Editor's Dedication

This work is dedicated to Rebecka Rutledge Fisher, whose encouragement was essential throughout its development.

Acknowledgements

Great thanks are due to the authors and associate editors for their distinguished contributions and patience, and especially to Senior Editors Janice Stern, who supported the work from its inception, and Katie Chabalko, who guided its completion.

Contents

Part 1 The Ecological Range of Relationships Between Behavior and Health

Part II Knowing in Behavioral Medicine: Epistemic Foundations

Part III Key Influences on Behavior and the Relationships Among Behavior, Health and Illness

Part IV Approaches to Changing Behavior Related to Health

Part V Key Areas of Application in Prevention and Disease Management

Part VI Interventions to Enhance Quality of Life

Part VII The Contexts of Behavioral Medicine Science and Practice

Part 1

The Ecological Range of Relationships Between Behavior and Health

Introduction

1

Edwin B. Fisher, Linda D. Cameron,
Alan J. Christensen, Ulrike Ehlert, Yan Guo,
Brian Oldenburg, and Frank J. Snoek

As defined by the International Society of Behavioral Medicine (http://www.isbm.info/about-isbm/charter/), behavioral medicine is:

> … the interdisciplinary field concerned with the development and integration of psychosocial, behavioral and biomedical knowledge relevant to health and illness and the application of this knowledge to prevention, etiology, diagnosis, treatment and rehabilitation. The scope of "behavioral medicine" extends from research efforts to understand fundamental biobehavioral mechanisms; to clinical diagnosis and intervention; to disease prevention and health promotion.

This volume embraces the breadth of that definition and emphasizes a very wide range of subjects including fundamental aspects of learning, emotion, cognition, genetics and epigenetics, and brain-behavior relationships as well as our still emerging understanding of how natural and built environments, sociocultural factors, and public policies influence behavior and behavior change. The interventions behavioral medicine includes are correspondingly broad, from individual interventions to improved stress management to policy approaches to designing communities that promote physical activity and implementing national health plans that encourage healthy behaviors. In short, behavioral medicine encompasses the entirety of the range of relationships between behavior and health. It is this breadth of both conceptual perspectives and application that this volume seeks to convey.

The contributions of behavior to health and health care have often been limited by failure to

E. B. Fisher (ed.), *Principles and Concepts of Behavioral Medicine*,
https://doi.org/10.1007/978-0-387-93826-4_1

identify and assert the roles of behavior and to articulate fully a view of *health as behavior*, how we live our lives. This is in sharp contrast to construing health status as some aggregate of clinical risks and clinical problems. For example, we may think about health as years of quality of life and the behaviors that comprise a life of quality, rather than as years of survival. Similarly, from a behavioral perspective, we can approach health not as managing this, that, or another clinical problem, but rather as promoting and guiding the core behaviors that comprise health across most all diseases and their risks:

- Eating a healthy diet, engaging in regular physical activity, sufficient and restful sleep
- Avoiding dangerous behaviors like smoking and excessive alcohol use
- Cultivating healthy relationships to give and receive social support
- Avoiding/minimizing perceived stress and subjective burden
- Getting screening appropriate to age, sex, family history, and genotype
- Taking appropriate medications

In emphasizing the range of influences on behaviors related to health, this book takes what has come to be termed a *socio-ecological perspective.* This is explained in more detail later in this chapter, but central to this perspective is attention to influences at multiple levels – biological, psychological, family, social, community, cultural, organizational, system, policy – and the relations among these levels, e.g., influences of community and cultural forces on family and individual behavior.

Scope of Behavior and Health

Behavior is central to the development, prevention, treatment, and management of a number of primary diseases and health conditions, including heart disease, cancer, stroke, pulmonary diseases, unintentional injuries, communicable diseases, diabetes, suicide, kidney diseases, liver diseases, and HIV/AIDS. According to the World Health Organization (World Health Organization, 2015a):

- Tobacco accounts for around six million deaths every year (including from the effects of exposure to second-hand smoke) and is projected to increase to eight million by 2030.
- About 3.2 million deaths annually can be attributed to insufficient physical activity.
- More than half of the 3.3 million annual deaths from harmful drinking are from non-communicable or chronic diseases.
- In 2010, 1.7 million annual deaths from cardiovascular causes have been attributed to excess salt/sodium intake.

The United States Centers for Disease Control and Prevention has estimated that 14 of the top 15 causes of death in the United States are attributable to modifiable behaviors, including physical inactivity, poor diet, smoking, alcohol and other drug use, poor injury control, inadequate sun protective behaviors, inappropriate use of medicines, insufficient immunization, unsafe sexual and reproductive practices, poor oral hygiene, and mental health problems (Heron, Hoyert, et al., 2009). Other countries report similar impacts. In Switzerland, for example, costs of stress management are estimated at 4.2 billion Swiss francs per year (Grebner, Berlowitz, et al., 2010).

The breadth of connections between behavior and health is formidable. In addition to the commonly recognized role of behaviors such as smoking, diet, and physical activity, other behaviors are also fundamental to the development of a number of diseases. For example, stress and stress management play important roles in the development and management of cardiovascular and other diseases, and unsafe sex practices increase the likelihood of contracting infectious diseases such as HIV/AIDs. Chronic conditions like diabetes require self-management of interlinked behaviors through careful monitoring of diet, physical activity, stress management, and complex disease-specific tasks such as blood glucose monitoring linked with adjustment of medication, diet, and activity. Behavioral and psychological interventions have been shown to enhance not only quality of life, but also survival through improved psychological adjustment as well as changes in risk behavior (Andersen, Yang, et al., 2008). Cutting across a number of these effects of behavior on health are interactions between behavioral and biological factors such as in cigarette smoking (True, Xian, et al., 1999) and behavioral and environmental influences on expression of genetic propensities for diabetes (Pratley, 1998) or excessive alcohol use (Ducci, Enoch, et al., 2008).

Behavior Matters[1] The broad roles of behavior in health and disease (Nater, Gaab, et al., 2006) were documented in a 2011 review (Fisher, Fitzgibbon, et al., 2011) that examined three major diseases (cardiovascular disease, cancer, and HIV/AIDS) and four major risk factors (tobacco use, poor diet, physical inactivity, and excessive alcohol consumption). Together, these account for great health impacts around the world. For example, the four risk factors account for an estimated 36.8% of all deaths in the USA (Mokdad, Marks, et al., 2004, 2005).

For each of these three major diseases and four major risk factors, the 2011 review examined six types of behavioral influence. The first was how behavioral, environmental, and genetic influences moderate one another. Five additional types of influence focused on the roles of behavior in the development of health problems, prevention, disease management, quality of life, and population approaches to health promotion.

Table 1.1 has been adapted from the 2011 review. It provides examples from published research of each of the six types of behavioral influence for each of the three major diseases as well as the four risk factors. As an example of the many ways in which behavior matters, alcohol use has impacts on health ranging from birth defects to accidents and injuries to alcohol-related liver disease and pancreatitis (Healthy People 2010, 2000). Genetic predispositions may incline the individual to excessive use but these are also moderated by psychosocial factors such as childhood maltreatment (Ducci, Enoch, et al., 2008). Although often difficult to treat, brief interventions can reduce drinking (U.S. Preventive Services Task Force (USPSTF), 2004; Whitlock, Polen, et al., 2004) and problems associated with alcohol (O'Connor & Whaley, 2007), while more intensive psychological treatments can improve quality of life among those recovering from excessive use (Arnedt, Conroy, et al., 2007). Along with tobacco use and physical activity, alcohol use stands as an area in which environmental modifications, such as reducing density of retail outlets, can be effective (The Guide to Community Preventive Services).

Another set of examples of how behavior matters surround cardiovascular disease, with which the roles of behavior range from the effects of stress on expression of the serotonin transporter gene (Williams, 2007) through the roles of diet, physical activity, smoking, and stress in the development (Eckel & Krauss for the AHA Nutrition Committee, 1998), prevention (Goldberg, Temprosa, et al., 2009), and management of disease (Fonarow, Gawlinski, et al., 2001; Ornish, Scherwitz, et al., 1998). Comprehensive, multi-sector community and population approaches to cardiovascular risk reduction have also documented reduced risk (Vartiainen, Puska, et al., 1994) and mortality (Puska, Vartiainen, et al., 1998).

Table 1.1 provides many additional examples across cancer, HIV/AIDS, tobacco use, poor diet, and physical inactivity. Chapters 2 and 3, *infra* on "Types of Diseases and their Causes" and "Risky Behaviors," provide far greater details of the roles of behavior in major diseases and health challenges around the world.

---

[1] This section is drawn from a paper co-authored by Fisher and his colleagues, Marian Fitzgibbon, Russell Glasgow, Debra Haire-Joshu, Laura Hayman, Robert Kaplan, Marilyn Nanney, and Judith Ockene. We are indebted to them for providing permission to draw at length from their paper, the full citation of which is, Fisher, E. B., Fitzgibbon, M. L., Glasgow, R. E., Haire-Joshu, D., Hayman, L. L., Kaplan, R. M., Nanney, M.S., & Ockene, J. K. (2011). Behavior matters. *American Journal of Preventive Medicine, 40*(5), e15–30.

Table 1.1 Behavior – health linkages among major "actual causes" of death and major diseases

Linkage 1 – behavioral, environmental, and genetic influences moderate one another
Tobacco use: Both environmental and genetic factors influence onset and persistence of smoking (Agrawal, Madden, et al., 2005; Heath, Kirk, et al., 1999; Madden, Heath, et al., 1999; Maes, Neale, et al., 2006)
Poor diet: Studies of food preferences indicate genetic influences are smaller than environmental influences (Perusse, Tremblay, et al., 1988; Reed, Bachmanov, et al., 1997)
Physical activity: In twin studies, greater physical activity levels are associated with lower rates of obesity in genetically high-risk individuals (Samaras, Kelly, et al., 1999)
Alcohol use: Childhood maltreatment exacerbates genetic influences on adult alcohol use and anti-social personality among women and men (Ducci, Enoch, et al., 2008)
Cardiovascular disease and diabetes Influence of serotonin transporter gene on cardiovascular risk is moderated by stress and environmental factors (Williams, 2007)
Cancer: Nutrition and lifestyle intervention reduces prostate gene expression and tumorigenesis in men (Ornish, Magbanua, et al., 2008)
HIV/AIDS: In monkey models of HIV, individual characteristics (sociability), stable versus unstable social conditions, and genotype for the serotonin transporter gene interact in their effects on disease progression (Capitanio, Abel, et al., 2008)
Linkage 2 – behavior influences health
Tobacco use: Numerous Surgeon General's reports have concluded that smoking is a leading cause of cancer, cardiovascular, and pulmonary disease and premature death (Centers for Disease Control and Prevention, 2004)
Poor diet: Systematic reviews conclude that obesity contributes to hypertension, hyperlipidemia, diabetes, CVD, and some cancers (Calle & Thun, 2004; Goldberg & King, 2007; Must, Spadano, et al., 1999; National Heart Lung and Blood Institute and National Institute of Diabetes and Digestive and Kidney Disease, 1998; Schulze & Hu, 2005; Sharma, 2007; United States Department of Health and Human Services, 2001)
Physical activity: Randomized trials and systematic reviews conclude that physical activity is associated with decreased all-cause mortality, (Blair, Kohl, et al., 1989) reduced risk for chronic diseases, reduced risk of breast cancer (Berlin & Colditz, 1990; Haskell, Lee, et al., 2007; Powell, Thompson, et al., 1987)
Alcohol use: "Alcohol abuse alone is associated with motor vehicle crashes, homicides, suicides, and drowning…. Long-term heavy drinking can lead to heart disease, cancer, alcohol-related liver disease, and pancreatitis. Alcohol use during pregnancy is known to cause fetal alcohol syndrome, a leading cause of preventable mental retardation" (Healthy People 2010, 2000)
Cardiovascular disease and diabetes Diet and obesity are risk factors for diabetes and cardiovascular disease (Eckel, Krauss, & for the AHA Nutrition Committee, 1998)
Cancer: Findings from systematic reviews, meta-analyses, large prospective studies, and randomized trials link risk for cancer with poor diet, physical inactivity, smoking, stress, and social involvement (Office of Behavioral and Social Sciences Research, 2007; Greenwald, Clifford, & Milner, 2001; Kuller, 1997; Matthews, Shu, et al., 2001; Rockhill, Willett, et al., 1999; Thune, Brenn, et al., 1997)
HIV/AIDS: There is "substantial and consistent evidence that chronic depression, stressful events, and trauma may negatively affect HIV disease progression" (Reiche, Nunes, & Morimoto, 2004; Leserman, 2008)

(continued)

Table 1.1 (continued)

Linkage 3 – behavior change interventions prevent disease
Tobacco use: A major multi-site trial demonstrated that smoking cessation programs substantially reduce mortality even when only a minority of patients stop smoking (Anthonisen, Skeans, et al., 2005)
Poor diet: Systematic reviews and randomized trials of interventions for childhood obesity show positive impacts on diet, weight gain trajectory, and weight loss maintenance, (Campbell & Hesketh, 2007; Connelly, Duaso, & Butler, 2007; DeMattia, Lemont, & Meurer, 2007; Epstein, Valoski, et al., 1994; Fitzgibbon, Stolley, et al., 2005; Summerbell, Waters, et al., 2005) and on insulin resistance (Savoye, Shaw, et al., 2007)
Physical activity: Among overweight, previously inactive women at risk for type 2 diabetes, accumulating 10,000 steps/day for 8 weeks improved glucose tolerance and reduced both systolic and diastolic blood pressure (Swartz, Strath, et al., 2003)
Alcohol use: A 15-min counseling for pregnant women increased abstinence from drinking 5X relative to controls and resulted in higher birth weights, birth lengths, and 3X reduction in fetal mortality (0.9% vs 2.9%.) (O'Connor & Whaley, 2007)
Cardiovascular disease and diabetes Lifestyle interventions focusing on diet, weight loss, and exercise can reduce the incidence of diabetes in persons at risk for the disease (Diabetes Prevention Program Research Group, 2002; Tuomilehto, Lindstrom, et al., 2001; Lindstrom, Ilanne-Parikka, et al., 2006)
Cancer: In a number of large prospective longitudinal studies and meta-analyses, physical activity has been linked to reduced risk of colon cancer (Albanes, Blair, & Taylor, 1989; Ballard-Barbash, Schatzkin, et al., 1990; Lee, Paffenbarger, & Hsieh, 1991; Martinez, Giovannucci, et al., 1997; Meyerhardt, Heseltine, et al., 2006; Samad, Taylor, et al., 2005; Thun, Calle, et al., 1992)
HIV/AIDS: The US Preventive Services Task Force recommends high-intensity behavioral counseling to prevent sexually transmitted infections for all sexually active adolescents and for adults at heightened risk (U.S. Preventive Services Task Force (USPSTF), 2008)
Linkage 4 – behavior change interventions improve disease management
Tobacco use: Self-management skills (e.g., setting quit date, planning for coping with temptations to relapse) help individuals quit smoking (Fiore, Bailey, et al., 2000)
Poor diet: Randomized behavioral interventions show that peer nutrition education positively influences diabetes self-management in Latinos (Perez-Escamilla, Hromi-Fiedler, et al., 2008)
Physical activity: Randomized clinical trials show that exercise training reduces HbA1c among those with diabetes (Boule, Haddad, et al., 2001)
Alcohol use: Brief behavioral counseling interventions with follow-up produce small to moderate reductions in alcohol consumption that are sustained over 6- to 12-month periods or longer.(US Preventive Services Task Force (USPSTF), 2004; Whitlock, Polen, et al., 2004)
Cardiovascular disease and diabetes Diabetes self-management programs improve disease management (Norris, Engelgau, & Narayan, 2001) and metabolic control (Anderson, Funnell, et al., 1991, 1995; Aubert, Herman, et al., 1998; Clement, 1995; Greenfield, Kaplan, et al., 1988; Muhlhauser & Berger, 1993; Norris, Lau, et al., 2002; Pieber, Brunner, et al., 1995; Rubin, Peyrot, & Saudek, 1989, 1993) including among older adults and ethnic minorities, (Anderson, Herman, et al., 1991; Glasgow, Toobert, & Hampson, 1991; Glasgow, Toobert, et al., 1992) and reduce complications (The Diabetes Control and Complications Trial Research Group, 1993, 1995) as well as myocardial infarction, stroke, or death from cardiovascular disease (The Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) Study Research Group, 2005)

(continued)

Table 1.1 (continued)

Interventions promoting comprehensive lifestyle changes for patients with coronary artery disease can reduce progression of coronary atherosclerosis and cardiac events (Ornish, Scherwitz, et al., 1998) and increase smoking cessation, improve functional capacity, lower LDL cholesterol, and reduce all-cause mortality (Fonarow, Gawlinski, et al., 2001)
Cancer: Randomized trials of patients with cancer indicate that physical activity increases functional capacity during chemotherapy, (MacVicar, Winningham, & Nickel, 1989) improves marrow recovery and decreases complications during peripheral blood stem transplantation, (Dimeo, Fetscher, et al., 1997) and decreases fatigue and other symptoms associated with radiation therapy and chemotherapy (Mock, Dow, et al., 1997)
HIV/AIDS: Behavioral medicine interventions have improved adherence and helped individuals cope with the disease and its impacts, in turn improving their general disease management and quality of life (Office of Behavioral and Social Sciences Research, 2007)
Linkage 5 – psychosocial and behavioral interventions improve quality of life (QOL)
Tobacco use: Improved health-related QOL is a significant health outcome for ex-smokers compared to current smokers (Crothers, Griffith, et al., 2005; Garces, Yang, et al., 2004; Ostbye & Taylor, 2004; Wilson, Parsons, & Wakefield, 1999)
Poor diet: In randomized trials, lifestyle interventions show improved nutritional status and quality of life and less depressive symptoms and improved physical functioning (Drewnowski & Evans, 2001; Scheier, Helgeson, et al., 2005; Fontaine & Barofsky, 2001)
Physical activity: Randomized trials show physical activity improves quality of life in older adults (Drewnowski & Evans, 2001; Rejeski, Brawley, & Shumaker, 1996) and improves quality of life and fatigue in breast cancer survivors (Courneya, 2003)
Alcohol use: Cognitive-behavioral treatment of insomnia among those recovering from excessive alcohol use improved measures of sleep as well as depression, anxiety, and quality of life (Arnedt, Conroy, et al., 2007)
Cardiovascular disease and diabetes Comprehensive behavioral disease management interventions among patients with cardiovascular disease or diabetes show benefits for a variety of clinical indicators as well as reduced general distress and depressive symptoms, (Blumenthal, Sherwood, et al., 2005) emotional and social functioning, (Castaldo & Reed, 2008) reduced anxiety and depressed mood, (Vale, Jelinek, et al., 2003) general quality of life (Ades, Pashkow, et al., 2000; Cochran & Conn, 2008; Lalonde, Gray-Donald, et al., 2002; Yu, Sheung-Wai Li, et al., 2003)
Cancer: Randomized psychosocial interventions show decreased psychological distress, pain and nausea secondary to treatment, and improve quality of life and immune system modulation (Antoni, Lehman, et al., 2001; Lepore, Helgeson, et al., 2003; Lieberman, Golant, et al., 2003; Penedo, Dahn, et al., 2004)
HIV/AIDS: Stress-management interventions enhance emotional status and quality of life (Antoni, Caricco, et al., 2006; Scott-Sheldon, Kalichman, et al., 2008)
Linkage 6 – health promotion programs improve health of populations
Tobacco use: Antismoking campaign in California that includes counter-media, youth prevention programs, cessation services, and tax increases reduced smoking and accompanying rates of cardiovascular disease (Fichtenberg & Glantz, 2000) and death rates from lung cancer (Jemal, Thun, et al., 2008)
Poor diet: Mass-media health education campaigns (Stern, Farquhar, et al., 1976) and policy and environmental supports (McAlister, Puska, et al., 1982; Puska, Nissinen, et al., 1985) can lead to significant improvements in fruit, vegetable, and fat consumption in general populations.
Physical activity: Community-wide walk to school programs increase walking and biking to school (Staunton, Hubsmith, & Kallins, 2003), and walking and fitness trails increased physical activity in a rural African-American population (Brownson, Housemann, et al., 2000)

(continued)

Table 1.1 (continued)

Alcohol use:
Guide to Community Preventive Services reports that regulating density of outlets for alcohol reduces consumption and that enforcing laws prohibiting the sale of alcohol to minors reduces underage consumption (The Guide to Community Preventive Services)
Cardiovascular disease and diabetes
Working with mass media, food producers, community-level campaigns, diverse professionals, informal opinion leaders, and the health system, a regional program in North Karelia, Finland, reduced cardiovascular risk factors (Vartiainen, Puska, et al., 1994) and mortality (Puska, Vartiainen, et al., 1998) as well as cancer risk factors (Luostarinen, Hakulinen, & Pukkala, 1995)
Cancer:
In 2006, overall cancer death rates declined because of 50% reduction in male smoking from 47% in the 1960s to less than 23% (Thun & Jemal, 2006)
HIV/AIDS:
Behavioral medicine programs have made major contributions to slowing the spread of HIV/AIDS; from 150,000 cases per year in the early 1980s to approximately 40,000 today (Centers for Disease Control and Prevention, 2005)

Global Trends in Health and Behavior[2]

Life expectancy has increased markedly over the past 50 years, with an ever increasing proportion of the world's population expected to live until late adulthood. Between 1950 and 1990, life expectancy at birth increased from 40 years to 63 years in developing countries (World Bank, 1993). More recently still, average life expectancy increased to 68 years globally in 2007, with a disproportionately large portion of that increase occurring in countries in Asia, including China (WHO, 2009).

Despite the global increases in average life expectancy, recent decades have witnessed a marked increase in non-communicable diseases (NCDs). The global prevalence of non-communicable diseases is expected to rise from 43% in 1998 to 66% in 2030 (WHO, 2008). Key growth will include cardiovascular and respiratory diseases with their behavioral risk factors of unhealthy diet and alcohol consumption, physical inactivity, and tobacco use (WHO, 2005). Among risk factors, tobacco use itself is projected to cause more premature death and disability than any other single disease, with mortality attributed to tobacco use projected to increase from 5.4 million deaths in 2004 to 8.3 million deaths in 2030 (WHO, 2008). A major contributor to this is the increased uptake of tobacco use in very populous countries such as China.

Amidst significant improvements in health, both social and economic disparities remain a major cause of poor health and disease. Attention to disparities and to the social determinants of health has grown dramatically, spurred in large measure by the leadership of the United Nations. It has placed health in the context of human equity and human rights dating back to the UN Universal Declaration of Human Rights (1948) and the Alma Ata Declaration, which advocated achievement of 'Health for All' (1978). A major initiative included the Commission on Social Determinants of Health, chaired by Sir Michael Marmot. The Commission reviewed the evidence surrounding global health inequalities and the "causes of the causes," culminating in the final report, *Closing the Gap in a Generation* (Commission on the Social Determinants of Health, 2008). The three main recommendations in the report proposed to reduce ill health and disadvantage are (1) improving daily living conditions; (2) redressing the inequitable distribution of power, money, and resources; and (3) improving measurement and

[2] This section is adapted and updated from Oldenburg B, De Courten M, Frean E. The contribution of health psychology to the advancement of global health. In Suls, J., Davidson, K. W., Kaplan, R. K. (eds) Handbook of Health Psychology Guilford Press, 2010.

understanding of the problem and assessing the impact of action. The pertinence of behavior to the first two is clear and great. These issues of social determinants of health, non-health policy and health, and equity/inequity are discussed at length in numerous chapters, especially those by Sherlaw et al. and by Siddiqi et al., *infra*.

Characterizing Overall Burden of Disease The Global Burden of Disease (GBD) framework, developed in 1992 with the support of the World Bank and World Health Organization, summarizes the wide-ranging and sometimes seemingly contradictory information available on morbidity, mortality, and other health outcomes. Prior to the GBD framework, evidence for policy-making was limited primarily to disease-specific mortality statistics. The initial and subsequent GBD studies provide a more comprehensive measure that aggregates and standardizes measures of mortality, disability, impairment, and illness that arise from disease, injury, and risk factors. GBD studies combine the years of life lost due to premature mortality and healthy years of life lost due to disability in a "Disability-Adjusted-Life-Year" (DALY) (Lopez, Mathers, et al., 2006). One DALY, therefore, is equal to 1 year of full health lost, whether by death or by disability. This allows direct comparison of impacts of diseases that cause early death with impacts of those that cause prolonged suffering or disability.

An analysis of global DALYs and life expectancy between 1990 and 2013 (DALYs Collaborators, Murray, et al., 2015) noted interesting differences in changes in life expectancy and DALYs. Worldwide life expectancy at birth rose by 6.2 years from 1990 to 2013, from an average of 65.3 years to 71.5 years. A more complex picture emerges in considering DALYs, and, a key component of DALYs, years of life lived with disability, YLDs. With increased numbers living longer, the worldwide total YLDs have increased and the total DALYs have increased for non-communicable diseases. The authors conclude that an epidemiological transition is occurring in which global health is improving but population growth, aging, and increased non-communicable diseases have increased the numbers of DALYs and YLDs.

Global Goals and Health In 2000, the United Nations set a group of eight Millennium Development Goals (MDGs) for achievement by 2015. Four were directly related to health: reduce child mortality, improve maternal health, combat HIV/AIDS, malaria and tuberculosis, and increase access to safe drinking water and sanitation (UN, 2008). In May of 2015, the WHO reported on progress toward the health-related goals in each of the 194 countries for which data were available (World Health Organization, 2015b). Drawn from the WHO's description, this section summarizes the "mixed" results to date:

- **Child deaths halved** – Since 1990, child deaths have been reduced almost by half – falling from an estimated 90 deaths per 1000 live births to 46 deaths per 1000 live births in 2013. This progress, however, has not achieved the goal of reducing the death rate by two-thirds. Less than one-third of all countries achieved or were on track to meet this target by the end of 2015. The top killers of children aged less than 5 years are now: preterm birth complications, pneumonia, birth asphyxia, and diarrhoea.
- **Saving more mothers** – The number of women who died due to complications during pregnancy and childbirth has almost halved between 1990 and 2013. This however is also insufficient to reach the goal of 75% reduction by the end of 2015. The maternal mortality ratio has fallen in every region. However, 13 countries with some of the world's highest rates have made little progress in reducing these largely preventable deaths. In the WHO African Region, 1 in 4 women wanting to prevent or delay childbearing does not have access to contraceptives, and only 1 in 2 women gives birth with the support of a skilled birth attendant. Less than two-thirds (64%) of women worldwide receive the recommended minimum of 4 antenatal care visits during pregnancy.
- **Reversing the spread of HIV** – In 2013, 2.1 million people were diagnosed with new infections, down 38% from 3.4 million in 2001. At the same time, expansion of WHO recommendations regarding who is eligible for treatment have increased the numbers who

will need to be reached in order to achieve the goal of universal access to treatment for HIV. The world was projected to have exceeded the target of placing 15 million people in low- and middle-income countries on antiretroviral therapy (ARTs) by the end of 2015. By the end of 2013, almost 13 million people received ARTs globally. Of these, 11.7 million lived in low- and middle-income countries, representing 37% of people living with HIV in those countries.

- **Increasing access to safe drinking water and sanitation** – Although the global target for increasing access to safe drinking water was met in 2010, the WHO African and Eastern Mediterranean Regions fall far short, particularly for people living in rural areas or with income poverty. Almost one billion people still have minimal access to basic sanitation and are forced to defecate in open spaces such as fields and near water sources. Lack of sanitation facilities puts these people at high risk of diarrheal diseases (including cholera), trachoma and hepatitis.

Other key indicators of health noted in the appraisal of progress toward Millennium Development Goals make clear the broad role of behavior in health worldwide:

- Life expectancy at birth has increased 6 years for both men and women since 1990.
- Two-thirds of deaths worldwide are due to non-communicable diseases.
- In some countries, more than one-third of births are delivered by cesarean section.
- In low- and middle-income countries, only two-thirds of pregnant women with HIV receive antiretroviral therapy to prevent transmission to their baby.
- Over one-third of adult men smoke tobacco.
- Only 1 in 3 African children with suspected pneumonia receives antibiotics.
- 15% of women worldwide are obese.
- The median age of people living in low-income countries is 20 years, while it is 40 years in high-income countries.
- One quarter of men have elevated blood pressure.

Following the 2015 appraisal of progress toward the *Millennium Development Goals*, members of the United Nations adopted the *Sustainable Development Goals: 17 Goals to Transform our World*. Their broad objectives, to be achieved over the next 15 years, are “to end poverty, protect the planet, and ensure prosperity for all as part of a new sustainable development agenda” (United Nations, 2015). The 17 goals range widely including, for example, “climate action” and “responsible production and consumption.” Under the overarching health goal to “Ensure healthy lives and promote well-being for all at all ages,” specific targets are:

- By 2030, reduce the global maternal mortality ratio to less than 70 per 100,000 live births
- By 2030, end preventable deaths of newborns and children under 5 years of age, with all countries aiming to reduce neonatal mortality to at least as low as 12 per 1000 live births and under-5 mortality to at least as low as 25 per 1000 live births
- By 2030, end the epidemics of AIDS, tuberculosis, malaria and neglected tropical diseases and combat hepatitis, water-borne diseases and other communicable diseases
- By 2030, reduce by one third premature mortality from non-communicable diseases through prevention and treatment and promote mental health and well-being
- Strengthen the prevention and treatment of substance abuse, including narcotic drug abuse and harmful use of alcohol
- By 2020, halve the number of global deaths and injuries from road traffic accidents
- By 2030, ensure universal access to sexual and reproductive health-care services, including for family planning, information and education, and the integration of reproductive health into national strategies and programs
- Achieve universal health coverage, including financial risk protection, access to quality essential health-care services and access to safe, effective, quality and affordable essential medicines and vaccines for all
- By 2030, substantially reduce the number of deaths and illnesses from hazardous chemicals and air, water and soil pollution and contamination

- Strengthen the implementation of the World Health Organization Framework Convention on Tobacco Control in all countries, as appropriate
- Support the research and development of vaccines and medicines for the communicable and noncommunicable diseases that primarily affect developing countries, provide access to affordable essential medicines and vaccines, in accordance with the Doha Declaration on the TRIPS Agreement and Public Health, which affirms the right of developing countries to use to the full the provisions in the Agreement on Trade Related Aspects of Intellectual Property Rights regarding flexibilities to protect public health, and, in particular, provide access to medicines for all
- Substantially increase health financing and the recruitment, development, training and retention of the health workforce in developing countries, especially in least developed countries and small island developing States
- Strengthen the capacity of all countries, in particular developing countries, for early warning, risk reduction and management of national and global health risks

As with the previous Millennium Development Goals, these Sustainable Development Goals make clear the critically important contribution of behavior to health around the globe.

Historical and Conceptual Roots of Behavioral Medicine

Behaviorism

An important foundation for the development of behavioral medicine has been the intellectual tradition and empirical approaches of behaviorism in western psychology of the twentieth century. Neil Miller, a major figure in twentieth-century behaviorism and in the application of behaviorism to complex behavior and psychotherapy (Dollard & Miller, 1950), contributed greatly in the development of behavioral medicine. Many important areas of behavioral medicine have their roots in behavior therapy and its application to mental health and psychotherapy of behaviorism and the "laws of learning" (Wolpe, 1969). For example, biofeedback (Cox, Sutphen, et al., 1998), stress-management interventions featuring relaxation and active coping with stressors (Bishop, Kaur, et al., 2005; Levenkron, Cohen, et al., 1983; Nater, Gaab, et al., 2006; Penedo, Dahn, et al., 2004; Surwit, van Tilburg, et al., 2002), group and individual interventions for weight management or smoking cessation (Lichtenstein, Harris, et al., 1973; Stuart, 1967), all are based in behavior therapy and were integral to the early development of self-control and self-management interventions in the 1960s (Bandura, 1969; Goldfried & Merbaum, 1973; Kanfer, 1970).

The connections between behavioral medicine and behaviorism were also social and organizational. The first meeting of the US Society of Behavioral Medicine (SBM) in 1979 was held in conjunction with a meeting of the Association for the Advancement of Behavior Therapy (AABT, now called the Association for Behavioral and Cognitive Therapies). W. Stewart Agras, the founding president of SBM (1979–80) was also president of AABT (1985), and a number of major contributors to behavioral medicine and obesity research have been presidents of AABT (Richard Stuart, 1974–75, G. Terrence Wilson, 1980–81, and Kelly Brownell, president of both AABT and SBM in 1988–89) as was Gerald C. Davison (1973–74), the senior author of this volume's chapter on Values in Behavioral Medicine.

Behaviorism has evolved considerably over recent decades to encompass and explain complex patterns of behavior, including "self control," addictions, and even community approaches to substance use disorders. This evolution has included articulation of the linkages among complex behaviors, including through the growing field of behavioral economics. It has also expanded in scope to include a broad range of social, organizational, and economic determinants of behavior, sharing much with socio-ecological models in community and public health. Approaches to alcohol abuse, for example, may emphasize economic substitutability of alcohol and positive addictions and promote alternatives to drinking rather than focusing on reducing alcohol consumption itself (Vuchinich & Tucker, 1996).

Behaviorism, behavioral economics, and their evolution as a foundation of behavioral medicine are more fully explored in the present chapter by Rachlin and colleagues, *infra*.

Cognitive Psychology and Decision Making

As behaviorism has grown to address complex patterns of behavior, so too the "cognitive revolution" led much of psychology toward explorations of attention, perception, problem-solving, and memory processes shaping behavior (Mandler, 2002). With this, many behavioral medicine researchers increasingly turned their attention to cognitive and decision-making processes directing health behavior. Applications of cognitive psychology to behavioral medicine have included research on illness schemata and their roles in shaping health information processing, health behaviors, adjustment to illnesses, health outcomes, and even survival (Cameron, Durazo, & Rus, 2015; Crawshaw, Rimington, et al., 2015). Public health emphases on disease prevention fueled research on risk perception and its influence on decisions to engage in protective behaviors such as vaccinations (Weinstein, Kwitel, et al., 2007) and risky behaviors such as cigarette smoking (Slovic, 2001). Economic models of rational decision making gave rise to models of health decision making such as the Health Belief Model (Janz & Becker, 1984), with decisions being viewed as calculations made by weighing the health risks with the benefits versus costs of the health behavior. Advances in social cognition and affective science fostered the development of increasingly sophisticated theories of health cognition that incorporated social influences (e.g., norms and social learning), emotions (e.g., fear), and dual-coding (deliberative and automatic thought) processes (Ajzen, 1985; Bandura, 1977; Leventhal, 1970). Self-regulation theories of health behavior evolved to incorporate these processes into models of the dynamic processes through which individuals set health goals, engage in actions to attain them, and evaluate their progress in goal attainment (Carver & Scheier, 1998; Leventhal, Bodnar-Deren, et al., 2012).

Cognitive theory and research inform an array of behavioral medicine interventions. For example, health communications commonly reflect the application of social learning theory with model characters displaying healthy behaviors. Cognitive behavior therapy is used to treat numerous health conditions, including depression and anxiety disorders (Hollon, Stewart, & Strunk, 2006), as well as substance abuse (McHugh, Hearon, & Otto, 2010) and binge eating (Painot, Jotterand, et al., 2001). Mindfulness interventions have proliferated, with mounting evidence of their benefits for individuals with chronic pain, cancer, epilepsy, and numerous other conditions (Carlson, 2012). Decision aids designed to assist individuals facing complex medical decisions (e.g., choices of cancer treatment) are increasingly commonplace, and they have been shown to improve knowledge, increase participation in "shared decision making," and reduce decisional conflict (Stacey, Légaré, et al., 2014). Research revealing the automaticity of many health behaviors is guiding the development of "nudge" and other strategies to encourage healthy choices through priming, such as by using small plates to reduce food consumption or narrow glasses to reduce alcohol intake (Marteau, Hollands, & Fletcher, 2012).

Psychosomatic Medicine

Psychosomatic medicine and behavioral medicine have much in common. According to the journal *Psychosomatic Medicine*, the field includes "experimental and clinical studies dealing with various aspects of the relationships among social, psychological, and behavioral factors and bodily processes in humans and animals" (http://journals.lww.com/psychosomaticmedicine/pages/aboutthejournal.aspx). Nevertheless, there are differences in emphasis and tradition between the two, including:

1. The significantly longer tradition of psychosomatic medicine and its clear dedication to and establishment in medicine
2. The relative lack of research concerning prevention in psychosomatics

3. The strong orientation of behavioral medicine toward neuroscience and experimentally based methodologies
4. The clear dedication of behavioral medicine toward inclusion of a very broad range of disciplines relative to the greater emphasis in psychosomatics on medicine, psychiatry, and psychology
5. The fact that psychosomatics has its origins in psychoanalysis such as in the work of Franz Alexander (Alexander & Benedek, 1950). In 1950, Mitscherlich implemented the first department for psychosomatic medicine at the University Hospital Heidelberg, Germany (Mitscherlich, 1995). He was strongly engaged in implementing a psychoanalytically driven holistic bio-psycho-social view for diagnosis and treatment of medically ill patients. In German-speaking countries this psychoanalytic tradition is still very much alive and present at university institutions. In contrast, the roots of behavioral medicine come from learning theories, behavior therapy, and psychophysiology. Therefore research and teaching is present in psychology, neuroscience, and medicine such as internal medicine and psychiatry.

Decades ago, these fields showed large differences in their research methods with an emphasis on case studies in psychosomatics and experimental studies in behavior medicine. Recent research methodologies in psychosomatics and behavior medicine are more similar, especially in the USA where the differences and the separation between both research fields are much less than was the case in the past. Both psychosomatic and behavioral medicine engage in research on mind-body-interactions. Therefore in both disciplines psychological and somatic aspects and their interaction are studied. Both disciplines have also come to draw on a broad set of variables to explain a variety of diseases and disorders. These substantive similarities are reflected in the American Psychosomatic Society being member of the International Society of Behavioral Medicine since the 1990s. Indeed, many behavioral medicine research groups publish their findings in journals such as *Psychosomatic Medicine* or the *Journal of Psychosomatic Research*.

Public Health and the Ecological Perspective

Within public health and much literature seeking to address population approaches to health, an "ecological model" of health has gained substantial popularity (McLeroy, Bibeau, & Steckler, 1988; Sallis & Owen, 2015). In ecological or socio-ecological approaches, the behavior of the individual is viewed as guided by layers of influences including the family, proximal social influences such as social networks or neighborhoods, organizational influences such as worksite or community systems or health-care systems, and larger social influences such as government, policy, and large economic structures. Different models may identify different numbers of layers of influence and different components of each, but they share two important emphases: (1) that the behavior of the individual reflects the influence of all the layers; and (2) that the layers interact in their influence so that, e.g., communities may influence families but families may also influence communities.

Many applications and research initiatives in behavioral medicine embrace the multi-layered influences of the socio-ecological model. For example, research in India extending the findings of the Diabetes Prevention Program (described in the chapter on obesity by Johnston et al., *infra*) examines cultural and community factors surrounding healthy diet, physical activity, and diabetes; recruits the influence of the family; and promotes key behaviors of the individual. Similarly, cognitive behavior therapy for postpartum depression in Pakistan is delivered through the primary care system by peer "Lady Health Workers" and is presented and described in ways that take into consideration cultural views and stigma surrounding mental health in rural Pakistan (Rahman, 2007).

In addition to breadth of influence, the socio-ecological model moves attention "upstream" to focus on how policy, organizational, cultural, social, and community characteristics influence family and individual practices that in turn can significantly impact on prevention and care. This then leads to greater attention to upstream determinants in prevention and their influence on populations that share the same upstream determinants. This supports substantial interest in primary prevention and populations in behavioral medicine and provides a conceptual link with public health in which the population and prevention emphases are especially paramount.

There is a fundamental congruence between behaviorism's emphasis on individual history and experience guiding behavior, and socio-ecological perspectives' articulation of the social and organizational layers that are the architecture of that history and experience. Although experimental psychology and behaviorism focused on the behavior of individuals through much of their history, Skinner extended these principles to the behavior of groups and organizations in 1953 with *Science and Human Behavior* (Skinner, 1953) and behavioral economics has further extended the behavioral perspective to include broad policies and incentives (see Rachlin et al., *infra*). Both socio-ecological perspectives and contemporary behaviorism share then an emphasis on individual behavior as being shaped by experience across a wide array of settings and, as highlighted in the ecological perspective, the organizational and policy level structures of the settings the individual experiences. Both also share the assumption that these same approaches to analyzing individual behavior can be applied to the behavior of larger social units such as groups or organizations and the influences of their environments – including individuals within them.

Interestingly, both behaviorism and socio-ecological perspectives share a sensitivity to blaming the victim in analyses of individual behavior or behavior problems. Both would look to socioeconomic, cultural, family, and individual experiences among other background factors in seeking to explain important health behaviors such as smoking, obesity, physical inactivity, type A behavior, and impulsiveness.

Key, Cross-Cutting Concepts

There are a number of concepts and perspectives that underlie behavioral medicine in all the breadth of its discovery and application. Among them are the following.

Principles of Behavior Change Are Not Necessarily Consistent with Perspectives of Clinical Medicine

What makes most sense in behavior change may make little sense from the perspective of medical priorities. Consider shaping self-management skills. One might begin by working in areas in which individuals have skill and confidence and are most likely to succeed (Bodenheimer, Lorig, et al., 2002; Lorig & Holman, 2003), even if that is not the area that is most important for their health. Thus, an individual who smokes and is only a little overweight might begin by focusing on physical activity, even though their smoking is a greater concern. This is not just an academic concern. Among those with diabetes who smoke, a major barrier to quitting smoking may be concern about weight gain, a concern reinforced by clinical emphasis on bodyweight in diabetes. Strongly discouraging weight gain is likely to provoke relapses to cigarettes as a familiar anorexic agent. Instead, it is important to encourage individuals to accept modest weight gain following smoking cessation. This principle may lead to a path to behavior change that seem circuitous or unnecessarily prolonged to clinicians who are focused on "fixing the problem." Appreciation of the wisdom of the behavioral approach, that emphasizes building on strengths and small successes, should not be assumed among patients or clients as well as clinical colleagues.

Distinctions Among Behaviors Do Not Follow Distinctions Among Clinical Diseases

The classifications of diseases into those that are infectious or non-communicable or into categories such as cancers, lung diseases, or cardiovascular diseases do not correspond to meaningful distinctions among behaviors. A number of behavioral influences cut across all of these. Further, many determinants of these behaviors and general principles for changing them extend across clinical categories. That is, for example, the determinants of smoking and nicotine addiction are quite independent of whether smoking ends up causing heart disease or cancer. Instead, distinctions among behaviors need to be articulated in behavioral terms. Quitting smoking is very different than losing weight, adhering to a regimen of antihypertensive medication, or managing stress. They all entail very different behaviors. As obvious as this may seem, consider how often "adherence" is used in an undifferentiated way as if adherence to a diet were the same as adherence to taking a pill two times a day or adherence to recommended physical activity.

Because research related to health is often organized in terms of disease categories, lessons about behavior change in one area may not be received in others. Key lessons from adherence to medication regimens, for example, include the value of prompts and linking medication-taking to other behaviors (Conn, Ruppar, et al., 2016). These are likely to extend across different medications and different risk factors or diseases for which they are intended. Occam's razor, the law of parsimony, encourages scientists to conclude the simplest relationship among events until data prove otherwise. Following this well-respected principle of science, we should assume that strategies like prompts and linking medication to other behaviors will extend, for example, from adherence to antihypoglycemic medication to adherence to antidepressants, rather than waiting for evidence in the one before applying evidence from the other.

