. Abscesses may be compressible and Doppler interrogation may show increased blood flow in the wall with no signal from the center of the pus collection [368]. Ultrasounds may also be used to follow response to therapy. This has been discussed in the section on exit-site infections.

Catheter Removal

Indications

The need for catheter removal occurs under various conditions. These may be broadly categorized under two headings: catheter malfunction and complicating medical conditions with a functioning catheter. Finally, the catheter may be removed electively because it is not needed.

Catheter Malfunction

The decision to remove the catheter is usually made only when conservative measures (described in the sections on early soft catheter complications and catheter obstruction, and in Table 14.10) to restore function have failed. Catheter malfunction requiring catheter removal may be seen in the following conditions: 1) intraluminal obstruction with blood or fibrin clot or omental tissue incarceration, 2) catheter tip migration out of the pelvis with poor drainage, 3) a catheter kink along its course, 4) catheter tip caught in adhesions, and 5) accidental break in the continuity of the catheter.

Functioning Catheter with a Complication

Under the following conditions catheters may have to removed: 1) recurrent peritonitis with no identifiable cause; 2) peritonitis due to exit-site and/or tunnel infection; 3) catheter with persistent exit-site infection; 4) tunnel infection and abscess; 5) late recurrent dialysate leak through the exit site or into the layers of the abdominal wall; 6) mycobacterial or fungal peritonitis; 7) bowel perforation with multiple organism peritonitis; 8) refractory peritonitis of other causes; 9) severe abdominal pain either due to catheter impinging on internal organs or during solution inflow; and 10) catheter cuff extrusion with infection.

Functioning Catheter That Is No Longer Needed

This situation is encountered after a successful renal transplantation or peritoneal dialysis is discontinued because dialysis is no longer needed, or the patient transfers to another form of dialysis.

Removal Methods

Uncuffed Catheter

Removal of the uncuffed catheter is a simple procedure. After cutting the anchoring suture the catheter is simply pulled out and the opening is covered with a sterile dressing.

Cuffed Catheters

A Tenckhoff catheter inserted through the midline may be removed at the bedside. After preparation of the operating field, local anesthesia is applied around the cuffs, the incisions are reopened, the cuffs are excised, and the catheter is pulled. The incisions of catheters removed for cuff/tunnel infection should be packed open and allowed to heal by

second intention. In our experience, calcium–sodium alginate fibers (Kaltostat Wound Dressing) are excellent for wound packing. The fibers absorb exudate very efficiently, control minor bleeding, and protect the wound from contamination. Once-daily dressing change is usually sufficient for wound packing with the fibers.

The catheters inserted through the belly of the rectus muscle require surgical dissection in the operating room to remove. Although the catheter can be removed using a local anesthetic, patient comfort usually dictates a general anesthetic, particularly for the Toronto Western Hospital, swan-neck abdominal Missouri, and presternal catheters. After an appropriate surgical scrub and routine draping the incision is reopened. The anterior rectus fascia is reopened along the site of the previous incision and the catheter/cuff/flange are sharply dissected free of the ingrown rectus muscle. The previously placed fixation sutures in the flange and the purse-string sutures are cut and, with traction and continued sharp dissection, the abdominal portion of the catheter is removed. Care must be taken to protect the underlying viscera. The remaining small opening into the abdomen is closed with O or OO Prolene® sutures. The anterior fascia is reapproximated in a similar fashion. Depending on the clinical indication for removal, the incision may either be closed or packed open and allowed to heal by second intention.

Swan-Neck Presternal Catheter

Removal of a swan-neck presternal peritoneal dialysis catheter is a surgical procedure performed in the operating room, preferably with general anesthesia. After an appropriate surgical scrub and routine draping of both the chest and abdomen, both the chest and abdominal incisions are reopened. Bleeding is controlled with electrocautery. Using blunt and sharp dissection, the two cuffs at the bent portion of the catheter are freed from the adjacent subcutaneous tissue. Working from the abdominal incision, the catheter is divided between sutures *above* the titanium connector. The chest portion of the catheter is pulled out in a cephalad direction through the chest (parasternal) incision. The abdominal part of the catheter is then removed in an identical way as described for the swan-neck Missouri abdominal and Toronto Western Hospital catheters. Depending on the clinical indication for removal the two incisions may either be closed or packed open and allowed to heal by second intention.