Diseases Pose Distinct *Behavioral* Challenges

Notwithstanding the point just made that important behavioral processes transcend categories of disease, it is also the case that different diseases do pose distinct challenges to those they affect. For example, individuals may be more likely to achieve sustained abstinence from smoking following a myocardial infarction than following a diagnosis of chronic obstructive pulmonary disease. This difference in abstinence rates probably reflects likelihoods of survival with each disease and the consequently different incentives for smoking cessation with each one (Fisher, Brownson, et al., 2004; Gritz, Kristeller, & Burns, 1993). Similarly, ketoacidosis or hyperglycemia in diabetes, sudden inability to breath in asthma, the shame attached to obesity in some cultures, the blame attached to cigarette smoking in others, the compromises of daily activities and intimacy that come with many diseases, all of these pose very different patterns of threat, annoyance, and distress. In terms of treatments, adherence to insulin injections in diabetes or to use of controller and responder medicines in asthma may entail many differences from adherence to an antihypertensive medication or to a statin for cholesterol. The psychological and behavioral peculiarities of different diseases and health challenges need to be understood if interventions are to address them effectively.

As discussed in the chapter on psychological factors in health by Snoek et al., *infra*, diabetes distress reflects both distinctive features of diabetes and the burdens it provides and is often linked with depression, which is more prevalent among those with diabetes. For those who are both depressed and appreciably distressed by diabetes, treatment needs to be integrated and to reflect an understanding of the specific demands of diabetes as well as depression (Snoek, Bremmer, & Hermanns, 2015). For other diseases in which depression is often a factor such as coronary heart disease and heart failure or chronic obstructive pulmonary disease, the relative roles of disease-specific distress and depression probably need to be explored.

Behavior and Health Behaviors Are Fundamentally Contextual

Variability by setting and context is not just "noise" but true variance reflecting important influences that need to be understood and considered. As noted previously and in a number of chapters, the socio-ecological perspective that integrates individual-level influences with family, social, community, organizational, and policy influences has been widely adopted and used in behavioral medicine and public health (Christensen, 2000; McLeroy, Bibeau, & Steckler, 1988; Sallis & Owen, 2015). A key emphasis of a socio-ecological perspective is that layers of influence interact as, e.g., families may influence communities just as communities may influence families. The role of a specific influence, then, will depend on the contexts in which it is provided. Success of a worksite chronic disease management program, for example, may depend in large measure on other features of the workplace. For example, success could depend on whether employees are provided release from duties to attend program meetings, whether human resources policies are supportive of chronic disease management, the quality of employee health benefits (in countries in which employer-provided health insurance is common), and the leadership of company executives in setting an organizational climate that encourages those with chronic diseases to use the program. Across all of these, "are worksite chronic disease management programs effective" might not be the correct question to ask. The answer will be determined by a variety of factors outside the program itself.

Interaction of Genes and Behavior Is the Norm, Not the Exception

With very few exceptions, there is no gene expression without environmental and behavioral moderation and very little behavior without genetic moderation or propensity. See chapter by Strahler, Mueller-Alcazar, and Nater, *infra.* A classic example of this is with diabetes among Pima Indians. Pima Indians in the USA show "the highest reported prevalence of type 2 diabetes mellitus … of any population in the world" (Pratley, 1998, p. 175). Yet, Pimas living in Mexico have relatively low levels of diabetes. Ample evidence links genetics to diabetes *within* the Pima population (Pratley, 1998). Thus, the expression of a genetic propensity for diabetes is dependent on exposure to a food environment sufficient to trigger it. The interaction of genes and environment around nutrition and metabolism extends to the intrauterine environment in which adverse nutritional status including over- or undernutrition may lead to epigenetic effects that program the fetus for metabolic problems in adult life (El Hajj, Schneider, et al., 2014).

Expression of the serotonin transporter gene provides an interesting example of the complexities of gene X environment interaction. It turns out that the same genotype can have both advantageous and disadvantageous effects. The work of Williams and his colleagues (2001, 2008) initially pointed to the long alleles of the serotonin transporter gene as the "bad actors"; individuals with one or two long alleles seemed to have significantly greater blood pressure responses to stress and greater CVD risk. However, in a longitudinal study of depression among young adults, the number of *short* alleles (either one or two) was related to greater likelihoods of depression and suicidality (Caspi, Sugden, et al., 2003). In other studies of Williams and his group (2003), whether the bad actor is the long or short allele appears to vary by sex and group origin, e.g., Sub-Saharan Africa, Asia, etc.

We tend to think of these and other genetic effects as conferring a vulnerability to some disease or condition. From this perspective, it is confusing that, in some studies, a particular genotype is associated with a benefit while in other studies the same genotype is associated with a risk or harm. Williams and his colleagues have suggested another way of framing these influences, as conferring a greater or lesser sensitivity to environmental influences (Belsky, Jonassaint, et al., 2009). Thus, in a study of depression among young adults, those with two short alleles of the serotonin transporter gene reported greater depression than those with other genotypes *if* they had been exposed to early adversity in childhood or recent negative life events. However, among those exposed to positive early environment or recent positive events, those with two short alleles reported the least depression (Taylor, Way, et al., 2006). It seems that the two short alleles confer not advantage or disadvantage, *per se*, but greater responsiveness to the environment, for good or ill.

Other studies have also noted a similar pattern of greater or lesser sensitivity to environment conferred by genetics. In one study, observers' measures of poor home and neighborhood quality during adolescence predicted lower self-esteem in young adulthood among those with short alleles of the serotonin transporter gene. In contrast, there were no effects of home and neighborhood quality among those with two long alleles (Jonassaint, Ashley-Koch, et al., 2012). In a study of those exposed to a series of hurricanes in the US state of Florida during 2004, county-level indices of joblessness and crime moderated the effects of the serotonin transporter gene in a remarkable interaction. In counties with low crime/low unemployment, the short allele was associated with lower levels of post-traumatic stress disorder, but in counties with high crime/high unemployment, the short allele was associated with greater risk of post-traumatic stress (Koenen, Aiello, et al., 2009). Putting these findings together, sensitivity to environment may be, itself, influenced by genetic variation. Thus, genotype is far from destiny, independent of context. Rather, sensitivity to context is itself embedded in some genotypes – no doubt further influenced by other contexts in the external, phenotypic, and intracellular environments. Also, as detailed in the chapter by Strahler, Mueller-Alcazar, and Nater, *infra*, epigenetic effects of environment and behavior add further complexity.

Reciprocal Determinism Is Very Important

The ways in which environments may moderate the effects of interventions delivered to the individual, and the complex interactions among genes and environments run parallel to what others have called "reciprocal determinism" (Bandura, 2001). This refers to the complex interrelationships between human behavior and the environment. The environment influences our actions but our actions also influence the environment. For example, a family may teach a daughter to recognize her talents and express them proudly. The daughter may then influence her community to be more supportive of women's talents. Continuing up the ladder of complexity, one can see the same kind of reciprocity in the influence of:

- the group on the individual and the individual on the group;
- the organization on the division and the division on the organization; and
- policies on organizations and organizations on policies.

This pattern of reciprocal influence of the environment on the agent and of the agent on the environment is a very important dynamic across all living systems. It poses an important counterpoint to more primitive models such as those which get lost in debate over whether genes *or* environment are important, models that seek a single cause and in which a single thing can be only a cause or an effect, but not both.

It is worth noting that, statistically, interactions are even handed. They do not confer greater influence or reality to one or the other components of the statistical interaction. Whether we graph the influence of A as dependent on the presence/absence of B or the influence of B as dependent on the presence/absence of A, it is the same interaction. Consider the work of Meaney and colleagues on how maternal rearing and gene expression interact in their influence on adult stress response (Meaney & Szyf, 2005; Zhang, Labonte, et al., 2013). One could say that the expression of genes in adult stress response is dependent on maternal rearing, or one could say that the impact of maternal rearing on adult stress response is dependent on particular genes. Both refer to the same data. Similarly, the relationships among genes, environment, and diabetes among the Pimas can be stated in either of two ways:

- Genetic factors associated with membership in the Pima population have a strong influence on prevalence of diabetes among a population exposed to the obesigenic environment of US diet and food distribution
- The obesigenic environment of the USA has a strong influence on prevalence of diabetes among a population genetically predisposed to high rates of diabetes

Both accurately describe the same data. What is "figure" and what is "ground," that is, what is moderating what, can be a matter of perspective. The constant, however, is that multiple levels interact.

Individual Responsibility Versus It Takes a Village[3]

The concept of individual responsibility has been used to denote the importance of individual behavior in health and health care, for example, in Knowles' influential 1977 editorial in *Science,* "Responsibility for Health" (Knowles, 1977). However, the appeal to individual responsibility can be used as an argument to minimize attention to behavior. In the clinical setting, we often hear "…there's nothing I can do if the patient doesn't want to help himself." At the policy level, the parallel argument suggests that investment in programs to help individuals improve health behaviors is wasted because those behaviors will ultimately be decided by the individuals themselves.

"Responsibility" is shaped by the contexts of people's lives. Socioeconomic status, social isolation, and associated stress (Adler & Matthews, 1994; Glanz, Basil, et al., 1998; Parmenter, Waller, & Wardle, 2000; Steptoe & Wardle, 1999; Wardle & Steptoe, 2003) have great influence on health behaviors. Cultural influences are also profound (Kumanyika, 2005; Steptoe & Wardle, 1999) especially with eating behaviors and feeding practices such as in the valuing of meat and other high-fat foods in cultures in which they were unavailable in the past (Kumanyika, Obarzanek, et al., 2008). Inconsistent and changing health recommendations may also cause skepticism that further encourages retention of unhealthy practices (Wasserman, Flannery, & Clair, 2007) especially in communities that are marginalized from mainstream culture (Corbie-Smith, Thomas, & St. George, 2002). Heavy marketing of high-fat and high-sugar foods (Barr-Anderson, Larson, et al., 2009), alcohol (Anderson, Bruijn, et al., 2009), and cigarettes (Lovato, Linn, et al., 2003) especially targeting children is commonplace and effective. In low-income neighborhoods, disproportionate outdoor advertisements (Kwate, Jernigan, & Lee, 2007; Kwate & Lee, 2007; Kwate & Meyer, 2009) and limited access to stores selling healthy foods are well documented (Block, Scribner, & DeSalvo, 2004; Powell, Chaloupka, & Bao, 2007). These influences are substantial, e.g., a 1.46 odds ratio of being obese associated with living in neighborhood with fast-food outlets but without supermarkets *after controlling* for education, income, and other individual characteristics (Morland, Diez Roux, & Wing, 2006). Economic, social, environmental, and cultural factors account for substantial portions of individual and group differences in health behaviors.

Striking a balance between individuals and their environment is critical (Minkler, 1999). Behavioral interventions are clearly effective (Fisher, Fitzgibbon, et al., 2011), including those implemented at the community and population level. The balance among individual, community, environmental, and policy influences and an emphasis on behavior cutting across all of them will make substantial contributions to both improving health and well-being and reducing health-care costs.

Global Perspective

Behavioral medicine as a field has been developing in and across many countries around the world. This is reflected in the increasing membership of the International Society of Behavioral Medicine that includes member societies from Australasia, Chile, China, Hong Kong, Hungary, Japan, Korea, Mexico, Romania, Slovakia, Thailand, Venezuela, Western, Central, and Eastern Europe, and the USA. Across these countries and societies, emphases have varied, depending on different historical traditions such as in the strong tradition of psychosomatic medicine in Europe, noted above, but the contributions to the field now come from every continent of the world.

---

[3] This section is drawn from a paper co-authored by Fisher and his colleagues, Marian Fitzgibbon, Russell Glasgow, Debra Haire-Joshu, Laura Hayman, Robert Kaplan, Marilyn Nanney, and Judith Ockene. We are indebted to them for providing permission to draw at length from their paper, the full citation of which is, Fisher, E. B., Fitzgibbon, M. L., Glasgow, R. E., Haire-Joshu, D., Hayman, L. L., Kaplan, R. M., Nanney, M. S., & Ockene, J. K. (2011). Behavior matters. *American Journal of Preventive Medicine, 40*(5), e15–30.

These differences notwithstanding, the underpinning health issues and challenges to be addressed by the field of behavioral medicine are now very global in nature. While the fundamental principles of behavior and biology are considered universal, the moderation of their expression by the environment and other influences, as discussed above, varies across populations, nations, and regions of the world. How behavioral medicine interventions can be appropriate and effectively disseminated given this incredible diversity is a major challenge to the field. A good example of this lies in the rapid increase and uptake of digital technologies across the world. This is both an incredible opportunity for the field of behavioral medicine and also a major challenge. Designers of digital programs and platforms, for example, need to recognize and plan for the fact that the applications they design are likely to be used by people worldwide, in very different cultures, settings, and health settings.

Noteworthy successes of international spread of behavioral medicine include the Chronic Disease Self Management Program that was developed by Kate Lorig and her colleagues at Stanford University in the USA (Lorig & Holman, 1993; Lorig, Ritter, & Plant, 2005). It has now been implemented in many countries (e.g., Fu, Fu, et al., 2003) and is licensed in 26 countries outside the USA (http://patienteducation.stanford.edu/programs/cdsmp.html). Williams' Lifeskills program has integrated cognitive-behavioral interventions for anger and stress management and cardiovascular risk reduction and shown these effective in varied countries (Williams & Williams, 2011). Both of these successful programs have emphasized a well standardized intervention and protocol that is implemented in a similar way in different settings but with, of course, modifications such as for food choices or culturally specific ways of discussing stressors or anger-inducing interactions.

Another approach to global dissemination places more emphasis on adapting interventions to the needs and strengths of intended audiences as well as system, cultural, organizational, and setting characteristics. Interventions are defined by their key components or the functions they fulfill while encouraging local planning of how they are operationalized (Aro, Smith, & Dekker, 2008; Fisher, Ballesteros, et al., 2015; Fisher, Earp, et al., 2010; Hawe, Shiell, & Riley, 2004). In this approach, a program may look very different in different settings while still being guided by the key functions or characteristics that identify it. An example of success in this is the spread of diabetes prevention programs. It is striking – as well as a key example of the effectiveness of behavioral interventions – that in China (Li, Zhang, et al., 2008), Finland (Tuomilehto, Lindstrom, et al., 2001), and the USA (Diabetes Prevention Program Research Group, 2002), remarkably similar initiatives were successful in preventing diabetes through diet, physical activity, and weight loss. At the same time this intervention approach requires considerable tailoring to cultural and other characteristics of a variety of international settings (Aziz, Absetz, et al., 2015), including in India as described in detail in the chapter by Johnston, Foreyt, and colleagues, *infra.*

The challenge of thinking globally, examining what continuities exist across, and what specific features distinguish, varied countries, groups, and cultures, provides behavioral medicine a valuable stimulus to a better understanding of its principles and constitutive elements. This book is intended to reflect this interplay among fundamental and global continuities, distinctions among peoples and settings, challenges in global dissemination, and intellectual efforts to forge a coherent set of ideas and principles that can embody behavioral medicine while keeping it a vibrant, dynamic approach that is capable of embracing and adapting to new challenges and insights.

What Is Global?

Across much of this introductory chapter and most all of the chapters in the book, concern for global applicability and dissemination is common. This raises questions about what is meant by "global." In contrast to "international" which is generally applied to things intended to span national and cultural differences (e.g., "international" organizations), global is often used to refer to both distinctive features of cultures as well as to features that transcend cultures, and to their interweaving. In the previous illustration of the key features of diabetes prevention, physical activity and weight management need to be adapted to cultural, population, organizational, and system characteristics of the settings in which they are applied, such as in an emphasis on family and group influences in India. Similarly, the chapter on peer support (Fisher et al., *infra*) describes how expressions similar to "It wasn't anything she did or said, it was knowing she was there" are common in many different cultures, pointing to a universal value of social connection. Specific ways in which social support is provided or exchanged (e.g., Dutton, 2012), however, include the importance of implicit and explicit support in cultures emphasizing collectivist versus individualist values. These point to the importance of cultural differences in how possibly universal influences are manifest (e.g., Kim, Sherman, & Taylor, 2008). Similarly, the approach to interventions described previously as emphasizing tailoring to implementation settings of core features or functions (Aro, Smith, & Dekker, 2008; Fisher, Ballesteros, et al., 2015; Fisher, Earp, et al., 2010; Hawe, Shiell, & Riley, 2004) entails a consideration of both what is universal and what is particular.

As a working model, we encourage the expectation that there are core characteristics of processes or influences which are universal. How they are implemented or manifest, on the other hand, may be very culture- and setting-specific. This reflects the interweaving of the universal and the particular in "global."

Plan for the Book

This book is organized to provide basic knowledge about behavioral medicine, how it may be applied, who does it, how it develops evidence and knowledge, and important bodies of knowledge that underlie it, including genetics, behaviorism itself, stress, social and cultural influences, and the social determinants of health and health disparities, including the broad range of influences from outside health care and health policy. It then provides chapters detailing a number of approaches to behavioral medicine, including health education, early detection and screening, promoting adherence to treatments, patient-provider interaction, and approaches broader than the individual including peer or social support, communities, and policies. The following section of the book examines the application of behavioral medicine to key areas of risk, prevention, and health care. Topics in this section are cigarette smoking, physical activity, weight management and obesity, violence and injury, chronic disease management, interventions for communicable diseases, including for HIV/AIDS and among high-risk groups, psychological factors in health and disease, and the growing application of genetics in prevention, decision making, and health. A subsequent section examines behavioral medicine approaches to enhancing quality of life including among children and families and at the end of life. The book then closes with a series of chapters examining cross-cutting issues – values and behavioral medicine and a behavioral medicine perspective on health care and the value it adds, or sometimes fails to add – and, then, a chapter that looks toward the future in emerging fundamental science including information technology, and the editors' closing chapter identifying important future trends and directions.

The focus of the book is on the very broad range of concepts in behavioral medicine and how they can be applied globally. Because of that range, comprehensive review of evidence in all areas would necessitate either a book far too lengthy to be of broad use or one that foregoes explication and exploration of concepts in order to catalog specific findings. Additionally, the field grows at such velocity that any such broad evidence review would be out of date before it were published, let alone read. Consequently, the present volume is written to sample broadly from the evidence supporting the many relationships between behavior and health discussed in the book. It is planned to sample wisely so as to include those major areas of evidence (e.g., the roles of behavioral risks in development of diseases that pose major population burden). But it does not include all evidence that may support the topics it addresses. Thus, the individual chapters are not systematic reviews or evidence reviews or meta-analyses, but presentations of key concepts and exemplary evidence to support them. They are intended to be useful both to the student first exploring behavioral medicine and to those experienced in the field but perhaps wanting to learn about previously unexplored areas or the evolution of favorite topics. For both, they provide a conceptual base from which to begin work in an area, to understand its topography and key concepts, and to be familiar with seminal and enduring patterns of findings.

Additional Sources of Interest

The *Encyclopedia of Behavioral Medicine* edited by Marc Gellman and Rick Turner (Springer, 2013) includes over 1200 entries on specific topics in behavioral medicine. As such, it provides an authoritative and comprehensive complement to the current volume's emphasis on concepts and broad principles.

Behavioral medicine is addressed in many journals representing the fields of medicine, public health, psychology, nursing, social work, etc. Journals that have been closely associated with the field and which readers might consult to expand their familiarity with it include:

Addictive Behaviors	*American Journal of Public Health*
Annals of Behavioral Medicine	*Health Psychology*
International Journal of Behavioral Medicine	*Journal of Behavioral Medicine*
Journal of Consulting & Clinical Psychology	*Patient Education and Counseling*
Psychosomatic Medicine	

Presentation of the range of behavioral influences on health as well as the range of influences on those behaviors that in turn influence health entails a variety of perspectives. For example, depression is, at once, a major risk for cardiovascular disease, a contributing and complicating factor in smoking and smoking cessation, a frequent accompaniment to (and perhaps antecedent of) diabetes, and a central factor in quality of life. In a book such as this, it is desirable that each chapter stands on its own. Consequently, the discussion of depression in a number of chapters in the book will be somewhat overlapping. We have not sought to eliminate this overlap in order to maximize convenience to the reader and the desired presentation of topics in integrated, comprehensive manners as opposed to piecemeal with multiple references to key information in varied sections of the book.

Because of the breadth and range of topics covered by the chapters, there is no single outline or format that would suit all of them. By design, the chapters pursue varied organizational approaches as judged by their authors to fit best the topics they address. We have also encouraged the authors to include their own perspectives in their chapters. As a result, we hope the book represents the field as well as the diversity of perspectives of individuals and groups within it. It should be noted that the opinions or perspectives articulated in the chapters are not necessarily those of the editors or endorsed by them. Behavioral medicine is a vibrant and sometimes contentious field, so we hope the book captures this.

For those who already identify themselves as being part of behavioral medicine, we hope the book enhances your appreciation of our field, its collegiality, and the satisfaction of working in a field that has so much potential to improve global health. For those new to behavioral medicine, we hope the book welcomes you and encourages you to join in!

Overview of Types of Disease, Their Epidemiology, and Treatments

Shajahan Yasin, Carina K. Y. Chan, and Kaitlyn E. Brodar

Behavioral medicine addresses the full range of diseases that affect humans. Fully describing these, their causes, and treatments would require a book of its own. For the reader's convenience, we summarize here some of the major types of diseases and health problems with which those in behavioral medicine frequently deal.

Much of the material in the text is drawn from general descriptions of diseases and health problems from the World Health Organization and other organizations. To avoid multiple references to these within the text, we have cited them at the beginning of each section to which they are pertinent. For more detailed coverage of diseases on which a reader may wish to focus her or his work, good starting places are major texts in medicine such as *Cecil's Textbook of Medicine* (Goldman & Schafer, 2016) and *Harrison's Principles of Internal Medicine* (Kasper, Fauci, et al., 2015) or major texts in other fields of behavioral medicine, such as *Primary Care: A Collaborative Practice* in nursing (Buttaro, Trybulski, et al., 2013).

Obesity

General reference: *Obesity and overweight* (World Health Organization, 2015d).

Obesity is often defined by body mass index (BMI), which is calculated by the formula: weight in kg divided by height in meters squared. A BMI that exceeds 30 kg/m^2 is generally considered indicative of obesity. BMI between 25 and 29 is considered overweight. This is not absolute, however. For people of Asian origin lower cutoff values for obesity has been recommended (Zeng, He, et al., 2014).

There are some limitations in the use of BMI as it may be elevated by muscular mass. Excess body fat, especially central and visceral fat, may be a more precise characterization of disease risk. Body fat may be assessed by diameter at the level of the waist. A ratio of waist-to-hip circumference that is equal to or greater than 0.9 in men and 0.85 in women has been used to assess risks associated with obesity (World Health Organization, 1999).

Epidemiology

The prevalence of overweight and obesity has been increasing in both adults and children in the United States as well as around the world. The World Health Organization reports that in 2014, 1.9 billion adults and 42 million children worldwide were overweight or obese (World Health Organization, 2015d). Obesity appears to be increasing 30% faster in low- and middle-income countries than in higher-income countries. This results in a "double burden" of disease for lower-income countries. While they still struggle with infectious diseases, noncommunicable diseases are now also on the rise, primarily due to the rising obesity rates.

The genes and environment of an individual combine to promote obesity. In genetically prone individuals, a sedentary lifestyle and excess food, especially carbohydrates with a high glycemic index, combine to increase risk. Individuals from a lower socioeconomic status (SES) and/or with lower education levels bear a disproportionate burden of the prevalence of obesity. Part of the reason for this is that obesity has been associated with limited access to healthy food, and individuals from a lower SES background are less likely to have access to grocery stores or markets with a full range of food options (Pechey & Monsivais, 2015). Instead, they may obtain food from "convenience stores," tiendas, or other stores emphasizing high fat, high carbohydrate, or "fast" food (Morland, Diez Roux, & Wing, 2006).

Obesity and overweight are risks for multiple health problems. A *partial* list includes coronary heart disease, hypertension (high blood pressure), stroke, type 2 diabetes mellitus, abnormal blood lipids, cancer (especially colon, breast, and endometrial cancer), osteoarthritis, sleep apnea, gallstones, and reproductive problems, including menstrual irregularities and infertility (World Health Organization, 2015d). Medical costs related to obesity are estimated to exceed $200 billion annually in the United States alone (Spieker & Pyzocha, 2016). Obesity also has a significant impact on an individual's day-to-day activities; for example, one study found that obesity was associated with a significant increase in days absent from work (Cawley, Rizzo, & Haas, 2007).

Prevention, Management, and Treatment

Managing obesity requires a multidisciplinary approach that involves modifying the lifestyle of the affected individual. The two key aspects of most interventions include structured dietary interventions and a strategy to increase physical activity.

Dietary interventions, which can be complex, include reduction of caloric intake, with increased intake of foods with low glycemic index and increased consumption of soluble fiber (from fresh fruits and vegetables). Consultation with a dietitian is often recommended.

Similarly, patients benefit from a balanced exercise plan, ideally developed in consultation with an exercise physiologist. This includes a mix of aerobic, stretching, and strength exercises gradually increasing in intensity. It is important to incorporate exercise into daily activities, like using stairs as opposed to elevators and increasing walking activities.

With the help of a psychologist or similarly trained professional, cognitive behavioral intervention strategies like goal setting, stimulus control, assertive communication skills, stress management, and managing relapse are important components of interventions that are often neglected.

A number of anti-obesity drugs are available and have been shown to be effective. These should be used in combination with behavioral modification strategies. Surgical options are also available and are reserved for patients with severe obesity or those with comorbid conditions. Two common procedures are bypass surgery and laparoscopic placement of an adjustable gastric band. Importantly these procedures need to be complemented with dietary advice and counselling.

Cardiovascular Disease

General reference: *Cardiovascular diseases* (World Health Organization, 2015a).

Cardiovascular disease (CVD) may be defined as all the diseases of the heart and circulation and includes coronary heart disease (which may present as angina and heart attack), arrhythmia, heart failure, congenital heart disease, as well as cerebrovascular disease and stroke.

Many people with underlying disease of the blood vessels have no symptoms, so that a heart attack or stroke may be the first symptom of disease. However, many individuals with coronary artery disease have early symptoms which may include chest pain or discomfort and breathlessness, especially on exertion such as when running or on climbing stairs. Pain may also be precipitated by stress and anxiety.

Heart attack symptoms include pain or discomfort in the center of the chest which may radiate to the arms, left shoulder, jaw, or back (National Heart Lung and Blood Institute, 2015a). The individual may develop difficulty in breathing, vomit, or break into a cold sweat.

Heart attacks, or myocardial infarction, and strokes are usually acute events and are mainly caused by an abrupt blockage in blood vessels that prevents blood from flowing to the heart or brain. This is due to buildup of fatty deposits or plaques on the walls of the blood vessels that supply the heart or brain. Rupture of these plaques can result in sudden block to the blood flow. Strokes can also be caused by rupture and bleeding from blood vessels in the brain or from blood clots.

A stroke most commonly manifests as sudden weakness of the face, arm, or leg, usually on one side of the body (National Stroke Association, 2016). Confusion, difficulty speaking or understanding speech, visual disturbances in one or both eyes, difficulty walking, dizziness, and loss of balance or coordination may also occur. Some forms of stroke may present with severe headache and loss of consciousness, indicating a brain bleed.

Three major categories of stroke are recognized by the CDC: ischemic, transient ischemic, and hemorrhagic (Centers for Disease Control and Prevention, 2013b). Ischemic strokes are the most common and are caused by a blockage in an artery that inhibits blood flow to the brain. Transient ischemic strokes are also caused by artery blockage, but are much shorter, with the blockage generally lasting less than 5 min. Finally, hemorrhagic strokes result from leakage or bursting of an artery, which damages surrounding brain cells. They are generally caused by high blood pressure or an aneurysm.

Arrhythmias are abnormal beats of the heart or abnormal heart rhythm (American Heart Association, 2015a). Rhythm abnormalities may result in slowing of the heartbeat (bradycardia), speeding of the beat (tachycardia), and irregularity of the heart rhythm. The effects of these arrhythmias are related to what impact they have on cardiac output or the ability of the heart to pump blood. When the abnormal rhythm is of short duration, the individual may tolerate this quite well. However, an individual can go into a cardiac arrest when the ventricles go into a severe tachycardia or go into fibrillation as no blood is pumped into the rest of the body, including the brain. A common form of arrhythmia is atrial fibrillation in which the atria go into very rapid and uncoordinated beats. In such instances the atria are ineffective in pumping blood, and the blood in the atria may form a thrombus or clot. Such thrombus can dislodge and enter the circulation, blocking blood flow to the organs. If this happens to the brain, it can cause a stroke. The risk of arrhythmias tends to increase with age. Damage to the heart by myocardial infarction or heart failure is often a trigger for arrhythmias. Other factors that can provoke arrhythmias include alcohol, cigarettes, recreational drugs, and some prescribed medications.

Heart failure occurs when the heart is unable to pump enough blood to meet the needs of the body (American Heart Association, 2016a). Heart failure occurs gradually; as the heart fails, blood backs up in the veins and causes fluid to build up in the tissues. The symptoms of heart failure include edema (due to excess fluid in body tissues), shortness of breath, coughing and wheezing, tiredness, and fatigue. Most cases of heart failure result from damage to the heart from coronary artery disease or previous heart attack and hypertension.

Epidemiology

According to the World Health Organization, CVDs are the leading cause of death globally; every year more people die from CVDs than from any other cause (Alwan, 2010). An estimated

17.5 million people died from CVDs in 2012, which constituted 31% of all deaths (World Health Organization, 2015a). Low- and middle-income countries are disproportionately affected; over 80% of CVD deaths take place in low- and middle-income countries. They occur almost equally in men and women. As great as the toll of CVD is, the WHO also notes that "most cardiovascular diseases can be prevented by addressing behavioral risk factors such as tobacco use, unhealthy diet and obesity, physical inactivity and harmful use of alcohol using population-wide strategies" (World Health Organization, 2015a). It has been estimated that behavioral risk factors are responsible for about 80% of coronary heart disease and strokes (Alwan, 2010). Smoking is an especially strong risk factor for heart disease, increasing the likelihood of dying from coronary heart disease and cerebrovascular disease by two- to threefold. Among people who stop smoking, risk of cardiac events can fall by 50%. Risk of heart attacks, stroke, and peripheral vascular disease decreases significantly over the first 2 years after stopping smoking.

Prevention, Management, and Treatment

In addition to smoking cessation, other behavioral modifications such as reducing salt intake, increasing intake of fruits and vegetables, regular physical activity, and avoiding harmful use of alcohol have been shown to reduce the risk of cardiovascular disease (World Health Organization, 2015a). Cardiovascular risk can also be reduced by preventing or managing hypertension, diabetes, and elevated blood lipids, all of which are powerful risk factors for heart disease and stroke. In addition to individual-level interventions, these objectives can be accomplished at the community level, with the aim to reduce cardiovascular mortality. An exemplar of primary prevention was conducted in North Karelia, Finland (Puska, Vartiainen, et al., 1998). It took a comprehensive approach that included working through primary care such as to improve blood pressure screening and control but also with food producers to create more health alternatives to traditional high-fat foods and with communities and media to promote healthier lifestyles including smoking cessation. Over time, lifestyles became healthier (e.g., reduction in dietary fat intake, salt consumption, smoking), risk factor levels were lower (e.g., decreased serum cholesterol, blood pressure), and, associated with these risk reductions, mortality from CVD declined markedly relative to other areas of Finland (Jousilahti, Laatikainen, et al., 2016; Puska, Vartiainen, et al., 2009).

Underlying behavioral risks for CVDs are some of the major forces driving social, economic, and cultural changes of modern life that include globalization, urbanization, and ageing of the population. These are often considered "the causes of the causes." These forces have been recognized, for example, as contributing to substantial CVD in Central and Eastern Europe in the years following the breakup of the Soviet Union (Kopp & Réthelyi, 2004). On the basis of such evidence, the WHO (Alwan, 2010) suggests that governments should enact policies that create conducive environments for making healthy choices affordable and available to motivate people to adopt and sustain healthy behavior.

Treatment of Acute Events Heart attacks and strokes are typically acute events. In both cases, prompt treatment can halt or reverse damage and is therefore of great importance. Therefore, health professionals should be familiar with the signs and symptoms of heart attack and stroke and encourage immediate medical assistance when they are noted. As identified by the US Centers for Disease Control, the signs and symptoms of these two conditions are described in Table 2.1.

For immediate treatment of a heart attack, thrombolytic medications are used to dissolve blood clots in the coronary arteries, in combination with nitroglycerin to improve blood flow and aspirin to prevent additional clotting (National Heart Lung and Blood Institute, 2015b). Coronary angioplasty is also employed to open blocked arteries.

Acute treatment for ischemic strokes involves administering tissue plasminogen activator (tPA), which can dissolve the blood clot blocking the

Table 2.1 Major signs and symptoms of heart attack and of stroke (Centers for Disease Control and Prevention, 2015a, b)

Major symptoms of a heart attack	Signs and symptoms of stroke
Pain or discomfort in the jaw, neck, or back	Sudden numbness or weakness in the face, arm, or leg, especially on one side of the body
Feeling weak, light-headed, or faint	Sudden confusion, trouble speaking, or difficulty understanding speech
Chest pain or discomfort	Sudden trouble seeing in one or both eyes
Pain or discomfort in arms or shoulder	Sudden trouble walking, dizziness, loss of balance, or lack of coordination
Shortness of breath	Sudden severe headache with no known cause
Additional symptoms, *more common among women:* Unusual or unexplained tiredness Nausea or vomiting	

artery (American Heart Association, 2016c). Endovascular treatment, which utilizes a stent retriever to capture and remove the clot in the artery, may also be used after tPA has been administered. Hemorrhagic strokes are typically treated with the endovascular procedure described above or with surgery, which involves placing a metal clip on the burst or leaking artery.

Long-Term Treatment and Management of CVD Individuals with CVD must adhere to a long-term disease treatment and management plan, which will most certainly include behavioral changes and may also involve medication and/or various medical and surgical procedures (American Heart Association, 2016d).

Lifestyle Changes Treatment varies across different types of cardiovascular problems, but common to each is the primary role of lifestyle changes. Following a nutritious, heart-healthy diet that includes fruits, vegetables, whole grains, and fish and limits on sodium, trans fats, sugar, alcohol, and red meat is essential (National Heart Lung and Blood Institute, 2015b). Stress management and regular physical activity are also important, and it is strongly suggested that individuals with CVD quit smoking.

Medication Medication can also be utilized to treat and manage cardiovascular conditions. In the case of myocardial infarction, ACE inhibitors are often prescribed to reduce blood pressure (National Heart Lung and Blood Institute, 2015b). Blood thinners and anticlotting medications may also be used to prevent blood clots from forming. Beta-blockers are prescribed to relieve pain and reduce the heart's workload, and statins are used to lower cholesterol levels.

Many of the same medications used to treat myocardial infarctions are also used to treat heart failure, in addition to angiotensin II receptor blockers (ARBs), aldosterone antagonists, and diuretics, each of which acts in different ways to reduce blood pressure (American Heart Association, 2016b). To treat arrhythmias, antiarrhythmic medication is used to encourage a normal heart rhythm by preventing pacemaker cells from firing abnormally (American Heart Association, 2016c). Calcium channel blockers and beta-blockers may also be prescribed.

Medical and Surgical Procedures In some cases, surgical treatment may be necessary. Coronary artery bypass grafting, which involves grafting a healthy artery or vein to go around a site of blockage to create a new path for blood flow to the heart, is frequently used as a treatment option for a myocardial infarction (National Heart Lung and Blood Institute, 2015b). This procedure may also be used for heart failure (American Heart Association, 2016c). Other options include coronary angioplasty, in which a stent is placed to keep an artery open; valve replacement; and, in more drastic situations, a heart transplant. Pacemakers may be implanted to treat arrhythmias. Other devices include implantable cardioverter-defibrillators which are surgically inserted devices which counteracts abnormal firing of pacemaker cells (American Heart Association, 2015b). Left ventricular assist device may also be used to help the failing heart pump blood (American Heart Association, 2016c).

Other procedures for treating arrhythmia include ablation, in which heart tissue with abnormal firing is targeted and destroyed so that surrounding tissue can grow and function normally, and defibrillation, which involves shocking the heart in order to establish a normal rhythm (American Heart Association, 2016b, c).

Cancer

General reference: *Cancer* (World Health Organization, 2016c).

Cancer, which may also be called malignant tumors and neoplasms, is a term used for a group of diseases in which cells in the body divide uncontrollably and invade other tissues. This is due to damage of genetic material of the cell producing mutations which cause unrestrained growth and spread of cells. Cancer cells can spread to other parts of the body through the blood and lymph systems. This process is referred to as metastasis and is the major cause of death from cancer. There are more than 100 different types of cancer. Most cancers are named for the organ or type of cell in which they start. For example, cancer that begins in the lung is called lung cancer; cancer that begins in melanocytes of the skin is called melanoma.

The transformation from a normal cell into a tumor cell is not fully understood but is thought to be a multistage process. Initially, precancerous lesions may form which then turn into malignant cancers. These changes are thought to be due to interaction between a person's genetic factors and external agents or carcinogens, which may include physical carcinogens, such as ionizing radiation, chemical carcinogens, such as asbestos as well as components of tobacco smoke, and biological carcinogens, such as infections from certain viruses and bacteria.

Epidemiology

The WHO estimates that after CVD, cancer is the next leading cause of death worldwide (Alwan, 2010), accounting for 8.2 million deaths in 2013, 62% of which occurred in low- and middle-income countries (Global Burden of Disease Cancer Collaboration, 2015). The most common causes of cancer death are due to cancers of the lung, breast, colon, stomach, and liver. In countries with high income, the leading causes of deaths due to cancer are lung cancer among men and breast cancer among women (Alwan, 2010). The incidence of cancer rises dramatically with age and is thought to be due to a buildup of risks for specific cancers that increase with age as well as a decline in cellular repair mechanisms that counteract the uncontrolled division of cells in carcinogenesis.

Risk Factors for Cancer

The National Cancer Institute (www.cancer.gov) lists four major behavioral factors that may be considered major risk factors for cancer. These include use of tobacco, unhealthy diet, inadequate physical activity, and alcohol misuse. These often occur together. An in-depth discussion of these behavioral risk factors can be found in Chap. 3 by Chan and Yasin, *infra*.

Among infective agents, hepatitis B and hepatitis C are implicated in liver cancer, human papillomavirus (HPV) in cervical cancer, *Helicobacter pylori* in stomach cancer, and Epstein-Barr virus in Burkitt lymphoma. Together, these infective agents are estimated to cause up to 18% of cancer burden (Parkin, 2006). There are now effective vaccines against hepatitis B and HPV that are effective in the prevention of liver cancers and cervical cancers.

Many cancers of the hematological system, breast, lung, and thyroid are also caused by exposure to ionizing radiation, including medical radiation through x-rays, computed tomography (CT), and fluoroscopy. Reducing radiation exposure is an important strategy to prevent cancers (National Research Council, 1990).

Prevention, Management, and Treatment

Early detection and treatment of cancer are key strategies in reducing its incidence. There are two components in the early detection efforts, screening, and early diagnosis.

Early Detection, Screening, and Diagnosis Early diagnosis is particularly relevant for cancers of the breast, cervix, mouth, larynx, colon and rectum, and skin (World Health Organization, 2016h). For diagnosis to occur, individuals must be identified as eligible for diagnostic evaluation. Education and awareness of early signs and symptoms of cancers may help identify those who may benefit from diagnosis. The World Health Organization notes that some early signs of cancer include lumps, sores that fail to heal, abnormal bleeding, persistent indigestion, and chronic hoarseness.

Screening is defined as the systematic application of a test in a population without symptoms. The aim of screening is also to identify persons who have abnormalities that are suggestive of a specific cancer, to refer them for further tests that can lead to a diagnosis, and to facilitate prompt treatment. For a screening program to be efficacious, it should be cost-effective, affordable, acceptable, and accessible. The screening test should be available to the majority of the at-risk population.

Evidence supports especially early detection and/or population screening for breast cancer, ideally by mammography; for colorectal cancer, by fecal samples, sigmoidoscopy, or, ideally, colonoscopy; for cervical cancer, by the "Pap test" (developed by Georgios Papanikolaou, also called "cervical smear"); for oral cancer, by inspection of the mouth; for melanoma or cancer of the skin, by visual inspection by the individual, relationship partners, or health workers (Curiel-Lewandrowski, Chen, & Swetter, 2012); and, supported by recent evidence, lung cancer. Screening for prostate cancer is controversial with patients advised to discuss options with their physician.

The advisability of screening varies by age, family history, other demographic characteristics, and presence of other risk factors (e.g., smoking history). Details for who should be tested and when are available through the websites of the American Cancer Society (American Cancer Society, 2015) and the US Preventive Services Task Force (US Preventive Services Task Force, 2016).

Although screening can be an effective preventive approach when it is part of a public health program, it is important to realize that indiscriminate testing which is not evidence based can be harmful both through false-positive test results or unnecessary treatment, which can result in unnecessary distress, and by increasing costs due to unnecessary tests and treatments (see Kaplan et al., Behavioral Medicine and the Benefits of Health Care: A Critical Appraisal and the Need for Exnovation, *infra*.).

Management Treatments for cancer vary widely and include surgery, chemotherapy, and radiation therapy. Each of these can be curative, but this depends on the particular cancer and the stage at which treatment is initiated. Two important changes in cancer treatment include chemotherapy guided by pharmacogenetics and immunotherapy. Recent advances in genetics have led to the ability to select chemotherapeutic agents according to individual genotypes (National Cancer Institute, 2014). This is expected to improve the precision and effectiveness of treatment over that guided purely by clinical characteristics, stage, and progression of cancer. Immunotherapies are developing that stimulate and enhance the body's own immunologic processes to combat cancers.

Because of advances in treatment as well as timely detection and diagnosis, many cancers are becoming chronic diseases (Hewitt, Greenfield, et al., 2006). Thus, ongoing "survivorship" is an important area of cancer care that includes management similar to that of other chronic diseases. As cancer survivors age and develop other chronic diseases, the care of their cancer and those other diseases needs also to be addressed. Survivors of cancer including, for example, childhood cancer, may be at risk for developing other cancers, further complicating their care.

Palliative care including psychosocial support is an important but too often neglected dimension of cancer care. Ideally, it should be initiated from the time of diagnosis, not necessarily as a major emphasis but as a dimension of comprehensive care. The continuum from survivorship through palliative and end-of-life care includes the importance of psychosocial support, pain management, and support for the families of those with cancer, both before and after death should it occur. Psychosocial supportive services enhance quality of life even among those with noncurable cancer (Spiegel, 2012) and may extend survival (Andersen, Yang, et al., 2008; Spiegel, 2001).

Diabetes Mellitus

General reference: *Diabetes* (World Health Organization, 2016f).

Diabetes is a chronic disease that is characterized by chronic elevation of blood glucose levels (hyperglycemia). It is a result of the pancreas not producing enough insulin (insulin insufficiency) and/or the tissues in the body lacking the ability to use insulin effectively (insulin insensitivity). Insulin is a hormone that regulates blood sugar levels. Hyperglycemia, or raised blood sugar, over time leads to serious damage to many of the body's systems, especially the nerves and blood vessels.

Diabetes mellitus is diagnosed by measuring the level of plasma glucose either in the fasting state or 2 h after a meal. The current WHO diagnostic criterion for diabetes is fasting plasma glucose equal to or above 126 mg/dl (7.0 mmol/l) or 2 h postprandial plasma glucose of equal or above 200 mg/dl (11.1 mmol/l) (World Health Organization, 2006).

Epidemiology

WHO estimates that the global prevalence of diabetes in 2008 was 10% in adults aged 25 years and over (Alwan, 2010). The International Diabetes Federation estimates the current number of individuals with diabetes worldwide at 415 million and estimates this will grow to 642 million by 2040 (International Diabetes Federation, 2015).