Operations in Peritoneal Dialysis Patients

Extra-Abdominal

A number of operative procedures may be carried out in the dialysis patient. The patients may undergo a variety of extra-abdominal operations such as coronary artery bypass, lower extremity revascularization, carotid endarterectomy, and, on occasion, the creation of a hemodialysis access. Prior to the operative procedure the dialysis fluid should be drained. Since the abdominal cavity has not been violated, dialysis may be started immediately following the patient's return to the surgical floor. Special caution is required in patients who have presternal catheters. Patients undergoing coronary artery bypass surgery or thoracotomy require particular attention to the location of the presternal catheter to avoid damage to the catheter. Peritoneal dialysis may be restarted on the day of surgery in the supine position in these patients.

Abdominal

A whole series of abdominal operations may be contemplated and carried out in patients on chronic ambulatory peritoneal dialysis. The operations range from cholecystectomy to colectomy to hernia repairs. Operations on the abdominal wall carry less risk to the patient from the standpoint of developing peritonitis or catheter loss. These operations include all abdominal wall hernias and they can be carried out with some ease and a high degree of safety.

Intra-abdominal procedures on the intestine or the gallbladder for acute or chronic disease may predispose to a risk of infection or loss of the catheter secondary to infectious complications. Procedures such as laparoscopic cholecystectomy can be carried out with minimal risk of spillage of bile or contaminated contents, and after rinsing the abdominal cavity the catheter can be rested and dialysis begun in a few weeks time. In the case of a perforated viscus such as a perforated sigmoid diverticulum or a perforated peptic ulcer with peritoneal soilage the catheter will undoubtedly be lost at that setting. It is safer to remove the peritoneal catheter with massive abdominal soilage because the presence of a foreign body will often prolong or potentiate the risk of persisting infection. Once the patient

is recovered from the acute intra-abdominal process consideration can be given to restarting peritoneal dialysis. Depending upon the extent of peritonitis and intra-abdominal adhesion formation, peritoneal dialysis may or may not be possible.

In general, prior to abdominal procedures the abdomen should be drained prior to operation. In our institution we use a first-generation cephalosporin as a prophylactic antibiotic for elective operations and therapeutic antibiotics based on culture for operations associated with significant intra-abdominal soilage. As mentioned, those patients having significant intra-abdominal peritonitis are better served by removal of their catheter at the time of their initial operation with a re-establishment of peritoneal dialysis at a future date. After an elective operation such as cholecystectomy, in-and-out exchanges in the supine position are started immediately after the patient reaches the floor. We limit the volume of exchanges to 1 L and heparin 1,000 units per liter are added to the fluid. These exchanges continue until the dialysate is clear. Ceftazidime 500 mg is added to the last exchange and that exchange is not drained. Metronidazole 500 mg *per os*/intravenous/rectal is used for 5 days following elective procedures. The day following the operation, in-and-out exchanges are repeated until the dialysate is clear and again 500 mg of ceftazidime is added to the last exchange, which is not drained for 12 h.

To prevent incisional hernia/leak ambulatory peritoneal dialysis is delayed for 2–6 weeks depending upon the type of operation and the general condition of the patient. Collagen maturation is slower in diabetic, immunosuppressed, and undernourished patients. Restart of peritoneal dialysis should be delayed in such patients.

Concluding Remarks

Peritoneal catheters are lifelines for peritoneal dialysis patients. While advances in catheter placement and subsequent care have made it possible to obtain and maintain access to the peritoneal cavity safely over an extended period of time, catheter-related complications remain responsible for over 20% transfers out of peritoneal dialysis. Meticulous care starting prior to catheter insertion with choosing the site of insertion, appropriate surgical techniques, and subsequent care are essential to the success of peritoneal access. Complications must be addressed early to save the catheter and the peritoneum complimented by the use of appropriate imaging techniques. Further research and innovation will form the basis of future improvements in outcomes.

Chapter 15
Monitoring the Functional Status of the Peritoneum

D.G. Struijk and R. Khanna

The integrity of the peritoneal membrane is essential for long-term treatment of peritoneal dialysis (PD) patients. Unlike an artificial kidney used for hemodialysis, the peritoneal membrane consists of living tissue. This implies that the properties of this membrane are not constant, but may change under the influence of endogenous or exogenous factors. Thus, it is important to monitor the peritoneal membrane in time. Data obtained during follow-up are crucial in the development of more biocompatible solutions. For the individual patient these data could be used to tailor the dialysis adequacy or to predict clinical problems such as ultrafiltration failure or peritoneal sclerosis.