Diabetes is classified into several categories (American Diabetes Association, 2014):

Type 1 Diabetes Type 1 diabetes, which previously was known as insulin-dependent diabetes and juvenile-onset diabetes, results from immune destruction of the insulin-producing beta cells of the pancreas. In the majority of cases, type 1 diabetes develops before the 40th year, with a peak in puberty. Those with type 1 diabetes require daily administration of insulin for survival. Individuals present with polyuria (excessive passing of urine), polydipsia (excessive thirst), weight loss, and often with constant hunger and fatigue. The presentation can be quite sudden.

Type 2 Diabetes Previously known as non-insulin-dependent or adult-onset diabetes, type 2 diabetes results from resistance to the effects of insulin. Type 2 diabetes accounts for 90% of diabetes cases around the world. Symptoms are usually gradual in onset, but may be similar to those of type 1 diabetes. Due to the gradual onset, many individuals may not be diagnosed until several years after onset. In some instances, complications due to long-standing diabetes may be the occasion for initial diagnosis.

Until recently, type 2 diabetes was seen only in adults, but with increasing childhood obesity around the world, it is now also occurring in children. The risk of developing type 2 diabetes increases with age, obesity, and lack of physical exercise.

Gestational Diabetes This condition involves hyperglycemia with onset or first symptoms during pregnancy. Symptoms are similar to those experienced in type 2 diabetes. It is generally diagnosed through screening during pregnancy. Most cases resolve upon delivery, but a history of gestational diabetes is a risk factor for subsequent type 2 diabetes.

Impaired Glucose Tolerance (IGT) and Impaired Fasting Glycemia (IFG) Impaired glucose tolerance (IGT) and impaired fasting glycemia (IFG) are intermediate conditions in which glucose levels are elevated, but do not meet criteria for diabetes. People with IGT or IFG, which is also referred to as prediabetes, are at a higher risk of developing diabetes.

Impacts and Complications

Diabetes is a cause of significant morbidity. It is the leading cause of renal failure. In developed countries, it is a major cause of visual impairment and blindness (Resnikoff, Pascolini, et al., 2004). Lower limb amputations are ten times more common among those with diabetes (Icks, Haastert, et al., 2009). Most of the complications of diabetes develop gradually. They can be disabling or even life-threatening. Some of the major complications of diabetes include:

Heart and blood vessel disease. Diabetes significantly increases the risk of cardiovascular problems, including coronary artery disease, stroke, narrowing of arteries due to plaques (atherosclerosis), and high blood pressure. For men, erectile dysfunction often results from compromised blood flow.

Nerve damage (neuropathy). Excess sugar can damage the capillaries that supply the nerves, especially in the legs. This can result in symptoms like tingling, numbness, burning, or pain that usually begins distally in the toes or fingers and spreads proximally. This eventually leads to loss of all sensation in the limbs. Healing of cuts and blisters can be delayed, and these can become infected. Severe damage to nerves and vessels may require amputation of the toe, foot, or even leg.

Kidney damage (nephropathy). Diabetes can damage the tiny capillaries that are part of the filtering system in the kidneys. Over time this can lead to kidney failure or irreversible end-stage kidney disease, requiring dialysis or a kidney transplant.

Eye damage. Diabetes is the leading cause of blindness among adults resulting from damage to the blood vessels of the retina (diabetic retinopathy). Diabetes increases the risk of cataracts and glaucoma.

Skin and mouth conditions. Individuals with diabetes are prone to bacterial and fungal skin infections. Gum infections can also occur especially when associated with poor dental hygiene.

Other health complications. Diabetes may also increase the risk of osteoporosis and has also been associated with increased risk of Alzheimer's disease and vascular dementia.

Prevention, Management, and Treatment

The risk of developing type 2 diabetes increases with age, obesity, and when there is a family history of diabetes. Certain racial groups including those of African origin, Hispanic Americans, American Indians, and Asians of Indian origin seem to be at heightened likelihood of developing diabetes (Spanakis & Golden, 2013). But these group propensities are highly influenced by the environment. The classic example of this is among the Pima Indians, who have one of the highest rates of diabetes in the world if they live in the United States, indicative of a strong genetic propensity for the disease, but a low prevalence if they live in traditional settings in Mexico, indicative of the role of environment in moderating that genetic propensity (Pratley, 1998).

The most important modifiable risk factors for the prevention of diabetes are being overweight and physically inactive. Even among those at high risk because of insulin insensitivity and abnormally high blood sugar levels, behavioral interventions can prevent and delay diabetes (Diabetes Prevention Program Research Group, 2002).

Diabetes entails many of the issues encountered in chronic diseases, including lifestyle approaches to prevention and management; sophisticated medical treatments; diverse complications, affecting individuals from childhood to old age; and challenges to individuals and their families; diabetes is an important model of chronic disease in general. It also is a model of interventions that can achieve appreciable benefits in terms of reducing risks of complications and progress.

The Diabetes Control and Complications Trial was a landmark that showed convincingly that good blood glucose control in those with type 1 diabetes reduces complications of the disease (The Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) Study Research Group, 2005). Interpretation of that finding extends also to type 2 diabetes. Studies of care of type 2 diabetes through the UK Prospective Diabetes Study (UKPDS) have shown relationships between chronic elevated glucose levels, complications of diabetes, and mortality and benefits of improved glucose control (UK Prospective Diabetes Study Group (UKPDS), 1998a, b). This leads to glucose control being a major objective in diabetes management. This is often measured by glycosylated hemoglobin, a measure of the proportion of hemoglobin cells in the bloodstream that have a glucose molecule attached to them. The more the average level of glucose in the blood, the greater the percentage of hemoglobin molecules that are glycosylated. Good glucose control is generally viewed as a glycosylated hemoglobin (or "HbA1c") value of less than 7% or 53 mmol/mol, but this objective is moderated clinically by other factors, especially age (American Diabetes Association, 2014). A number of medications have been developed to improve blood glucose control. These operate through varied pathways including altering digestion and processing of carbohydrates that are major sources of glucose as well as enhancing insulin function and glucose metabolism (American Diabetes Association, 2015).

Management of diabetes is best accomplished through a collaborative relationship among the health-care team, the patient, and her or his family. The aim of management is to keep blood glucose levels close to normal so as to prevent acute, extreme excursions and to delay and prevent long-term complications. Recent guidelines, however, have endorsed moderating blood glucose goals to individual characteristics, including age and other clinical features such as history of severe hypoglycemic episodes, advanced microvascular or macrovascular complications, or extensive comorbid conditions (American Diabetes Association, 2015). Treatment involves healthy diet and weight management, regular physical activity, monitoring of blood sugar, various medications to enhance glucose metabolism, and, often, insulin therapy. Additionally, it is important for those with diabetes to avoid tobacco use, as smoking greatly increases the risk of cardiovascular diseases among those with diabetes (Jia, 2013). The following paragraphs provide an overview of key components of diabetes management (American Diabetes Association, 2016).

Monitoring Blood Glucose In type 1 diabetes, self-monitoring of blood glucose is an integral part of the treatment plan. Frequency of self-monitoring may vary across situations but is generally recommended before meals and before going to sleep. With insulin treatment of type 2 diabetes, as well, frequent daily self-monitoring of blood glucose is recommended.

HbA1c is assessed periodically and provides a measure of average blood glucose level over the previous 2–3 months and serves as an indicator of diabetes control. HbA1c however provides no information on glucose variability.

Dietary recommendations are generally in line with those for the general population, with increased intake of fruit and vegetables, whole grains, and fish and with moderate calorie restriction. Fiber intake should be increased. On the other hand, foods which are absorbed rapidly and converted to sugar in the blood (referred to as foods with a "high glycemic index") should be avoided. Salt intake should be reduced and alcohol should be consumed only in moderation.

Regular exercise, especially aerobic exercise, is important in maintaining weight and improving glucose control as it improves insulin sensitivity. It also reduces blood pressure and cholesterol levels.

Weight Management Overweight (body mass index of 25.0 to 29.9 kg/m^2) and obesity ($BMI > 29.9\ kg/m^2$) are major risk factors for type 2 diabetes and cardiovascular disease. Even a small reduction in weight of 5–10% can reduce the risk for diabetes or improve blood glucose control among those with the disease.

Medication Because it is defined as an inability to produce insulin, all patients with type 1 diabetes require insulin and careful monitoring to avoid hypoglycemic as well as hyperglycemic events. In type 1 diabetes, the use of pump therapy and continuous glucose monitoring (CGM) sensors are becoming increasingly popular.

Most patients with type 2 diabetes eventually require medications. These may be oral medications like metformin, which is often a first-line therapy, or a whole range of newer medications to enhance glucose metabolism. Worldwide, there is a tendency to "undertreat" diabetes by continuing diet and exercise recommendations or insufficient medication in spite of persistent obesity and poor glucose control rather than moving patients to insulin therapy. The expanded range of medications available and the evidence especially for cardiovascular benefits of good blood glucose control argue for more proactive treatment of diabetes early in the course of the disease (Skyler, Bergenstal, et al., 2009).

An important feature of diabetes is that it is *fundamentally progressive*. That is, it tends to worsen. This has several important implications. While it is eventually necessary for many, patients may see the recommendation of insulin therapy as indicating a failure on their part (Funnell, Kruger, & Spencer, 2004). Instead, the advisability of insulin should be understood as part of the natural course of diabetes amidst understandable difficulty in managing blood sugar – many lean and fit adults with type 2 diabetes take insulin. Additionally, the fundamentally progressive nature of diabetes means that individuals can manage their disease assiduously, but still experience complications and worsening clinical status. This of course can be very discouraging for the individual. Management of diabetes needs to balance (a) determined efforts for a healthy lifestyle and appropriate use of medications with (b) recognition that although diabetes may be managed, it is progressive and unpredictable, so that outcomes cannot be assured, and with (c) support from the clinical team, family, and friends, for the patient in coping with the many challenges diabetes presents. Behavioral medicine programs can help patients and families cope with the psychological and behavioral demands of living with diabetes, both in youth and adults.

Chronic Obstructive Pulmonary Disease

General references: *Chronic obstructive pulmonary disease* (COPD) (World Health Organization, 2016b) and *Burden of COPD* (World Health Organization, 2016d).

Chronic obstructive pulmonary disease (COPD) is a life-threatening lung disease resulting from irreversible damage to the airways and the lung tissue due to inhaled irritants, usually cigarette smoke. COPD is confirmed by pulmonary function tests that assess the ability of the lungs to inhale and exhale air. For example, "FEV1" or "forced expiratory volume 1" is the amount of air the individual is able to exhale in 1 s. These tests are used for assessing severity as well as response to treatment.

COPD consists of two conditions: emphysema and chronic bronchitis. In emphysema, the alveoli and alveolar walls in the lungs are damaged, resulting in reduction of the amount of gas exchange. In chronic bronchitis, the bronchi and bronchioles which line the airways are inflamed due to chronic irritation. This results in mucus formation and thickening of the bronchioles. Chronic bronchitis may be diagnosed if an individual coughs with sputum 3 months in a year for two consecutive years. People with COPD usually have varying degrees of both emphysema and chronic bronchitis.

Patients with COPD complain of progressive breathlessness with periodic acute episodes often brought about by respiratory infections, air pollution, or cardiac failure. Initially breathlessness is only evident on exertion, but eventually it is evident at rest as well. Cough often in the mornings with excess of clear or yellow sputum is often a feature. In late stages, patients tend to lose considerable weight. Generally, if due to smoking, symptoms become evident after the age of 40.

Epidemiology

The WHO estimates that more than 65 million individuals worldwide have COPD. COPD was the cause of over 3 million deaths in 2005, 90% of which were in low- and middle-income countries (World Health Organization, 2016b). The main cause of COPD is smoke from tobacco use either directly from smoking or secondhand smoke (Alwan, 2010). As tobacco use among women in high-income countries has increased, the prevalence of the disease is now becoming equal in men and women. Individuals with asthma (see next section) and who smoke are at even higher risk for COPD. A rare cause for COPD is a genetic disorder called alpha-1-antitrypsin deficiency.

People with COPD are at increased risk of respiratory infections including the common colds and pneumonia that can be quite severe and life-threatening (Mayo Clinic, 2015b). Risk of cardiac disease is also increased, partly because of the shared and strong risk factor of cigarette smoking. Hypertension is also associated with COPD. Lung cancer is more common among those with chronic bronchitis even when the effect of smoking is taken into account. Individuals with COPD are also at higher risk of coronary artery disease and lung cancers due to all three conditions having common risk factors.

Prevention, Management, and Treatment

The vast majority of cases of COPD are due to smoking cigarettes. Therefore, emphasis has to be on preventing smoking and on programs for smoking cessation (see Chap. 24 by Borland, *infra*).

As noted, COPD is not curable, and the best approach is in prevention and slowing the rate of progression. Patients should be encouraged to stop smoking at every opportunity and should be referred to smoking cessation programs. Most patients who succeed in stopping smoking fail to do so on the first few attempts (Fisher, Brownson, et al., 2004). Smoking cessation efforts should be framed to encourage individuals to view failure not as a sign of inability to quit but as part of a common path to cessation.

Once COPD is diagnosed, treatment is directed at preventing exacerbations and improving airway flow with the use of bronchodilators. Flu vaccination annually and pneumococcal pneumonia vaccination can help to reduce respiratory exacerbations. Examinations to regularly screen for hypertension, coronary artery disease, and lung cancer are essential for proper disease management. Supplemental oxygen may also be used in severe cases. The damage caused by COPD is irreversible, but individuals can learn ways of utilizing their remaining lung capacity as efficiently as possible. Inhaled or oral steroids as well as antibiotics when required are also common to assist with disease management. Additionally, pulmonary rehabilitation is a behavioral medicine intervention that promotes exercise, effective breathing, and appropriate medication usage and can increase both length and quality of life for people with COPD (Nguyen, Harrington, et al., 2015; Sahn, Nett, & Petty, 1980).

Bronchial Asthma

General reference: *Bronchial asthma* (World Health Organization, 2016a).

Asthma is a chronic pulmonary disease that is characterized by reversible airflow obstruction. The airways tend to be hyperactive to inhaled substances that cause an allergic reaction in the airways. Airway inflammation is considered to be the fundamental process underlying these features of the disease.

A good history and physical examination are all that is usually required for diagnosis, but in some instances lung function tests may be needed. These include spirometry to assess the narrowing of the bronchi and peak flow meter measurements. Occasionally, diagnosis can only be made by demonstrating hypersensitive airways by provoking the airways to constrict by administering drugs like histamine or methacholine to provoke a reaction in the airway.

Asthma can develop at any age, but typically begins during childhood. Although a common myth is that people outgrow their asthma as they become adults, reoccurrence in later years is common, suggesting persistence of the underlying condition with variation in expression. The classic symptoms of asthma are recurrent wheezing, episodic breathlessness, and chronic cough. Symptoms can be mild and intermittent to severe and life-threatening. A wheeze that occurs when exhaling is especially common in children. Many people with asthma only present with a chronic cough. Symptoms are often worse at night and in the early hours of the morning.

Epidemiology

Asthma is the most common chronic disease among children. The WHO estimates that approximately 150 million individuals around the globe suffer from asthma, and rates appear to be rising by about 50% each decade. Deaths from asthma exceed 180,000 annually and occur much more frequently in low- and middle-income countries and in low-income populations within countries in part due to underdiagnosis and undertreatment as well as air pollution and other environmental factors that are often more pronounced in low-income communities. Asthma creates a substantial burden to individuals and families and restricts an individual's activities for a lifetime. In the United States alone, approximately $6 billion is spent on health-care costs related to asthma each year.

Asthma is likely to have genetic as well as environmental causes. It has been postulated that home construction limiting ventilation, urban living, and/or parental emphases on germ avoidance have led to a lack of exposure of the immune system to infectious antigenic stimuli in childhood. According to this "hygiene hypothesis," this may be a factor in the growing incidence of asthma and other autoimmune and allergic diseases in the developed world (Weiss, 2002). Environmental exposures, however, may also play a role in rising asthma rates; in particular, individuals who live near controlled animal feeding operations that generate high levels of exposures to bacteria are significantly more likely to develop asthma (Heederik, Sigsgaard, et al., 2007; Sigurdarson & Kline, 2006). Parental smoking during pregnancy has also been associated with a significant increase in the likelihood that a child will become asthmatic (Harju, Keski-Nisula, et al., 2016). Additionally, asthma has been linked with obesity, also increasing globally (Beuther, Weiss, & Sutherland, 2006; Chih, Chen, et al., 2016).

Exercise can trigger an attack especially in a cold and dry environment. Irritants in the air, especially those encountered in the workplace like chemical fumes and gases, can also trigger asthma. In many cases, individuals with asthma are allergic to environmental allergens like dander from pets, cockroaches, dust mites, and pollen. Other more general triggers include smoke, drugs like aspirin and beta-blockers, and strong emotions.

Milder forms of asthma disturb sleep, which can impact work productivity including time being away from school or work. Children with milder forms of asthma that have not been diagnosed may only manifest as underperforming academically at school (Mayo Clinic, 2015a). Asthma, however, is a serious disease and is a frequent cause of hospitalizations and avoidable death, especially in low-income groups and families with considerable psychosocial stress in which access to medications and adherence to care may be compromised (Miller & Strunk, 1989).

Prevention, Treatment, and Management

While asthma itself may not be preventable, there are many ways of preventing asthma attacks and managing the disease to live a full life with it (National Asthma Education and Prevention Program Third Expert Panel on the Diagnosis and Management of Asthma, 2007). A noted expert and colleague, Robert Strunk, emphasized in his work that people should not restrict their activities to manage their asthma but should manage their asthma to live full lives. Identifying and avoiding allergens and triggers are important. Flu and pneumonia vaccinations can help in reducing the likelihood that these conditions will trigger an asthma attack. Monitoring and identifying flare-ups and taking the appropriate medications early can also help abort an attack. Management of asthma requires education and patient involvement. A stepwise approach to the management of asthma is now recommended. An asthma action plan, developed in partnership with the patient, can be very useful in monitoring symptoms (Asthma UK, 2016; National Heart Lung and Blood Institute, 2007). In particular, it helps the patient to understand what medications are needed and when and identifies worsening asthma so that help can be obtained early.

Peak expiratory flow meters are portable devices that can be used at home to monitor airflow obstruction, similar to pulmonary function testing discussed under COPD. The mainstay of treatment is inhaled corticosteroids – "controller" medications – which reduce the hypersensitivity of the airways and also reduce inflammation. Short-acting agonists – "responders" – are drugs that dilate the airways to relieve attacks and are generally given through an inhaler, but may also be given orally or intravenously.

Behavioral medicine programs training parents and/or youth with asthma in proper use of medications and medication adherence and avoidance of triggers can reduce symptoms and associated hospital and emergency care (Fisher, Strunk, et al., 2009; Krieger, Takaro, et al., 2009; National Asthma Education and Prevention Program Third Expert Panel on the Diagnosis and Management of Asthma, 2007).

Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

General references: *HIV/AIDS* (World Health Organization, 2015c) and *Guideline on when to start ART and on PrEP for HIV* (World Health Organization, 2015b).

The human immunodeficiency virus (HIV) affects and weakens the immune system, which results in reduction in the surveillance and defense systems against infections and some types of cancer. As the virus destroys immune cells, infected individuals gradually become immunodeficient.

Diagnosis of HIV infection occurs through blood tests detecting the presence or absence of HIV antibodies. After infection there may be a latent period of up to 2 weeks before tests become positive. About 50% of infected persons develop symptoms of viral infection about 2–6 weeks after infection. This is called acute retroviral syndrome and may consist of fever, sore throat, rash, and joint pains. Patients then go into an asymptomatic phase in which there is a slow progression to severe immunodeficiency.

Epidemiology

HIV has claimed more than 25 million lives over the past three decades. There were approximately 36.9 million people living with HIV in 2014. Sub-Saharan Africa is the most affected region, with nearly 1 in every 20 adults living with HIV. In 2014, 2 million people were newly infected with HIV. That same year, HIV was responsible for 1.2 million deaths, 150,000 of which were children under 15 years of age (World Health Organization, 2015c).

HIV Transmission Transmission occurs through blood-to-blood contact between infected and non-infected individuals. Most often this occurs through sexual intercourse. Heterosexual intercourse is now the dominant mode of spread around the world. The presence of other sexually transmitted diseases, especially those that are associated with genital ulcers, facilitates sexual transmission of HIV. Intravenous drug use that involves needle sharing is another common form of transmission. A third path of transmission is from an infected mother to child in utero, during labor, or through breastfeeding. The final mode of transmission is through blood products. Fortunately, this has become extremely rare with screening of blood products.

About 50% of untreated individuals develop AIDS within 10 years of HIV infection, 30% develop milder symptoms, and 20% will still be entirely symptom-free after 10 years. Initial manifestation may occur in skin and mucous membranes and manifest as shingles, genital herpes, and oral and vaginal candida infections. As more severe immunodeficiency develops, patients start developing opportunistic infections.

Prevention, Management, and Treatment

Prevention The mainstay of reducing risk of HIV infection is by limiting exposure to the virus and to the risk factors. Key approaches recommended by the WHO for HIV prevention include:

Male and female condom use. Consistent use of male and female condoms during vaginal or anal penetration can be effective against the spread of HIV. Male condoms have an 85% or greater protective effect against the sexual transmission of HIV and other sexually transmitted infections (STIs).

Voluntary medical male circumcision. Medical male circumcision reduces the risk of heterosexually acquired HIV infection in men by approximately 60% and may also be beneficial in preventing HIV transmission in women and lowering sexually transmitted infections in both sexes (Quinn, 2007).

Harm reduction for injecting drug users. People injecting drugs should use sterile injecting equipment, needles, and syringes. The WHO recommends a comprehensive package of interventions for HIV prevention and treatment (World Health Organization, 2014) that includes:

- Programs offering free needles and syringes to discourage sharing these
- Opioid substitution therapy for those dependent on opioids
- Evidence-based interventions, including brief psychosocial interventions for those with harmful alcohol or other substance use
- HIV testing and counselling
- HIV treatment and care
- Low-cost or free access to condoms
- Management of STIs, tuberculosis, and viral hepatitis

Testing and Counselling All people exposed to risk factors should be tested for HIV and other STIs, and if positive they should be encouraged to access necessary prevention and treatment services without delay. The WHO also recommends offering testing for partners or couples.

All testing and counselling services should include the five Cs recommended by WHO (World Health Organization, 2015c): informed consent, confidentiality, counselling, correct test results, and linkage to care, treatment, and other services. Mandatory or coerced testing by health-care providers, government or other authorities, or from partners or family members is generally not advised as it infringes on human rights and discourages high-risk individuals from seeking care and may drive the problem underground. The US Centers for Disease Control and Prevention recommends that “everyone between the ages of 13 and 64 get tested for HIV at least once as part of routine health care” and that those at heightened risk be tested more frequently, including every 3–6 months for sexually active gay and bisexual men (Centers for Disease Control and Prevention, 2016).

Elimination of Mother-to-Child Transmission of HIV HIV transmission from an HIV-positive mother to her child during pregnancy, labor, delivery, or breastfeeding is called vertical or mother-to-child transmission (AIDS info, 2016). If no treatment is instituted, HIV transmission rates are between 15% and 45%. However, if the mother and child are provided with antiretroviral drugs, mother-to-child transmission can be nearly fully prevented. The WHO recommends lifelong treatment should be offered to HIV-positive pregnant women regardless of their CD4 counts.

Management The WHO now recommends that antiretroviral therapy should be initiated in everyone living with HIV at any CD4 cell count (World Health Organization, 2015e). In addition, the use of daily oral preexposure prophylaxis is recommended as a prevention choice for people at substantial risk of HIV infection as part of combination prevention approaches. This expanded use of antiretroviral therapy keeps people living with HIV alive and healthier and reduces their risk of transmitting the virus to partners.

The current antiretroviral drugs do not cure but suppress the HIV infection. These drugs have essentially made HIV/AIDS into a complex chronic disease requiring long-term and continuing management. To monitor their benefit, CD4 (which is a measure of the degree of immunodeficiency) and plasma viral load (which is an indication of degree of viral replication) should be assessed every 3–4 months to assess the progression of the disease.

Antiretroviral therapy has also been used for prevention. If an HIV-positive person adheres to an effective antiretroviral therapy regimen, the risk of transmitting the virus to their uninfected sexual partner can be reduced by 96%. For couples in which one partner is HIV-positive and the other HIV-negative, the WHO recommends offering antiretroviral therapy to the HIV-positive partner regardless of her/his CD4 count. Additionally, antiretroviral drugs taken by the HIV-negative partner can be effective in preventing HIV transmission from the HIV-positive partner.

Following exposure to HIV, the use of antiretroviral drugs within 72 h of exposure can prevent infection. This is often recommended for healthcare workers following needlestick injuries in the workplace.

Tuberculosis

General reference: *Tuberculosis (TB)* (World Health Organization, 2015e).

Tuberculosis (TB) is caused by the bacteria, *Mycobacterium tuberculosis*, and most often affects the lungs. TB is spread from person to person through air droplets. Active TB manifests as cough, fever, night sweats, and weight loss. Symptoms may be mild for weeks, which may lead to delayed care-seeking as well as increased time for transmission to other people. Tuberculosis often affects young adults, in their most productive years. TB has a high mortality rate without treatment.

Epidemiology

According to the WHO (World Health Organization, 2015e), TB is second only to HIV/AIDS as the greatest worldwide killer caused by a single infectious agent. In 2011, 8.7 million people fell ill with TB and 1.4 million died from it. Over 95% of TB deaths occur in low- and middle-income countries, and it is among the top three causes of death for women aged 15 to 44. Because HIV weakens immune protection, TB is a leading killer of people living with HIV, causing one-quarter of all deaths among them.

Tuberculosis is closely linked with poverty. Overcrowding and malnutrition are common predisposing factors. Diabetes, smoking, and alcoholism are also significant risk factors for tuberculosis.

Many people have latent TB. Although infected with TB, they remain asymptomatic. People who are co-infected with HIV and TB are 20 to 30 times more likely to become sick with active or symptomatic TB. Risk of active TB is also greater in persons suffering from other conditions that impair the immune system.

Prevention, Management, and Treatment

TB is a treatable and curable condition. Active, drug-sensitive TB is treated with a standard 6-month course of four antimicrobial drugs. It is recommended that the drugs are given under direct supervision by a health worker to ensure adherence, also called directly observed therapy or DOT. This is in the interest both of the infected individual and of the broader community in order to avoid partially completed treatment, which can provide the opportunity for development of drug-resistant strains of TB.

Multidrug-resistant tuberculosis (MDR-TB) is a form of TB caused by bacteria that do not respond to isoniazid and rifampicin, the two most powerful, first-line (or standard) anti-TB drugs. It is becoming more common. This is attributable to several factors, including the increasing prevalence of TB linked with the worldwide HIV/AIDS problem and frequent poor adherence, providing suboptimally treated bacteria the opportunity for mutations to drug-resistant forms. Patients with multidrug-resistant TB require more toxic second-line drugs that need to be given for longer periods.

Mental Disorders

General reference: *Mental health action plan 2013–2020* (World Health Organization, 2013).

Mental disorders are changes in thoughts, feelings, and behaviors that produce significant distress or affect the person's ability to function effectively. Mental health is an integral part of health and well-being. This is reflected in the definition of health in the Constitution of the World Health Organization: "health is a state of complete physical, *mental and social well-being* and not merely the absence of disease or infirmity" (emphasis added) (World Health Organization, 1946).

The Diagnostic and Statistical Manual of Mental Disorders (DSM) (American Psychiatric Association, 2013) is widely used as the standard diagnostic manual for diagnosing mental disorders. It is now in its fifth edition (DSM-5), which provides a better framework to guide accurate and consistent diagnoses and the study of associations between disorders. Categories of mental disorders included in DSM-5 (American Psychiatric Association, 2013) are presented in Table 2.2.

Table 2.2 Categories of mental disorders included in DSM-5

Classification of mental disorders (DSM-5)
Neurodevelopmental disorders
Schizophrenia spectrum and other psychotic disorders
Bipolar and related disorders
Depressive disorders
Anxiety disorders
Obsessive-compulsive and related disorders
Trauma- and stressor-related disorders
Dissociative disorders
Somatic symptom disorders
Feeding and eating disorders
Elimination disorders
Sleep-wake disorders
Sexual dysfunctions
Gender dysphoria
Disruptive, impulse control, and conduct disorders
Substance use and addictive disorders
Neurocognitive disorders
Personality disorders
Paraphilic disorders
Other disorders

Mental problems can also be understood using the perspective of lifespan development with some specific mental disorders typically diagnosed in childhood (e.g., autism spectrum disorder), adolescence (e.g., eating disorders), early adulthood (e.g., schizophrenia), adulthood (e.g., depressive and anxiety disorders), and late adulthood (e.g., neurocognitive disorders).

Epidemiology

According to the WHO (World Health Organization, 2013), certain individuals and groups may be at a higher risk of developing mental health problems. In addition to genetic predispositions, exposure to adversity at a young age is an established preventable risk factor for mental disorders. Other causes of vulnerability include economic poverty, other chronic diseases, membership in ethnic groups that are subject to discrimination, human rights violations, discrimination based on sexual identity, living in war zones, exposure to natural disasters, and exposure to domestic violence and abuse.

Mental disorders frequently lead to poverty and homelessness. Stigmatization and discrimination may result in restriction of the right to work or obtain an education. In many countries, health insurance coverage or available services for mental problems are less comprehensive than for physical health problems.

Mental health problems are associated with elevated risk of disability and mortality (Sartorius, Holt, & Maj, 2015). Reviews indicate the odds ratio for the effect of depression on all-cause mortality is 1.7 and the relative risk for schizophrenia is 2.59 (Prince, Patel, et al., 2007). Mental disorders are also strongly associated with suicide risk, suicide being the second most common cause of death among young people worldwide.

Comorbidity Mental disorders may affect and in turn be affected by many other diseases. Diseases like cancer, cardiovascular disease, diabetes, and HIV/AIDS are associated with elevated levels of depression and anxiety disorders. Conversely, anxiety and depression predispose people to myocardial infarction and diabetes (see Snook, et al., *infra*). Many risk factors such as low socioeconomic status, alcohol use, cigarette smoking, and stress are common to both mental disorders and noncommunicable diseases.

Mental health problems are discussed in further detail in Chap. 30 by Snoek et al., *infra.* Here we focus on three broad areas of frequent concern in behavioral medicine: depression, anxiety disorders, and schizophrenia.

Depression (World Health Organization, 2016e)

Depression is characterized by sadness or depressed mood and loss of interest or pleasure. Depression should be distinguished from day-to-day emotional responses to challenges in daily living. Moderate to severe depression can result in great suffering and can lead to suicide.

Depression is a common illness worldwide; it accounts for 4.3% of the global burden of disease and is among the largest single causes of disability worldwide at 11% of all years lived with disability globally. It is more common in women. While depression is very common, much of it goes unrecognized, and even when recognized, it may be untreated or inadequately treated. Social stigma associated with depression is a major barrier in treatment.

Diagnosis and Symptoms The cardinal symptoms of depression are a depressed mood with loss of interest, an inability to experience pleasure in normally enjoyable acts (anhedonia), and a reduced energy. In addition to poor self-esteem, guilt and disturbed sleep and appetite are common. Thoughts about self-harm may also occur. The more of these clinical features the patient displays, the more severe depression is judged to be. Anxiety symptoms like irrational worry, fear, and feeling tense often coexist with depression.

It is important to distinguish people with depression who have manic episodes. Bipolar disorder typically consists of both manic and depressive episodes separated by periods of normal mood. Manic episodes involve elevated or irritable mood, hyperactivity, rapid or pressured speech, inflated self-esteem, and a decreased need for sleep with increased energy. Poor judgment may lead to financial or other decisions harmful to the self.

Contributing Factors and Prevention Depression is often caused by the interaction of social, psychological, and biological factors. There are interrelationships between depression and physical health. For example, both cardiovascular disease and type 2 diabetes can lead to depression and vice versa.

Prevention programs can reduce depression. These include community approaches like prevention of child abuse and domestic abuse and/or measures that enhance cognitive, problem-solving, and social skills of children and adolescents (Gladstone, Beardslee, & O'Connor, 2011). Exercise programs also help to prevent or manage depression (Stanton & Reaburn, 2014).

Management Depression can be reliably diagnosed and effectively treated. Treatment options for moderate to severe depression include psychosocial support and psychotherapy, which may include cognitive behavior therapy, interpersonal psychotherapy, or problem-solving treatment. Medications are often beneficial in severe, recurrent depression and should be considered along with psychological treatments.

Suicide and Suicide Prevention According to the WHO (World Health Organization, 2015e), almost 1 million people die from suicide every year, a global mortality rate of 16 per 100,000, or one death every 40 s. Suicide is among the three leading causes of death among those aged 15–44 years in some countries and the second leading cause of death in the 10–24 years age group. In addition to these, suicide attempts are up to 20 times more frequent than completed suicide.

In addition to depression, alcohol use disorders and impulsivity are major risk factors for suicide. Suicide prevention involves multiple strategies (Mann, Apter, & Bertolote, 2005). Managing depression and alcohol and substance abuse effectively as well as follow-up with those who have attempted suicide can reduce suicide rates. Strategies restricting access to common methods of suicide like firearms or pesticides have also been shown to be effective in reducing suicide rates.

As many as two-thirds of those who commit suicide will have had contact with a primary care physician within the previous month. Thus, vigilance by health-care providers to identify vulnerable individuals may be an important preventive strategy (Luoma, Martin, & Pearson, 2002).

Anxiety and Stress-Related Disorders

From the perspective of the evolution of *Homo sapiens*, anxiety is an important adaptive response to a threat (National Institute of Mental Health, 2016b). In many circumstances of contemporary life, however, it can become maladaptive. Features of maladaptive anxiety include the response being disproportionate to the level of threat, persistence or worsening, disruption of normal functioning, or association with appreciable physical symptoms. Such features may become associated with enduring changes in behavior, cognition, and patterns of behavior such as in phobias or other patterns of avoidance or in obsessive or compulsive patterns.

The DSM-5 groups together generalized anxiety disorder, social phobia, specific phobia, and panic disorder in the general category of "anxiety disorders." It distinguishes them from other conditions generally viewed as also related to anxiety and stress, including obsessive-compulsive disorders and post-traumatic stress disorder.

Genetic predispositions contribute to some anxiety and stress disorders, including those characterized by panic, generalized anxiety, or agoraphobia as well as phobias about specific objects, like insects or some animals. Environmental stressors, however, play an important role. Nearly all of the anxiety disorders are affected in some way by external prompts and the way the individual processes or reacts to them.

Diagnosis Patients with anxiety and stress disorders experience emotional distress with troubling thoughts and somatic symptoms that may be accompanied by disturbances of sleep, concentration, or social or occupational functioning. The various disorders, however, differ in presentation and treatment.

In generalized anxiety disorder, the patient experiences consistent worry over multiple areas of his or her life for at least 6 months (National Institute of Mental Health, 2016b).

Panic attacks are characterized by a transient episode of intense fear and a sense of impending doom (e.g., fear of dying, losing control), with accompanying physical symptoms, such as chest pain, dizziness, and shortness of breath. If such acute anxiety episodes occur in predictable response to external stimuli, the disorder is called phobia. Examples include phobia induced by animals, heights, and interpersonal situations (social phobia).

Post-traumatic stress disorder (PTSD) has gained considerable attention in recent years as it has been widely recognized among veterans of combat as well as victims of a number of other traumatic stressors, including sexual violence and discrimination related to ethnic and sexual identity and, especially in community samples, loss of a loved one (Breslau, Kessler, et al., 1998). Additionally, DSM-IV identified acute stress disorder (ASD) as a disorder which also follows a severely stressful event like the near loss of life or limbs. The symptoms of both these conditions are the same and include re-experiencing thoughts and memories including nightmares and flashbacks, avoiding situations that remind the individual of the event and symptoms that increase arousal like irritability, outbursts of anger, irritability, and sleep difficulties (American Psychiatric Association, 1994). PTSD and ASD differ primarily in terms of whether diagnosis is made within or after 4 weeks following an instigating traumatic event, although some controversy surrounds their differentiation (Bryant, Friedman, et al., 2011).

Obsessive-compulsive disorder (OCD) manifests as recurrent obsessions (thoughts and impulses that are difficult to suppress) and compulsions (repetitive behaviors) that serve to reduce anxiety (National Institute of Mental Health, 2016a).

Management Anxiety and stress disorders can often be treated effectively with psychological therapy (National Institute of Mental Health, 2016b). Key strategies include the behavioral and cognitive approaches of encouraging positive behavior, exposure-based interventions that extinguish anxiety responses to feared stimuli, and changing dysfunctional patterns of thinking that often surround anxiety and responses to stimuli that evoke it. Anxiolytic medications and, increasingly, antidepressant drugs are often prescribed in moderate and severe anxiety disorders.

Psychotic Disorders and Schizophrenia

Psychotic disorders are mental disorders in which thoughts and emotions are so impaired that there is a loss of contact with external reality. The prototypical psychotic disorder is schizophrenia, a chronic and severe mental disorder that affects how a person thinks, feels, and behaves (National Institute of Mental Health, 2016a; World Health Organization, 2016g). Manifestations of schizophrenia include hallucinations (false sensory perceptions), delusions (fixed false beliefs), and thought process disturbances. The split referred to in the name, “schizophrenia” (as in “schism”) does not refer to multiple personalities, but an inferred splitting off from reality. Over time, individuals with schizophrenia experience a progressive decline in function marked with apathy, social withdrawal, lack of will or motivation, and blunted affect (lack of emotional expressiveness).

Symptoms of schizophrenia may be characterized as positive or negative. Among the positive are active hallucinations, delusions, thought disturbances, and inappropriate verbal and overt behavior. Among the negative symptoms are withdrawal, flat affect, and diminished feelings or pleasure disturbance. Compared to positive symptoms, negative symptoms have been linked to worse outcomes and poorer functioning (Rabinowitz, Levine, et al., 2012).

Schizophrenia has been estimated to affect between 0.5% and 1% of the world’s population with an onset in late adolescence and early adulthood (Centers for Disease Control and Prevention, 2013a). Onset tends to be later in women. It accounts for more days of hospitalization worldwide than any other health problem. Approximately one-third of individuals with schizophrenia attempt suicide. The exact etiology of schizophrenia is unknown, but it is clearly multifactorial with strong genetic factors interacting with psychosocial and developmental factors (National Institute of Mental Health, 2016b). Heritability includes propensity for a range of related problems referred to as schizophrenia spectrum disorders, schizoid tendencies, or schizo-affective disorder.

As with other chronic conditions, management of schizophrenia focuses on maintaining social roles and quality of life, not cure. Psychosocial programs help patients manage interpersonal stressors and facilitate maintenance of key social roles such as employment. Family interventions (Goldstein, 1992) have been shown to be successful in reducing families’ reactions to their family member with schizophrenia; for example, criticality and emotional overinvolvement are understandable, but nevertheless exacerbate disturbance. These interventions have been shown to reduce hospitalization (Falloon, Boyd, et al., 1982). Programs that provide structured living and work environments may enable those with schizophrenia to live relatively independently and enjoy satisfying lives. Most will require antipsychotic medications especially to treat acute psychotic episodes. However, these medications may have side effects like movement disorders and may contribute to obesity and, thereby, diabetes and cardiovascular disease.

Conclusion

Our understanding of disease and illness over the past decades has included a growing recognition of multifactorial causes including genetic, psychological, and social factors, all of which contribute to our risks of morbidity and mortality. Our lifestyles and behaviors are strongly influenced by the family, community, economic, and physical environments in which we live, and as such these environments contribute substantially to many of the diseases we suffer. As our understanding of disease development has come to recognize the interactions among these many influences, so our understanding of diseases has come to recognize interactions among them. These include the influences of mental health and physical diseases on each other and the fact that, especially among chronic conditions, co-occurrence of several or "comorbidity" is normative.

Behavioral medicine of the future will focus much attention on the interactions among influences and among conditions detailed here. Health, prevention, and health care of the twenty-first century will increasingly recognize the interplay of biology, behavior, and environment in leading to illness and in helping to prevent, cure, and manage it. In these, the behaviors and lifestyles of individuals and groups will play central roles.

Risky Behaviours

3

Carina K. Y. Chan and Shajahan Yasin

Behaviours and Health

Human behaviours play significant roles in health promotion and disease prevention. As discussed in this chapter, the aetiology of many diseases is influenced by a combination of non-modifiable, medical and psychosocial factors, but certain behaviours are highly associated with increased mortality and morbidity. Although physiological predictors are important, many chronic (communicable and noncommunicable) diseases can also be understood in terms of modifiable lifestyle or behavioural risk factors. Undoubtedly, understanding and changing behaviours pose great challenges as they can never be explained by one simple process (e.g. one gene or one virus). Instead, the interplay between biological, psychological, social, organizational and system/policy-related factors within cultural contexts needs to be considered. As some risk factors (e.g. age, family history and race/ethnicity) and health are often unchangeable, strategies that focus on modifying maladaptive behaviours or adopting health-protective ones may be especially effective means for promoting health and preventing diseases.

People in all walks of life engage in various types of behaviours that are directly or indirectly affecting their health status and/or future health outcomes. "Health behaviour" can be defined as any activity undertaken for the purpose of preventing or detecting disease or for improving health and well-being (see Conner & Norman, 1995 for a review). However, it must be noted that although health behaviours do have health implications, individuals are not necessarily driven by health goals when they engage in those behaviours. For example, exercise may be performed for different reasons such as personal enjoyment, social engagement and/or weight management. Health behaviours, in general, can be categorized into two groups: health enhancing or health impairing. Behaviours such as physical activity, healthy dietary intake, weight control, sun protection and cancer screening are health protective and can enhance health or facilitate early detection of diseases. Risky behaviours, by contrast, are any activities that will increase the likelihood of disease onset and injury. More specifically, they are risk factors that can raise the

probability of adverse health outcomes (World Health Organization, 2009a). Behaviours such as sedentary lifestyle, low fruit and vegetable consumption, smoking, excessive alcohol consumption, unsafe sexual practices and non-compliance to medical recommendations are likely to put one at risk of developing future illnesses and/or accelerating disease progression. Intuitively, individuals should opt for health-enhancing rather than health-impairing behaviours; however, the decision to adopt health-enhancing behaviours and quit the risky ones is not always a straightforward process.

As people travel through the lifespan, they face different health risks and problems. As a result, their preventive needs and goals change with age. For example, adolescents have become more sedentary due to increased screen-based behaviours (e.g. television and computer use). Young adults may consume alcohol more often because of the social groups they belong to. Working class individuals may develop unhealthy eating habits due to more convenient access to fast food, and the middle-aged to older populations may not have adhered to their medical regimens and/or regular screening recommendation. Even though people are sometimes fully aware of their risky behaviours, knowledge alone is often insufficient to stop people from doing them. For some chronic diseases, education was found to have only small to moderate effects on disease outcomes and patient empowerment (see Warsi, Wang, et al., 2004 for a review). Moreover, some risky behaviours may be enjoyable and addictive, while the adverse effects of which can be too long delayed to be perceived. All these make behaviour change an even more challenging task.

Rising cost in lives lost and medical costs due to risky lifestyle behaviours have posed health and economic burdens to both developed and developing countries (e.g. Dans, Ng, et al., 2011; Pratt, Macera, Wang, 2000). In 2005, the World Health Organization (WHO) reported that 60% of worldwide deaths are related to noncommunicable diseases such as cardiovascular disease, stroke, cancer, diabetes and chronic respiratory diseases, with over 80% of these deaths occurring in low- and middle-income countries (World Health Organization, 2005). Scientific evidence has shown that some key behavioural determinants and lifestyle factors are related to these health conditions.

Health Risk Behaviours

The WHO identified the leading risk factors for mortality around the globe in 2008. They were high blood pressure (responsible for 13% of world deaths), tobacco use (9%), high blood glucose (6%), physical inactivity (6%), overweight and obesity (5%), high cholesterol (5%), unsafe sex (4%) and alcohol use (4%) (World Health Organization, 2009a). Of these, the four that are not themselves behaviours, high blood pressure, high blood glucose, overweight and obesity and high cholesterol, are nevertheless strongly influenced by diet, physical activity and other risk behaviours (Brown & Siahpush, 2007; Bullen, 2008). The global spread of these health risks is also transiting to low- and middle-income countries where the burden of chronic and noncommunicable diseases may be in multiples of that in high-income ones. For burden of diseases (measured in terms of disability-adjusted life years (DALYs)), the leading risks were underweight (6% of global DALYs), unsafe sex (5%), alcohol use (5%) and unsafe water, sanitation and hygiene (4%), followed closely by high blood pressure (4%) and tobacco use (4%) (World Health Organization, 2009a).

There are unique demographic and geographic patterns in the distribution of these health risks. For example, in many underdeveloped countries, undernutrition continues to be a primary concern related to unhealthy diet. People consume insufficient protein, vitamins and minerals which potentially affect the development of children. Among the developed and developing countries, rising body mass index increases people's risk of developing noncommunicable diseases. The transition of risk factors (e.g. from underweight to obesity) and the double burden of diseases (coexistence of infectious and noncommunicable diseases) in developing countries (e.g. India) highlight more serious health, social and economic implications affecting developing regions (Gupta, Joshi, et al., 2008).

It is critical to understand why some individuals are more exposed to certain health risks and are more vulnerable to developing some kind of diseases than others. The initiation and maintenance of risky behaviours can be attributed to individual health choices, sociocultural values and the environment in which one is situated. The determinants of engaging in these health risk behaviours work at different levels, and some may be more impactful than others for certain subgroups in the population. Besides, some individuals may be more at risk to engage in certain types of behaviours depending on their developmental phases in the lifespan. An ecological approach to understanding the contributions of these factors takes into account the multilevel influence of individual, social, community, organization, environment and policy (Sallis & Owen, 2015).

Figure 3.1 illustrates the ecological model of the determinants of health behaviours across the human lifespan. At an individual level, evidence has demonstrated that health behaviours are underpinned by complex decision-making and goal-setting processes influenced by cognitive, affective and social variables (Ajzen, 1985; Cameron & Leventhal, 2003; Conner & Norman, 2005). In addition, a range of environmental and contextual factors are related to health behaviours in youths (e.g. Brown, Pfeiffer, et al., 2009; De Wit, Stok, et al., 2014; Lawman & Wilson, 2012) and adults (e.g. Giskes, van Lenthe, et al., 2011; Wendel-Vos, Droomers, et al., 2007).

Family influence is powerful especially early in individuals' developmental phases. For children and adolescents, the family plays a primary role in shaping cultural and social values, beliefs and tradition behaviours (DiClemente, Santelli, & Crosby, 2009). This can include transfer of health knowledge, facilitation of adopting healthy habits and discouraging health risk behaviours. Familial support for health behaviours may be social, emotional, tangible or instrumental and may be transmitted through modelling. As people develop through the lifespan, school, community, neighbourhood and workplace also provide additional settings to facilitate the adoption and maintenance of health (risk) behaviours.

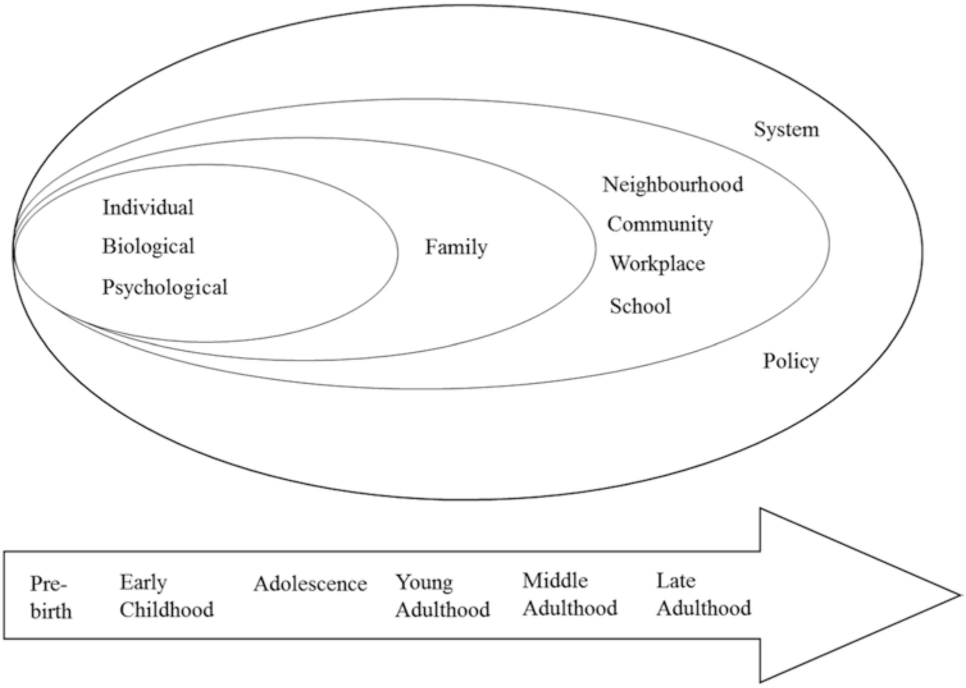

Fig. 3.1 An adapted ecological model of the determinants of health behaviours throughout the life course

Last but not the least, the involvement of the society at a health system or policy level can reduce certain risky behaviours. Policies and health systems can have great impact on whole populations over a long period of time. Policy initiatives can provide directives for investing in relevant and appropriate resources as well as collaborating with public and private stakeholders in supporting individuals to take health-protective actions. These directives and collaborations can foster opportunities (e.g. urban planning with the presence of safe walking trails), facilitate support (e.g. access to affordable healthy food) and provide cues (e.g. economic and labelling disincentives for unhealthy choices) to help people adopt healthy or reduce unhealthy behaviours. Modifying the environment and changing policies may lead to more permanent behaviour change than conducting individual-based health promotion programmes although the time lag between scientific discovery and policy uptake and adoption remains very long. The translation of research evidence to policy and healthcare delivery is particularly important in high-risk populations and resource-poor and developing countries because chronic diseases and health risk behaviours are likely to be more prevalent among these peoples and regions (Chan, Oldenburg, & Viswanath, 2015).

In general, policy approaches can influence behaviours via three major pathways: physical environment and access, economic environment and communication environment (Brownson, Haire-Joshu, & Luke, 2006; Novak & Pelaez, 2004) (see also chapter by Sherlaw et al. in this volume). The orientation of health systems towards preventing and controlling chronic diseases may promote the reduction of risk behaviours. Many healthcare systems have a focus on managing acute health problems such as infectious diseases and maternal and child health. Gradually shifting the healthcare system to address the chronicity of many diseases at this new age is an ongoing challenge but may be a more feasible and sustainable strategy to address the shift in health risks, especially for developing countries (Allotey, Reidpath, et al., 2011; Yasin, Chan, et al., 2012).

Identifying the ecological determinants of risky behaviours at different points in the lifespan is crucial for designing effective intervention strategies. Additionally, understanding the characteristics and distributions of these modifiable risky behaviours can help target specific subgroups in the population who are at greater risk of developing and maintaining unhealthy behaviours.

Table 3.1 summarizes the associations of some common risk behaviours and their diseases.

Table 3.1 Common health risk behaviours and their associations with chronic diseases

	Some common chronic diseases						
Risk factors	CVD	Diabetes	Cancer	Stroke	Chronic respiratory diseases	Hypertension	HIV/AIDS
Overweight/obesity	X	X	X	X		X	
Sedentary behaviour	X	X	X	X		X	
Physical inactivity	X	X	X		X	X	
Elevated cholesterol	X	X	X	X		X	
Low fruit and vegetable intake	X	X	X	X		X	
Energy-dense diet	X	X	X	X		X	
Tobacco use	X	X	X	X	X	X	
Excessive alcohol consumption	X		X	X			
Unsafe sexual practices			X				X
Omission of appropriate medical screening and vaccination		X	X		X	X	

Many health risk behaviours including sedentary and physically inactive lifestyle, unhealthy diet, tobacco and alcohol abuse, unsafe sexual practices and omission of recommended screening and vaccination programmes are preventable and modifiable. They can also be specifically defined to be addressed in health promotion programmes. This chapter describes a sample of these common risky behaviours that are associated with increased burden of diseases across the lifespan. It also reviews risk factors that are closely related to behaviours, such as obesity. The determinants related to the development and maintenance of these behaviours are addressed within various contexts. The multiple levels at which determinants operate will be considered globally using the ecological approach and with reference to different populations.

Gene-environment interactions are important determinants of several behavioural risks, including obesity (Bouchard, 2008; Qi & Cho, 2008), alcohol consumption and tobacco use (Heath, Madden, et al., 2003). These are not covered in the present chapter but are addressed extensively in the chapter on genetics, behaviour and behaviour-genetic interactions by Nater and colleagues (*infra*).

Overweight and Obesity

Although obesity is not, itself, a behaviour, it is so closely related to behaviours and such a growing, worldwide health problem that it deserves inclusion in its own section of a chapter on *risky behaviours*. At its base, obesity is a result of imbalance of energy expenditure and intake over time. When one's energy expenditure cannot compensate with one's energy intake, the gradual positive shift of caloric intake can result in obesity. Among adults, obesity and overweight have been defined through the use of the body mass index (BMI), a measure of weight relative to height (kg/m^2). It is generally recommended that adults maintain their BMI within the range between 18.5 and 24.9. A BMI of 25 or above and 30 or above indicates overweight and obese status, respectively. While this is a general guideline for assessing obesity risk across all age groups of adults and both genders, some adjustment for population differences may be needed to take into account the variability in normative weight and general body-build. For example, individuals who come from cultures of smaller body-built (e.g. Asia) may be overweight even when their BMI has not reached the general guideline. For groups of Chinese origin, BMI values of 24.0 (for men) and 23.0 kg/m^2 (women) have been recommended as cutoffs for obesity (Zeng, He, et al., 2014). A waist-to-hip ratio has been suggested to be more indicative and be more accurate in defining overweight and obesity in Asia. Waist circumference is another measure to identify those at risk by virtue of overweight (men, greater than or equal to 102 cm; women, greater than or equal to 88 cm) (Han, Lean, & Morrison, 1995).

Obesity and Health Outcomes

Energy imbalance, overweight and obesity pose significant health, social and economic burdens to individuals and societies. The burden of overweight and obesity accounts for approximately 10% of direct medical costs of countries globally (Withrow & Alter, 2011). In 2010, overweight and obesity have caused 3.4 million deaths worldwide (Ng, Fleming, et al., 2014), some as a result of chronic conditions associated with overweight and obesity (e.g. diabetes). Elevated BMI has multiple adverse metabolic effects on blood pressure, cholesterol and insulin resistance. The burden of some common chronic conditions can be attributed to overweight and obesity. These include 44% of diabetes, 23% of ischaemic heart disease and between 7 and 14% of certain types of cancer (World Health Organization, 2000, 2009a). Evidence has documented the relationship between obesity and cardiovascular disease (Pérez Pérez, Ybarra Muñoz, et al., 2007) and pancreatic cancer (Michaud, Giovannucci, et al., 2001). Excessive body weight is also a risk factor of osteoarthritis (Grotle, Hagen, et al., 2008) and lower back pain (Shiri, Karppinen, et al., 2010).

Early onset of obesity will have lifelong impact on health and well-being. Consistent evidence has shown that overweight and obesity during childhood and adolescence can lead to premature mortality and physical morbidity such as diabetes, hypertension and ischaemic heart diseases in adulthood (e.g. Reilly & Kelly, 2011). Apart from physical consequences, other adverse psychological and behavioural issues associated with increasing BMI among children include poorer self-esteem (Mirza, Davis, & Yanovski, 2005; Strauss, 2000), lower peer esteem (Mirza, Davis, & Yanovski, 2005), higher levels of sadness and loneliness and development of other risk behaviours, e.g. smoking and alcohol consumption (Strauss, 2000).

Who Is Overweight or Obese?

According to data from the WHO, more than 1.9 billion adults, 18 years and older, were overweight in 2014, among whom 600 million were obese. This amounted to a global adult prevalence of 39% for overweight and 13% for obesity (World Health Organization, 2015b).

The current prevalences of overweight and obesity reflect sharp increases in recent decades. The prevalence of obesity, for example, had nearly doubled between 1980 and 2008 (World Health Organization, 2014f). Similarly, the prevalence of those who were overweight had increased from 29 to 37% for men and from 30 to 38% for women between 1980 and 2013 (Ng, Fleming, et al., 2014). It is estimated that by 2030, the global prevalence of overweight may be 38% and that for obesity may rise to 19.7%. With projected population growth, this would result in 2.16 billion overweight and 1.12 billion obese adults worldwide (Kelly, Yang, et al., 2008).

Overweight and obesity among children have drawn increasing alarm and have become public health concerns worldwide. The global prevalence of overweight and obesity among children had grown from around 5% in 1990 to 7% in 2012 (World Health Organization, 2014f). For 2013, the WHO estimated that 42 million children under the age of 5 were overweight or obese (World Health Organization, 2015b). This rise of infant and childhood obesity is not confined to high-income groups but has been observed in low- and middle-income countries (World Health Organization, 2011b).

There is considerable difference in the distribution of obesity around the globe. Certain groups of people are more likely to be obese than others. According to the World Health Statistics, in 2008, the prevalence of obesity among adults was the highest in the WHO region of the Americas (23.5% for men, 29.7% for women), followed by the WHO region for Europe (20.4% for men, 23.1% for women) and the WHO region for the Eastern Mediterranean (13% for men, 24.5% for women). By contrast, the WHO region for Africa (5.3% for men, 11.1% for women) and WHO region for Western Pacific (5.1% for men, 6.8% for women) had much lower prevalence, with the WHO region for Southeast Asia (1.7% for men, 3.7% for women) the lowest (World Health Organization, 2014f). These regional differences, however, need to be considered in light of the use of Western BMI norms for obesity.

Some clear patterns of gender differences emerged. In the top three WHO regions, over half of the women were overweight, and among the overweight, half were obese. In all WHO regions, women were more likely to be obese than men. For example, teenage Iranian girls showed a higher prevalence of overweight and obesity than boys (Kelishadi, Pour, et al., 2003). Other factors must interact with gender, however, to explain overweight and obesity risk. Among adolescents in the United States, for example, males have been found to have higher intakes of energy and fat, and females are more likely to meet healthy eating recommendations (Xie, Gilliland, et al., 2003).

Obesity was once considered a problem in high-income countries due to economic growth, urbanization and westernization. Indeed, statistics still show that the prevalence of raised BMI increases as a function of countries' income level (Neuman, Finlay, et al., 2011). Although the prevalence may seem low relative to the high- and middle-income countries, among low- and middle-income countries, there is a trend of rapid increase in overweight and obesity prevalence (e.g. in the Middle East, North Africa, Latin

America and the Caribbean) (Popkin & Gordon-Larsen, 2004; Prentice, 2006), upward shift in BMI levels for the overweight and obese and rising waist circumference across age groups (e.g. in China) (Popkin & Slining, 2013). Asia may seemingly have a lower prevalence in overweight and obesity relative to other regions; however, the fast rate of increase and the early onset among younger populations and in those with lower BMI have posed serious concerns (Yoon, Lee, et al., 2006). All these imply that these regions will be hit by more chronic diseases in upcoming years.

Overweight and obesity seem to be unequally distributed within countries with racial/ethnic minorities having the highest obesity risk across different socioeconomic status (SES) groups (Scharoun-Lee, Kaufman, et al., 2009). In the United States, for example, ethnic disparities in BMI and waist circumference are apparent and have become wider between non-Hispanic blacks and non-Hispanic whites (Beydoun & Wang, 2008). This may be explained, in part, by differences in dietary intake among these groups. In the United States, blacks have been found to have the highest intake of energy and total fat (Xie, Gilliland, et al., 2003). Minority populations, especially minority women, are disproportionately affected (Rosenberg, Kipping-Ruane, et al., 2013).

More important than ethnicity, there is a relationship between SES and obesity patterns (Scharoun-Lee, Kaufman, et al., 2009). These relationships are moderated in complex ways, however, by the income level of the country. Within more affluent or industrialized countries, the relationship between obesity and income tends to be inverse. Socioeconomic status (e.g. income, education and occupation) and associated factors such as food insecurity help explain disparities in prevalence of overweight and obesity (Ali & Lindström, 2006). Income is influential in determining dietary intake (e.g. fat, protein, vegetable and carbohydrate and sugar intake) and subsequently body weight. By contrast, within some developing countries such as China and the Philippines, increase in income is associated with higher dietary fat consumption (Popkin & Gordon-Larsen, 2004; Popkin, Paeratakul, et al., 1995). While childhood obesity remains largely a problem of the more affluent low- and middle-income countries, the pattern for adults is somewhat mixed. There is emerging evidence to suggest, however, that the burden of obesity is shifting towards the poor in middle-income countries. In low-income countries, obesity increases with SES for both genders, but this association is mixed for men and is largely inverse for women in middle-income countries (Dinsa, Goryakin, et al., 2012).

Education is another major SES factor associated with diet and obesity. Higher education level is associated with lower body weight in developed countries. For children, parental education is a strong predictor of childhood obesity (Lamerz, Kuepper-Nybelen, et al., 2005). More educated adults and parents are probably more likely to follow dietary recommendations and adopt less risky behaviours than their less educated counterparts. Furthermore, evidence has shown that adolescents from lower SES backgrounds tended to have poorer diets, more fat and refined sugar intake and less consumption of fruits and vegetables (Hanson & Chen, 2007; Xie, Gilliland, et al., 2003).

What Explains Excessive Weight?

The search for biological determinants of obesity has included examination of genetic composition and family history. Scientific advances have suggested some evidence that obesity may be related to genetic defects with several candidate genes identified playing significant roles in its pathogenesis (Boutin & Froguel, 2001). Genetic variations may affect the physiological regulation of hunger, satiety and food intake (Bell, Walley, & Froguel, 2005). Although a biological explanation for the development of obesity seems plausible, the surge in obesity in the past few decades, far more rapid than population genetic shifts can explain, points to the importance of environmental factors and lifestyle changes towards more caloric intake and less energy expenditure.

The two most proximal risk factors for maintaining long-term energy imbalance, overweight and obesity are sedentary lifestyle and/or insufficient physical activity and unhealthy eating habits (particularly the consumption of energy-dense diet). In addition to their impact on obesity, they influence a number of other health conditions. Sedentary lifestyle and fruit and vegetable consumption are discussed in separate sections of this chapter. More general unhealthy eating is discussed in the following.

Determinants of Unhealthy Eating

Sociocultural Factors

For children and youths, the physical and sociocultural environments influence children's eating patterns and diet quality, mostly at the individual and household levels. Physical factors include availability and accessibility of food options and portion sizes. What is readily available at home, easily accessible and ready to be eaten determine children's eating behaviours. Children are also more likely to eat more when larger portion size is offered. Sociocultural factors that are especially relevant for youth's dietary behaviours are primarily parental influence and family processes. More specifically, there are associations among a range of parent, child and family factors, e.g. parental intake with children's fat and soft drink consumption, parent and sibling intakes with adolescents' fat intake, less encouragement and prompts given with energy intake and less parental education with fat intake (see Patrick & Nicklas, 2005; van der Horst, Oenema, et al., 2007 for reviews).

Similarly, parental involvement and family cohesion are associated with eating behaviours (Moore & Harre, 2007). Having a supportive home food environment (e.g. joint meals and communal meals) can facilitate more healthy eating (De Wit, Stok, et al., 2014) and less fast-food intake among young people (Burgess-Champoux, Larson, et al., 2009). Having adolescents involved in food preparation is associated with lower fat intake, less carbonated beverages consumption among girls and lower intakes of fried food among teenage boys (Larson, Story, et al., 2006). The family context may be a good channel to facilitate healthy eating among youth. It is also important to note that the changing role of women may have also adversely affected eating and physical activity patterns which are critical determinants of body weight, especially in developing countries (Martorell, Kettel Khan, et al., 2000).

Built Environment

Studies have shown associations between environmental factors and dietary behaviours (e.g. Giskes, van Lenthe, et al., 2011) in adults. Globalization of food markets has made food very convenient to access. The local food environment can influence food choices easily within communities. Some evidence has suggested that the presence of supermarkets and fast-food stores is related to obesity prevalence in the United States, with lower obesity prevalence in areas having at least one supermarket whereas areas with at least one franchised fast-food restaurant had a higher prevalence (e.g. Morland & Evenson, 2009).

High intake of energy-dense food (e.g. consumption of high-sugar food, sweetened beverages and saturated fat) is a problem in many countries with urbanization and modernization. This shift in eating climate also affects young people much earlier and has implications for early onset of overweight and obesity. Living in an urban environment is related to a range of behavioural patterns that can impact on diet and body weight. The transition to urbanization especially in developing countries also explains the distinct difference in BMI and physical activity between rural and urban residents. For example, the BMI of urban teens in Iran was significantly higher than that of their rural counterparts (Kelishadi, Pour, et al., 2003). In India, the prevalence of obesity was highest for urban population, followed by urban slum and then rural populations among both men and women, with those living in rural reporting higher activity levels (Yadav & Krishnan, 2008). The difference in obesity risk between urban and rural residence may be related to the distinctly different characteristics in the environment, e.g. transportation, food marketing, availability of food, etc.

Similar rural versus urban difference in obesity prevalence, however, may not necessarily exist in other regions, e.g. Europe (Peytremann-

Bridevaux, Faeh, & Santos-Eggimann, 2007). It should be noted that the definition of rural and urban areas can vary between different countries and for many developed countries; residents may not be confined to either urban or rural areas for working and living purposes. Furthermore, access to and the availability of fast food and restaurants, for example, are also reasonably convenient in rural as well as urban districts in developed regions.

Sedentariness and Physical Inactivity

In 2011, physical inactivity was identified as the fourth leading risk factor for global mortality, causing 6% of all deaths (Frank, Andresen, & Schmid, 2004). Sedentary behaviour (typically defined as prolonged sitting) was also seen as an important contributor to the development of many noncommunicable diseases. Sedentary behaviour is defined as any waking activity characterized by an energy expenditure of less than 1.5 metabolic equivalents and a sitting or reclining posture (World Health Organization, 2011b). These may include television watching, computer usage and travelling in vehicles to name a few examples. By contrast, physical activity is "bodily movement that is produced by skeletal muscles which requires energy expenditure" (World Health Organization, 2014d) and can be carried out in various domains such as recreational (e.g. playing sports, gardening), transport (e.g. walking or cycling to school and work), household and occupational (e.g. construction) activities. Sedentary behaviours and physical activity are related to each other, but they are also distinct concepts. Research has shown that sedentariness may not always be associated with physical inactivity and vice versa (Salmon, Owen, et al., 2003).

Physical Inactivity, Sedentariness and Health Outcomes

Physical activity is an essential component of a healthy lifestyle. Research in the past decades has established that regular physical activity is linked to many physical and mental health benefits for males and females of all ages and conditions (Sedentary Behaviour Research Network, 2012). The benefits of regular physical activity vary across individual's health conditions and age. In general, evidence has shown that regular physical activity is associated with reduced risk of all-cause mortality (Gupta, Goel, et al., 2012), longevity (Lee & Paffenbarger, 2000; Paffenbarger & Lee, 1999) and the prevention of several chronic diseases. Physical activity can influence bodily mechanisms via blood lipids, body weight, blood pressure, metabolic changes, glucose tolerance, insulin resistance, immunologic functions and hormonal regulation. Individuals who are more active were found to have lowered risk of type 2 diabetes (Boyle, Keegel, et al., 2012), colon cancers (Hu, Willett, et al., 2004; Myers, Atwood, & Froelicher, 2003), breast cancer (Sesso, Paffenbarger, & Lee, 1998; Thune, Brenn, et al., 1997), pancreatic cancer among those who are overweight (Michaud, Giovannucci, et al., 2001) and prostate cancer (see Warburton, Nicol, & Bredin, 2006 for a review). Besides, there is also evidence to support routine, weight-bearing exercise across all age groups of people for better bone health (e.g. Berard, Bravo, & Gauthier, 1997) and reduction of fall risk among adults (Gregg, Pereira, & Caspersen, 2000).

Physical inactivity, by contrast, increases the risk of many noncommunicable diseases (Lee, Shiroma, et al., 2012) and can be attributed for approximately 21–25% of breast and colon cancers, 27% of diabetes and 30% of ischaemic heart disease (World Health Organization, 2014d). Furthermore, time spent in sedentary activities may result in decreased overall energy expenditure and has been found to associate with weight gain in children and youth (Hu, Manson, et al., 2001) and with overweight and obesity in children (Mitchell, Mattocks, et al., 2009) and adults (Brown & Siahpush, 2007).

While the physical health aspects have been emphasized, there is also compelling evidence to show that physical inactivity is related to mental health and cognitive functioning. Physical activity can help to alleviate stress and fatigue (Proctor, Moore, et al., 2003) and enhance self-confidence, satisfaction and general well-being (Liu, Hu, et al., 2011). Recent evidence suggests that physical activity can counteract depression (Eriksen & Bruusgaard, 2004; Van Uffelen, van Gellecum, et al., 2013), reduce psychological distress (Hassmen, Koivula, & Uutela, 2000; King, Taylor, et al., 1989; Netz, Wu, et al., 2005) and enhance quality of life via positive psychological outcomes such as positive affect, self-efficacy and self-esteem in older populations (Perales, del Pozo-Cruz, & del Pozo-Cruz, 2014). Physical fitness has also been demonstrated to beneficially influence cognitive processing among older adults (Strawbridge, Deleger, et al., 2002). Regular physical activity may also reduce poor cognitive functioning in middle age (Elavsky, McAuley, et al., 2005) and cognitive decline and dementia in the elderly (Colcombe & Kramer, 2003).

Globally, the recommended level of physical activity for adults (18–64 years old) is 150 min of moderate-intensity activity per week or 75 min of vigorous activity per week or an equivalent combination of both. For children and youth under 18 years old, an accumulation of at least 60 min of moderate- to vigorous-intensity activity daily is recommended. Increasing the duration to 300 min of moderate- and 150 min of vigorous-intensity activity is suggested to have additional health benefits for adults (Singh-Manoux, Hillsdon, et al., 2005). Accumulating even short bouts (10-min bouts, three times per day) of moderate physical activity throughout the day can produce similar training effects as those of a single, longer (30-min) bout (World Health Organization, 2010).

Who Is (In)active?

In 2010, the global prevalence of physical inactivity (fewer than five instances of 30 min of moderate activity per week or fewer than three instances of 20 min of vigorous activity per week) among adults 18 years old or above is estimated to be 23% (20% men and 27% women) (World Health Organization, 2015a). Physical activity level varies across the human lifespan, but in general, it decreases with age and during adulthood. Physical inactivity is also more prevalent in older adults. While one might expect that children and adolescents are in the developmental phase where they have the most amount of energy and are usually highly active (e.g. in sports and other general activities), statistics have shown alarming evidence that many young people are living a predominantly sedentary lifestyle. About 81% of schoolgoing adolescents are physically inactive (World Health Organization, 2015a), and sedentary behaviour has been found to increase during puberty (Brodersen, Steptoe, et al., 2007; van Sluijs, Page, et al., 2010). Approximately 34% of young people spend more than 2 h watching TV per day (Marshall, Gorely, & Biddle, 2006). In general, young people between 2 and 18 years old spend 2–4 h on screen-based activities and 5–10 h sedentary daily (Salmon, Tremblay, et al., 2011). For adults, the median reported sitting time per day was around 5 h in a 20-country international study. Adults between 18 and 39 years old and with post-school education had higher sitting times (Bauman, Ainsworth, et al., 2011). Over 40% of men and women watched two or more hours of television each day (Clark, Sugiyama, et al., 2010).

The prevalence of regular physical activity also differs across several demographic characteristics. Overall, participation in physical activity decreases as people grow older (King, Castro, et al., 2000; van Stralen, De Vries, et al., 2009), with women experiencing greater decline in older age groups than men (Brownson, Boehmer, & Luke, 2005). Gender is a consistent demographic correlate of physical inactivity. This difference is more distinct in earlier than later stages in the lifespan. Male youths are less inactive than their female counterparts (Brodersen, Steptoe, et al., 2007; Caspersen, Pereira, & Curran, 2000; Sallis, Prochaska, & Taylor, 2000; Telama & Yang, 2000). In general, women and girls tend to be less active than men and boys (e.g. Caspersen, Pereira, & Curran, 2000; Moore & Harre, 2007; Trost, Owen, et al., 2002). Women are also more inactive than men in adulthood (Dumith, Hallal, et al., 2011; World Health Organization, 2002, 2006) with young women being slightly less active than middle-aged women (World Health Organization, 2015a). Middle-aged (45–64 years) and older-aged (65 years or above) people are more sedentary than their younger counterparts (25–44 years) (Clark, Sugiyama, et al., 2010).

Some ethnic groups are also more sedentary than others. Among students in the United Kingdom, for example, Asians are less active than whites and blacks are more sedentary than whites (Brodersen, Steptoe, et al., 2007). However, when geographic regions are compared, adolescents in the WHO Southeast Asia regions show lower prevalence of insufficient physical activity (74%) than those in the WHO East Mediterranean (88%), African (85%) and Western Pacific regions (85%) (World Health Organization, 2015a). Differences in activity levels also exist among countries of varying economic development (Dumith, Hallal, et al., 2011). In high-income countries, the prevalence of physical inactivity (41% men and 48% women) has doubled that in low-income countries (18% men and 21% women) (World Health Organization, 2015a).

Determinants of Sedentary and Inactive Behaviours

Apart from demographic factors, other correlates that explain physical activity generally include psychological and sociocultural factors, behavioural attributes and skills and the physical environment (Ford, Merritt, et al., 1991). In general, there has been a decline in work-related, transportation and home activities and increase in sedentary activity (see Bauman, Sallis, et al., 2002 for a review). The determinants summarized below can work alone or in combination with one another to explain activity levels.

Sociocultural Factors

Disparities in activity level exist between people of different socioeconomic status (SES) (Gidlow, Johnston, et al., 2006). Low SES is consistently found to be associated with less physical activity, among adolescents (Hanson & Chen, 2007; Stalsberg & Pedersen, 2010) and adults (King, Castro, et al., 2000; Trost, Owen, et al., 2002). Similarly, sedentariness also increases with low SES (Clark, Sugiyama, et al., 2010; van Sluijs, Page, et al., 2010). Furthermore, women of low SES and ethnic minority seem to have reported less activity (Caspersen & Merritt, 1992; Caspersen, Merritt, et al., 1990; Caspersen, Pereira, & Curran, 2000; Telama & Young, 2000). Some evidence has suggested that those coming from lower socioeconomic groups are less likely to use recreational facilities even if they have access to them, and they tend to perceive their environment as not very supportive for physical activity (Giles-Corti & Donovan, 2002). It is also likely that the disadvantaged group may have weaker social cohesion in the neighbourhood or friends with whom they can engage in activities. This may also partly explain the education inequalities in television viewing (Owen, Sugiyama, et al., 2011; Teychenne, Ball, & Salmon, 2012). Furthermore, the relationship between SES and physical activity may be dependent on the type of physical activity in developing countries (Bauman, Ma, et al., 2011); e.g. higher education and affluence are associated with more leisure-time activity, but less activity at work.

Social support has been suggested to be a consistent positive factor that is associated with physical activity for both adults and youths (see Bauman, Sallis, et al., 2002; Panter & Jones, 2010; Sallis, Prochaska, & Taylor, 2000; Sterdt, Liersch, & Walter, 2014; Trost, Owen, et al., 2002 for reviews). The range of social support may include physician's influence, support from friends and peers and support from spouse and family. For children, parental influence is quite instrumental for different types of activities including leisure-time physical activity and overall activity level through direct involvement, encouragement and modelling (Edwardson & Gorely, 2010). For youth in particular, peers and praise (Beets, Vogel, et al., 2006) and having fun with friends (Humbert, Chad, et al., 2008) affect activity levels. To encourage young people to be active, integrating different types of activities and having variety in the programmes are preferred (Humbert, Chad, et al., 2008). Encouraging children and youth to be active school commuters is associated with more physical activity (Faulkner, Buliung, et al., 2009). Parental influence is less clear, but parents' attitude, encouragement and transport are important determinants of activity (Edwardson & Gorely, 2010). Parental behaviours also correlate with television viewing, which is an important indicator of sedentary behaviour (Salmon, Tremblay, et al., 2011).

Environmental Factors

Industrialization has led many to join an urbanized and sedentary workforce. The overwhelming rise in technology use implies that screen-based activities have become a core part of most people's lives from young to old. Advances in technology have reduced daily physical activity substantially. The appeal of television and electronic games and the rising use of screen-based devices for study, work and recreation have substantially increased sedentary time among many adults and children. The built environment plays a big role in facilitating active and/or promoting sedentary behaviours (Giles-Corti & Donovan, 2002; Humpel, Owen, & Leslie, 2002; Panter & Jones, 2010; Sallis, Bowles, et al., 2009; Sterdt, Liersch, & Walter, 2014), and its characteristics can be understood in the following domains: availability/accessibility, infrastructure, safety and aesthetics (Brownson, Hoehner, et al., 2009; Humpel, Owen, & Leslie, 2002).

Living environments built to support physical activity are more likely to increase activity level. Having facilities available and accessible in the built environment is one of the important elements of a supportive environment (Bauman, Reis, et al., 2012). This applies to both the domestic environment and the larger neighbourhood. At home, evidence has shown relationships between home equipment and physical activity (Humpel, Owen, & Leslie, 2002). At work, employees' working occupations that demand long work hours and whose job nature requires low occupational physical activity are at risk of inactivity (Kirk & Rhodes, 2011).

In a study of 11 countries of broad geographic and socio-political diversity, neighbourhood characteristics associated with meeting physical activity guidelines included the presence of sidewalks and bicycle facilities, having shops and transit stops near home and the availability of low-cost recreation (Sallis, Bowles, et al., 2009). In fact, these attributes in the built environment can facilitate a few different domains (e.g. transportation, recreation) of physical activity and especially walking. Having convenient access to physical activity opportunities (e.g. close to their living area, good transportation facilities) has also been found to be important to increase activity levels in youths (Humbert, Chad, et al., 2008). The relationship between neighbourhood walkability and sedentary behaviour, however, seems inconsistent. People living in environments with lower levels of walkability have also reported more television viewing (Owen, Sugiyama, et al., 2011). On the contrary, others have found the opposite with high-walkable neighbourhood associated with higher levels of sedentary time (Van Dyck, Cardon, et al., 2010). Other additional factors may be interacting with the individual and/or the environment to affect sitting time.

While designing environments to support physical activity is an emerging international public health agenda, there are still very distinct differences between some developed and developing countries. For example, developed countries such as the Netherlands, Denmark, Australia and New Zealand have cities and roads planned to accommodate cyclists, and hence, active travel is more prevalent. By contrast, for developing countries such as Malaysia and India, similar built facilities may not be a national priority, and with high incidence of traffic accidents and injuries, this mode of physical activity is probably not encouraged, and hence, these behaviours are much less prevalent.

There is evidence to suggest that some safety-related attributes (e.g. light traffic, safe neighbourhood) in the environment are related to activity level (Casagrande, Whitt-Glover, et al., 2009; Humpel, Owen, & Leslie, 2002; Trost, Owen, et al., 2002). However, the relationship is shown to be weaker than the attributes described above (see Humpel, Owen, & Leslie, 2002 for a review). More recently, evidence of a relationship between neighbourhood safety and active travel has been mixed (Panter & Jones, 2010), and this could be due to the difference in interpretation and perception of safety which may vary between a minor (e.g. unstable weather, wetland, unattended dogs) to major concerns (e.g. crime rate in the area, busy roads and traffic). Some of these safety factors may be more significant in developing countries, e.g. Malaysia and India. Neighbourhood aesthetics are also important. Perceived neighbourhood characteristics such as pleasant scenery (e.g. connected to parks, beaches and/or nature) and attractive local areas are associated with activity level or walking. However, association between the actual quality of natural features in the neighbourhood and activity was not confirmed (Humpel, Owen, & Leslie, 2002; Panter & Jones, 2010).

Low Fruit and Vegetable Intake

Diet affects the physiology in our body including blood pressure, cholesterol level, blood glucose and body mass. A healthy diet is generally rich in fruits, vegetables, whole grains and fibre and low in saturated fats, sugar and sodium. The World Health Organization (2003) recommends a daily consumption of at least five servings of fruits and vegetables and fat that is less than 30% of total dietary energy with less than 10% from saturated fat and 1% from *trans* fat.

Low Fruit and Vegetable Consumption and Health Outcomes

Low fruit and vegetable consumption is an important risk factor for chronic diseases. In 2008, about 1.7 million (2.8%) of deaths are attributed to low consumption of fruits and vegetables globally (World Health Organization, 2009a). Approximately, 14% of gastrointestinal cancer death, 11% of ischaemic heart disease death and 9% of stroke death were attributable to an insufficient consumption of fruits and vegetables. Diet high in fat and/or sugar intake, resulting in low fruit and vegetable consumption, is associated with oral cancer (World Health Organization, 2009a). Fruits and vegetables play protective roles in preventing cancer (Block, Patterson, & Subar, 1992), stroke and coronary heart disease (Ness & Powles, 1997). Increasing the consumption of green leafy vegetables also reduces the risk of type 2 diabetes (Carter, Gray, et al., 2010), cancers (Boeing, Bechthold, et al., 2012; Lock, Pomerleau, et al., 2005) and heart disease and stroke (Lock, Pomerleau, et al., 2005).

Who Is at Risk?

Fruit and vegetable intake varies substantially among countries in different geographic regions as it depends a great deal on cultural, agricultural and economic environments. Although there is an increase in fruit and vegetable production worldwide, inadequate consumption remains. In the United States, between 1994 and 2005, the proportion of men and women eating fruits and/or vegetables five or more times per day was around 20 and 30%, respectively (Michels Blanck, Gillespie, et al., 2008). In 2011, only 8.2% of Australian adults had met the guidelines. The prevalence of inadequate fruit and vegetable intake has increased over time ranging from 47% (fruit) and 86% (vegetable) in 2001 to 52% (fruit) and 92% (vegetable) in 2012 (Heart Foundation, 2012). The prevalence of inadequate intake is also high among children and young people (Cooke, Wardle, et al., 2004; Kimmons, Gillespie, et al., 2009). Data on developing countries are very scarce. A World Health Survey conducted with 52 mainly low- and middle-income countries revealed that 77% of men and 78% of women consumed less than the minimum recommended level of fruits and vegetables in 2002–2003 (Hall, Moore, et al., 2009). The low fruit and vegetable consumption prevalence ranged from 37% (Ghana) to 99% (Pakistan). Other countries with high prevalence of low intake were China, Nepal, Ecuador and Mauritania.

Significant gender differences in the likelihood of low fruit and vegetable intake were reported, with males more likely to report low intakes in developed countries (Kimmons, Gillespie, et al., 2009; Story, Neumark-Sztainer, et al., 1998). In the United States, it was found that girls were more likely to meet the recommendations of fruit and vegetable intake, whereas boys had higher intakes of added sugar (Kelishadi, Pour, et al., 2003). Similar evidence has suggested that boys ate vegetables less frequently than girls in the United Kingdom and New Zealand (Cooke, Wardle, et al., 2004; Moore & Harre, 2007).

Determinants of Fruit and Vegetable Intake

Dietary behaviours can be explained by individual differences and sociocultural factors. The environment also plays a unique role in promoting and hindering healthy eating. Food choices are largely related to ecological factors in addition to personal preferences. Research has shown that healthy food choices are more likely to be facilitated and sustained if the environment provides availability and convenient access to these options (see Kamphuis, Giskes, et al., 2006 for a review).

Socioeconomic Status (SES)

There appears to be a SES gradient with respect to fruit and vegetable intake. Overall, consumption increases with increasing SES (Hall, Moore, et al., 2009; Hanson & Chen, 2007). Low SES was associated with poorer diets, i.e. inadequate consumption of fruits and vegetables and more fat and refined sugar intake (Petti, 2009). Some racial and ethnic minority groups are at greater risk (Cooke, Wardle, et al., 2004; Story, Neumark-Sztainer, et al., 1998). These observations may be explained partly by the availability, selection and accessibility of fresh fruits and vegetables at food stores in communities of different SES. Evidence has demonstrated that poorer quality of fresh produce and fewer grocery stores were present in communities of ethnic minority and low SES, suggesting a possible pathway of the disparities on this health risk behaviour (Zenk, Schulz, et al., 2006).

Sociocultural Norms

As noted in the discussion of unhealthy eating, the family is highly influential. Having regular family meals (Burgess-Champoux, Larson, et al., 2009), authoritative parenting style, parental modelling and peer normative beliefs (Cullen, Baranowski, et al., 2001) have been found to be associated with more fruit and vegetable consumption in children and adolescents.

Sociocultural norms include religious beliefs, especially among religions that emphasize particular dietary patterns. For example, Buddhism and Hinduism teach believers not to harm and encourage vegetarian diet, and Seventh-Day Adventists follow strict dietary guidelines and are mostly vegetarians. Religiosity can be understood in terms of believers' attachment to particular religions and adherence to specific teaching. Evidence has also shown that people who report higher religiosity and spirituality consume more fruits and vegetables (see Tan, Chan, & Reidpath, 2013 for a review). A religious neighbourhood can act, in part, like a community. Being affiliated with a strong religious community that discourages unhealthy eating may have neighbourhood effects on the believers' dietary qualities (Tan, Chan, & Reidpath, 2014).

Preferences, Availability and Accessibility

Socio-environmental factors can promote and inhibit healthy food intake. For youth, home availability of fruits and vegetables and taste preference are suggested to have direct associations with fruit and vegetable consumption for adolescent populations (Hanson & Chen, 2007; van der Horst, Oenema, et al., 2007). Determinants of home availability included social support for healthy eating, family meal patterns, family food security and socioeconomic status. The availability of fruits and vegetables at home is a powerful determinant of intake, predicting more consumption even when taste preferences are low. When availability was low, however, taste preference did not make a difference in intake among a group of adolescents in Minnesota (Ransdell & Wells, 1998). Similarly, the school food environment has also been shown to shape dietary behaviours. Having snack vending machines in schools is associated with lower daily consumption of fruit (Kubik, Lytle, et al., 2003).

At a population level, (un)healthy food choices depend, to a great extent, on the type of food stores and restaurants present in the neighbourhood. Evidence has shown that eating behaviours differ across neighbourhoods with different accessibility to grocery stores and supermarkets. The presence of supermarkets is related to more fruit and vegetable consumption by residents (Morland, Wing, & Roux, 2002) and meeting fruit and vegetable recommendations (Casagrande, Whitt-Glover, et al., 2009).

Tobacco Use

Since the beginning of the twentieth century, tobacco use has been rising steadily with the introduction of cigarette manufacturing. With the expansion of worldwide population, it is estimated that there are 1 billion smokers around the world (World Health Organization, 2014e). Tobacco smoking is a leading risk for mortality and contributes to an extremely heavy economic burden to societies and is undoubtedly a public health issue. The consumption of cigarettes has reached global epidemic proportions with an estimation of over 15 billion cigarettes smoked daily worldwide. The top five countries where the most number of cigarettes are consumed are China, the United States, Japan, Russia and Indonesia (World Lung Foundation, 2015). The following section will discuss tobacco use in the form of smoking and exposure to second-hand smoke.