Direct evaluation of the peritoneal membrane is not feasible, as until now no simple, effective, and safe procedure exists to obtain peritoneal tissue during the dialysis period. Peritoneal tissue can be obtained during surgical procedures for various indications, which usually also mark the end of the peritoneal dialysis treatment. Fortunately, each dialysis exchange can provide valuable information about peritoneal structure and function. In this chapter the various methods to indirectly analyze the peritoneal membrane will be described. First, attention will be given to measurement of markers in peritoneal effluent. Secondly, monitoring the peritoneal membrane by using its properties to transport solutes and water will be discussed.

Mesothelial Cell Markers

The Mesothelium

The main function of the mesothelium is prevention of friction between abdominal organs when they move, and thereby prevention of the formation of adhesions. During PD, mesothelial cells are also likely to be involved in local host defense [1]. The currently used PD solutions are toxic to cultured mesothelial cells [2]. They reduce cell viability [3], inhibit the synthesis of interleukin (IL)-6 and prostaglandins [4], and induce apoptosis [5]. Data obtained from incidental peritoneal biopsies indicate that PD leads to signs of mesothelial degeneration and regeneration [6–12], as well as replacement of the mesothelial cell layer by a thick fibrous band in long-term PD patients [13] and patients who develop peritoneal sclerosis [12, 14]. Acute infectious peritonitis is associated with discontinuity or denudation of the mesothelial layer [8, 12–15]. Remesothelialization usually occurs after the infection has been cured but it might be incomplete [8, 13, 16]. Mesothelial-cell cultures from effluents during peritoneal dialysis show markedly varied morphologic features, ranging from a cobblestone-like appearance similar to that of mesothelium derived from omentum to fibroblast-like cells or mixed cell populations [17].

Cancer Antigen 125 (CA125) as a Marker of Mesothelial Cell Mass

In vivo study of the mesothelium has become possible by the discovery of CA125 as a marker of mesothelial cell mass or cell turnover in stable continuous ambulatory peritoneal dialysis (CAPD) patients [18, 19]. CA125 is a glycoprotein with a molecular weight exceeding 200,000 Dalton in gel filtration experiments [20]. However, size heterogeneity is present. The murine monoclonal antibody OC125 detects two subunits, 237,000 Da and 186,000 Da. Higher and lower molecular weight subspecies, present in the cytoplasm and extracellular matrix of CA125-producing cells, were found

using other monoclonal antibodies [21]. CA125 is expressed in coelomic epithelium during embryonic development [22]. In adult tissues, CA125 has also been demonstrated on the epithelium of the female genital tract and on mesothelial cells in the pleura, pericardium, and peritoneum, particularly in areas of inflammation and adhesions [22]. The function of CA125 is unknown.

CA125 in Serum During Various Conditions and Renal Replacement Therapy

The development of a radioimmunoassay for CA125 concentrations in serum [23] enabled its use as a tumor marker for ovarian neoplasm's [24–29]. It has also been detected in cells of some benign ovarian tumors and in other carcinomas, especially in those of the uterus, cervix, and breast [30, 31]. Besides increased serum CA125 levels in ovarian cancer, increased concentrations in various other conditions have also been found, such as endometriosis [32], pelvic inflammatory disease [33], and malignant peritoneal mesothelioma [34], and in patients with various liver diseases [35].

During renal replacement therapy most studies on this subject showed that serum concentrations in hemodialysis patients [36–38] and PD patients [18, 39, 40] were similar to those obtained in individuals with normal renal function. One study reported higher concentrations in hemodialysis and PD patients than in normal controls and patients with a functioning kidney graft [41]. Another study in hemodialysis patients only showed increased serum concentrations when fluid in the serosal cavities (peritoneum, pleura, or pericardium) was present [42]. In contrast, low values have also been described in PD [43]. One study reported an increase in serum CA125 after implantation of a PD catheter and during peritonitis [44], but the latter finding could not be confirmed in another investigation [45]. The difference between the two studies is that peritonitis, catheter implantation, and other abdominal surgery were taken together in the former [44], but abdominal surgery and catheter removal were not included in the latter [45]. It can be concluded from the above studies that serum CA125 is not influenced by renal function or by the type of renal replacement therapy.