Smoking and Health Outcomes

Tobacco kills approximately 6 million people each year. The WHO estimated that by 2020, 7.5 million will die from both direct tobacco use and second-hand smoke, accounting for almost 10% of global deaths with many deaths occurring prematurely (World Health Organization, 2011b). Almost one in eight deaths of adults over the age of 30 is due to smoking (Giskes, Kamphuis, et al., 2007). Tobacco smoke contains hundreds of dangerous substances including tar, nicotine and carbon monoxide. Adverse health effects of smoking are not limited to the smokers themselves, but also non-smokers who are exposed to passive smoking. Research has shown that cigarette smoking dramatically increases the risk of cancer (e.g. lung, oral and pharyngeal, pancreatic, colon and cervical) (World Health Organization, 2009a), chronic bronchitis and respiratory diseases, cardiovascular disease (Petti, 2009), cardiovascular disease and stroke (Bullen, 2008; Shah & Cole, 2010), chronic pancreatitis (Alexandre, Pandol, et al., 2011), osteoporosis (Ward & Klesges, 2001) and fracture (Kanis, Johnell, et al., 2005). It was estimated that tobacco smoking alone was responsible for 71% of lung cancer deaths around the world with 18% coming from high-income countries (Shah & Cole, 2010). Furthermore, attention should also be put on the high prevalence (about one-third of adults globally) of exposure to second-hand tobacco smoke among adults and children (World Health Organization, 2009b). Around 1% of worldwide mortality can be attributed to exposure to second-hand smoke (Öberg, Jaakkola, et al., 2011).

Who Smokes?

Globally, it is estimated that there are over 1 billion smokers and an estimated consumption of 6 trillion cigarettes annually (World Health Organization, 2011b) with 80% of these smokers living in low- and middle-income countries. Although there has been a decline in the prevalence of cigarette smoking in recent decades in some developed countries, the overwhelming majority of smokers begin tobacco use before they reach adulthood. In 2011, the global smoking prevalence among adults at the age of 15 or above was 36% for males and 8% for females. Between 2006 and 2012, the prevalence of current tobacco use among adolescents aged 13 to 15 years old was 20% for males and 10% for females worldwide (World Health Organization, 2009a). Older adolescents (15 years) are more likely to use tobacco than younger (13 years old) ones (World Health Organization, 2014f).

Boys are more likely to smoke than girls, and this gender difference is more distinct in some countries. In Cyprus, Nepal and Sri Lanka, for example, smoking is less common among girls (Christophi, Savvides, et al., 2009; Kabir & Goh, 2014). In general, men smoke more than women. In some regions, men are 10 (Southeast Asia region) to 15 (Western Pacific region) times more likely to be smokers than women (World Health Organization, 2011b). In some individual countries, including China and India, the gender gap is even greater (World Health Organization, 2011a). Cultural orientation of individual countries may explain distinct gender difference. The gender gap has narrowed substantially in recent times, especially in developed countries. Countries with a Western cultural orientation (e.g. the United States, the United Kingdom and New Zealand) have higher female smoking prevalence than other countries (Tyas & Pederson, 1998).

Smoking prevalence also varies across WHO regions, with the highest in the European region (29%) and lowest in the African region (8%). Although smoking prevalence is highest among upper-middle-income countries (World Health Organization, 2011b), low- and middle-income countries are where the burden of tobacco-related illness and death is heaviest (World Health Organization, 2014e).

Determinants of Tobacco Use

The determinants for tobacco use are multidimensional, and they include a combination of individual, sociocultural and environmental factors throughout the lifespan. This section focuses on the sociocultural precursors and environmental correlates associated with the initiation and maintenance of this risky behaviour.

Modelling and Social Learning

Parents, grandparents, siblings, peers, teachers and friends are likely to be the source of modelling smoking behaviours of young people. Peers' tobacco use is the most powerful determinant among youth smoking (Christophi, Savvides, et al., 2009; Peters, Wiefferink, et al., 2009; Tyas & Pederson, 1998). Parents and grandparents who smoke are also strong predictors of the likelihood of smoking among youth (Christophi, Savvides, et al., 2009; Peters, Wiefferink, et al., 2009) as is the sight of smokers at home and in public (Abraham & Sheeran, 2000). Exposure to smokers is also likely to influence individuals' attitudes and perception of social norms, especially among youths. Parental involvement (Harakeh, Scholte, et al., 2005), two-parent family (Tyas & Pederson, 1998) and parenting style (Tyas & Pederson, 1998; Wang, Ho, et al., 2015) have been suggested to be protective factors of youth smoking. Additional evidence has identified maternal care, control and authoritative (as opposed to authoritarian) parenting as associated with lower likelihood of adolescent smoking in Hong Kong (Wang, Ho, et al., 2015).

Socioeconomic Status and Education

Socioeconomic status (SES) and education are reliable determinants of smoking prevalence, smoking initiation and cessation (see Hiscock, Bauld, et al., 2012 for a review). In general, it has been suggested that low SES is associated with greater cigarette smoking (Hanson & Chen, 2007). The socioeconomic inequality also exists in low- and middle-income countries, and there is a differential relationship between SES and smoking for men and women. For men, smoking is disproportionately prevalent in the poor, whereas for women, the poorest and the richest are the most likely to smoke (Hosseinpoor, Parker, et al., 2012).

As might be expected, higher education and higher income are associated with better knowledge of smoking. Among some developed countries, evidence has shown that lower socioeconomic status is associated with lower awareness of smoking harms and nicotine misunderstanding (Siahpush, McNeill, et al., 2006). Furthermore, education is related to smoking frequency (Allison, Adlaf, et al., 1999), suggesting that disadvantaged groups may be more at risk. Some evidence has shown that those who had not completed high school were over three times more likely to smoke daily compared to their post-secondary counterparts in Canada (Allison et al., 1999). For youths, having parents with lower education increases the odds for smoking (Christophi, Savvides, et al., 2009). School curriculum and knowledge about the adverse effects that smoking can bring have been found to influence adolescents' attitudes and tobacco use (Kabir & Goh, 2014). Raising awareness and providing health information are important precursors for helping people make informed decision.

Marketing, Advertising, Accessibility and Availability of Cigarettes

Environmental factors beyond the family also affect the susceptibility to cigarette smoking. Strong evidence has shown tobacco marketing and advertising to be strong predictors of smoking initiation among adolescents. Those who are receptive to tobacco advertisement are more susceptible to smoke. This finding is consistent for students in both developed (Evans, Farkas, et al., 1995; Henriksen, Feighery, et al., 2004) and developing countries (Saito, Yasuoka, et al., 2013). Similarly, the density of retail cigarette advertising in school neighbourhood is also found to be related to high school smoking prevalence (Henriksen, Feighery, et al., 2008). Other evidence has also supported the effect of tobacco marketing on progression to established smoking (Biener & Siegel, 2000), with antismoking advertising having more positive effects on those in preadolescence and early adolescence by preventing smoking initiation (Wakefield, Flay, et al., 2003).

Access to and availability of cigarettes are highly significant predictors of smoking behaviour among youth (Tyas & Pederson, 1998; Woodruff, Candelaria, et al., 2003). The likelihood of smoking among adolescents is higher when the ease of buying cigarettes from a store increases (Christophi, Savvides, et al., 2009) or when they can have easy access at home (Woodruff, Candelaria, et al., 2003). The density of tobacco retailers near school areas is associated with students' access behaviours. The more the retailers, the more likely smokers were to buy their own cigarettes (Harakeh, Scholte, et al., 2005).

Policy and Society Influence

Legislation and policy change are influential determinants of behaviour, and this is evident in the case of smoking. In the past decades, the implementation of policies banning workplace smoking has witnessed a change in tobacco use among employees. More specifically, there has been a decline in cigarette consumptions or smoking prevalence in some developed countries, e.g. Australia, Canada, Germany and the United States (e.g. Brownson, Hopkins, & Wakefield, 2002; Chapman, Borland, et al., 1999; Fichtenberg & Glantz, 2002; Kabir & Goh, 2014; Sorensen, Barbeau, et al., 2004). This kind of environmental intervention not only reduces the frequency of smoking among smokers but also protects non-smokers from second-hand smoke. Similar efforts in developing countries are growing, but data on their enforcement and effectiveness are limited.

Tobacco taxes and cigarette prices are other system-level determinants of smoking. Increasing taxes has seen reduction in tobacco use, and raising cigarette prices can also reduce overall consumption (Brownson, Hopkins, & Wakefield, 2002; Chaloupka, Cummings, et al., 2002). These effects are likely to be stronger among those who are especially sensitive to the price of cigarettes such as youth and, in low- and middle-income countries, adults (Jha, 2009). However, most tax levy studies have been conducted in developed countries. Similar evidence in developing countries is very often unavailable. In particular, for countries where regulatory and enforcement capacity is low, policies may take time to be fully implemented, and they may be complicated by political and economic constraints. Furthermore, the implementation of health policies (e.g. taxation) in developing countries can sometimes be in competition with other political, economic and cultural conditions that should be taken into consideration.

Alcohol Consumption

Alcohol is a psychoactive substance that is commonly used as part of the modern lifestyle and is deemed a normative behaviour in some social contexts. In most Western cultures, alcohol beverage is an integral part of many occasional and communal events such as celebration of success, wedding, birthday and casual enjoyment. The majority of individuals in developed nations normally begin alcohol consumption some time during adolescence and young adulthood. However, excessive or hazardous alcohol consumption is a health risk factor and can lead to damaging or fatal consequences.

Health Impacts of Alcohol

Although some evidence suggests that some consumption can decrease the risk of coronary heart disease, stroke and diabetes (Corrao, Rubbiati, et al., 2000), heavy and prolonged drinking has been implicated in behavioural, social and health problems. In fact, harmful use of alcohol can become a serious public health burden and a cause to health inequalities (Beaglehole & Bonita, 2009). The harms associated with alcohol use very often outweigh its benefits, and the modest benefits are seemingly only applicable to a small segment of the populations (Jackson, Broad, et al., 2005). In 2012, about 5.9% of global deaths were attributed to alcohol use, and around 3.3 million people die from harmful use of alcohol each year (World Health Organization, 2014b). Heavy alcohol consumption can have adverse health and social effects on drinkers via three main pathways: (1) toxic effects on organs and tissues, (2) intoxication leading to cognitive and motor impairment, and (3) dependence. Both acute intoxication and chronic excessive drinking can have adverse effects on the brain, central nervous and muscular system, liver, heart and gastrointestinal system (Shield, Parry, & Rehm, 2013). Hepatic cirrhosis, cancer, injuries and alcohol dependence (Shield, Parry, & Rehm, 2013) are major consequences of harmful alcohol use which can have impacts beyond the individual. The alcohol-related burden of diseases is also much heavier for poor populations or lower-income countries.

In the age between 20 and 39 years old, about 25% of total deaths can be attributed to alcohol. Evidence from case-control studies has suggested that the risk of injury increases with increased alcohol consumption, with female being more at risk of injury (McLeod, Stockwell, et al., 1999). Not only does the quantity of drinking affect health, the pattern of drinking is also highly relevant to health outcomes. Approximately 20% of deaths in motor vehicle accidents can be attributed to excessive alcohol consumption, and very often the cases are due to heavy episodic drinking, also referred to as binge drinking (World Health Organization, 2014b). Teen alcohol use is also related to other health risk behaviours such as risky sexual behaviour and associated sexually transmitted diseases.

Distribution of Alcohol Consumption

The total volume and pattern of alcohol consumption are indicators of risky drinking behaviour. There is substantial variation in alcohol consumption across regions. According to the World Health Organization, developed and high-income countries have the most alcohol consumption. Globally, individuals above 15 years old drink on average 6.2 litres of pure alcohol per year. In 2010, the adult per capita consumption of alcohol was highest in the European region and lowest in the Eastern Mediterranean region (World Health Organization, 2014b). It is projected up until 2025 that alcohol consumption is expected to continue to increase. However, it is important to note that high consumption does not always equate to high alcohol-related problems.

There is a clear gender difference in drinking behaviour. Men drink more and tend to have more alcohol-related problems than women (Kerr-Corrêa, Igami, et al., 2007; Nolen-Hoeksema, 2004). In 2010, the average total alcohol per capita consumption was 21.2 litres and 8.9 litres for men and women, respectively. Women are more often lifetime abstainers than men (Wilsnack, Vogeltanz, et al., 2000). The difference may be explained, in part, by the differences in body composition and different rates of alcohol metabolism. In addition, social habits, customs and cultural expectation can also influence alcohol use in men and women. Age also influences alcohol consumption. Heavy drinking is more prevalent among young adults (Jackson, Sher, & Park, 2005) probably due to the change in social contexts associated with this stage of development. Among young adults between 20 and 24 years old, males were 2.4 times more likely than females to consume alcohol heavily (Allison, Adlaf, et al., 1999). About 11.5% of drinkers have heavy episodic drinking patterns (World Health Organization, 2014b).

The WHO European region and WHO region of the Americas have the highest proportions of current drinkers among adolescents, while the WHO Southeast Asia region and WHO Eastern Mediterranean region have the lowest. Heavy drinking rates are also highest among adolescents in the WHO European region but more prevalent in older age groups in the Southeast Asia region. The distribution of the levels and patterns of alcohol consumption can also be understood in terms of economic wealth. The prevalence of current drinkers and episodic heavy drinking is highest in high-income countries. Conversely, the number of abstainers decreases with economic wealth (World Health Organization, 2014b).

Determinants of Alcohol Consumption

Sociocultural Factors

Similar to smoking, research has consistently found that familial factors and peers play a critical role in predicting both youth and adult drinking (Jessor, Donnovan, & Costa, 1991; Weitzman, Folkman, et al., 2003). Peers are salient and available models especially during adolescence and young adulthood. The presence of peer drinkers contributes to high-risk alcohol use by direct influence, modelling and perceived norms (Borsari & Carey, 2001). Longitudinal studies have also supported the association between peer drinkers and subsequent alcohol use among adolescents (Leung, Toumbourou, & Hemphill, 2014). Furthermore, drinking with friends and the presence at an event of others who are intoxicated have been found to predict heavy episodic drinking among university students (Clapp & Shillington, 2001).

Parental influence plays a role in shaping attitudes towards and beliefs about drinking among youth (Borsari, Murphy, & Barnett, 2007). Living with parents appears to be protective against binge drinking (Bartoli, Carretta, et al., 2014), suggesting that parental control or the family environment may play a role in reducing this risky behaviour. The presence of family members at drinking events was also protective against heavy episodic drinking (Clapp & Shillington, 2001).

Socioeconomic status has complicated associations with drinking status, volume and patterns. People from lower SES tend to drink heavier, whereas those from higher SES drink more frequently (Grittner, Kuntsche, et al., 2013; Huckle, You, & Casswell, 2010), but SES does not always explain differences in alcohol-related consequences. However, some evidence has suggested that people with lower SES may be more vulnerable to alcohol-related problems (Grittner, Kuntsche, et al., 2012) which may be partially related to a lack of resources and access to care and supportive networks (World Health Organization, 2014b).

Contextual factors such as culture, religion and legal consequences are important determinants of abstention and drinking behaviours. In some countries, e.g. Brunei, Iran and Saudi Arabia, there can be serious legal consequences for drinking due to local laws and regulations. Other countries prohibit drinking among some subgroups in the populations due to social, cultural and/or religious norms (e.g. Muslims in Malaysia). Religion strongly predicts abstention (Michalak, Trocki, & Bond, 2007). Denominations such as the Seventh-Day Adventists, Mormons and Muslims prohibit alcohol, and drinking is therefore scarce among these religious groups.

Environmental Factors

The physical, economic and communication environments are all influential determinants of drinking behaviours. The built environment that has high density of alcohol outlets is found to be associated with the intensity and frequency of drinking (Weitzman, Folkman, et al., 2003). Alcohol promotional activity is associated with alcohol consumption among young people. Non-drinkers being exposed to alcohol advertising activities were more likely to become drinkers. Advertising also increased the likelihood of drinking for drinkers and non-drinkers (Smith & Foxcroft, 2009). Policies that regulate the environment are effective in reducing harm caused by alcohol. Interventions that address alcohol consumption through its pricing and availability, enforcement of legislation related to drinking-and-driving, increasing taxes and banning alcohol advertising have been identified as cost-effective means to reduce alcohol-related harm (Anderson, Chisholm, & Fuhr, 2009).

Risky Sexual Behaviours

Risky sexual behaviours contribute substantially to the burden of sexually transmitted infections (STIs) and the deadly human immunodeficiency virus (HIV). The predominant mode of transmission of HIV is sexual; however, there are other channels (e.g. sharing contaminated needles, receiving unsafe injections/blood transfusions, experiencing accidental needlestick injuries) through which HIV can be transmitted. Risky sexual behaviours can be defined as any sexual activity that increases the likelihood of contracting HIV or STIs or becoming pregnant. They often involve early initiation of sexual intercourse, unprotected sexual intercourse, inconsistent use of condoms (Taylor-Seehafer & Rew, 2000) and having multiple (and sometimes anonymous) sex partners. Early sexual experience is a risk as early initiation is more likely to be non-consensual, less likely to be protected against pregnancy and infection and predictive of a greater number of lifetime sexual partners (Wellings, Collumbien, et al., 2006). Each year there are about 333 million new cases of STIs worldwide with the highest rates in young adults (between 20 and 24 years old) and older adolescents (15 and 19 years old). At the end of 2013, there were approximately 35 million people living with HIV, 2.1 million of whom were newly infected (World Health Organization, 2014c).

Risky Sexual Behaviours and Health Consequences

Risky sexual behaviours are predictors of teenage pregnancy, serious sexually transmitted diseases and infections, e.g. HIV and human papillomavirus (HPV), which are also responsible for chronic diseases such as AIDS and cervical cancer, respectively (Danaei, Vander Hoorn, et al., 2005). In 2013, it was estimated that 1.5 million deaths were due to HIV/AIDS globally with over 1 million deaths in the WHO region of Africa (World Health Organization, 2014a). HIV targets the immune system, weakening the patients' defence systems against infections. Gradually, the virus impairs the immune functioning of the body, and individuals eventually become immunodeficient and are susceptible to infections and diseases that normal healthy immune systems can fight off (World Health Organization, 2014c). STIs are a major global cause of acute illness, infertility, long-term disability and death in men, women and infants. Over 30 bacterial and viral pathogens have been identified that can be transmitted sexually. The four common curable STIs are *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *syphilis* and *Trichomonas vaginalis* (World Health Organization, 2012).

Who Is at Risk?

Global data show that diversity in sexual behaviours and the prevalence of different risky sexual behaviours vary hugely among countries and by age and gender. Risky sexual behaviours may also be exacerbated at different stages of development (e.g. adolescence) and developmental vulnerabilities.

In general, sexual activity begins in late adolescence (15–19 years old), but there is enormous variability in this, and the trend seems to be shifting towards younger age. Across different samples, between 1 and 30% of men had their first sexual intercourse before the age of 15 and between 0.2 and 46% for women (Wellings, Collumbien, et al., 2006). Huge variation exists across regions. The age at which women have their first sexual experience is also dependent on the normative age of marriage in different countries, while the same may not be true for men (Wellings, Collumbien, et al., 2006). The trend of later marriage has been observed in many countries. This has increased premarital sexual relationships and the number of sexual partners. This is, however, more prevalent among industrialized countries than developing countries.

Among unmarried youth, between 29 and 63% of adolescent boys have had sexual experience in most countries, as compared to between 1 and 63% among adolescent girls. More boys than girls reported having two or more sexual partners in the previous year (Wellings, Collumbien, et al., 2006). For developed countries, the proportions of young men and women with sexual experience were fairly similar, about 46–59%.

Certain groups of people are more vulnerable than others, and they include sex workers, men who have sex with men and who have multiple sexual partners, bisexual men, women or men who experience sexual violence and children and young people who have been abused (World Health Organization, 2007). Evidence linking sexual activity with ethnicity has been mixed (Kotchick, Shaffer, et al., 2001).

Condom use is a key indicator of safe sex practice. National surveys in developed countries showed that condom use has increased over time and that its use by young people has also increased substantially in developed countries (Wellings, Collumbien, et al., 2006) and developing countries (Cleland & Ali, 2006). This increase is offset, however, by an increased number of sexual partners, which is another risk factor of sexual health (Clark, 2004; Johnson, Mercer, et al., 2001). In general, it is more common in men than in women to have had more than two sexual partners in the previous year, with reported rates higher in developed than in developing countries (Wellings, Collumbien, et al., 2006).

Determinants of Risky Sexual Behaviours

Broad social and environmental determinants contribute to risky sexual behaviours and interact with each other and individual characteristics to predict sexual health risk.

The family influences and shapes sexual values, sex roles and expected sexual behaviours, especially among youth. Some family structures and processes have been found to be protective against risky sexual behaviour. Parents play an important role in communicating sex-related topics, and evidence has suggested that gender-specific parenting plays a role in predicting risky sexual behaviours in adolescents. Parental monitoring has been found to be more protective against risky sexual behaviours for boys than girls, whereas parental warmth and emotional connections are more important for girls (Kincaid, Jones, et al., 2012).

Socioeconomic status in terms of family income and education has been found to correlate with initiation of sexual intercourse and teenage pregnancy, but no clear consistent relationships were reported between these SES indicators and consistency of condom use and number of sex partners (e.g. Santelli, Lowry, et al., 2000). It is probable that such relationships depend on other contextual variations, e.g. perception of the partner (Green, Fulop, & Kocsis, 2000), meaning of the relationship (Gebhardt, Kuyper, & Greunsven, 2003) and gender stereotypes (Marston & King, 2006).

Cultural norms associated with gender roles can also shape sexual behaviour patterns. Gender differences and relative power in sexual relationships (Matser, Heiligenberg, et al., 2014; Tschann, Adler, et al., 2002) as well as gender stereotypes (Tschann, Adler, et al., 2002) can influence the negotiation process of safe sex practice. Influences of gender role expectations and cultural norms can be quite complex. In sub-Saharan Africa, for example, married women found negotiation for safe sex practice more difficult than single women (Lagarde, Pison, & Enel, 1996), and lower condom use was prevalent among married couples (Clark, 2004).

The kind of relationship between the partners matters when understanding condom use (Marston & King, 2006; Parsons, Halkitis, et al., 2000). Partnership factors such as steadiness and duration of the relationship (Gebhardt, Kuyper, & Greunsven, 2003), perceived risk presented by sexual partner (Chapman, Borland, et al., 1999) and perceptions of benefits and costs (Green, Fulop, & Kocsis, 2000; Marston & King, 2006) are associated with inconsistent condom use. Men who use the Internet to look for sex partners are more likely to have unprotected sex (Liau, Millett, & Marks, 2006).

Religion and religious teaching often shape attitudes and normative beliefs of sexual behaviours. Some relationships exist between religiosity and sexual behaviours, attitudes towards sex and self-efficacy to negotiate safe sex. Evidence has demonstrated that high religiosity is associated with lower likelihood of engaging in sexual intercourse among adolescents (Kotchick, Shaffer, et al., 2001), later sex initiation, more condom use (Zaleski & Schiaffino, 2000) and greater likelihood of refusing unsafe sexual encounters among female adolescents (McCree, Wingood, et al., 2003). The association between religiosity and sexual behaviours, however, is stronger for adolescent females than males (Rostosky, Wilcox, et al., 2004).

Nonadherence to Recommended Cancer Screening and Vaccination Guidelines

Screening for disease and vaccinations are preventive behaviours of increasing importance as understanding of diseases and biological approaches to their prevention, early detection and treatment increase. The elimination of polio and smallpox during the twentieth century, for example, is a major public health victory directly attributable to biological discoveries but also to behavioural and public health campaigns to disseminate and implement the vaccines resulting from those discoveries. Childhood immunization and flu vaccination are common and successful strategies for improving public health (e.g. Colditz, Brewer, et al., 1994; Jordan, Connock, et al., 2006; Nichol, Lind, et al., 1995). At the same time, considerable controversy surrounds the use and promotion of screening in many areas. Here, we focus on several cancers for which there is strong evidence both regarding the value of screening and vaccination and evidence regarding the prevalence and factors influencing dissemination of screening and vaccination.

A considerable proportion of cancer burden can be prevented by early detection and treatment (Palli, del Turco, et al., 1986; Smith, 2014; World Health Organization, 2008). To date, prevention efforts worldwide have focused on cancers that are more prevalent and would have higher successes in the treatment and prognosis should they be detected earlier. Many developed countries have also issued cancer screening guidelines and practices or implemented national screening programmes targeting at-risk groups (e.g. Smith, Cokkinides, & Eyre, 2007). According to GLOBOCAN for 2008, breast cancer is the leading cause of cancer death in women (Ferlay, Shin, et al., 2010; Jemal, Bray, et al., 2011). Cervical cancer is also one of the common causes of cancer death for women in developing countries. While screening is one of the secondary preventive measures for cervical cancer, it is also preventable through vaccination against human papillomavirus (HPV) infection. This section discusses in more detail two common cancer screening behaviours (screening women via mammography for breast cancer and screening sexually active women using cytology smears for precancerous lesions) and an immunization behaviour (HPV vaccination).

A mammogram is an X-ray picture of the breast used to check for breast cancer (e.g. lumps or breast abnormality) in women who may have no signs or symptoms. Early detection of breast cancer symptoms means that treatment can be initiated earlier in the course of the disease and sometimes may prevent cancer spread. Mammography screening has been associated with a decline in (e.g. Andersson & Janzon, 1997) and risk reduction of (e.g. Palli, del Turco, et al., 1986) breast cancer. There was a reduced mortality among women between 40 and 74 years old, particularly for those over 50 years old (B. H. Marcus, Forsyth, et al., 2000). While there is evidence to show a reduced cancer mortality of 15%, the magnitude of this effect remains uncertain, and there is also a chance of overdiagnosis (Gøtzsche & Jørgensen, 2013).

A cervical smear test (the Papanicolaou smear, also known as Pap smear) is a screening test to detect abnormal changes in the cells of the cervix and human papillomavirus (HPV), which is responsible for over 99% of cervical cancer worldwide (Walboomers, Jacobs, et al., 1999). Evidence has shown associations between HPV testing and reduction in the number of advanced cervical cancers and deaths (Sankaranarayanan, Nene, et al., 2009). National screening programmes have been implemented in developed countries such as Australia, New Zealand and the United States. However, there are still substantial proportions of women who are nonadherent to the recommended screening guidelines, in particular, among women in developing countries (Sankaranarayanan, Budukh, & Rajkumar, 2001). In the last decade, the discovery, development and testing of the HPV vaccine have made the prevention of cervical cancer even more promising. The HPV vaccine approved for use in females aged between 9 and 26 years old was first introduced in 2006. The vaccine provides protection against infection of four types of HPV which are responsible for approximately 70% of all cervical cancers (Cutts, Franceschi, et al., 2007), HPV infections (Backes, Kurman, et al., 2009) and genital lesions in males (Giuliano, Palefsky, et al., 2011).

Who Does Not Screen or Vaccinate?

Prevalence data of cancer screening are more readily available among countries with screening programmes in place. In the United States, for example, 58% of women above 40 years old reported having had a mammogram in the last year, while 85% of adult women (above 18 years old) reported having had a Pap test in the preceding 3 years prior to 2004 (Smith, Cokkinides, & Eyre, 2007). In general, people of lower SES, lower education and ethnic minority are more likely to report inadequate screening (Claeys, Gonzalez, et al., 2002; Hsia, Kemper, et al., 2000; Kuitto, Pickel, et al., 2010). However, the reverse was true for HPV vaccine uptake. Those who are younger and with lower educational attainment and SES are more adherent (Brewer & Fazekas, 2007; Kuitto, Pickel, et al., 2010).

Other socio-demographic predictors have been associated with nonadherence. For example, unmarried women are less likely to report participation in mammography screening (Euler-Chelpin, Olsen, et al., 2008; Hsia, Kemper, et al., 2000), and ethnic minority groups are less likely to follow mammography and Pap test guidelines (Hsia, Kemper, et al., 2000; Williams-Brennan, Gastaldo, et al., 2012) and initiate and complete HPV vaccine doses (Kessels, Marshall, et al., 2012; Laz, Rahman, & Berenson, 2012). However, interactions between ethnic minority and other contextual variables (e.g. physician supply, rural and urban areas) have also been found (Coughlin, Leadbetter, et al., 2008). In developing countries specifically, women are very often uninformed, and their relatively lower education may have disempowered them to access healthcare or perform health-seeking behaviours (e.g. Denny, Quinn, & Sankaranarayanan, 2006).

Determinants of Nonadherence

Individual Factors

People's knowledge determines their awareness of cancers and related screening and vaccination issues (Kessels, Marshall, et al., 2012). In general, levels of knowledge about HPV, Pap test and cervical cancer in women have been poor, and this is worse for men (Klug, Hukelmann, & Blettner, 2008; Zimet, Liddon, et al., 2006). Unsurprisingly, knowledge is more inadequate among those in developing countries (Mutyaba, Mmiro, & Weiderpass, 2006; Wellensiek, Moodley, et al., 2002) and among minority groups (Gerend & Shepherd, 2011). Consistent evidence has suggested that individual's emotions and health cognitions can promote or inhibit cancer screening behaviours. Fear, anxiety and worry are the three most frequently reported emotions to predict screening (Consedine, Magai, et al., 2004), while perceived risk is the psychological and cognitive variable that has been found to affect individual's adherence to screening guidelines (Katapodi, Lee, et al., 2004; Vernon, 1999). Other individual psychosocial factors found to be associated with screening and vaccination acceptability and behaviours include perceived susceptibility, perceived benefits and barriers (Marlow, Waller, et al., 2009), perceived effectiveness (Brewer & Fazekas, 2007), cancer worry (Jung, Chan, & Viswanath, 2014) and exposure to mass media (Marcus & Crane, 1998).

Sociocultural Factors

Familial influence is an important determinant of screening and vaccination behaviours. For adolescents, parental awareness (Laz, Rahman, & Berenson, 2012), parental perception and perceived implication of sexual activities are associated with HPV vaccination (Brewer & Fazekas, 2007; Zimet, Liddon, et al., 2006). Family history of cancer influences the likelihood of following cancer screening guidelines (Hsia, Kemper, et al., 2000), and the absence of medical problems (Grosse Frie, Ramadas, et al., 2013) generally predicts inadequate screening.

Cultural and religious factors may interfere with or enhance protective and detective actions. Different cultural myths play significant roles in shaping cognitions among immigrants (Johnson, Mues, et al., 2008; Marlow, Waller, et al., 2009). Cultural norms, social values and implications of screening and vaccination (Williams-Brennan, Gastaldo, et al., 2012) are some of the predictors of nonadherence, especially among women in low- and middle-income countries. Religion has also emerged as a significant predictor, with Muslim or Hindu/Sikh females being less likely to accept HPV vaccination (Marlow, Waller, et al., 2009). Developing culturally appropriate education materials may be the way forward to enhance knowledge about cancer and screening guidelines (Farmer, Reddick, et al., 2007) and to narrow potential disparities in vaccine receipt in ethnic and religious groups.

Health Systems/Policy

The lack of resources and infrastructure in the health systems is one of the greatest barriers to screening and immunization in most developing countries (Denny, Quinn, & Sankaranarayanan, 2006). Healthcare systems in these countries generally emphasize acute health problems and are likely to have limited human and financial resources to target health risk behaviours associated with more chronic illness. In low-resource settings, the protocol used and logistics involved with screening and vaccination are likely to deviate from those used in more developed regions. For example, screening and vaccination sites need to be accessible to at-risk population to allow wide coverage. Screening needs to be of low cost and utilize low technology to provide prompt treatment of abnormalities (Denny, Quinn, & Sankaranarayanan, 2006).

Health insurance and the cost involved are key determinants to shape people's screening and vaccination intention and actual behaviours. Individuals without access to health insurance are less likely to comply with screening recommendations (Coughlin, Leadbetter, et al., 2008; Hsia, Kemper, et al., 2000; Sambamoorthi & McAlpine, 2003). The affordability of screening tests and accessibility to screening facilities have been suggested to be important determinants of screening behaviours (Bazargan, Bazargan, Bazargan, et al., 2004; Claeys, Gonzalez, et al., 2002; Williams-Brennan, Gastaldo, et al., 2012). New vaccines (e.g. for HPV infection) are usually more expensive and often more limited in developing countries than in developed ones. Hence, the relatively high cost to get vaccinated poses an extra burden in the developing world and may predict lower uptake (Kane, Sherris, et al., 2006).

Other Key Health Behaviours

In addition to those reviewed here, there are numerous other behaviours that have important influences on health. These include stress and stress management (see chapter by Siegrist, *infra*), adherence to treatments (Burke and colleagues, *infra*), satisfying relationships and social support (Uchino and colleagues, *infra*) and important areas of life that may not be thought of as health behaviours but which, nevertheless, have important impacts on health, such as work, recreation and relaxation, parenting and education (Sherlaw and colleagues, *infra*). Clearly, behaviour is not only a major contributor to health but a major component of it.

Summary

Health behaviours play critical roles in preventing a wide number of diseases and promoting long-term health. While the majority of infectious diseases can be prevented by practising good hygiene at the public health and individual levels, most common noncommunicable diseases require multiple health behaviour change for effective prevention and control.

This chapter has reviewed a selection of some major behavioural risks that contribute to the onset and maintenance of diseases, highlighting the specific subgroups of individuals by demographics and regions that are more susceptible to engaging in these risky behaviours. A combination of the health risk behaviours presented in this chapter is likely to accelerate the pace at which the chronic disease epidemic is emerging, specifically in developing countries. Identifying and understanding the distribution of these risk factors can help identify particular "at-risk" groups for health promotion "behaviour change" intervention. Compelling evidence has shown that the determinants of risky behaviours are multidimensional at multiple levels, and sometimes, they interact with individual differences on behavioural skills, health cognitions and motivation.

The risky behaviours described above do share some common ecological determinants at multiple levels. Physical, economic, political and sociocultural changes are important environmental factors to facilitate positive outcomes of behaviour change. One may ask how we can cure the environment to combat the high prevalence of risky behaviours. The built environment can provide opportunities for healthy and unhealthy choices, e.g. accessibility of food options, facilities and urban planning for physical activity. The costs associated with health risk behaviours is the major economic factor. Making healthy choices affordable is particularly relevant for bridging inequality in some behaviours. The same applies to making unhealthy choices more costly. The political environment is responsible for setting rules and regulations that may influence the adoption or cessation of health risk behaviours. However, the time lag between research discovery and translation to policy change and practice has been substantial. Smoking bans in public places and workplaces and nutrition and food marketing regulations have all taken many years to be implemented in real-life settings after research evidence became available. In the meantime, some of the determinants discussed in this chapter can be managed through individual and community actions. If risky behaviours could be discouraged through intervening at a greater number of ecological levels, the number of deaths and disabilities resulting from common preventable diseases could be greatly reduced.

Behavioral Medicine: Who Does It and Where

4

Justin M. Nash

Behavior is a determinant in health and illness, affecting morbidity and mortality, disparities in health and care, medical errors, patient safety, primary care shortage, and physician discontent and burnout (Association of American Medical Colleges, 2011). Preventing and managing costly chronic disease depends heavily on reducing smoking and improving diet and exercise (McGinnis, Williams-Russo, & Knickman, 2002; Mokdad, Marks, et al., 2005). Behavioral medicine is increasingly being recognized as an important part of the solution to improving health-care problems by enhancing health and wellness, better explaining disease etiology, improving adherence rates to existing treatments, and contributing to the development of new interventions (Office of Behavioral and Social Sciences, 2007). Principles of behavioral medicine are also relevant for health professionals to understand and manage their own emotions, stress, and competing demands while staying empathically connected with those they serve.

Individuals with expertise in behavioral medicine are being called upon to meet the growing demand to incorporate more behavioral and social science in health-related research and practice. Clinicians, educators, and researchers in health-related areas, both today and in the future, are in need of developing behavioral medicine knowledge and skills (Allan, Barwick, et al., 2004). Unfortunately, there is an insufficient number of capable faculty in medical schools and other health professional training programs to integrate behavioral and social science content into the curricula (Association of American Medical Colleges, 2011).

This chapter reports how behavioral medicine and its training are occurring in some key disciplines and professions that are involved in addressing complex health problems. Two fields, psychology and public health, have been instrumental in the development of behavioral medicine and have behavioral medicine built into the fabric of their disciplines. They are at the forefront of helping to infuse behavioral medicine principles and practices throughout health-related areas. Other health fields, including medicine, nursing, pharmacy, and dentistry, are increasingly incorporating behavioral medicine into some combination of their education and training, practice, and research.

The scope and variety of behavioral medicine and of the disciplines and contexts through which it is studied and applied make a chapter such as this a substantial challenge. This challenge is greatly magnified by the ways the disciplines and

E. B. Fisher (ed.), *Principles and Concepts of Behavioral Medicine*,
https://doi.org/10.1007/978-0-387-93826-4_4

settings of behavioral medicine also vary around the world. The framework of the chapter is primarily from the USA, but it is hoped that the inclusion of examples from other countries will help in the identification of principles and perspectives applicable worldwide.

Roots and Foundation of Behavioral Medicine

In 1977, behavioral medicine began to formally take hold in the USA when its definition was developed at the Yale Conference on Behavioral Medicine (Schwartz & Weiss, 1978). Within a year, both the Society of Behavioral Medicine and the *Journal of Behavioral Medicine* were created (Belar, 2008). At the time, relevant publications were coming out in the USA stressing the importance of health promotion and behavior, including the 1979 US Department of Health, Education, and Welfare report *Healthy People: The Surgeon General's Report on Health Promotion and Disease Prevention* and the 1982 Institute of Medicine report *Health and Behavior: Frontiers of Research in the Biobehavioral Sciences.* As a result, training programs specializing in behavioral medicine grew in number, while other health-related disciplines and professions began incorporating behavioral medicine training in their curricula. Internationally, the first International Congress of Behavioral Medicine was held in Uppsala, Sweden, in 1990, and the *International Journal of Behavioral Medicine* began publication in 1994.

The foundation of behavioral medicine rests upon and within a number of academic disciplines. Behavioral medicine is built not only on contributions from psychology and public health but also from anthropology, sociology, economics, communication, education, political science, social work, and, more recently, informatics. The unique and overlapping contributions of each discipline combine to create the interdisciplinary behavioral medicine endeavor, standing apart from while at the same time remaining inextricably part of its disciplinary origins.

Understanding behavioral medicine may fit with what the philosopher Gilbert Ryle (2009) describes as a category mistake: conceptualizing the category as something other than the elements that comprise it. In Ryle's example, a visitor to Oxford University who indicates appreciation of seeing the Bodleian Library, New College, Magdalen College, St. Catherine's College, and the Ashmolean Museum but then asks, "where is Oxford?" is committing the category error. The university, Oxford, is the libraries, the colleges, museums, etc. that comprise it, not something apart from them. In a similar way, behavioral medicine is a broad category that is made up of the work of health-care professionals such as dentists, epidemiologists, nurses, physicians, psychologists, public health professionals, and social workers. There is no "thing" of behavioral medicine apart from that work, but, as this chapter is intended to document, the breadth, excitement, and potential benefit of all that work – all that behavioral medicine – are great indeed.

Behavioral Medicine in Research

Behavioral medicine approaches that are used in the health professions are empirically derived and supported through research. A great number of academicians, from basic scientists to policy specialists and from many disciplines, have developed the principles, theories, and interventions used to modify behavior to improve health. The contributions from basic research to its application are illustrated in the work of one of the founders of behavioral medicine and one of its current leaders. Neil Miller, PhD, an eminent psychologist and founding member of the Academy of Behavioral Medicine Research, made important early conceptual and research contributions to the application of learning theory to complex human behavior (Dollard & Miller, 1950) and then extended that work to learned control over autonomic psychophysical processes. His groundbreaking laboratory research was applied by him and others to work in minimizing stress, treating disease, and promoting health (Miller, 1983). Edward Taub, PhD, then collaborated with Dr. Miller (Taub, Crago, et al., 1994) to develop constraint-induced movement therapy to promote neuroplastic changes in the brain that enhance motor recovery following stroke, traumatic brain injury, cerebral palsy in young children, multiple sclerosis, and other neurological injuries (Taub, Uswatte, & Mark, 2014).

Behavioral medicine research is increasingly being incorporated into larger research initiatives as the importance of behavior in health and illness is recognized internationally and in the USA. In the USA, the role of behavior is reflected in funding from the National Institutes of Health (NIH) and other agencies (e.g., Patient-Centered Outcomes Research Institute, Robert Wood Johnson Foundation, Agency for Healthcare Research and Quality). The National Institutes of Health in 2003 charted the "Roadmap for Medical Research" in the twenty-first century that recognizes the convergence of the biomedical and the socio-behavioral-cultural views of health and illness. The road map stimulated new ways of combining skills and disciplines in the physical, biological, and social sciences. Scientists extended beyond their individual disciplines to (a) more multilevel research from molecular biochemistry to individual behavior to social policy, (b) interdisciplinary research occurring in teams, and (c) patient-centered and relevant outcomes research. Other funding agencies similarly encouraged multilevel and interdisciplinary research including the behavioral determinants of morbidity and mortality, patient safety, and medical error reduction. Internationally, WHO calls for a stronger commitment to a multidisciplinary approach to research, including in the area of adherence, which is considered the primary determinant of treatment success (Sabaté, 2003).

Behavioral Medicine in the Health Professions

Behavioral medicine permeates many disciplines, professions, settings, roles, and activities in health. Behavioral medicine can occur as part of widely varying roles and activities, across different settings, and can be part of numerous professions. Those who engage in behavioral medicine activities do so in teaching, research, clinical, policy, or administrative capacities. Behavioral medicine professionals can conduct research, teach students, educate the public, intervene with individuals with chronic conditions, treat patients in clinics and hospitals, deliver community-based health program, or perform some other role.

The work can be conducted in academic institutions (e.g., teaching and research), community organizations (health, school), hospitals and clinics, fitness and wellness centers, businesses (e.g., employee health risk appraisal and health promotion), and government and nongovernment agencies, among other settings. Embracing the breadth of "cells to society," the target populations can involve the society or specific communities (e.g., health policy), patients in clinics and hospitals, individuals who are at risk (e.g., unsafe sex), children in schools or young adults in colleges, and healthy individuals (disease prevention), among others. The health-related issues addressed by those in behavioral medicine also vary widely but generally relate to the impact of behavior on health. The issues targeted can include disease prevention, physical and emotional health and well-being, sexual health, substance abuse prevention and management, physical activity engagement, addressing mental illness in patients with chronic disease, and nutrition and eating issues.

Describing a single model of the professional who does behavioral medicine is not possible. Few professionals identify themselves as doing behavioral medicine – they typically identify themselves within an established discipline or profession. For example, they do psychology, public health, nursing, or some other health-related professional work. Irrespective of their professional identity, there are some whose professional activities are primarily behavioral medicine in nature, while there are others who engage in behavioral medicine activities but in a more limited capacity. For example, a researcher may identify as a psychologist, or epidemiologist, or medical anthropologist, but the setting, role, and activities are primarily behavioral medicine in nature. Specialists in behavioral medicine, whose training and activities are focused on behavioral medicine, can come from a number of professions (e.g., anthropology researcher). Psychology, public health, and medicine are prominent among these.

An example of someone with more limited engagement in behavioral medicine is a nurse in an elementary school setting who is asked to help develop and implement a 6-month health promotion initiative to help students understand healthier food choices and identify opportunities for physical activity enhancement. In contrast to the behavioral medicine researcher, the school nurse's professional identity, setting, role, and activities are not specific to behavioral medicine. Behavioral medicine plays an important yet relatively limited role for the school nurse. Examples of professions in which the work involves behavioral medicine but not as the primary role can include medicine, nursing, dentistry, and pharmacy.