CA125 in Ascites

High peritoneal fluid concentrations of CA125 can be found in ascites of patients with liver disease [35], in fluid obtained during gynecologic surgery [46, 47], and in healthy women undergoing laparoscopy [47]. The cutoff value in the latter study was 8,450 U/mL, a value that exceeds normal serum concentration by about 2,000-fold. This suggests local intraperitoneal production or release. The decrease in serum CA125 that was found after paracentesis in patients with liver disease also suggests that CA125 in the ascitic fluid was the cause of the elevation [35]. The presence of CA125 in mesothelial cells [22], the high values in mesothelioma [34], as well as the increase after mechanic [48] and infectious [35] trauma to the mesothelium, make it likely that peritoneal mesothelial cells are the source of CA125 in peritoneal fluid.

Release of CA125 by Cultured Human Peritoneal Mesothelial Cells

Mesothelial cells can be obtained by enzymatic digestion of pieces of omentum [49] and cultured until confluence and for 10 days thereafter [50]. In two studies the CA125 concentration in the supernatant increased with the duration of culture and was proportional to the amount of cells brought into culture [18, 19]. The increase in supernatant CA125 was exponential before confluence and linear after that time point [19]. This is consistent with a constant production in time per cell. Most of the secretion was constitutive and from the apical side [19, 51]. On the contrary, in a recent study no relation was found between the number of mesothelial cells after lysis with trypsin and CA125 in the supernatant [52]. One study reported a limited increase in CA125 release after stimulation with cytokines such as IL-Iβ and tumor necrosis factor (TNF)-α at day 5 of the culture [51], but this could not be confirmed in two other studies using the same cytokines at day 8 of the culture [19] or after reaching confluence [52]. This suggests that stimulation with cytokines has some effect on CA125 production when the confluence of the monolayer is not perfect, but that a confluent mesothelial monolayer releases CA125 only constitutively. Finally, chronic exposure of mesothelial cells for 4 weeks to glucose (45 mM) decreased the CA125 content of their cytosol and the release of this antigen into the culture medium while cytokine production increased [52]. This confirmed earlier experiments from the same group and, as not all cell functions were reduced, the authors explained their results by changes in the phenotype of the mesothelial cells [53]. Whether the in vitro experiments can be extrapolated to the human situation remains questionable, as studies with more biocompatible dialysate solutions but still containing glucose almost universally demonstrated an increase of CA125 concentration in time (see below). Lysis of freshly isolated omental cells showed the presence of intracellular CA125, the amount ranging from 0.16 to 0.31 U/10^3 cells [19], indicating a marked intraindividual variability. CA125 is almost undetectable in lymphocytes, monocytes, granulocytes, and fibroblasts [45], making peritoneal mesothelial cells the most likely source for local CA125 release during PD. From the above in vitro studies with cultured

mesothelial cells showing a constitutive release after confluence, it can be concluded that CA125 released from mesothelial cells probably can be used for follow-up of mesothelial cell mass in individuals, as long as no lysis of cells occurs. It most likely cannot be used for interindividual comparison of mesothelial cell mass.

CA125 in Peritoneal Dialysate in Stable Peritoneal Dialysis Patients

Mesothelial cells in peritoneal effluent are CA125-positive when investigated with immunohistochemistry [18, 54]. The median percentage of CA125-positive cells was 92%, but ranged between 0 and 100%. Values between 75 and 100% were found in 80% of patients [54]. In most studies a relationship was found between the number of mesothelial cells in peritoneal effluent of PD patients and effluent CA125 concentration [18, 19, 54]. In one paper where the authors used flow cytometry analysis to count mesothelial cells in effluent and a radioimmunoassay to measure CA125 [55], no relationship was found. This might be caused by differences in methodology as the flow cytometry counting method for mesothelial cells has a poor correlation with results obtained by microscopy [54] due to the presence of clusters of mesothelial cells. Also, radioimmunoassay for the measurement of CA125 was not validated in peritoneal effluent and has been reported to be unreliable for low concentrations [56].