Given the broad range of professions and disciplines in behavioral medicine, describing the role of behavioral medicine in many of them is beyond the scope of a single chapter. Here, of necessity, is a selective describing of how psychology, public health, medicine, nursing, dentistry, and pharmacy incorporate and contribute to behavioral medicine.

Psychology

Psychology, as the science of behavior, has been instrumental in the formation of behavioral medicine and remains one of its core professions and disciplines. Psychologists continue to represent over 50% of the 2300 members of the US Society of Behavioral Medicine. Within psychology, the specialty of health psychology, with its focus on the promotion of health and prevention and management of disease, is most aligned with the objectives of behavioral medicine. The Society for Health Psychology, a division of the American Psychological Association (APA) currently has over 3500 members. In Europe, there is a separate organization of health psychologists, the European Health Psychology Society, with over 550 members.

William Schofield's landmark report in 1969 to the APA on "The Role of Psychology in the Delivery of Health Services" (Schofield, 1969) helped develop the eventual specialty of health psychology, as well as the formalization of behavioral medicine. In a 10-year span beginning in 1975, much occurred in the creation of health psychology. Two years before the 1977 Yale Conference on Behavioral Medicine, the Section on Health Research was created in the APA Division of Public Service. The Health Psychology Division of APA was subsequently formed within a year of the Yale Conference, and the journal *Health Psychology* was first published in 1982. The European Health Psychology Society was established in 1986 after an expert gathering in Tilburg, the Netherlands, and the Society's journal, *Psychology and Health*, began publishing a year later.

Training in health psychology was defined in 1983 at the Arden House National Working Conference on Education and Training in Health Psychology (Stone, 1983). At that time, a number of training programs in health psychology were developing at the doctoral, internship, and postdoctoral levels. As of 2015, the Association of Postdoctoral and Internship Centers website lists 423 internship programs providing supervised experience in health (behavioral medicine)-related areas.

Psychologists involved in behavioral medicine conduct research, professional practice, education and training, and advocacy across an array of community and health-care settings. As experts in human behavior, psychologists are grounded in psychological science and integrate knowledge from other areas such as biology, sociology, and public health as appropriate. Psychologists conducting behavioral medicine in health-care settings can engage in promoting health and preventing illness, addressing the needs of people with medical illness, assisting in stress and coping, and facilitating recovery, rehabilitation, and adjustment of health-related concerns (American Psychological Association, 2014). Common health issues addressed by psychologists include stress, adherence to medical regimens, pain, cardiovascular disease, cancer, tobacco and other substance use, eating and weight control, and physical activity (American Psychological Association, 2014). Psychologists in health-care settings can also contribute their behavioral medicine expertise in roles such as training and supervision, consultation, program development and evaluation, quality improvement, leadership and team coaching, and outcome evaluation (Belar, 2014; Nash, Khatri, et al., 2013; Nash, McKay, et al., 2012). Behavioral medicine psychologists often collaborate and sit on interprofessional teams with colleagues from medicine, nursing, sociology, anthropology, epidemiology, psychiatry, physical therapy, and public health. In the academic realm, psychologists are often at the forefront with their colleagues from other disciplines in developing theories and related interventions that are used by professionals in health-care settings to promote health and manage disease.

Public Health

Public health has long emphasized health of populations and especially prevention, as opposed to individual-level explanations or interventions. Sociology, political science, and health economics have always fit into public health and its training. Within these emphases, health education developed within public health but often with more of an emphasis on community health education and prevention than on the perspectives of psychology. To the extent it has focused on individual behavior, psychology and other behavioral sciences have lagged in their integration into public health (Schneiderman & Speers, 2001). Toward the end of the twentieth century, however, two conferences were held that marked a critical juncture in the role of behavioral and social science in public health (Coreil, 2009). The first, *Public Health in the 21st Century: Behavioral and Social Science Contributions*, was cosponsored by the US Centers for Disease Control and Prevention, the American Psychological Association, and other social science organizations and held in 1998. The second conference, *Towards Higher Levels of Analysis: Progress and Promise in Research on Social and Cultural Dimensions of Health*, was held in 2000 and organized by the National Institutes of Health. The theme in these meetings was the recognition that (a) knowledge about biological and genetic markers is important but limited in predicting who gets sick, who seeks treatment for health problems, and who recovers from illness and (b) behavioral and social sciences contribute to filling these gaps in our understanding of health. The relevance of behavioral and social science in public health has also increased as public health has expanded into new arenas of social welfare (including primary care services), reproductive health, child and family protection, injury prevention, and the health consequences of natural disasters, war, and political violence.

The social and behavioral sciences in public health address the behavioral, social, and cultural factors related to individual and population health and health disparities over the life course. More specifically, behavioral scientists provide insight into behavioral change occurring at different levels of analyses, and social scientists contribute to understanding organizational structure at the community level, including the utilization of community action, government, and health economic strategies (Schneiderman & Speers, 2001). Research and practice in this area contribute to the development, administration, and evaluation of programs and policies in public health and health services to promote and sustain healthy environments and healthy lives for individuals and populations (Coreil, 2009).

With the increased role of behavioral and social science in public health is the increased integration of behavioral and social science training in its curriculum. Coursework in social and behavioral sciences has become a mandated component of the core curriculum in all schools of public health in the USA seeking accreditation. The Association of Schools and Programs of Public Health (ASPPH) includes behavioral and social sciences as one of its core competency areas for the Master of Public Health (MPH) degree. The identified areas of learning within the behavioral and social science realm include, for example, (1) identifying the causes of social and behavioral factors that affect health of individuals and populations and (2) applying evidence-based approaches in the development and evaluation of social and behavioral science interventions.

Medicine

Physicians increasingly recognize that disease states cannot be prevented and managed without attention to the behavioral and social factors that are determinants of many health problems and serve as barriers to effective care. Physicians are expected to influence patients' behavior to promote health and prevent and manage chronic disease but in the past have often been ill-prepared in these areas. In the USA, there is now recognition of the importance of physician training in behavioral and social science. This now often begins prior to entering medical school as premedical students are expected to have an understanding of behavioral and social sciences. In its first change in 25 years, the Medical College Admission Test in the USA includes a new section, "Psychological, Social, and Biological Foundations of Behavior." The section tests students' understanding of behavior and behavior change, cultural and social differences that affect well-being, and the relationship among socioeconomic status, access to resources, and well-being.

Preparation in behavioral science continues in medical school, and not only in the USA but also in places such as Canada and Hungary as well. The Association of American Medical Colleges (2011) produced a report that provides a template for medical schools to incorporate behavioral and social sciences concepts in their curricula, as well as teaching methods for schools to implement the concepts. The report is built on other competency-based frameworks that help guide educators in designing medicine curricula. One framework from the US Institute of Medicine identifies six domains of behavioral and social science content and priority topics to be addressed in medical school (Cuff & Vanselow, 2004). Similarly, a report of the Royal College of Physicians and Surgeons of Canada (Frank, 2005) sets out specific roles which physicians must be trained to fulfill and the competencies that support fulfilling those roles. In Eastern Europe at Budapest, Hungary's Semmelweis University, the Institute of Behavioral Sciences, created in 1993, provides behavioral medicine courses to medical students (and dentistry and pharmacy students). Teaching behavioral and social sciences in medical school is not expected to produce specialists in behavior but to equip physicians with behavioral and social science-derived knowledge, skills, and attitudes required to practice medicine effectively (Cuff & Vanselow, 2004).

To redesign and enhance behavioral and social science curricula in medical school, the National Institutes of Health funded a mechanism (K07) and awarded nine grants to medical schools to develop medical education consistent with the Institute of Medicine recommendations (Cuff & Vanselow, 2004). The Indiana University School of Medicine, for example, used the funds to (a) infuse social and behavioral science into all for years for a total of 93 contact hours, (b) develop and use innovative interactive learning materials, including a simulation board game, to teach health policy and economics in a team-based learning context, and (c) create mechanisms to bring medical students in direct contact with community members and patients.

Nursing

Nurses are ideally positioned to use behavioral medicine to help improve health. In high- and middle-income and many low-income countries, nurses are located in virtually all patient care settings such as hospitals, long-term care, homes, schools, and the community (Institute of Medicine, 2011). Nurses, and in particular nurse leaders, have a growing focus on health promotion and risk reduction that extends beyond patient education and includes the facilitation of change. Clinical nurse leaders are being called upon to design and implement measures to modify risk factors and promote engagement in healthy lifestyles (American Association of Colleges of Nursing, 2013). The roles of clinical nurses remain in providing and coordinating care for the sick but are extending to include engagement with groups and communities around health promotion, secondary prevention, and risk reduction. For example, clinical nurses can develop clinical and health promotion and help patients access and interpret health information to identify healthy lifestyle behaviors. In addition, clinical nurses can evaluate the efficacy of health promotion and education modalities for use in a variety of settings and with diverse populations.

Diabetes care is one area in which nurses have long been actively involved, making major contributions in using behavioral medicine (Davidson, Ansari, & Karlan, 2007; Guthrie, Runyan, et al., 1964; Kahn, Fox, et al., 2009; Taylor, Miller, et al., 2003). In diabetes care, nurses can monitor patients between office visits, provide diabetes counseling, remind patients about appointments, and coordinate lab work and specialty care. In the USA, nurses and dietitians predominate among the ranks of Certified Diabetes Educators and their roles in ongoing diabetes management. The role of nurses is expanding to address other chronic conditions such as hypercholesterolemia, hypertension, and depression (Hiss, Armbruster, et al., 2007; Taylor, Miller, et al., 2003). In a care management role within an integrated care model, nurses are often at the nexus of care especially for those with complex problems, multiple morbidities, or frequent, avoidable hospital and acute care. This entails behavioral approaches to facilitate the patient's care and self-management of medical and behavioral health. Nurses in various specialty areas and at many educational levels are becoming competent in psychological interventions such as motivational interviewing and other health behavior enhancement approaches to improve patient health outcomes (Emmons & Rollnick, 2001; Maissi, Ridge, et al., 2011). All health settings can serve as a platform for health promotion interventions by nurses, including intensive care units, medical-surgical units, oncology units, emergency departments, and home health care.

The education of nurses is evolving to keep stride with the expanding role of nurses in addressing behavior and health. Nursing, along with other health disciplines, is developing a basic curriculum that includes the core competencies in health promotion and disease prevention (Allan, Barwick, et al., 2004; American Association of Colleges of Nursing, 2013; Institute of Medicine, 2011). Nursing education also seeks to create competencies in applying psychosocial, behavioral, and cultural approaches in practice (American Association of Colleges of Nursing, 2006). At the doctoral level, nursing education is also incorporating behavioral medicine principles, teaching concepts in public health, health promotion, evidence-based approaches, determinants of health, behavioral science, and cultural diversity. Advanced nursing graduates learn to analyze epidemiological and biostatistical data in the development, implementation, and evaluation of clinical prevention and population health (American Association of Colleges of Nursing, 2006). They are also competent in using assessment techniques at the organizational, systems, and community levels.

Dentistry

Oral health status can affect general health and quality of life. Among the pressing issues in oral health are those that involve behavior or psychological factors, including chronic facial pain, craniofacial birth defects and trauma, oral diseases related to behavior (e.g., tobacco use), and access to care for low-income and underserved minority groups (Mertz & O'Neil, 2002). The etiology of some oral diseases can include the modifiable lifestyle risk factors that are common to a number of chronic diseases: inadequate oral hygiene, tobacco use, diet, stress, and behaviors causing injuries. Dentists and other oral health providers (e.g., endodontists, periodontists, orthodontists, dental hygienists) are increasingly understanding the unhealthy effects of certain behaviors and the importance of enhancing health behaviors to prevent and control disease.

The structure of the dentistry practice in many ways is ideal to enhance health promotion. For some time, in many developed nations, people have visited the dental practice for routine visits more frequently than the medical practitioner (Ramseier, Suvan, et al., 2010). Continuity of care in dentistry allows unique opportunities for oral health providers to know their patients and therefore, become more involved in assessing and ensuring the overall health of their patients through screening, diagnosis, and referral (Wilder, O'Donnell, et al., 2008). These factors have led to broadening the role of dentistry to include, e.g., chronic disease management such as the important and insufficiently recognized relationship between periodontal disease and glycemic control in diabetes (Taylor, Burt, et al., 1996). The *British Dental Journal* has published a series of papers on a variety of preventive interventions, including dietary advice and smoking cessation (Watt, Daly, & Kay, 2003; Watt, McGlone, & Kay, 2003). Unfortunately, when oral health clinicians maintain conventional roles and their historical isolation from other health professionals, the opportunity to enhance health promotion is lost (Wilder, O'Donnell, et al., 2008).

In recognition of the opportunity for dental professionals to enhance health, the American Dental Education Association approved competencies for the new general dentist (American Dental Education Association, 2008). The competencies reflect that the general dentist addresses health-care issues beyond traditional oral health care with the goal of improving the health of society. Among the competency domains are those that reflect behavioral medicine. In particular, the "health promotion" domain includes the importance of applying prevention strategies (behavioral and educational in nature) and the need to contribute to improvement of oral health beyond those served in traditional practice settings. The "communication and interpersonal skills" domain includes the application of psychosocial and behavioral principles in patient-centered health care and communicating effectively with individuals from diverse populations. A part of the "patient care" domain is preventing, identifying, and addressing pain and anxiety in the dental patient and recognizing and managing substance abuse. Also among the competencies is participating with members of other health-care professions in the management and health promotion for all patients. Integrating dentistry with other health professions, including those in behavioral medicine, will help the effective implementation of health behavior change in the dental practice.

Pharmacy

Pharmacy has been long recognized as a profession that can address health promotion. Over 25 years ago, the World Health Organization held meetings on the role of the pharmacist in the health-care system, including the role of health promotion (World Health Organization, 1994). Before that the American Public Health Association had already outlined the public health role of the pharmacist in a pioneering statement (American Public Health Association, 2006). Pharmacists were declared an underutilized resource in promoting public health.

Pharmacies are considered the most accessible health-care entity in the community, and pharmacists are well recognized and highly credible health advisors (Kotecki, Elanjian, & Torabi, 2000). Pharmacies and pharmacists have access to a large proportion of the population, including those who are both healthy and ill and those who are not motivated to use other health services (Joyce, Sunderland, et al., 2007; World Health Organization, 1994). Community pharmacies are accessible sites to address key health behaviors through health screening (e.g., diabetes, cholesterol, osteoporosis) immunizations, pain control, participatory and clinical research, and counseling/health education (American Society of Health-System Pharmacists, 2008). Within these settings, pharmacists can actively engage in behavioral medicine activities including health education and disease prevention and control programs (American Society of Health-System Pharmacists, 2008; Maine, 2005). Within the health education realm, for example, pharmacists can develop patient education programs on safe and effective medication use or on topics such as tobacco cessation, exercise, and healthy nutrition (Crawford, 2005; Maine, 2005). Pharmacists can support the education and training of the population at an early age, such as through school health programs, to help children develop good health behaviors that can continue into adulthood. Furthermore, pharmacists can improve society's safe and effective use of medications by educating their health-care colleagues (American Society of Health-System Pharmacists, 2008; Crawford, 2005).

Education and training guidelines in pharmacy incorporate language related to pharmacists engaging in health promotion (Medina, Plaza, et al., 2013). Educational programs now train pharmacists to provide prevention, intervention, and educational strategies for individuals and communities to improve health and wellness and demonstrate a strong commitment to health promotion and illness prevention (e.g., provision of health screening, tobacco cessation counseling). In a Malaysian pharmacy school, for example, the curriculum includes a separate course on public health (Hassali, Shafie, et al., 2009).

While the long-standing interest in the public health role of pharmacists as health educators is considerable, the engagement and impact of pharmacists have been more limited, particularly in the USA (Kotecki, & Clayton, 2003; Kotecki, Elanjian, & Torabi, 2000). There are a few reports documenting pharmacist participation in health education and disease prevention. Challenges also exist, however, for pharmacists to counsel individuals on health behavior change. Pharmacists may feel health promotion is too far removed from the traditional role of dispensing medication, and they may lack interest and confidence in prevention activities targeting smoking, diet, and physical activity (O'Loughlin, Masson, et al., 1999; Watson & Hughes, 2012).

Australian pharmacists, in contrast, appear to be more active in health promotion and disease prevention and management (Joyce, Sunderland, et al., 2007). A variety of health promotion activities are currently conducted through community pharmacies as normal business, including smoking cessation, weight loss, sexual health, and alcohol awareness (Joyce, Sunderland, et al., 2007; Pharmacy Guild of Australia, n.d.). Activities in the USA may be catching up with such progressive models, however. For example, in a review out of Canada that includes studies from the USA, community pharmacists can be considered an important public health resource when providing clean needles to injection drug users as well as opioid substitution as part of a public health harm reduction model (Watson & Hughes, 2012).

There is a vision within the pharmacy profession to move beyond the manufacturing and selling of drugs and expand the role of community pharmacists to include more health education, health promotion, and disease prevention activities. The International Pharmaceutical Federation has taken up the concept of the "Seven Star Pharmacist," introduced by WHO, to engage pharmacists in activities like patient counseling for risk management and interventions to improve patient compliance (Habeeb Ibrahim, Jose, & Jegan, 2012). In the USA, as part of the health-care reform effort, there is a move for pharmacists to receive provider status (Clark, 2014). In a recent study reflecting the increasing scope of the pharmacist role, pharmacists directed a 12-week walking program in an employee health and wellness clinic (Fanous, Kier, et al., 2014). In addition, pharmacists in Asheville, North Carolina, used their accessibility and relationships with customers to enhance a diabetes management program that resulted in cost-effective clinical improvements (Cranor, Bunting, & Christensen, 2003).

Integrated Behavioral Medicine in Primary Care Settings

Around the world and in low- and middle-income as well as high-income countries, health care increasingly emphasizes the integration of treatment of individuals' health problems through medical settings, including primary care (Beaglehole, Epping-Jordan, et al., 2008). Behavioral medicine is becoming increasingly integrated into many medical specialty settings (e.g., rehabilitation units, transplant units), long-term care, and community-based health and social service sites. The integration of behavioral medicine into medical care is part of the evolving health-care system and its focus on improving the health of the population, providing better patient experience and outcomes, and lowering cost.

Primary Care

Among the medical settings in which behavioral medicine is taking a more active role is primary care. As many as a third of primary care patients meet diagnostic criteria for mental health problems that often go unrecognized and undertreated, and visits to primary care practitioners are driven by patients' psychological problems, such as anxiety, panic, depression, and stress (Wang, Lane, et al., 2005). Depression, for example, can go undetected in primary care both in the USA (Martin, Williams, et al., 2005) and other regions of the world including Hong Kong (Chin, Chan, et al., 2014), New Zealand (Carey, Jones, et al., 2014), and the UK (Mitchell, Vahabzadeh, & Magruder, 2011). Unaddressed mental illness is one factor accounting for poor control of high-risk and costly chronic illness. The preventable and modifiable unhealthy behaviors (e.g., smoking, sedentary lifestyle, poor diet) that are not being adequately addressed are also contributing to costly chronic disease (Mokdad, Marks, et al., 2005). Physicians in primary care, although expected to identify and manage their patients' behavioral health issues, are not necessarily interested or adequately prepared to do so.

Enhancing behavioral medicine services in primary care can address costly mental illness and chronic disease by targeting comorbid mental and physical illnesses and by enhancing health behavior. Services for behavioral issues can be more accessible for patients who would not normally seek such services (e.g., mental health related) because of stigma or difficulty overcoming other barriers (e.g., long wait lists, long commutes to services) (Croghan & Brown, 2010). Individuals from ethnic/racial minority backgrounds and underserved individuals, who may have the most difficulty in accessing services, may benefit most from behavioral medicine services being delivered in primary care settings (Gum, Iser, & Petkus, 2010; Pingitore, Snowden, et al., 2001).

Patient-Centered Medical Home

Within the USA, a strong emphasis is to transform primary care practices into patient-centered medical homes (PCMHs). The National Committee for Quality Assurance (NCQA) began a recognition program in 2008, which has led to 7000 primary care practices (about 10%) gaining the status of PCMH (www.ncqa.org/HomePage.aspx). Within the Veterans Administration Health Administration, a similar rollout in 2010 transformed its primary care services into Patient-Aligned Care Teams (PACT), another version of the PCMH, in recognition of its utility and efficiency (Kearney, Post, et al., 2014).

The PCMH concept is consistent with tenets of the Patient Protection and Affordable Care Act of 2010 (Runyan, 2011) in the USA and the Triple Aim framework of improving population health and patient experience at a reduced cost (Berwick, Nolan, & Whittington, 2008). The concept is also consistent with the proceedings from the 1978 World Health Organization's conference at Alma-Ata (World Health Organization, 2008), which highlighted the importance of addressing mental health in primary care using language that is incorporated into the PCMH model but did not use the term itself.

Fundamental to the PCMH is a recognition that is shared with behavioral medicine: most prevention and management occurs outside, not within the clinical setting – "nobody lives in a patient centered medial home."[1] Both behavioral medicine and the PCMH emphasize the influences of family, community, and social and eco-

nomic determinant and seek to find ways to incorporate them in care and prevention. The PCMH incorporates elements of the Chronic Care Model that are designed in part to prevent costly illness (Coleman, Austin, et al., 2009). The model involves behavioral medicine principles and approaches that include, among other elements, informing and activating patients to engage in health behaviors and self-management of illness (Fromer, 2011).

In the PCMH, whole-person integrated care is delivered by an interprofessional team of healthcare providers. Care is comprehensive and focuses on quality and safety. Comprehensive, whole-person care addresses the behavioral as well as physical health needs of patients (Taylor, Lake, et al., 2011). In addressing behavioral health needs, components of behavioral medicine are understood and delivered by a range of healthcare providers in order to better prevent and manage chronic disease.

Within a strong emphasis on team-based care (Collins, Hewson, et al., 2010; Hogg, Lemelin, et al., 2009), behavioral medicine specialists are serving as important members of the PCMH team. They are valuable in providing patient care, guiding their health professional colleagues' use of behavioral medicine strategies and offering their expertise to enhance team functioning. Behavioral medicine specialists can provide much needed access to quality behavioral health care by treating mental and behavioral health-related conditions. They can also decrease the load on the medical providers and help improve coordination of care. As leaders in the practice with administration skills, they can assist in the development and evaluation of the behavioral medicine services that are integrated into the medical setting. With empirical abilities, they can help with quality improvement initiatives. Cost offset and fewer hospitalizations have been demonstrated for primary care patients who receive behavioral medicine services (Blount, Schoenbaum, et al., 2007). Clearly, there is a wide range of roles for behavioral medicine within the PCMH and primary care. The next section details several among these (Nash, McKay, et al., 2012; Nash, Khatri, et al., 2013).

Patient Care and Consultation

Health professionals with expertise in behavioral medicine can provide patient care directly, in face-to-face encounters, and indirectly, in serving as a consultant to other members of the treatment team. The behavioral medicine specialist can guide the medical team in routine screening of patients considering the number of patients in primary care who have unidentified or unaddressed behavioral health needs (Croghan & Brown, 2010). Once screened, evidence-based interventions are used to address mental illness (e.g., mood and anxiety disorders), enhance health behavior (e.g., related to obesity, sedentary lifestyle, and tobacco use), and manage chronic diseases and their comorbidities such as depression and comorbid diabetes (Katon, Von Korff, et al., 2004), coronary heart disease (Frasure-Smith & Lespérance, 2010), and chronic pain (Dobscha, Corson, et al., 2009; Kroenke, Bair, et al., 2009).

In the consultation role, the behavioral medicine specialist can provide expert guidance to primary care team members on patient-related and practice management issues. The consultation process can help the primary care team to know how best to use behavioral medicine resources, engage primary care team members in comanaging patients, support the decision-making or primary care team members, integrate a behavioral medicine component into the medical treatment of the patient, guide the physician and primary care team's use of behavioral medicine interventions such as motivational interviewing, and help physicians address behavioral health issues at early stages of development. Consultative roles can broaden the reach and influence of the behavioral medicine specialist's expertise across the practice (Robinson & Reiter, 2007).

Teaching and Supervision

Academic primary care centers serve as training ground for different health professionals (e.g., physicians, nurses, pharmacists). A specialist in behavioral medicine in the primary care setting has an opportunity to have an active role in formal training initiatives for health professionals, including physicians. For example, some primary care physician residency programs for decades have enlisted the expertise of behavioral scientists in the formal training of resident physicians (Fischetti & McCutchan, 2002; McDaniel, 1995). Psychologists in primary care are also increasingly creating opportunities for psychology training in primary care settings. Recognized training programs are established at the psychology doctoral, internship, and fellowship levels in integrated primary care (Bluestein & Cubic, 2009; Garcia-Shelton & Vogel, 2002).

Program Development and Evaluation

Many professionals with concentrated training in behavioral medicine are from academic disciplines (e.g., public health, psychology). The research skills that these professionals develop through their academic training are useful in primary care settings where performance assessment is increasingly required and technology is increasingly used in delivery of care. Research skills can be combined with understanding ways to meaningfully use health information technology to improve patient safety, satisfaction, and quality of care, particularly as it relates to behavioral health (Gardner, Kelleher, & Pajer, 2002). For example, behavioral medicine specialists can help with data management and tracking systems, including those that are web-based, for use in primary care settings (Grypma, Haverkamp, et al., 2006; Unützer, Choi, et al., 2002).

Integrated Behavioral Medicine Care in Worksite Settings

The workplace, where adults spend about half of their waking life, is a useful setting to reach and help people to engage in healthy behaviors. Worksite policies and programs can include some combination of delivering health-promoting educational programs at the worksite, creating incentives to use off-site facilities (e.g., fitness clubs), and offering employee health benefits (e.g., flu shots, hypertension screenings). Most worksite health promotion programs use behavioral medicine approaches to prevent chronic disease by promoting physical activity (Freak-Poli, Cumpston, et al., 2013) and reducing tobacco use (Cahill & Lancaster, 2014). It is in employers' interests to improve the health of their workforce, especially if employers are bearing the costs of health insurance.

The workplace is where large groups of smokers and sedentary adults are available to be reached and helped. Worksite smoking cessation programs in developed countries are encouraged by antismoking laws and use a variety of proven approaches, some policy related (e.g., not hiring smokers) and others medical (e.g., offering varenicline, nicotine replacement) and behavioral (e.g., counseling; (Cahill & Lancaster, 2014)). In developing countries, there remains a need to test and demonstrate the effectiveness of worksite smoking cessation programs. Physical activity is also emphasized in worksite health promotion programs, following WHO guidelines encouraging at least 30 min of moderate-intensity physical activity on most days (Freak-Poli, Cumpston, et al., 2013). To combat the increasing problem of positive energy imbalance in the Netherlands, health promotion strategies now extend beyond education or communication approaches to include environmental modifications. Environmental modifications are being tested in the worksite to increase movement for those workers who are spending a disproportionate amount of time either standing or sitting as part of work duties (Engbers, van Poppel, et al., 2005).

Behavioral Medicine by Community Members

Behavioral medicine health-care activities are not limited to licensed clinicians in professional settings. Individuals in the community can also play a critical role in promoting health using behavioral medicine. Individuals in a support capacity, referred to as "community health workers," "lay health advisors," "promotores," "peer support specialists," and other terms, make important contributions to health, health care, and prevention (Fisher, Coufal, et al., 2014). Based on foundations in behavioral medicine, peer supporters, under the guidance of licensed health professionals and in the communities and contexts of individuals they serve, link people who share knowledge and experience; provide emotional, social, and practical assistance for how to achieve and sustain health behaviors; help people cope with health-related stressors; and help with navigating the health-care system.

Peers from the community have been in a health-care support role all over the world for several decades (Bhutta, Lassi, et al., 2010). The services offered range widely, including provision of safe delivery; counseling on breastfeeding; management of uncomplicated childhood illnesses; preventive health education and treatment for malaria, TB, HIV/AIDS, STDs, and NCDs; and rehabilitation of people suffering from common mental health problems. Evidence demonstrates that community members add significantly to the efforts of improving the health of the population, particularly in those settings with the highest shortage of motivated and capable health professionals (Bhutta, Lassi, et al., 2010; Fisher, Coufal, et al., 2014). The services from community members in a support role have helped in the decline of maternal and child mortality rates and have also assisted in decreasing the burden and costs of TB and malaria (Bhutta, Lassi, et al., 2010). A measureable impact has been demonstrated in reducing disease burden in the management of hypertension, reduction of cardiovascular risk factors, control of diabetes, management of HIV infection, and screening in cancer (Fisher, Coufal, et al., 2014). Fisher and colleagues (2012) reported on programs in Cameroon, South Africa, Thailand, and Uganda that developed and evaluated peer support interventions for adults with diabetes. Assessments showed improvements in symptom management, diet, blood pressure, body mass index, and blood sugar levels for many of those taking part in the programs (see also Fisher et al., *infra*).

Thailand's success in promoting health through behavioral medicine is built on the vast network of community members, called Village Health Volunteers, who have been part of the Thai health system for over 35 years and have extended basic health care to remote areas of the country at relatively low cost. The role of volunteer corps is to assist in controlling and preventing disease. Among their many health promotion activities, they urge villagers to avoid smoking and alcohol and recommend regular exercise. They also assist pregnant women. The World Health Organization (Bhutta, Lassi, et al., 2010) reported evidence that the Village Health Volunteers helped curb infectious diseases and reduce infant mortality rates to one of the lowest in Asia.

Concluding Comments

Behavioral medicine is, in most places, not a profession or even a specialty area. It does not reside in one discipline or health-care profession and is not limited to health-care settings. Behavioral medicine is an area of interest or focus with a variety of professionals and even laypersons (e.g., peer coaches) who are interested in understanding and impacted health through behavior change. There is an increased emphasis on using behavioral medicine to improve the health of populations by incorporating behavioral change principles in policies and by delivering behavioral approaches in a number of settings (from health care specific to school to workplace). There is also an increased emphasis on understanding, researching, and teaching the role of behavior in health, whether it is in medical schools, in schools of public health, or in training programs of the allied health professions. Behavioral medicine, as an area of interest, is remarkably wide-ranging, whether the focus is at the cellular (e.g., neuroplasticity) or the societal level (e.g., policy). Behavioral medicine is also wide-ranging in covering the entire lifespan, from cradle to grave.

Behavioral medicine, with its variety and breadth, presents a challenge to define and grasp while bringing complex health problems a rich and useful set of perspectives and evidence.

Randomized Clinical Trials in Behavioral Medicine

Kenneth E. Freedland, Sara J. Becker,
and James A. Blumenthal

Introduction

Randomized controlled trials (RCTs) are the gold standard tests of interventions in many different areas of clinical research, and the core methodologies of RCTs cut across all of them. Nevertheless, each field tends to have its own distinctive methodological issues. This chapter discusses current issues in biobehavioral trial methodology, with an emphasis on interventions for the prevention or treatment of clinical problems in behavioral medicine. It is written from the perspective of researchers who are actively engaged in testing behavioral interventions for medically ill patients. The randomized controlled trial is a highly respected research paradigm in the medical community, and evidence of efficacy, effectiveness, and cost-effectiveness based on rigorous RCTs enhances the credibility of biobehavioral approaches in the medical settings that we seek to influence. This chapter highlights the many strengths of RCTs, how well suited they are to some of the most important objectives of clinical research, and their importance in behavioral medicine. Although other methods also play important roles in biobehavioral intervention research, the focus of this chapter is on randomized controlled trials.

Adapting to the Culture of Medical Trials

The disciplines that comprise the field of behavioral medicine share a commitment to conduct rigorous scientific research and to promote evidence-based practices, but their research cultures differ from one another in some respects. For example, nursing researchers usually ground their clinical trials in theories of nursing practice or health behavior change (Alligood, 2013). In contrast, physicians who conduct RCTs to test collaborative care interventions (Rollman, Belnap, LeMenager, Mazumdar, Houck, et al., 2009; Rollman, Belnap, LeMenager, Mazumdar, Schulberg, et al. 2009) or medications for psychiatric comorbidities in medically ill patients (Glassman, O'Connor, et al., 2002) tend to do so with little attention to any theoretical underpinnings of these approaches.

Methodological traditions that do not meet mainstream medical research standards sometimes arise within particular disciplines or specific areas of clinical investigation. For example, psychotherapy trial reports often include extensive exploratory analyses of numerous potential moderators of treatment effects or post hoc searches for subgroups that either did or did not benefit from the intervention (Wolitzky-Taylor, Arch, et al., 2012; Hendriks, van der Schee, & Blanken, 2012; Grilo, Masheb, & Crosby, 2012). These kinds of exploratory and post hoc analyses tend to be received with resounding skepticism by biostatisticians and biomedical trialists, especially when numerous factors are examined or the primary outcomes are not significant (Sun, Briel, et al., 2011, 2012).

Persistent allegiance to traditions that are incompatible with more widely accepted methodological standards of clinical research can hurt our ability to compete for grant funding, publish our trials in high-impact medical journals, and influence clinical practices and policies. Thus, when planning a biobehavioral RCT, it can be helpful to review standard clinical trial methodology textbooks (e.g., Friedman, Furberg, & DeMets, 2010) and expert guidance published in high-impact medical journals (e.g., White, Horton, et al., 2011) and consider whether there are any ways in which the research plan needlessly departs from widely accepted biostatistical principles or other current methodological standards.

On the other hand, some of the differences between biobehavioral and biomedical trial methodologies would be difficult if not impossible to eliminate. For example, most behavioral intervention trials can be single-blinded but not double-blinded. This means that the outcome assessors are kept in the dark about which participants were randomly assigned to which group, but the interventionists and the participants themselves know the group to which they have been assigned. Because they are not double-blinded, the broader medical research community tends to question the methodological quality of even the most rigorously designed and scrupulously conducted behavioral trials (Relman & Angell, 2002). This may seem unfair, but it does little good to complain. It is better to find ways to measure and, when possible, to ameliorate the potential biases and other problems that these sorts of methodological limitations may impose on our trials. In single-blinded trials, for example, analyses of data derived from treatment credibility and outcome expectancy measures can be used to evaluate whether differential expectancies may have influenced the results (Smeets, Beelen, et al., 2008).

In typical biomedical RCTs, patients are randomly assigned in double-blind fashion to an active medication or to a seemingly identical but biologically inert placebo. It is difficult to maintain the double-blind in some drug trials. This can occur, for example, if pronounced side effects are common in the treatment arm but rare in the placebo arm. In most drug trials, however, no one knows which participants are taking the active medication and which ones are taking a placebo. This makes it possible to treat all participants in a nearly identical fashion, regardless of the group to which they have been assigned. For instance, neither group is likely to receive more clinical attention than the other group in a typical double-blinded RCT.

Single-blinding can open the door to a variety of unplanned differences between behavioral intervention and control groups. One of the most serious concerns is that the participants' propensity to seek other forms of treatment for the target condition may differ between the intervention and comparison arms of a behavioral trial (Freedland, Mohr, et al., 2011). For example, in an RCT of cognitive behavior therapy (CBT) for depression, the participants in the CBT arm may be more or less likely than those in the comparison arm to obtain antidepressants from their own nonstudy physician. This might occur in the comparison arm because the participants know that the investigators are not going to give them any treatment, and so they seek it on their own, outside of the study. On the other hand, it might occur in the intervention arm if the therapists tend to advise their patients to ask their nonstudy physician about antidepressant medications. These sorts of unplanned differences between treatment and comparison arms can make it more difficult for behavioral researchers to isolate the therapeutic effects of their interventions than it is for pharmaceutical trialists to do so with medications.

The boundaries of the experimental unit can also be more difficult to delineate in a biobehavioral than in a biomedical trial. In a typical drug trial, no one other than the study participant takes the study medication or placebo. In many behavioral trials, however, the target behaviors are imbedded in a social context. Dietary intervention trials, for example, can directly or indirectly influence the behaviors of family members in ways that can either enhance or diminish the efficacy of the intervention for the study participants (Quattrin, Roemmich, et al., 2012).

In short, clinically relevant RCTs in behavioral medicine are not pristine laboratory experiments. They are conducted within clinical and social environments that can affect trial outcomes in complex and sometimes unanticipated ways. These limitations and complexities do not diminish the importance and value of biobehavioral trials, but they increase the need for careful planning and monitoring. They also help to explain why other paradigms will also continue to play important roles in behavioral intervention research.

Defining the Purpose of the Trial

In any research endeavor, careful articulation of the purpose of the study should guide all other decisions. This includes such fundamental questions as whether to conduct an RCT or some other type of study and, if an RCT best fits the purpose of the research, how the trial should be designed.

An important consideration when defining the primary purpose of an RCT is whether its main aims are mechanistic, explanatory, or pragmatic. In medical research, *mechanistic* or *experimental* trials are usually conducted to investigate relationships among biological variables (Karanicolas, Montori, et al., 2009). In behavioral medicine, mechanistic or experimental trials are used to investigate behavioral or biobehavioral relationships. A recent RCT, for example, examined whether hostility reduction is associated with concomitant changes in blood pressure or other indicators of cardiovascular autonomic function (Sloan, Shapiro, et al., 2010). *Explanatory* (also known as *efficacy*) trials investigate whether or how well an intervention works under relatively optimal, tightly controlled conditions, whereas *pragmatic* (also known as *effectiveness*) trials evaluate interventions under more typical clinical practice conditions (Tunis, Stryer, & Clancy, 2003; Schwartz & Lellouch, 1967; MacRae, 1989; Thorpe, Zwarenstein, et al., 2009). Many studies blend the characteristics of two or three of these kinds of trials, although most RCTs can be described as being predominantly one kind or another.

Another important consideration when defining the primary purpose of an RCT in behavioral medicine is whether the primary outcome is a behavioral, an intermediate, or a clinically important medical variable. Many researchers in behavioral medicine aspire to improve major medical outcomes such as to reduce the incidence of asthma attacks, prevent cancer progression and metastasis, or prolong survival in heart failure. We aim to achieve these goals by targeting behavioral risk factors such as inadequate exercise or smoking or psychosocial problems such as stress or anxiety. We also aim to modify the biobehavioral or physiological pathways that mediate the effects of behavioral and psychosocial factors on medical outcomes. Consequently, trialists in behavioral medicine are concerned with at least three different kinds of outcomes: proximal behavioral targets, distal medical outcomes, and biobehavioral or physiological intermediate outcomes (also known as mechanisms or mediators).

In short, it is necessary to consider which types of trials to conduct, with which outcomes, and in which sequence, in order to have an impact on clinically important problems in behavioral medicine. For example, depression is a common psychiatric comorbidity in a heart condition known as atrial fibrillation (AF), and it is a risk factor for mortality in patients with AF (Frasure-Smith, Lesperance, et al., 2009). It is also associated with several biobehavioral factors, including elevated heart rate and medication nonadherence, which could plausibly mediate the effect of depression on mortality in AF. Little is known about how to treat depression in this particular patient population. Even less is known about whether potential mediators such as heart rate or nonadherence can be improved in these patients by treating their depression or whether doing so can reduce their mortality risk. Thus, there are several different reasons to conduct an RCT. However, it would not be feasible to simultaneously answer all of these questions in a single trial. A programmatic series of studies would be necessary, but where would be the best place to begin? Should mechanistic, explanatory, and pragmatic trials be conducted in any particular sequence, and if so, which one? And which primary outcomes should be chosen for these trials?

One could argue that the best place to begin would be with tightly controlled explanatory trials with depression (the behavioral target) as the primary outcome, in order to determine the best way to treat depression in these patients under relatively optimal conditions. It might be necessary to develop a novel, highly innovative treatment for these patients. However, rather than starting from scratch, most researchers would probably borrow interventions such as cognitive behavior therapy (CBT), problem-solving therapy (PST), or interpersonal therapy (IPT) that have already been well tested in other patient populations such as in depressed psychiatric patients. It might be necessary to modify these interventions to adapt them to the particular needs of patients with AF, but it might not be. For example, the behavioral activation component of CBT might have to be modified in order to ensure that it is medically safe (Skala, Freedland, & Carney, 2005), but in most other respects, CBT for depressed AF patients would probably be fairly similar to CBT for depressed psychiatric patients. Whether or not the interventions would have to be modified, these trials would help to identify the most efficacious treatments for depression in patients with AF.

However, it may not be possible to conduct a pristine efficacy study, even if it were the first behavioral intervention trial ever conducted in this patient population, because many of these patients will have access to antidepressant medications and perhaps to behavioral treatments for depression as well. The fact that there may have been little or no research on antidepressants or behavioral treatments for depression in this particular population does not necessarily prevent them from being used in clinical practice. Also, medications and surgical procedures for cardiac or other medical problems could affect some of the participants' psychiatric functioning during the trial. These variables might induce "noise" in the trial's outcomes or create unintended differences between the groups (i.e., biases). Both of these problems can make it difficult to conduct tightly controlled behavioral efficacy trials in medical patient populations. They can also make it difficult, from both ethical and clinical perspectives, to employ control groups that provide no treatment, a placebo, or a weak intervention for the condition of interest. If pure efficacy trials would be unrealistic, somewhat more pragmatic RCTs of treatments for depression would probably be the first stage in this line of research.

Relatively pragmatic trials could take a variety of different forms, none of which would involve comparing behavioral interventions to clinically irrelevant attention, placebo, or no-treatment control groups. A behavioral intervention might be compared to whatever treatment (if any) patients get as part of their usual medical care. Alternatively, if antidepressants are routinely prescribed for these patients, a trial might compare the effectiveness of a behavioral intervention plus antidepressant therapy to antidepressant therapy alone. This kind of pragmatic trial would help to determine whether it is possible to improve upon existing clinical practices and, if so, how much added clinical value interventions such as CBT, PST, or IPT might provide.

One could argue instead that the best place to start would be with a mechanistic trial, to determine whether treating depression improves intermediate biobehavioral or medical outcomes such as heart rate that influence the risk of mortality in AF. In this type of trial, heart rate would be the primary outcome and depression would be a secondary outcome. It is important to recognize, however, that improvement in an intermediate outcome such as heart rate provides no guarantee that a treatment will also improve clinically meaningful outcomes such as mortality, as the Cardiac Arrhythmia Suppression Trial (CAST) (Echt, Liebson, et al., 1991) and many subsequent trials have shown. Nevertheless, mechanistic trials that target intermediate biobehavioral or medical outcomes are usually smaller and less expensive than trials that target reductions in deaths, strokes, or other major clinical events, and positive findings can help build the case for conducting larger and more expensive trials that do target clinically important outcomes.

However, the success of this sort of mechanistic trial depends on achieving a wide differentiation between the groups in the psychosocial or behavioral target of interest. In the present example, it would be necessary to ensure that most cases of depression in the treatment arm would improve and that most cases in the control arm would persist. Improving depression may or may not decrease heart rate in patients with AF. Answering that question would be the purpose of the mechanistic trial, but it is a question that simply cannot be answered in a controlled, experimental fashion unless a large effect of treatment on depression can be achieved.

If the intermediate outcomes of interest are relatively inexpensive to obtain, and if they do not impose a substantial burden on the participants or the study staff, they could be included as secondary outcomes in efficacy or effectiveness trials of treatments for depression. In the present example, it would be neither difficult nor expensive to obtain heart rates on patients in a depression treatment trial. Thus, it might be possible to “kill two birds with one stone”, i.e., conduct a trial that has both explanatory and mechanistic aims. However, if the intermediate outcomes are relatively expensive or burdensome to obtain, it would be better to start with efficacy or effectiveness trials with the behavioral target as the primary outcome and postpone the mechanistic studies until highly efficacious or effective treatments for comorbid depression in AF have been identified.