A first cross-sectional analysis with a commercial microparticle enzyme immunoassay to measure CA125 concentrations in the effluent of the long night dwell in 24 patients on continuous ambulatory PD yielded values ranging between 5.2 and 76 U/mL, median 18 U/mL [18] (the measurements of CA125 are done on the effluent of the patient itself; centrifugation or concentration procedures are not necessary). Subsequently, it was shown that CA125 dialysate concentrations increased linearly during a 4-h dwell [57, 58] as well as dwell exceeding 4-h [59]. Because of the effect of time on concentrations, low values have been found when measured after a 4-h standardized dialysis dwell [60], which implies that either the method should be accurate in the low range, or longer dwells should be used. Although the glucose concentration of the dialysate has no significant effect on CA125 release [57], a high glucose concentration will cause more ultrafiltration and therefore decrease effluent CA125 concentration. To compare CA125 in samples with various dwell times it was advised to calculate appearance rates of CA125 [59]. One group advocates correction of CA125 appearance rate for body surface area, but the evidence is not convincing [61].

Dialysate CA125 is not influenced by gender [39]. The majority of cross-sectional studies found no relationship between CA125 appearance rate and patient age in adults [39, 61] and children [62, 63]. One study suggested a relation between CA125 and persistent inflammatory state, indicated by elevated serum IL-15 levels, and leading to a negative influence on nutritional status [64]. Due to the limited number of patients included in the cross-sectional studies, and the various methodologies used, normal baseline values for dialysate CA125 have not yet been established.

CA125 and Peritoneal Transport

Mesothelium is unlikely to be directly involved in the transport of solutes from the circulation to the dialysate [65]. Transport is dependent mainly on vascular surface area, that is, the number of perfused peritoneal capillaries [66, 67]; but an indirect effect of mesothelial cells cannot be excluded. Cultured mesothelial cells are able to produce various cytokines, chemokines, and prostaglandins, some of which are vasoactive [68] and involved in the changes in peritoneal permeability that occur during peritonitis [69–71]. Some studies reported a positive correlation between dialysate-to-plasma ratios of creatinine and dialysate CA125 [55, 72, 74], while this was not found in other studies [39, 58, 60–62]. This positive relation was found especially in the early phase of the dialysis treatment and might be explained by cytokines and vasoactive substances produced by mesothelial cells [73, 74]. The increase in peritoneal transport in time has been explained by neovascularization in the peritoneal membrane [75]. This could explain the disappearance of the initial relation between CA125 and peritoneal solute transport in long-term peritoneal dialysis.

Dialysate CA125 and Duration of Peritoneal Dialysis

A first cross-sectional analysis in stable PD patients showed a large interindividual variability of dialysate CA125 during the first 2 years of PD in some patients [60]. All patients treated for more than 4 years, however, had values below 12 U/mL. A similar effect of duration of PD was confirmed in some later studies [39, 54, 62, 72] but not in others [55, 58, 61, 62]. Differences in duration of follow-up or methodology of the CA125 determinations may have caused these variable results. However, a decrease in CA125 appearance rate has been found during longitudinal analysis [57, 76, 77]. Low values have been found in peritoneal sclerosis patients [78–79]. It can be concluded that a single low CA125 appearance rate is difficult to interpret. Serial longitudinal observations showing a decrease suggest loss of mesothelial cell mass.

Temporary discontinuation (peritoneal resting) has been advocated in PD patients with peritoneal hyperpermeability and ultrafiltration failure [80, 81]. Patients treated with peritoneal resting for clinical signs of peritoneal membrane failure later on during their treatment had lower dialysate CA125 levels than those not needing temporary discontinuation [58]. Although experience is limited, peritoneal resting might lead to an increase in effluent CA125 [79]. In one study it was suggested that, when CA125 concentration did not increase after withdrawal of peritoneal dialysis, this was predictive for peritoneal sclerosis development [79].

Dialysate CA125 and Peritonitis

Acute peritonitis causes an early increase in CA125 appearance rate to more than twice the control value obtained after recovery from infection [45]. The maximum value is reached on the second day and is followed by an initial decrease, and then followed by a second increase on days 4–6. Patients with a large increase in CA125 had more severe peritonitis, as judged by higher effluent cell counts and higher hyaluronan appearance rates. The time-course during peritonitis suggests an initial increase due to massive release from necrotic mesothelial cells, followed by remesothelialization. However, this explanation needs further confirmation.