If the ultimate goal is to improve survival in patients with AF and comorbid depression, the statistical power of this larger, more expensive trial will depend more on the number of clinical events (i.e., deaths) than it does on the number of participants. In studies that have relatively uncommon events as outcomes, large numbers of participants have to be enrolled to ensure that there will be enough events and hence adequate power (Friedman, Furberg, & DeMets, 2010). The target sample size in this example would be so large that a multicenter RCT would probably be necessary. A trial involving multiple sites and hundreds or thousands of participants is unlikely to be funded unless smaller trials and other preliminary studies have paved the way for it. Thus, it is necessary to think in terms of conducting an entire line of research rather than banking on a single behavioral trial to change the prevention or treatment of a major medical problem such as AF.

RCTs provide the best way to answer many treatment-related questions, but not all of them. For example, Scherrer, Svrakic, et al. (2013) conducted a retrospective cohort study of the psychiatric sequelae of prescription opioid use in 49,770 Veterans Administration (VA) health-care system patients. They found that long-term (>90 days) opioid use significantly increased the risk of developing major depression. It would not have been ethical to randomize patients to receive or not receive an opioid medication specifically to study whether exposure to opioids increases the risk of depression, and it would probably not have been feasible to conduct a sufficiently large RCT to investigate this question with adequate power. Also, a randomized trial would not have approximated the actual clinical practice patterns that were captured in this database study. Thus, a prospective RCT would not have been the best approach, given the purpose of this study.

If an investigator decides that an RCT would be the best way to address a particular question, he or she then has to make a variety of decisions about the design of the trial. Typical Phase II and III drug trials have to comply with widely accepted methodological standards and with Food and Drug Administration (FDA) rules and regulations

(Katz, 2004). Consequently, pharmaceutical researchers may have fewer decisions to make about how to design their trials than behavioral scientists have to make about theirs. Trial design can be quite challenging in behavioral medicine. Investigators often have to make difficult tradeoffs between competing demands and compromises between scientific objectives and ethical or practical constraints.

Some of the most important RCT design decisions depend on the trial's primary purpose (Freedland, 2013; Karanicolas, Montori, et al., 2009). If a design decision serves the primary purpose of the trial, it is probably a good one. If it is at odds with the trial's primary purpose, it is probably a bad one. For example, behavioral scientists often want to answer many secondary or exploratory questions in addition to testing their primary hypothesis. If this can be accomplished unobtrusively, the study's productivity is likely to increase accordingly. However, if a large battery of secondary or exploratory measures strains the budget or substantially increases respondent and staff burdens, the trial may fail to meet its main aims due to low recruitment, high attrition, or other serious difficulties. Relatively simple trials can be more productive than excessively complex trials (Yusuf, Collins, & Peto, 1984).

Defining the Population

Background

The impetus for conducting a clinical trial in behavioral medicine usually originates in the recognition of an important problem or unmet need in a particular group of patients or in a population at risk for the development of a particular medical condition. In fact, the problems and needs of specific populations define entire lines of clinical research. They are usually identified through epidemiological research and other kinds of observational studies. The rationale for conducting an RCT usually builds on these sorts of studies.

Representative Samples

A key challenge for a relatively pragmatic trial is to ensure that the enrolled sample is representative of the population of interest. The generalizability of the sample to the target population encompasses several different kinds of characteristics, including the participants' sociodemographic attributes, health status, and ability and willingness to adhere to the experimental intervention. Narrow selection criteria can minimize error variance in outcome variables, enhance internal validity, and make it easier to conduct tightly controlled efficacy trials, but these advantages may come at the expense of enrolling unrepresentative samples and diminishing external validity. Relatively pragmatic trials usually have more inclusive eligibility criteria, to ensure that the results can be generalized to typical patients or at-risk individuals. These issues are often articulated as a trade-off between internal validity (e.g., enrolling a homogeneous sample of patients who are likely to have high treatment adherence and study completion rates) and external validity (e.g., enrolling a sample that is more representative of problem as it exists in population at large, even if that means including participants who may not adhere to the entire treatment plan or who may not fully cooperate with the study protocol).

Timing

Behavioral medicine interventions may target individuals who are still healthy but at risk for a disease (primary prevention), patients who are in the early stages of a disease and at risk for adverse outcomes (secondary prevention), or patients in more advanced stages of a disease who are at risk for further morbidity, disability, or mortality (tertiary prevention). Whether to intervene early or late in the disease process is an important consideration that has many implications for research strategies, treatment delivery, and the benefits that might be expected.

Specification of the target population often focuses on a particular event or stage in the progression from being at risk for a medical illness, developing the illness, and experiencing its adverse consequences. Receptivity to behavioral medicine interventions can be increased by capitalizing on times when patients may be particularly interested in changing health-related cognitions and behaviors. "Teachable moments" (Hochbaum, 1958) often emerge from disruptive medical events such as an acute myocardial infarction or a serious, abnormal finding on a medical screening test. The positive benefits or negative consequences of relevant health-related behaviors tend to be more salient at such times. Intervening during teachable moments early in the course of a chronic condition may be a particularly effective way to motivate long-term behavior change (Keefe, Buffington, et al., 2002).

Matching Populations to Interventions and Vice Versa

The decision to focus on individuals with specific characteristics both influences and is influenced by the characteristics of the intervention. For instance, an intervention that targets an elderly and/or chronically ill population may have to accommodate a broader range of treatment settings and delivery options than one that targets a younger and healthier population. The INSPIRE trial (Blumenthal, Babyak, et al., 2006), for example, tested a stress management intervention for lung transplant candidates. The intervention was delivered via telephone rather than in person because the patients were severely medically ill and resided in widely dispersed communities around the United States. Face-to-face sessions would not have been feasible.

Behavioral medicine clinicians and researchers have traditionally focused on direct interventions with individual patients who have specific health conditions. However, growing awareness of the value of social support in health promotion has increased interest in indirect interventions involving spouses, parents, or other caregivers for many different conditions. In recent years, behavioral interventions have been extended to dyads and family systems, school and work communities, and entire neighborhoods.

Dyadic interventions target the patient along with a family member or other associate; examples include parent-child, husband-wife, patient-life partner, and patient-caregiver dyads. Similarly, interventions for families or for alternate support systems target the patient along with a network of individuals who serve important roles in the patient's life. Interventions targeting dyads and families aim to reduce vulnerability to physical illness by alleviating individual and shared stressors, promoting positive interactions between the patient and others, and teaching the skills that are needed to prevent and manage chronic disease. Recent studies provide evidence that including members of the patient's support network can help to promote health behavior change and to treat psychosocial problems in patients with chronic diseases (Keefe, Buffington, et al., 2002).

Social and Organizational Units

Behavioral RCT methodology has also been extended to interventions for classrooms, schools, or school systems; work environments; and even entire communities. For instance, an intervention trial might be conducted to test new ways to decrease cigarette smoking at school. Unlike typical clinical trials in which individual people are the units of randomization, this RCT would randomize entire organizational units (i.e., "clusters") to intervention or comparison conditions. These studies are therefore known as *cluster randomized trials.* The clusters have a hierarchical structure. In this example, entire classrooms at multiple schools might be randomly assigned to a smoking reduction intervention or to a control condition. The classrooms are the unit of randomization, the students are clustered within the classrooms, and the classrooms are clustered within schools. Special statistical techniques have to be used to account for the similarities (i.e., correlations) within the clusters. For example, the students' socioeconomic status may tend to be similar within the participating schools and different between the schools, and this could contribute to differences in smoking rates between schools.

The end result of cluster randomization is still a comparison of an intervention vs. a comparison condition. Since classrooms are the units of randomization, the statistical power to detect significant differences between the intervention and comparison conditions depends on the number of classrooms and on the similarity of students within classrooms (the intra-class correlation), not on the number of students. In other words, researchers planning such a trial would have to think in terms of enrolling a large number of classrooms rather than just a large number of students (Friedman, Furberg, & DeMets, 2010).

Large-scale interventions have the potential to reach numerous at-risk individuals in cost-effective ways (Glasgow, Vogt, & Boles, 1999; Gaglio, Shoup, & Glasgow, 2013), but testing them in randomized, controlled trials can be difficult, whether or not cluster randomization is employed. To some extent, the failure of RCTs to show widespread benefits of community smoking interventions may reflect the problems of fitting large-scale interventions into research methodologies that were originally designed for testing discrete, individual-level interventions. In the COMMIT trial (COMMIT Investigators, 1995), for example, standardization of the intervention constrained the freedom of community groups to guide the intervention according to their own judgment. Thus, the "community-based" nature of the intervention may have been compromised in the interest of conforming to a standardized, internally valid RCT design. This raises questions about whether alternative study designs might be needed to test these kinds of interventions (Fisher, 1995).

Defining the Outcomes

In many areas of medical research, "hard" clinical endpoints, i.e., death and objective measures of medical morbidity, are the gold standard for evaluating treatment efficacy. However, large, multicenter trials are usually required to study hard endpoints with adequate statistical power. These trials are expensive, and it is difficult to obtain funding for them. A less expensive alternative for testing behavioral interventions is to focus on patient-reported (subjective) outcomes, such as mood states, health behaviors, or health-related quality of life. The Patient Reported Outcomes Measurement Information System (PROMIS) covers many outcomes of interest to behavioral trialists, with state-of-the-art measures and assessment software (Barile, Reeve, et al., 2012; Gershon, Rothrock, et al., 2010; Riley, Pilkonis, & Cella, 2011). Further research is needed to evaluate the validity and sensitivity to treatment-related change of the PROMIS measures in a variety of patient populations. Thus, behavioral researchers should consider using PROMIS measures as secondary outcomes, along with better-established measures as primary outcomes.

Unfortunately, it is possible for an intervention to have little impact on objective clinical outcomes despite having positive effects on subjective outcomes. When hard clinical outcomes are too expensive to study, and patient-reported outcomes are insufficient, an alternative is to target surrogate or intermediate biological outcomes. In patients with type 2 diabetes, for example, poorly controlled blood glucose levels can result in painful and debilitating complications such as neuropathy and cardiovascular morbidity. An RCT was recently conducted in Northern Ireland to test a self-monitoring intervention for patients with newly diagnosed diabetes. The primary outcome measure was an intermediate or surrogate endpoint, glycated hemoglobin (HbA_{1c}), which is a laboratory test of how well blood glucose has been regulated in recent weeks.

However, there are well-known limitations to reliance on surrogate endpoints (DeMets & Califf, 2002). As important as HbA_{1c} is in the management of diabetes, it is not as important as the downstream clinical effects of poor glucose regulation, i.e., the hard clinical outcomes of diabetes such as neuropathy, blindness, and acute myocardial infarction. Also, treatments that have positive effects on surrogate outcomes can turn out to have either no effect or negative effects on hard clinical endpoints. The Cardiac Arrhythmia Suppression Trial (CAST), which was briefly discussed in a previous section, is the classic example of this all-too-common problem. A preliminary study showed that several drugs were effective in reducing the frequency of potentially lethal cardiac arrhythmias in patients with a recent myocardial infarction (Cardiac Arrhythmia Pilot Study (CAPS) Investigators, 1988). Based on these encouraging results, a larger, placebo-controlled, multicenter trial was conducted to determine whether these drugs could reduce the incidence of sudden cardiac deaths. Unfortunately, in the larger trial, patients who were randomly assigned to the anti-arrhythmic drugs were *more* likely to die than were those who were given a placebo (Echt, Liebson, et al., 1991).

Of course, there have been trials in which treatments of intermediate factors or surrogate medical outcomes have yielded clinically important benefits, including in diabetes. For example, the Diabetes Control and Complications Trial (DCCT) showed that intensive insulin management slows the development and progression of retinopathy and microalbuminuria in patients with insulin-dependent diabetes mellitus, relative to conventional therapy (DCCT Research Group, 1993). Still, there are many examples of trials in which treatments for intermediate factors or surrogate outcomes have either yielded no clinical benefit or have caused unexpected harm. Medical researchers are wary of surrogate endpoints because of their troubling experiences with trials such as CAST. Nevertheless, surrogate outcomes can be successfully employed in relatively small behavioral trials such as the recently completed Smart Heart Trial (Blumenthal, Sherwood, et al., 2005), and they can help to provide a basis for larger, multicenter trials with hard clinical endpoints (Rozanski, Blumenthal, et al., 2005).

The Enhancing Recovery in Coronary Heart Disease (ENRICHD) study was one of the largest clinical trials ever conducted in the field of behavioral medicine. Its purpose was to determine whether treatment of depression and low perceived social support (LPSS) can reduce the incidence of recurrent myocardial infarction or death in patients with a recent myocardial infarction. Unfortunately, the intervention had no effect on this hard clinical outcome (Berkman, Blumenthal, et al., 2003). In hindsight, many of the researchers who were involved in ENRICHD have wondered whether its design could have been improved and whether it might have yielded better results if it had been preceded by some smaller trials with surrogate endpoints. A proposed model for designing RCTs based on intermediate or surrogate endpoints is depicted in Fig. 5.1.

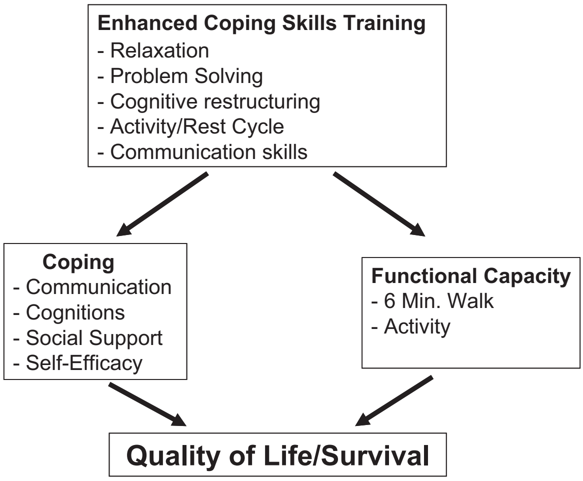

Fig. 5.1 A proposed model for designing randomized controlled trials using intermediate endpoints. Stage 1 consists of a single-center evaluation of a specific behavioral intervention. If successful, this intervention would be repeated at multiple centers, to assess the reproducibility of findings (stage 2). In both stages, intermediate endpoints, such as change in vascular function or plaque size during carotid ultrasonography, would be used to minimize necessary sample size and follow-up time. If reproducible results are obtained during stage 2, a multicenter intervention trial would be performed in stage 3, in which subjects would be observed for the occurrence of hard cardiac events such as cardiovascular mortality and morbidity (Adapted from Rozanski, Blumenthal, et al., 2005)

Defining the Intervention

Background

Defining and refining interventions for clinically significant problems in behavioral medicine can be challenging due to the multitude of factors that influence health-related behaviors. Behavioral medicine interventions fit the British Medical Research Council's definition of complex interventions: "*Complex interventions in health care, whether therapeutic or preventative, comprise a number of separate elements which seem essential to the proper functioning of the intervention although the active ingredient of the intervention that is effective is difficult to specify*" (MRC Health Services and Public Health Research Board, 2000, p. 1).

The process of defining complex interventions is iterative and includes multiple decision points (Craig, Dieppe, et al., 2008). Based on a literature review and our experience in conducting RCTs, we have identified several key dimensions of behavioral medicine interventions: type of treatment, target, modality, setting, delivery personnel, and intensity (see Table 5.1). Investigators have to make decisions about each dimension in planning the intervention for a behavioral RCT.

Table 5.1 Dimensions that represent critical decision points in the definition of an intervention

Dimension	Description
1. Content or type of intervention	Specific type of treatment selected to treat the target condition and target population
2. Target of treatment	The population that serves as the focus of treatment. This decision point includes (a) demographic and clinical characteristics of the identified patient population, including stage of disease progression, (b) decision whether to focus solely on the patient or to include members of the patient's clinical care and social support network
3. Treatment modality	How the treatment will be delivered to the patient
4. Treatment setting	Where the treatment will be physically delivered to the patient
5. Delivery personnel	Training background and pedigree of the health-care provider(s)
6. Intensity	Level of commitment required by the patient as determined by the frequency of treatment sessions, length of each session, and duration of the treatment program
7. Quality control	Use of procedures to ensure uniform delivery of the treatment protocol including therapist training, manuals or session outlines, and ratings of therapist adherence and competence

Type of Treatment

Educational, behavioral or cognitive-behavioral, self-regulatory, exercise or physical activity, and lifestyle interventions are common in behavioral medicine. Most of the RCTs in this field are tests of these types of interventions, either alone or in combination.

Educational interventions help patients acquire the knowledge and skills they need to prevent or manage disease. Health education interventions should do more than impart information to passive recipients; they should also provide opportunities to actively discuss questions and concerns and to receive personalized feedback (Goldman, 1988; Hatfield, 1988; Bisbee, 1991). Health education interventions typically include information about a particular medical condition and its prevention or treatment and about behavioral strategies for coping with it.

Behavioral treatments (BTs) refer to problem-focused behavioral and cognitive-behavioral interventions for stress, depression, anxiety, or other conditions that can affect physical health outcomes and that can also be distressing or disabling in themselves. Most BTs emphasize ongoing assessment of relevant cognitions and behaviors, explicit definition of treatment targets, and a collaborative relationship between the therapist and the patient. BTs often require a significant commitment of time for behavioral homework assignments.

Self-regulatory treatments (SRTs) help patients to become more aware of their physical symptoms and to control physiological parameters such as heart rate and muscle tension. Examples include biofeedback, relaxation, and mindfulness techniques. Biofeedback enables patients to learn how to control certain bodily states by amplifying physiological processes and using auditory, visual, or tactile signals to display them. Relaxation and mindfulness techniques focus the patient's attention on, and thereby increase control over, breathing, muscle tension, or other physiological processes.

Physical activity and exercise interventions help patients to increase physical activity and/or decrease sedentary behavior. The health benefits of these interventions depend upon sustained changes in daily activities.

Lifestyle or self-management interventions modify habits such as diet, physical activity, or medication adherence that influence risk for chronic health conditions and/or management of such conditions. They often include an emphasis on problem solving or similar approaches to addressing barriers to desired behaviors. Some target multiple health behaviors and involve frequent monitoring of treatment adherence.

The treatment approaches discussed above can also be combined. Treatments that blend elements of health education, BT, SRT, physical activity, and lifestyle modification, in various combinations, are becoming increasingly popular as evidence of their effectiveness accumulates. It can be difficult to precisely define the "active ingredients" of a single complex intervention (Craig, Dieppe, et al., 2008), and it becomes considerably more difficult when several treatment approaches are combined into a single package.

The challenge is not only that behavioral medicine interventions often contain multiple active ingredients but also that these ingredients may interact with one another to produce results that are not entirely predictable from the effects of the individual ingredients. In addition, combined interventions may have multiple targets, such as several different health-related behaviors (Prochaska, Spring, & Nigg, 2008; Spring, Moller, & Coons, 2012). It may not be feasible, in a single RCT or even in a series of RCTs, to pinpoint which ingredients of a complex, multitarget intervention are responsible for which outcomes. There is also the possibility that benefits rest on synergies among ingredients, so that there are no necessary and sufficient ingredients to be found. This is one of the reasons why many researchers are more interested in finding creative ways to improve the outcomes of complex interventions than in parsing their ingredients in minute detail. It is also one of the reasons for the growing interest in conducting trials that are more pragmatic than explanatory and in systematic approaches to behavioral intervention development such as the multiphase optimization strategy (MOST) (Collins, Baker, et al., 2011). In the MOST approach, different combinations of intervention components are tested and refined in early-phase treatment development studies. This paves the way for larger RCTs in which the efficacy or effectiveness of the entire complex intervention can be evaluated more definitively.

We recommend a three-tiered strategy for selecting the treatment when planning an RCT. First, treatments that have already been shown to be efficacious for the medical condition of interest should be considered. Second, if proven treatments are not available or appropriate for patients with that condition, investigators should consider ones that have been shown to be efficacious for similar conditions. Finally, if neither of these strategies identifies a promising intervention, investigators should consider devising a new treatment approach. If possible, a novel treatment should be based on a conceptual model of how it affects the mediators that are believed to link the disorder to adverse outcomes and of resiliency and vulnerability factors within the patient population. For example, Fig. 5.2 displays a conceptual model of coping skills training. It shows how this type of intervention could affect clinical outcomes by improving coping abilities and by increasing physical functioning in patients with chronic obstructive pulmonary disease (COPD).

Treatment Setting

Behavioral interventions have been tested in a wide variety of health service settings including outpatient clinics, inpatient units, emergency

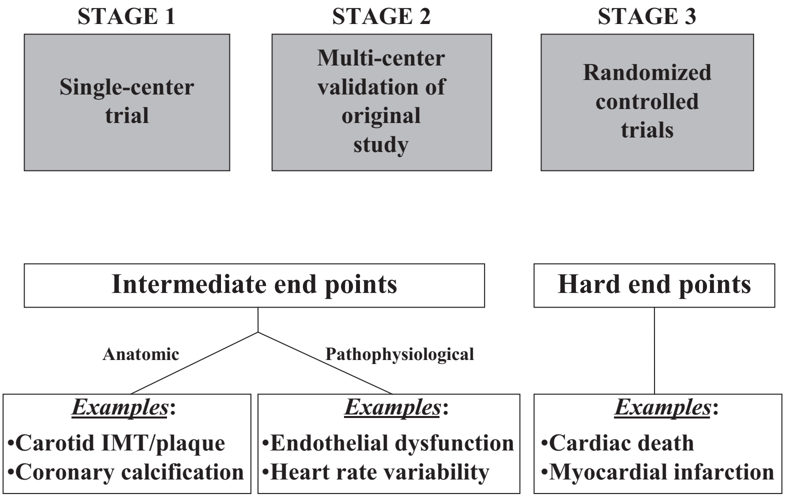

Fig. 5.2 Conceptual model of how a coping skills intervention affects treatment outcomes. In this proposed model, the coping skills intervention is hypothesized to improve quality of life and increase survival by improving coping abilities and increasing functional capacity

departments, and others. This is necessary in order to determine how to implement these interventions in health-care environments where they are both needed and deliverable. On the other hand, interventions that are delivered in settings such as outpatient clinics typically place the burden of transportation on the patient. This can pose a formidable barrier to treatment adherence for patients who are fragile, severely ill, mobility impaired, or unable to afford transportation.

Consequently, there is growing interest in providing interventions at more convenient locations, such as in the patient's home, school, place of employment, or residential treatment facility. In some cases, this may require some travel on the part of the interventionists. However, telehealth technologies (discussed in more detail below) are increasingly being used to facilitate *remote* interventions in natural environments (Reed, McLaughlin, & Milholland, 2000).

Treatment Modality

Historically, both intervention research and clinical practice in behavioral medicine have been confined to face-to-face individual or group treatment modalities. Although face-to-face interactions may offer therapeutic advantages in terms of the ability to focus attention on and emphasize key interactions or processes, these modalities have the disadvantage of requiring patients to make multiple, time-consuming clinic visits. Individual therapy is often considered to be the default modality for behavioral treatment, although there is some evidence that group therapy may be more effective for certain problems (Saab, Bang, et al., 2009). Moreover, technological advances have created new possibilities for the delivery of treatment services via novel channels that have the potential to reduce patient burden, facilitate the exchange of information between patient and provider, and ameliorate rising health-care costs.

Telehealth, which has been defined as "the use of telecommunications and information technology to provide access to health assessment, diagnosis, intervention, consultation, supervision, education, and information across distance" (Nickelson, 1998, p. 527), is becoming an accepted treatment delivery method in behavioral medicine. In one RCT, for example, a telephone-based intervention that included education about stress and health, instruction in specific coping skills, and information about relapse prevention was compared to usual care for patients awaiting lung transplantation (Napolitano, Babyak, et al., 2002). Patients who received the intervention reported superior outcomes on measures of perceived stress, depressive symptoms, general well-being and quality of life, and pulmonary-specific quality of life.

New telehealth technologies are emerging as viable options for the delivery of behavioral medicine interventions. Intervention delivery via video conferencing has been investigated in a number of areas including obesity management, smoking cessation, and biofeedback (Jerome & Zayor, 2000). Patients tend to report moderate to high levels of satisfaction with this modality (Nesbitt, Hilty, et al., 2000).

Internet-based treatments also have been developed and tested for a wide range of clinical problems in behavioral medicine. Examples include insomnia (Strom, Pettersson, & Andersson, 2004), chronic lower back pain (Buhrman, Faltenhag, et al., 2004), smoking cessation (Feil, Noell, et al., 2003), eating disorders (Zabinski, Wilfley, et al., 2001), and recovery from heart transplant (Dew, Goycoolea, et al., 2004).

Interactive technologies including computer programs, audio and video programs, and virtual reality (VR) systems also have considerable potential for the provision of remote behavioral health services. Handheld computers, smartphones, and portable devices that monitor various physiological parameters are increasingly being used to collect patient assessment data and remind patients to adhere to interventions (see Lynx, Brockmiller, et al., 2003). They can be designed to provide communication tailored to patient characteristics such as racial or ethnic group, risk factor status, behavioral history, or symptom severity (Noell & Glasgow, 1999). By combining real-time computer graphics with sensorimotor tracking devices, VR programs create realistic, treatment-relevant environments in which the patient can become fully immersed (Rothbaum, Hodges, et al., 1999). The evidence to date generally supports the efficacy of these interactive technologies (Noell & Glasgow, 1999), particularly as part of more comprehensive interventions. However, there have been few empirical comparisons of modalities and little research on their relative cost-effectiveness (Whitten, Mair, et al., 2002).

An important feature of these evolving technological modalities is that they introduce opportunities for new content of interventions. For example, the sort of monitoring of fluctuations in blood sugar as a function of variation in daily behaviors and diet that is possible with smartphone assembly and transfer of data and computer-based analysis and feedback is unimaginable with conventional paper records and clinician reviews.

It is important to recognize that standards of ethical and professional conduct governing RCTs in behavioral medicine are not altered by the use of novel technologies. Investigators considering novel treatment delivery methods must therefore take steps to ensure the same level of informed consent, patient confidentiality, quality assurance, and documentation of services that they would for trials of traditional treatment modalities (see Reed, McLaughlin, & Milholland, 2000).

In addition, the rapid pace of technological change makes it difficult to use standard trial designs, since RCTs can take years to plan, conduct, and analyze. Consequently, a new methodological framework, the Continuous Evaluation of Evolving Behavioral Intervention Technologies (CEEBIT), was recently proposed as an agile alternative to traditional approaches for evaluating innovative behavioral intervention technologies (Mohr, Cheung, et al., 2013). The CEEBIT framework relies on continuous evaluation of new technologies to refine ones that are promising and weed out ones that produce poor outcomes.

Treatment Intensity

The intensity of a behavioral intervention is usually characterized in terms of the frequency and length of treatment sessions and the duration of active treatment. Trade-offs between the duration and frequency of sessions are often made in order to minimize the participant burden, such that frequent sessions are relatively brief and infrequent sessions are longer. Most disease management interventions have had durations of less than 6 months, although some have used telehealth approaches to provide booster sessions over longer periods (Krumholz, Currie, et al., 2006).

Treatment intensity depends to a large extent on the type of treatment. For instance, physical exercise and lifestyle change interventions require frequent participation, with structured activities often scheduled on a daily basis. In contrast, educational and behavioral interventions often require fewer formal sessions, with many RCTs delivering weekly 50- or 60-min sessions. Decisions about intensity are also closely related to decisions about target populations, settings, and treatment modality. The respondent burden has to be acceptable for the target population. This is especially important when testing treatments for chronically ill or debilitated patients, which must take into account their severity of illness, medical or psychiatric comorbidities, and access to transportation, telehealth, or information technologies.

Dosage issues are systematically investigated in Phase I drug research, before the efficacy of a drug is evaluated in Phase II/III RCTs. There has been considerable methodological progress over the past decade in Phase I research (Jaki, Clive, & Weir, 2013). Consequently, pharmaceutical researchers can now use a variety of methodologically advanced strategies to determine optimal dosages before proceeding with larger trials. In contrast, treatment dosage or intensity decisions in behavioral medicine trials are seldom informed by systematic, early-phase dosage studies. Many dosage decisions are simply based on tradition, precedent, or estimates of the tolerance of the intended audience. For example, a researcher might decide to test a 6-session version of a behavioral intervention in an RCT simply because a 6-session version was used in previous studies. A shorter or longer version of the intervention might be more efficacious for the target problem or population, but the RCT will not shed any new light on this question because it will only evaluate a 6-session intervention.

Treatment intensity deserves more systematic attention in behavioral medicine research, for a number of reasons. Interventions that are too intensive may be too inefficient and burdensome, especially for very ill or debilitated patients, but ones that are not intensive enough may not be efficacious. Intensive interventions are more difficult to implement in clinical practice and more expensive to deliver than less intensive interventions, but patients with complex or treatment-resistant problems may need more intensive treatment than do other patients. Also, from a population perspective, a highly efficacious treatment that reaches only a small proportion of those for whom it is intended may achieve less than a modestly efficacious treatment that has broader reach. An optimal balance among these considerations can be difficult to achieve, but it is too consequential to ignore. It is as important to evaluate different dosages in early-stage clinical research on complex interventions as it is to investigate different combinations of treatment components.

However, larger studies may also be needed to investigate the effects of different dosages of an intervention on clinically relevant outcomes. Exercise interventions provide an informative example. An exercise prescription typically includes type of exercise (e.g., walking, biking, strength training), frequency (e.g., three times per week, daily), duration (e.g., 20, 30, or 60 min), and intensity (e.g., percentage of maximum heart rate or subjective rating of perceived exertion). However, there is uncertainty as to the optimal dosage of exercise for different medical conditions. Exercise promotes better health outcomes in a wide variety of medical conditions including colon cancer (Lee, Paffenbarger, & Hsieh, 1991), gallstones (Leitzmann, Rimm, et al., 1999), osteoporosis (Block, Smith, et al., 1987), and cardiovascular disease (Blair, Kohl, et al., 1995; Lee, Hsieh, & Paffenbarger, 1995; Leon, Connett, et al., 1987). Some exercise is better than none, but how much exercise is needed is unknown even for conditions such as coronary heart disease in which the health benefits of exercise are very well established (Jolliffe, Rees, et al., 2001; Oldridge, Guyatt, et al., 1988).

The issue of the optimal intensity of exercise is especially relevant for psychiatric conditions such as major depression. The SMILE trial (Blumenthal, Babyak, et al., 1999) demonstrated that the effects on depressive symptoms of aerobic exercise three times per week for 16 weeks are comparable to those produced by antidepressant medications. In SMILE, however, exercise was confounded with social support, and all patients randomized to exercise received the same exercise prescription (70–85% heart rate reserve, three times per week). In an effort to identify the optimal exercise prescription, the DOSE study (Dunn, Trivedi, et al.,

2005) randomized patients to one of four aerobic exercise groups that varied total energy expenditure and frequency or to an exercise placebo control condition. Approximately 80 min of moderate intensity aerobic exercise for a person who weighs 70 kg was more effective than a lower dose of exercise, although there was no difference in effectiveness as a function of the frequency of exercise training. These results confirm the value of well-designed RCTs in helping to establish the optimal intensity level of exercise. This approach could be extended to other interventions, such as relaxation or mindfulness training.

Treatment Delivery Personnel

Few interventions in behavioral medicine are the sole province of any single discipline. For example, disease management interventions for heart failure, diabetes, or depression have been delivered by nurses, case managers, physicians, pharmacists, social workers, dietitians, physical therapists, psychologists, information systems specialists, and even nonprofessional peers (Krumholz, Currie, et al., 2006). Within and across these professions, the levels of education, specialized training, and clinical experience required to deliver these interventions in the context of clinical trials have varied considerably. In a meta-analysis of psychotherapy outcome studies, Crits-Christoph and colleagues (1991) found that the use of experienced therapists reduces the proportion of variance in treatment outcomes that is attributable to therapist effects rather than to the intervention itself. However, reliance on highly trained and experienced therapists may limit the external validity and translational potential of a trial if the intervention is likely to be delivered in clinical practice settings by therapists with substantially less training or experience.

Multifactorial Intervention Research

The preceding sections addressed a variety of characteristics of behavioral interventions. In some cases, multiple studies may be needed to optimize and evaluate any one of these characteristics. Furthermore, optimizing *combinations* of these characteristics may not be a realistic goal for a single RCT, or even for a series of RCTs, because there may be too many combinations of interest to test in this fashion. In this circumstance, quality improvement (QI) research designs may provide more realistic alternatives for multimodal tweaking of complex interventions. Well-designed RCTs typically yield stronger evidence of efficacy or effectiveness than QI studies are able to produce, but QI studies are more feasible in some cases, and they can be very informative (Fan, Laupacis, et al., 2010).

Defining the Comparison Condition

The vast majority of pharmaceutical trials compare a single medication to a placebo that closely resembles the medication but that lacks its active ingredient. The decision to include a placebo arm in a standard efficacy drug trial is an easy one, because there are no better alternatives. In contrast, behavioral trialists have to choose from among a variety of comparison conditions. The choice is often difficult and sometimes controversial. In fact, it is not unusual for grant reviewers to raise more concerns about the comparator than about the intervention that a proposed trial is designed to evaluate.

The comparison conditions that are used in most behavioral RCTs can be divided into three categories. The *traditional* control groups are the familiar ones that are discussed in behavioral research methodology textbooks (e.g., Nock, Janis, & Wedig, 2008; Kazdin, 2003), including no treatment, wait list, attention, and nonspecific control conditions, as well as a variety of active comparators. *Existing practice* (EP) comparators have been given relatively little attention in standard methodology textbooks, yet they are playing an increasingly important role in behavioral intervention research in general and behavioral medicine research in particular. EP comparators include "usual care" (also known as "treatment as usual"), the current "standard of care," and others (Freedland, Mohr, et al., 2011). Finally, in at least three major trials, behavioral interventions have been compared to *pill placebo* control conditions (DeRubeis, Hollon, et al., 2005; Diabetes Prevention Program Research Group, 1999; Orchard, Temprosa, et al., 2005; Elkin, Shea, et al., 1989). Such trials have to include an active drug arm in addition to the pill placebo arm so that the participants can be blinded as to whether the pills they are taking are active drugs or placebos (assuming that they are randomized to a pill arm rather than to the behavioral intervention arm).

As emphasized throughout this chapter, major design decisions in behavioral intervention research depend on the study's primary purpose. This is especially apparent in decisions about comparators. For example, some investigators incorrectly assume that it is always necessary to control for attention when testing a behavioral intervention. If the main purpose of a trial is to determine whether a particular intervention is superior to an alternative intervention that exposes patients to the same amount of clinical attention, then it is indeed necessary to control for attention. If the main purpose of the trial is something else, it may be unnecessary to control for attention, and, in some cases, it would be counterproductive to do so (Freedland, 2013).

McDermott and colleagues (2011) tested a novel intervention for patients with peripheral arterial disease. It included eight telephone calls with a trained health counselor and focused on adherence to cholesterol-lowering medications and on encouraging patients to discuss cholesterol management issues with their physician. The pragmatic purpose of the trial was to determine whether cholesterol outcomes could be improved by adding this intervention to the patients' usual medical care. In order to answer this question, it was necessary to compare the intervention (plus usual care) to usual care alone. The investigators designed their trial accordingly. The usual care control condition was well suited to the primary aim of the trial.

However, the investigators also included an attention control condition. It is not clear why they decided to add this third arm to the trial, but it is likely that they did so in order to forestall any concerns about failing to control for attention. As it turned out, the attention control arm complicated the interpretation of the findings, and the intervention vs. usual care comparison was more informative than the intervention vs. attention control comparison. Routine medical care for peripheral artery disease usually does not include an ancillary counseling program that provides little more than diffuse clinical attention. Thus, the attention control condition did not help to answer the RCTs primary question, i.e., whether patients would have better outcomes if they were to receive a cholesterol counseling intervention than if they receive only their usual medical care for peripheral artery disease. Unexpectedly, the outcomes in the attention control condition were *worse* than those in the usual care arm. This created a situation in which the intervention was superior to the attention control condition, but not superior to usual care. Consequently, patients are no better off if given this intervention than if they simply receive standard medical care, even though the intervention could be called "efficacious" relative to a clinically artificial attention control condition. The authors themselves questioned the inclusion of the attention control arm in their trial (Pagoto, McDermott, et al., 2013), as did one of us (Freedland, 2013).

The primary purpose of a behavioral trial always depends, to some extent, on the stage of the research program of which it is a part. For example, in the initial test of a novel behavioral intervention, the investigator's goal may simply be to determine whether it has any detectable effect on an outcome of interest. This calls for a relatively small trial and hence a relatively lenient control condition. Comparison to a much more stringent condition, such as to an established treatment for the same problem, would require a much larger study and would be premature at such an early stage in the research program (Mohr, Spring, et al., 2009).

Establishing Quality Control Procedures

Rigorous quality control (QC) procedures are needed to ensure that the treatment protocol is implemented properly and consistently. Treatment-related QC activities include therapist training, use of a treatment manual, and assessments of treatment adherence and therapist competence. QC procedures should include a feedback loop in which assessments of adherence and competence inform revisions to the treatment protocol and therapist training.

The goal of therapist training is to ensure that the therapists have the skills and experience they need to deliver the intervention properly and familiarity with the clinical population that is the target of the intervention. The training should emphasize standardization of treatment procedures and promotion of adherence to them by all intervention staff. It should begin before the therapists start conducting their treatment sessions and should be led by supervisors with experience delivering the study intervention or similar treatments. Common training techniques include didactic instruction, role plays, and live or recorded demonstrations of model cases.

Treatment manuals or protocols serve to formalize treatment procedures and processes. The ones that are used in RCTs typically describe the rationale of the intervention, specific treatment procedures or processes, required materials, and recommended time allocations. If the intervention is highly structured, the manual may provide a session-by-session agenda. If the intervention is flexible or adaptive rather than tightly structured, it may instead provide guidelines for setting session agendas and for planning the course of treatment. A meta-analysis of psychotherapy outcome studies (Crits-Christoph, Baranackie, et al., 1991) found that the use of manuals reduced variability in therapist effects. Manuals also provide information that can be used for replication, and subsequently for clinical dissemination, if the RCT shows that the intervention is efficacious. Thus, treatment manuals can assist in enhancing both the internal and external validity of an intervention (Barber, Krakauer, et al., 1997).

Treatment adherence refers to the extent to which therapists deliver the intervention as prescribed by the treatment protocol. Therapist competence refers to the skillfulness with which the therapists deliver the intervention (Waltz, Addis, et al., 1993). It is possible for a therapist to be adherent yet unskilled or to be skillful but nonadherent. The goal of treatment supervision in an RCT is to optimize both adherence and competence. Adherence and competence are often assessed by reviews of audio or video session recordings, with systematic ratings by the supervisor, other therapists, and/or independent observers. Ratings may be completed for every session, or for a random sample of sessions, depending upon the time and resources available for this labor-intensive activity. QC reviews of clinical documentation (e.g., problem lists, intervention checklists, treatment plans, etc.) may also be performed.

When developing the treatment-related QC procedures for an RCT, the investigators should try to identify the specific elements of the intervention that have been empirically or theoretically linked to treatment outcomes. These elements should be emphasized in training, manuals, and evaluations of adherence and competence. The investigators should select strategies to monitor these specific elements that balance efficacy and effectiveness concerns. For example, although frequent supervision sessions may increase the integrity of treatment delivery, this strategy may be harder to disseminate than completion of brief QC checklists. Finally, the investigators should develop criteria to determine satisfactory adherence and competence based on precedents, empirical findings, or the theory underlying the approach.

Proactive quality control procedures are also needed for many other aspects of behavioral RCTs. The most demanding and time-consuming QC task in most trials is to ensure that the study data are as accurate and as complete as possible. Traditionally, much of the data in behavioral medicine trials has been collected on paper forms and then manually entered into research databases. This process presents many opportunities for errors and missing data, but it does have the advantage of supporting QC efforts in which the databases are compared against the original paper forms or questionnaires. However, there is an ongoing shift toward paperless data collection methods. For example, responses to structured interviews may be recorded on tablet computers instead of on paper forms. This is much more efficient than the traditional approach, but it can be difficult to tell whether an item was accurately entered. For example, if an interviewer mistakenly enters “25” instead of “35” as the age of a research participant, this error could easily slip through retrospective QC checks. Consequently, it is becoming increasingly important to build interactive data integrity checks and other proactive QC procedures into the data collection plan for behavioral RCTs.

Some Lessons Learned from ENRICHD

The ENRICHD trial (Berkman, Blumenthal, et al., 2003) provides an informative example of the development and implementation of a behavioral intervention for a complex, multicenter RCT. (Two of the present authors [Blumenthal, Freedland] were ENRICHD Investigators.) Patients who met the study’s criteria for depression and/or low perceived social support (LPSS) were enrolled within 1 month after hospitalization for an acute myocardial infarction (MI). When the trial was being planned, there was considerable evidence that both depression and low perceived social support placed post-MI patients at increased risk for recurrent MI or death (Berkman, Leo-Summers, & Horwitz, 1992; Frasure-Smith, Lespérance, & Talajic, 1993), but little evidence that either of these psychosocial risk factors could be modified with treatment or that modifying them could improve medical outcomes. Several previous RCTs had suggested that stress management interventions were not beneficial (Jones & West, 1996) and might even be harmful (Frasure-Smith, Lespérance, et al., 1997) for patients with coronary heart disease, and it seemed possible that treatment of depression and LPSS might also produce no benefit or unintended adverse effects. Under these circumstances, the best option was to look for an intervention that was already established as safe and effective for depression and social or interpersonal problems in adults, even if little was known about its effects on medical outcomes in cardiac patients.

Thus, the primary purpose of ENRICHD was not to test any particular intervention; it was to determine whether treatment of depression and LPSS can improve medical outcomes after an acute myocardial infarction. In other words, the primary research question of the trial was about the medical outcomes, not about the intervention. Several empirically supported therapies were considered. CBT was eventually selected because there was more empirical evidence supporting CBT for depression than any other form of psychotherapy, particularly in elderly and medically ill populations. CBT had also demonstrated superiority to IPT for depression in withdrawn and socially dysfunctional patients. However, although there were many social support interventions to choose from (Hogan, Linden, & Najarian, 2002), neither CBT nor any other psychosocial intervention had ever been shown to improve social support in socially isolated patients. Thus, no known evidence-based treatment could fulfill the criterion of having demonstrated effectiveness for *both* depression and LPSS. Consequently, the investigators decided to focus on cognitive therapy for depression but to expand it so that it could also be used to treat LPSS.

The core treatment manuals for the ENRICHD trial were *Cognitive Therapy of Depression* (Beck, Rush, et al., 1979) and *Cognitive Therapy: Basics and Beyond* (Beck, 1995). The investigators also developed a supplementary treatment manual for ENRICHD. It discussed the application of CBT to the treatment of LPSS and depression in post-MI patients, the details of how to deliver individual CBT for the trial, and the protocol for group CBT sessions. The supplementary manual drew both upon the extant empirical literature on behavioral interventions for cardiac patients and upon the clinical expertise of the investigators.

The characteristics of the patient population posed several barriers to the delivery of CBT. Prior RCTs of psychosocial treatments for cardiovascular patients had been conducted with demographically homogeneous populations. In contrast, the ENRICHD population was highly diverse, with 48% women, 34% racial or ethnic minorities, 40% over the age of 60, and 24% with less than a high school education (Berkman, Blumenthal, et al., 2003). The diversity of the population necessitated the use of novel strategies such as training in a range of cultural competencies, developing strategies to destigmatize the treatment, minimizing jargon in written materials, and using metaphors to communicate key concepts (ENRICHD Investigators, 2001). Furthermore, it was necessary to translate the assessment and treatment materials into Spanish and to hire both English- and Spanish-speaking therapists.

The timing of the intervention was a key decision point in planning the trial. Some of the impetus for the ENRICHD trial came from the study by Frasure-Smith and colleagues (1993) which showed that depression was a significant predictor of mortality during the first 6 months following an acute MI. These findings suggested that depression should be treated as soon as possible after the MI to minimize the mortality risk. A countervailing consideration was that medical problems might dominate course of recovery over the first 6 months after the MI and that they would dilute the impact of depression, LPSS, and their treatment on clinical outcomes. Moreover, because CBT usually requires weeks or even months of active participation to alleviate depression, some investigators argued that it would be more appropriate to provide treatment later in the disease process when the patient's medical condition was more stable.

Ultimately, the investigators decided to intervene as soon as possible after the acute MI in an attempt to reduce cardiac morbidity and mortality. In hindsight, this decision may have undermined the outcomes of the trial in two ways. First, the decision to treat earlier rather than later posed several barriers to initiating treatment. Because the mortality risk is highest in the first few months after an index event, patients had to be screened within 28 days after their index event to qualify for the study, and treatment had to begin as soon as possible. This often required the initial screening to occur in the hospital within days after the acute MI, a time when patients are typically preoccupied with their medical condition and are often unaware of or unconcerned about their depression or inadequate social support. Patients who consented to participate often felt less distressed after returning home and resuming familiar routines and consequently had some second thoughts about participating in the intervention. Consequently, early intervention sessions were often spent engaging the patient and building a therapeutic alliance, instead of focusing on techniques to alleviate depression and LPSS (ENRICHD Investigators, 2001).

Second, the decision to intervene early may have diminished the impact of CBT on clinical outcomes. A secondary analysis of ENRICHD data showed that depression was not related to mortality during the first 6 months, but was related to clinical outcomes 9–12 months post-MI (Carney, Blumenthal, et al., 2003). Thus, delaying patient enrollment for several months after the acute MI might have been a better strategy than intervening earlier, at least in terms of the goal of reducing morbidity and mortality by treating depression and LPSS in post-MI patients.

As discussed above, interventions in behavioral medicine are often timed to coincide with teachable moments. An acute MI may be a teachable moment in some ways, but as we learned from ENRICHD, many patients are too ill, debilitated, or preoccupied in the first few weeks after an MI to be able to use it as a teachable moment. Thus, the timing of interventions in behavioral medicine should not be decided only on the basis of the patients' cognitive or emotional readiness to learn; their medical and physical readiness must also be taken into account.

Decisions about the intensity and delivery of the intervention were not especially controversial during the planning stage of the trial, but in retrospect, they may have been less than optimal. The investigators decided to deliver the intervention in a flexible manner that would translate to community settings and that patients would receive a minimum of six sessions over a maximum period of 6 months. Unfortunately, the overall differences between the treated and control groups turned out to be fairly modest (2 points on the

Beck Depression Inventory [BDI] and 2 points on the ENRICHD Social Support Instrument [ESSI]). These differences were much smaller than needed for a strong test of the investigators' "causal and modifiable cardiac risk factor" hypotheses about depression and LPSS.

It is possible that more prolonged or intensive CBT, particularly for patients with severe depression, might have produced better clinical outcomes. The trial was not designed to answer this question. However, a secondary analysis revealed that patients in the intervention arm whose depressive symptoms did not improve had worse medical outcomes than those whose depression did improve (Carney, Blumenthal, et al., 2004), even though the primary analysis did not show a between-group difference in medical outcomes (Berkman, Blumenthal, et al., 2003). In addition, participants in the intervention arm who had severe depression (e.g., Hamilton Depression scores of >26) at baseline or who did not show a sufficient response to CBT within 6 weeks were offered an antidepressant in addition to CBT. Cumulative rates of antidepressant use by the end of follow-up in the usual care and CBT arms were 21% and 28%, respectively. A post hoc analysis revealed that patients who received antidepressants had better medical outcomes than patients who did not (Taylor, Youngblood, et al., 2005).

Another major decision concerned how to deliver the intervention in a manner that would foster participant retention. Some patients were too infirm to attend frequent outpatient sessions, incapable of driving themselves to clinic visits, or unable to find transportation. Moreover, some were discharged from the hospital to skilled nursing facilities for extended stays, and some were rehospitalized. To overcome these logistical barriers to study retention, it was necessary to conduct the intervention in a variety of settings and to use several different treatment modalities. For patients who were unwilling or unable to have face-to-face sessions, CBT sessions were delivered by telephone. In some cases, the therapists had to take the treatment to patient instead of asking the patient to come to them. This meant delivering the intervention at the patient's home or at bedside in the hospital. Some patients were offered transportation to the clinic in order to help overcome real and perceived logistical barriers. The investigators realized that these outreach strategies would not translate very well into clinical practice, but understood that they were necessary to maximize therapy engagement and participant retention for the trial. This is an example of the difficult trade-offs that often have to be made in planning a biobehavioral RCT.

A complementary strategy to enhance retention was to offer a combination of individual and group CBT sessions. Although participation in group CBT sessions was encouraged, the challenges of recruiting participants (only one patient was enrolled for every 14 screened) made it difficult to enroll enough patients during the same period in the same locale to fill a treatment group with a minimum of three to four patients. For example, at the Duke University site in Durham, North Carolina, participants were enrolled from a broad geographic area, from as far away as Danville, Virginia, 54 miles north, or Fayetteville, North Carolina, 78 miles south. For these participants, it was not feasible to conduct CBT groups with any regularity. Some of the other sites allowed patients to participate in group CBT sessions via telephone.

By necessity, the delivery of the intervention required flexibility regarding the frequency and intensity of treatment, as well as specific session goals and assignments. However, this flexibility had to stay within the limits of fidelity to the treatment protocol. CBT therapists received intensive training and certification by the Beck Institute for Cognitive Behavior Therapy (founded by Aaron T. Beck, M.D., the developer of CBT) and a minimum of 2 h per week of supervision from experienced therapists, many of whom were ENRICHD co-investigators. The CBT sessions were recorded, and adherence to the treatment protocol was documented on standardized treatment data logs. Reviews of audio recordings and treatment logs served as the basis of individual and group supervision sessions. In addition, the Beck Institute staff reviewed the recordings of approximately 20% of the therapy sessions. Regular conference calls between the Beck Institute and the CBT supervisors also helped to promote treatment adherence and therapist competence.

ENRICHD was one of the first large, multicenter RCTs in which behavioral scientists with backgrounds in health psychology and behavioral medicine collaborated with cardiologists, biostatisticians, and other researchers who had little if any prior experience with behavioral intervention research. Everyone had to compromise despite strongly held opinions, in order to make this unprecedented collaboration succeed. For example, the cardiologists had to accept the fact that behavioral interventions for problems like depression in post-MI patients can take weeks or months to complete. This was especially difficult for the physician-investigators who worked in critical care settings, as they tended to think in terms of minutes or hours rather than weeks or months when treating acute myocardial infarctions.

In contrast, the concept of "keep it simple" was taken for granted by the cardiologists, biostatisticians, and investigators who had had extensive prior experience with large, multicenter trials, but was difficult to accept for the behavioral scientists who had primarily worked on single-site studies. For example, the preliminary plan for the trial included an extensive battery of psychosocial questionnaires. Many of these measures assessed factors that were of great interest to some of the researchers involved in the study but that were neither primary nor secondary outcomes of the trial. To the chagrin of their proponents, most of these measures had to be jettisoned in order to contain the cost and the respondent burden of the trial.

For many of the behavioral scientists, ENRICHD was also their first experience in working with a multicenter Data Coordinating Center (DCC). Most DCCs operate within biostatistics departments at universities or clinical research organizations. The DCC for the ENRICHD trial was affiliated with the Department of Biostatistics at the University of North Carolina in Chapel Hill. The DCC serves many functions besides data management and statistical analyses in a large trial such as ENRICHD, including coordinating the efforts of a widely dispersed, multidisciplinary research group, and holding both the investigators and the staff to high methodological and ethical standards for the conduct of the trial. Working with the DCC helped many of the behavioral scientists to become more aware of the importance of seeing beyond parochial research traditions and adapting to the wider culture of medical trials.

One of the most important attributes of that culture is an unshakable determination to continue pursuing significant research objectives despite disappointments and setbacks. Although ENRICHD was carefully designed and well conducted, the primary outcomes were disappointing. The intervention had weak effects on depression and LPSS, and the primary analyses failed to demonstrate that cardiac outcomes could be improved by treating depression and LPSS. Few of the behavioral scientists had ever been involved in a large, expensive, multicenter trial that did not turn out as well as they had hoped, but most of the medical scientists and biostatisticians had experienced similar or even worse disappointments in some of the other multicenter trials in which they had participated. As long as an RCT addresses an important question, is well designed, and is carefully conducted, they do not consider it a "failure" if the primary outcome analyses turn out to be nonsignificant. The negative results of an excellent RCT can be very useful, and secondary analyses can yield very informative findings, as they have in numerous publications based on ENRICHD data. The biomedical scientists were undeterred by the primary results of ENRICHD. The behavioral scientists learned from them that the best response was not to give up, but to keep trying and to conduct more research. Depression and LPSS are still risk factors for cardiac morbidity and mortality, better ways are still needed to help patients overcome these problems, and RCTs will continue to be essential in this line of research.

Summary and Conclusions

This chapter discussed a variety of methodological issues concerning the design and conduct of randomized clinical trials in behavioral medicine. It included issues with broad relevance, including the importance of meeting current standards of mainstream medical research while meeting the unique methodological challenges of behavioral intervention research. It stressed the vital importance of clearly defining the purpose of a behavioral trial before making key design decisions. It also included a number of more specific issues in the design of RCTs, including how the patient population, outcomes, intervention, comparison condition, quality control procedures, and, most importantly, the purpose and objectives of the trial are defined. Finally, it discussed the ENRICHD trial to illustrate how many of these issues affected the design, conduct, outcomes, and interpretation of findings of a major multicenter RCT in behavioral medicine.

All of these issues are important, but only to the extent that researchers in behavioral medicine continue to propose and conduct rigorous clinical trials to address clinically significant problems. Even when high-quality RCTs show that it is possible to improve upon usual care (Timbie, Fox, et al., 2012), it is difficult to change clinical practices in any area of health care and prevention. With a paucity of rigorous clinical trials, it is much more difficult! Unfortunately, there have been too few trials in most areas of behavioral medicine research and very few large, multicenter RCTs in any of them. This fuels skepticism among physicians and health-care policymakers about the clinical utility of behavioral medicine. Many of them doubt whether lifestyle risk factors such as smoking or physical activity are amenable to behavioral intervention or that psychosocial interventions can improve medical outcomes (Relman & Angell, 2002; Thombs, Roseman, et al., 2013).

We believe that the only way to overcome this challenge is for researchers in behavioral medicine to make a serious and sustained commitment to careful, programmatic intervention research. It is not enough to conduct small treatment development studies or small, single-site RCTs. These are important steps, and valuable in their own right, but they are unlikely to have a major impact on prevention efforts, clinical practices, or health-care policies unless they eventually culminate in large, multicenter RCTs. Unfortunately, funding for clinical research is very scarce, and it is especially difficult to obtain funding for large, multicenter trials which can cost millions or even tens of millions of dollars to conduct. Thus, it is imperative for researchers in behavioral medicine to vigorously advocate for funding to support more and larger RCTs and to make use of these funds to conduct rigorous trials of behavioral interventions for prevalent, clinically significant problems.

Research Approaches of Education, Applied Psychology, and Behavioral Science and Their Application to Behavioral Medicine

6

John P. Allegrante, Christel Hyden,
and Alfgeir L. Kristjansson

Introduction

Behavioral medicine is concerned with the broad and central role of behavior in the prevention and treatment of disease and improvement of quality of life (Fisher, Fitzgibbon, et al., 2011). Because behavioral medicine encompasses interdisciplinary knowledge from across a wide range of theories and best practices in relation to human health and behavioral and social change, it draws extensively on the research methods of education, applied psychology, and behavioral science. These methods are often employed by investigators and program evaluators to make causal inferences about whether organized intervention efforts designed to change health-related behaviors or the contextual factors that shape behavior result in the desired outcomes. But equally importantly, these methods provide valuable tools for formative research that can inform and guide development of evidence-based behavioral medicine programs, as well as program monitoring for ongoing assessment, improvement, and quality assurance.

In almost any discussion of research methods, scholars and practitioners will invariably get into epistemological debates about the relative value of different methods and different approaches. In the biomedical context and much of behavioral medicine research, historically the randomized controlled trial (RCT) has been seen as the "gold standard" by which novel clinical treatments are evaluated for their effectiveness in achieving a desired health outcome. However, given its standard requirement for a placebo, nonintervention, or alternate-treatment control arm, the RCT model of evaluation is limited in providing evidence about the effectiveness and value of the range of behavioral medicine approaches—approaches that now extend beyond the clinic and into the communities in which people live. As a consequence, research and evaluation efforts in behavioral medicine must go beyond the RCT and utilize different and complementary research strategies, designs, and methods to address health disparities and the myriad complexities of behavior and social factors.

This chapter presents the range of different research strategies, designs, and methods derived from education, applied psychology, and behavioral science that are used in behavioral medicine. The methods discussed in this chapter are often used in conjunction with the methods of RCTs and thus complement the research and evaluation process. Accordingly, we have organized the chapter into several major sections. In the first section, we begin by examining seven key questions that are typically addressed in behavioral medicine and illustrate how the research and program evaluation methods, including qualitative, quantitative, and mixed methods, are utilized in answering each of these questions. In addition to providing a primer on these methods, we include selected examples of how such methods have been applied across a wide and diverse range of problems, practice settings, and populations in behavioral medicine and public health. Although we have organized the sections of the chapter to include descriptions of methods that are principally applied to a specific question or phase of research, it is important to point out that all these methods have overlapping value—whether it is in formative evaluation, process evaluation, or summative evaluation—across the spectrum of the research process, from inception to conclusion. For example, although surveys and focus groups are commonly utilized methods for developing and answering research questions about the problem and the needs to be addressed during the formative phases of research, such methods are often used in the later phases of research and evaluation efforts when results are being interpreted and programs disseminated. In the second section of the chapter, we discuss community engagement in the research process as an integral element of conducting research and evaluation in behavioral medicine, reviewing both the basic concepts and principles of community-based participatory research, including illustrative examples and a discussion of key issues. In the third section, we turn our attention to concepts and issues in the translation of research into practice, a topic of growing interest as a next-generation challenge to those working in both the public health and behavioral medicine communities. Finally, we conclude the chapter with a discussion of some of the emerging challenges of conducting behavioral medicine research and their implications for the future.

Answering Key Research Questions in Behavioral Medicine

As in most applied behavioral and social research, behavioral medicine is oriented toward: (a) describing and conceptualizing behavioral phenomena, (b) understanding and explaining the causal mechanisms underlying behavioral phenomena, and (c) creating interventional programs designed to facilitate change or some alteration in the behavioral phenomena. Thus, the questions behavioral medicine seeks to address include: What is the problem and what is the need? With what intervention can we best address the problem? How was the intervention delivered? Was the intervention effective, and why or why not? Can the intervention outcomes be replicated? And how can the intervention be improved, scaled, and disseminated?

What Is the Problem and What Is the Need?

Health and human service programs are typically designed to serve people with demonstrated need, facilitate positive human development, and provide prevention and treatment resources to promote or restore health. When developing these programs, *needs assessment* is the critical first step in deciding whether there is indeed a need to be met, identifying the data to be gathered to understand the need, and generating data with which to begin the planning process in determining what types of programs, intervention approaches, or resources should and can be feasibly offered that hold promise to address the need or mitigate the defined problem.

Needs assessment typically examines social, behavioral, and epidemiological profiles of the community. It seeks to identify and address potentially modifiable social problems as well as the agencies, institutions, and programs currently serving the community, or addressing a specific need, to define and reconcile the discrepancy between “what is” and “what ought to be.” Approaches to answering these questions will vary, but major sources of relevant information in needs assessment include existing archival data about the problem, the experiences and conclusions of experts who know the situation well, and, perhaps most importantly, the perceptions and opinions provided by those directly affected. Once identified, needs can be prioritized and then used as the basis for setting goals and objectives for intervention programs (Isaac & Michael, 1995).

One straightforward method of assessing the needs of a community is simply to ask people about their needs through social surveys, personal interviews, and focus group interviews. At this phase, it is important to estimate the magnitude of need and avoid falling into the trap of proposing and evaluating potential solutions before fully understanding the scope of the problem and the potential objectives a proposed program might be designed to meet. Moreover, the context of need also should be examined in order to ensure efforts are appropriately directed; it is otherwise possible to have an accurate assessment of a community’s need, but fail to assess the cultural, social, or political context in which a program would be implemented or the community’s capacity to continue support and maintenance of the program.

Assessment and Planning Models

Numerous systematic techniques and planning models have been developed to guide needs assessment and the formative stages of intervention planning. While we cannot describe the many techniques and models available, we focus here on two relevant assessment and planning models that have gained popular use and have demonstrated value in a range of health-related and behavioral medicine research.

Delphi Method The Delphi method (or technique) is an iterative process whose purpose is to gather expert opinion and reach consensus of opinion on a defined topic through multiple iterations. It employs a series of questionnaires that are administered by a facilitator in multiple iterative survey rounds that are, in turn, interspersed with feedback and revisions of answers to the questionnaires in response to the feedback in each round until consensus is reached. Initially developed to improve technological forecasting (Linstone & Turoff, 1975, 2011), the method is especially useful when what is known about a phenomenon of interest is incomplete (Adler & Ziglio, 1996). The Delphi method incorporates components of (a) anonymity of the study’s expert participants and their opinions, (b) multiple rounds of iteration to achieve consensus of opinion, (c) controlled feedback, and (d) the opportunity for quantitative analysis and interpretation of data. Delphi panel studies have been used extensively in health-related research ranging from recent studies designed to clarify concepts of parenting practices around food (Gevers, Kremers, et al., 2014), to the determinants of adolescent coping strategies with cyberbullying (Jacobs, Dehue, et al., 2014), to establishing a framework of behavioral indicators for outcome evaluation of health promotion among individuals with suspected TB patients (Li, Ehiri, et al., 2014).

PRECEDE-PROCEED One of the most prominent and widely utilized models in health planning—PRECEDE-PROCEED—provides a comprehensive planning framework for assessing the health and quality-of-life needs, and for designing, implementing, and evaluating health promotion and other public health programs to meet those needs (Green & Kreuter, 2005). Originally developed to facilitate planning of health education efforts, it has been used extensively and more broadly in health promotion and disease prevention planning, at the national, state and local levels, and globally beyond North America. The model works by guiding program planners and evaluators through an eight-phase series of assessment and analytic steps that result in the formulation of measurable goals and objectives for the program. These are: (a) Phase 1: social assessment and situational analysis; (b) Phase 2: epidemiological assessment; (c) Phase 3: educational and ecological assessment; (d) Phase 4: administrative and policy assessment and intervention alignment; (e) Phase 5: implementation;

(f) Phase 6: process evaluation; (g) Phase 7: impact evaluation; and (h) Phase 8: outcome evaluation. The hallmarks of the model include its flexibility and scalability across health problems, populations, and practice settings; its participatory and iterative nature; and the platform it provides for generating evidence-based best practices. Numerous studies and health program planning efforts have demonstrated its utility. For a bibliography of over 1000 published applications of the model across a wide range of settings, populations, and health problems, see Green (2014).

Quantitative Research Methods

Social surveys provide an opportunity to describe phenomena by examining the responses from a large number of participants and looking for correlations among variables and patterns of cause and effect (McBurney & White, 2010). It is beyond the scope of this chapter to provide more than a brief overview of the survey method. Thus, instead of using illustrations from different levels of inquiry, we will present some general guidelines for the use of survey research in behavioral medicine and some of the considerations the investigator must take into account when planning surveys. There are many excellent texts and other resources on survey methods. Several that may be helpful to those wishing more information are: Aday and Cornelius (2009), *Designing and Conducting Health Surveys*; Dillman, Smyth, and Christian (2008), *Internet, Mail, and Mixed Mode Surveys*; Fowler (2014), *Survey Research Methods*; and Rea and Parker (2014), *Designing and Conducting Survey Research*. In addition, many texts focus on particular aspects of survey research, such as sampling techniques, questionnaire design, question construction, scaling, and data coding and analyses.

Questionnaire Development Survey research relies on the interplay of three key elements in questionnaire development: how a questionnaire is designed, how it is administered, and to whom it is administered. Questionnaire items must be valid, meaning that they must measure what they purport to measure, and they must be reliable, providing consistently reproducible responses (McBurney & White, 2010). Because questionnaires can be labor-intensive and expensive to develop, frequently researchers will use existing questions or instruments rather than designing their own, allowing them to rely on previous assessment work that has been done to establish the validity and reliability of the questionnaire items and to compare their results with those of previous studies that have employed the same instruments. However, when using existing questions in multicultural populations, items should first be tested for ethnic and racial appropriateness and cultural sensitivity, even if the questions have been used successfully with other population groups (Warnecke, Johnson, et al., 1997). Further, when items are translated to new languages or used in other countries or cultures, additional steps must be taken to ensure the quality of the translation and validity of the items. For example, the SF-36 and SF-12—two widely used measures of health status and quality of life—were developed as part of the RAND Medical Outcomes Study, a multiyear, multisite American study that was originally designed to explain variations in patient outcomes in relation to varying health insurance coverage in the United States (Newhouse, 1982; Ware, Kosinski, & Keller, 1996). These measures have been used extensively in the North American context. But use of these instruments in other countries, cultures, and languages has required additional psychometric testing to establish their clinical validity and to evaluate cross-cultural stability of questionnaire items and scoring algorithms (Bullinger, 1995; Coons, Alabdulmohsin, et al., 1998; Fukuhara, Bito, et al., 1998; Gandek, Ware, et al., 1998; Li, Wang, & Shen, 2003; Ngo-Metzger, Sorkin, et al., 2008; Perneger, Leplège, et al., 1995; Persson, Karlsson, et al. 1998).

When designing new questionnaire items, the investigator will need to consider the purpose of the questionnaire and what they expect to answer or accomplish with the research. For example, is the study seeking to simply describe the presence and characteristics of a phenomenon (e.g., “Who smokes during pregnancy?”) (Schneider, Maul, et al., 2008), to understand why and by what mechanism the phenomenon might occur (e.g., "What are pregnant women's knowledge and attitudes towards smoking?") (Owen & Penna, 2001), or to seek or evaluate potential solutions (e.g., "Is smoking cessation counseling being offered to pregnant women by their healthcare providers?") (Zapka, Pbert, et al., 2000). In addition, basic principles of questionnaire construction should be followed, including the use of clear, unambiguous items that are valid and reliable, avoidance of bias, logical sequencing, and permitting the data to be coded and analyzed in appropriate and meaningful ways. Steps in questionnaire development often include administering preliminary surveys, called *pilot-test surveys* (where focus groups may be used) to ensure the clarity of questions, determine the correlation between potential items (Zapka, Fletcher, et al., 1997), and conduct psychometric statistical testing to establish construct item validity and reliability or reproducibility (Meadows, Harvey, et al., 2000).

Method of Data Collection Investigators must also choose the method of administration and data collection. These include face-to-face or telephone interviews or self-administered questionnaires (via paper or Internet-based surveys). Each method of data collection will have distinct advantages and disadvantages. For example, face-to-face interviews allow for the development of rapport with a respondent and can be appropriate for respondents with low literacy rates, such as in a study conducted on behalf of the Government of Tanzania in which over 1800 households were interviewed about provision of health services (Abel-Smith & Rawal, 1992). However, face-to-face interviewing is also labor- and resource-intensive, and results depend on both the skill of the interviewer (some of the Tanzanian surveys had to be rejected due to poor interviewing) and on the willingness of the respondent to be honest rather than saying what they think the interviewer wants to hear (i.e., *social desirability bias*).

Self-administered questionnaires can be cost-effective and help avoid social desirability response biases, but can often result in low response rates and missing data. Moreover, there is no concrete way to know that a respondent understood each question and usually there is little or no opportunity to clarify those questions that may have been misunderstood (McBurney & White, 2010). In using self-administered questionnaires, the researcher also cannot be certain that the intended respondent is the one responding to the questionnaire or if the respondent is acquiring assistance from others. Surveys conducted on the Internet can be highly cost-effective and are often particularly appropriate for sensitive topics since the ability to complete the survey in privacy may result in less social desirability response bias (Cohall, Dini, et al., 2008). Internet-based surveys also include additional benefits, such as controlling for question order that can be administered to respondents based on previous answers. These include branching questions that ask about certain behavior, such as tobacco smoking, and questions thereafter that depend on the answer to the previous question (e.g., if "yes" then answer the next five questions about how much the respondent smokes, preferred brands, etc.; respondents that answered "no" would skip the brand items and be taken directly to the next part of the questionnaire). This kind of control over question sequence can be difficult to accomplish in a self-administered paper-and-pencil survey.

Sampling the Population Investigators must also decide on the kind of sampling design they will use to draw a representative sample from some larger population of interest. This is a critical decision because the generalizability of findings of a study depends heavily on the extent to which a sample may be truly representative of the population. The first set of these designs is *nonprobability samples* and include *purposive samples*. *Purposive samples* are designed to identify potential respondents for some particular purpose. For example, research intending to describe the experiences of Canadian adults with osteoarthritis (Gignac, Davis, et al., 2006) or gay Scottish men with HIV (Flowers, Duncan, & Knussen, 2003) would necessarily seek out those specific populations. Similarly, a study of nursing students' perceptions and health beliefs may focus on the students at a single university (Denny-Smith, Bairan, & Page, 2006), research on patient or provider knowledge and experiences may utilize only individuals at specific hospitals, clinics, or pharmacies (Bakken, Holzemer, et al., 2000; Johnson, Nowatzi, & Coons, 1996; Parker, Baker, et al., 1995; Pole, Einarson, et al., 2000; Secginli & Nahcivan, 2006), and surveys of specific professions may be distributed to potential respondents by using membership directories as sampling frames (Helft, Hlubocky, & Daugherty, 2003; Kenny, Smith, et al., 1993; Story, Neumark-Sztainer, et al., 2002) or at trade shows and professional meetings (Korelitz, Fernandez, et al., 1993). Other examples of nonprobability samples that have been identified include *Quota samples*, which seek to identify a certain number of respondents in the sample; *chunk samples* (sometime referred to as *convenience samples*), which study a group of respondents who happen to be available; and *snowball samples*, which is “chain sampling” that starts with a single or small group of initial respondents (often useful in hard-to-reach populations such as drug users or sex workers) who then identify potential other similar respondents (Aday & Cornelius, 2009). In each case, external validity, i.e., the potential to generalize to a larger known population will vary depending on the sampling design.

The second type of sampling design, which is more powerful, is *probability samples*. In using probability samples, researchers generally obtain respondents in a systematic manner such that the probability that any given individual within a defined universe (sometimes referred to as the *sampling frame*) of potential respondents representing a *population* will have an equal chance of appearing in the sample. *Simple random samples*, *systematic samples*, *stratified random samples*, and *cluster samples* all provide different probability-based methods for selecting appropriate population-based samples from the group of interest (Aday & Cornelius, 2009). National studies on knowledge, attitudes, behavior (Galuska, Will, et al., 1999; Glasgow, Eakin, et al., 2001; Knuth, Malta, et al., 2011; Lantz, House, et al., 1998), disease prevalence (Burney, Luczynska, et al., 1994; Tsugane & Sobue, 2001; Yang, Lu, et al., 2010), and their correlations typically use national probability samples, which allow investigators to generalize to the larger population within a statistically known margin of error (McBurney & White, 2010). In this way, investigators may calculate the probability that any one sample is not completely representative of the population from which it has been drawn; while sampling error cannot be eliminated, the extent of the error will be influenced by the sampling techniques chosen (Kelley, Clark, et al., 2003).

Collecting survey data, however, can be expensive and time-consuming. In some cases, the existing specialized and publicly accessible national data sets, which constitute a source of household and individual survey data for secondary analyses, can permit investigators to answer important questions without the time and expense of collecting new data. In the United States, the National Health Interview Survey (NHIS) (CDC, 2015a) includes US Census data to track health status, health-care access, and progress toward achieving national health objectives among household respondents; the Behavioral Risk Factor Surveillance System (BRFSS) (CDC, 2015b) comprises a monthly cross-sectional telephone survey that state health departments conduct with a standardized questionnaire to collect prevalence data from the adult US population on risk behaviors and preventive health practices that affect their health status; and the Health Information National Trends Survey (HINTS) (NCI, 2015) routinely collects nationally representative data about the American public’s use of cancer-related information and related topics. Some surveys, like the National Health and Nutrition Examination Survey (CDC, 2015c), combine individual interviews with physical examinations of a subsample of respondents to assess the health and nutritional status of adults and children. Such sources of national data have supported studies on a wide range of health topics, including characteristics related to participation in a smoking cessation trial (Graham, Papandonatos, et al., 2008); the influence of lifestyle on inflammation in men and women with type 2 diabetes (Jarvandi, Davidson, et al., 2012); and the relationship between physical activity and general mental health (Kim, Park, et al., 2012).

Finally, sampling designs can be mixed. Some studies, for example, mix sampling techniques by randomly sampling from within a sampling frame such as a professional directory or other listing of potential respondents (Stanwood, Garrett, & Konrad, 2002; White, Speechley, et al., 1995) or from purposively chosen study sites (Kurth, Kamtsiuris, et al., 2008). A study of the health of homeless children and housed, low-income children in Los Angeles utilized such mixed sampling techniques. The study employed a three-stage sampling strategy: (1) a purposive sample of shelters, (2) a systematic sample of families in shelters, and (3) a random sample of one child in each family (Wood, Valdez, et al., 1990). On a broader geographical scale, an investigation of suboptimal utilization of public health facilities in Afghanistan began with a sampling frame of six provinces, within which two districts were selected using mixed sampling technique representing urban and rural populations. Two community health centers (CHCs) were selected within each district and out of the two, one from the center of the district was identified and another from the broader geographical catchment area of the district. At the level of CHC, two villages were then selected: the village in which that CHC itself was situated and another study village from the CHC catchment. In this way, at the level of selection of study sites, priority was given to select a fair percentage of respondents from rural as well as urban areas. Using this method, the investigators gave priority to selecting a fair percentage of respondents from rural as well as urban areas and resulted in a total of 48 villages and 24 health facilities from 12 districts in 6 provinces (Singh, Sharma, et al., 2012). Similarly, an evaluation of the quality of public health services in India had no sampling frame from which to draw respondents. Based on the literature, the investigators chose a sample size of 500 respondents to be drawn from the state of Uttar Pradesh, which was divided for sampling purposes into three geographic regions: eastern, central, and western regions. The sample size of 500 was distributed to these three regions in proportion to the rural population of the respective region, and two districts representing each region were selected randomly and the number of respondents selected from each district was proportional to the rural population of the respective districts. Finally, inclusion criteria required that the respondent should have utilized services at the public health center in the previous 6 months, and initial identification of sampling units was accomplished by seeking referrals from village leaders and the medical staff at the health centers, with subsequent respondents being identified through snowball sampling (Narang, 2011).

Qualitative Research Methods

In comparison to the descriptive and correlational nature of the data obtained in surveys, qualitative research is usually exploratory and seeks to use inductive (starting with observations and developing hypotheses) rather than deductive (starting with extant hypotheses and testing them with observations) approaches to generate novel insights. Curry, Nembhard, and Bradley (2009) have noted that such methods are best utilized when (a) investigating complex phenomena that are difficult to measure quantitatively, (b) generating data necessary for a comprehensive understanding of the problem, (c) gaining insights into potential casual mechanisms, (d) developing sound quantitative measurement processes or instruments, and (e) studying special populations.

Qualitative research differs from quantitative research in that rather than counting occurrences, exploring correlations among variables of interest, and statistically testing hypotheses, qualitative research seeks to describe the complexity and range of occurrences or phenomena and provide a rich basis for generating hypotheses or gaining deeper insights into statistically demonstrated relationship among the variables of interest. Moreover, while quantitative research typically generates numeric data using standardized processes and instruments with predetermined response categories, qualitative research allows for the use of open-ended questions, discussions, and observations. These guided discussions also allow the respondent to identify, describe, or elaborate on concepts and concerns that may not have been previously anticipated by the investigators and not captured with the more closed-format questions of those found in surveys (Curry, Nembhard, & Bradley, 2009).

The two primary methods of qualitative data collection are in-depth interviews and focus group interviews. In-depth interviews allow for the exploration of individual experiences in great detail and can be particularly valuable for sensitive topics since the method maximizes privacy while also allowing the investigator to build rapport to increase candor. Focus groups are equally well suited for explorations of perceptions and traditions of social groups and understanding social processes, as the group interaction dynamic can serve as a catalyst to generate unique insights into understanding (Kreuger & Casey, 2015; Mermelstein, 1999). Research suggests that group discussions can also elicit more critical comments than interviews, with the synergy of the group allowing each participant to reinforce one another's vented feelings (Robinson, 1999). In this way, focus groups may be especially effective at facilitating comfort among socially marginalized or disempowered populations who might otherwise feel reluctant to give negative feedback or who may feel that any problems result from their own shortcomings (Curry, Nembhard, & Bradley, 2009; O'Brien, 1993; Robinson, 1999).

Examples of research in which such methods have been applied include studies designed to illuminate the health beliefs and folk understanding regarding diabetes among British Bangladeshis (Greenhalgh, Helman, & Chowdhury, 1998) and formative research processes focused on intervention development for hard-to-reach population groups by the AIDS Community Demonstration Project (Higgins, Oreilly, et al., 1996). Because of the increasing importance of such methods in health-related research, efforts to formulate and define standards for reporting qualitative research have been undertaken in recent years. For example, the 21-item standards for reporting qualitative research (SRQR) is designed to improve the transparency of qualitative research by providing clear standards for reporting of study methods and findings (O'Brien, Harris, et al., 2014).

As with quantitative methods, investigators using qualitative research methods must carefully define the target group that will be the most beneficial, using systematic scientific methods to develop the sample (Curry, Nembhard, & Bradley, 2009; Robinson, 1999). However, in contrast to quantitative sampling techniques that rely on statistical probability theory, the logic and power of the purposive sampling used in qualitative research lie primarily in the high quality of information obtained per sampling unit. Adequacy of the sample size is relative, a matter of ensuring that the sample is neither too small to support claims of informational redundancy or saturation, nor too large to allow the deep, case-oriented analysis that is the hallmark of so much qualitative work (Sandelowski, 1995). Thus, generally, the aim is to identify participants who are "information rich," have certain characteristics, possess detailed knowledge, or have relevant experience; to study their responses intensively; and to continue data collection until the point of theoretical saturation, i.e., when no new concepts emerge (Curry, Nembhard, & Bradley, 2009). Although it is not possible to define the number of participants in advance, a range of 20–30 individual interviews or 4–6 focus groups with 6–10 participants each is often adequate to achieve saturation (Morgan, 1996; Patton, 2002). However, studies involving more than one target population, more heterogeneous groups, or both, often require more episodes of data collection in order to ensure inclusion of multiple viewpoints. Examples include the AIDS Media Resource Project, which conducted 52 different focus groups with 351 participants (Kitzinger, 1994), and a multisite investigation into ethnic and gender differences in youth smoking which included 178 focus groups conducted in 11 states with 1175 participants (Mermelstein, 1999).

Finally, as with quantitative methods, investigators using qualitative methods should strive to maintain that same scientific rigor that typically characterizes quantitative research. This means aiming to reduce problems such as researcher bias, lack of reproducibility, or limited generalizability.

Mixed Methods

Increasingly, and in part due to a recognition of the complexity of the problems on which behavioral medicine focuses, current evaluation research practice is now emphasizing a blending of the two approaches in which qualitative findings add interpretive richness to the more objective findings of quantitative research. Such *mixed-method* approaches in health-related research have emerged in recent years (Chatterji, 2004;

Chatterji, Green, & Kumanyika, 2001; Clark, 2010; Peterson, Czajkowski, et al., 2013). The inherent strengths of quantitative and qualitative research approaches complement each other, and combining both methods not only reflects the complex nature of the problems facing behavioral medicine and public health, but can also improve the quality and scientific power of the data derived from the investigation of complicated health problems (Creswell, Klassen, et al., 2011). Examples of mixed-methods research include studies of vaccine reminders (Anderson, Sebaldt, et al., 2008), patient safety (Benning, Ghaleb, et al., 2011), HIV and sexually transmitted disease (STD) prevention (Pinto & McKay, 2006; Shain, Piper, et al., 1999), and smoking cessation (de Vries, Weijts, et al., 1992). Combining these two approaches can result in a synergistic effect where the outcome of the two together is greater than the effects of either approach used separately (de Vries, Weijts, et al., 1992).

Reports of qualitative findings enriching understanding of quantitative observations have also become more numerous in the literature in recent years. For example, in the Feeding Young Children Study, a randomized controlled trial of a bottle-weaning intervention among low-income families, the initial research questions at Women, Infants, and Children (WIC) nutritional clinics were formed via nutritionists' observation of 4- and 5-year-old children drinking from baby bottles. A pilot quantitative study confirmed that mothers did typically provide baby bottles to children well past the recommended weaning age (Bonuck & Kahn, 2002), but it was the subsequent focus group discussions that revealed the mothers were typically following feeding advice from the child's maternal or paternal grandmother. Moreover, while the mothers were open to changing behavior and learning new skills, they had concerns about implementing changes that were counter to the grandmothers' opinions and experiences. The qualitative findings put the quantitative child-feeding data into the larger context of family dynamics, and the subsequent intervention not only addressed the mothers' knowledge of feeding behaviors but also provided support and materials to help mothers to broach the topic at home with family members (Hyden, Kahn, & Bonuck, 2013). In this case, the insights gleaned from the qualitative research shed new light on the quantitative results and clarified the information needs of the target audience.

Mixed methods can also provide researchers with additional tools to validate the outcomes of studies. Sometimes referred to as *triangulation of methods*, if the results from each method suggest the same conclusion, then confidence in the results is strengthened (Steckler, McLeroy, et al., 1992). One evaluation design solution that encompasses several phases of evaluation research using mixed methods is the extended term mixed method (ETMM) approach. ETMM designs are long-term research plans following life spans of individual programs or policy initiatives by employing descriptive research methods in the early stages of program adoption and implementation followed by experimental designs at a subsequent stage. ETMM designs deliberately study and document environmental variables as a component of the research plan, allowing for explanations of causality based on both empirical and substantive knowledge gained on the program and its setting. This use of a variety of research methods at multiple points of a program or policy's life span can improve the quality of evidence and strengthen interpretations of causality by helping to shed light on a multitude of context, process, and input indicators. The investigator can also select the key variables and interactions to use as statistical or procedural controls to empirically test process–outcome links (Chatterji, 2004). For example, an evaluation of after-school supplemental education utilizing ETMM involved a year-long study integrating a matched-groups design with classroom observations and surveys. The research began with a 14-week formative phase conducted at the beginning of the semester to explore the program and its environment in depth, with the goal of providing feedback to developers, program personnel, and school staff in order to stabilize treatment delivery and improve fidelity. This "before" phase gathered process data using classroom observations and teacher surveys, and yielded evidence of the extent to which the observed program processes, inputs, and outcomes were consistent with the program's underlying theory and philosophy. In the last 16 weeks of the program, data collection continued with classroom observations and surveys to document changes on program inputs and processes over time in matched classrooms by grade—the summative or "after" phase. In this design, the findings of the formative phase were used to tighten the data-gathering and analytic design of the summative phase, and qualitative classroom observations triangulated the quantitative analysis of teacher surveys and student outcome measures (Chatterji, Kwon, & Sng, 2006).

In summary, the use of quantitative, qualitative, and mixed research methods in behavioral medicine research is critical to gaining an understanding of the problem and needs of the population. The use of such methods in systematic needs assessment enables investigators and program planners to gain an understanding of the scope and extent of the problem, identify potentially feasible approaches to addressing the problem and perceived needs, and set the stage for the formulation and development of intervention programs. Mixed methods are important in gaining a better picture of the impacts and outcomes of intervention programs, often providing insights into the barriers and enablers to intervention success.

Table 6.1 provides a summary of the three research approaches and methods for needs assessment discussed above, including selected characteristics by which the strengths and weaknesses of each method can be assessed.

With What Intervention Can We Best Address the Problem?

Once a problem has been identified, the question of what intervention can best address the problem then becomes the major focus of program developers. Answering this question relies heavily on both formative and process evaluation methods (Dehar, Casswell, & Duignan, 1993). Program and intervention development is typically shaped during a *formative evaluation* phase of research. This phase usually seeks to address questions about program design, process, and outcomes, and identify elements of the intervention approach that will be necessary to change what is known from a needs assessment about the potentially modifiable causal mechanisms of the behavior or circumstances that are the focus of change. During this process, behavioral researchers not only need to understand the incidence and prevalence of a problem but must also gather data that can answer several key questions about how that problem can be optimally addressed.

Formative research typically cannot be conducted from a distance and must include input from the community of interest, as well as from those who have access to and knowledge about the intended audience, in order to create programs that are acceptable, unique, and effective (Posavac, 2011). Formative evaluation research activities can include having members of the intended audience evaluate materials for clarity and effectiveness, conducting surveys or interviews with potential partners or participants to inform the direction and content of program activities, and pretesting recruitment strategies, data collection methods, and pilot intervention delivery with small groups representative of the larger intended audience (Dehar, Casswell, & Duignan, 1993). For example, Peterson, Link, et al. (2014) conducted a three-step approach to developing and evaluating a novel coronary artery disease self-management educational workbook to be used in a novel intervention being tested in a randomized controlled trial (Peterson, Charlson, et al., 2012). First, the investigators conducted interviews using grounded theory methods with a diverse cohort of patients to identify needs and perceptions. Second, they then incorporated the themes that emerged from the qualitative interviews into the design of the workbook content. Finally, they evaluated study participants' use of and experience with the workbook at the end of the 12-month study period, demonstrating that the focus on practical health information, behavior-specific self-efficacy, and how healthy behaviors decrease risk was highly relevant to achieving study outcomes.

In another example, within the Trial of Activity for Adolescent Girls (TAAG), a randomized, multicenter field trial to reduce the decline in physical activity in adolescent girls, each field center

Table 6.1 Summary of research approaches and methods and selected design characteristics

Characteristic	Quantitative methods	Qualitative methods	Mixed methods
Scientific method	Deductive or “top-down”: the researcher uses data to test or verify hypotheses and theories	Inductive or “bottom-up”: the researcher uses data collected in the field to generate new hypotheses and grounded theory	Deductive and inductive
Objectives	Description, explanation, prediction	Description, explanation, discovery	Multiple objectives
Nature of research	Objective; attempt to study behavior under controlled conditions	Subjective, personal, socially constructed; attempt to study behavior in natural environments and understand the context within which behavior occurs	Pragmatic; attempt to study behavior in multiple contexts or conditions
Nature of data and sources	Variables from surveys and experiments	Words, images, categories from documents, observations, interviews, ethnography, field notes	Mixture of variables, words, and images
Lines of inquiry	Closed-ended questions with predetermined approaches	Open-ended questions with a focus toward emerging approaches	Both open- and closed-ended questions focused on emerging and predetermined approaches
Data analysis	Correlation and other inferential statistical relationships	Description and identification of themes and patterns	Quantitative and quantitative presentation of multiple perspectives
Data results	Researcher framed; generalizable findings with a general understanding of respondent’s viewpoint	Respondent framed; particularistic findings with an in-depth understanding of respondent’s viewpoint	Corroborated findings that may be generalizable
Data reporting requirements	Statistical report including correlations, comparisons of means, and statistically significant findings	Narrative report including contextual description, categories, themes, and supporting respondent quotes	Statistical findings with in-depth narrative description and identification of overall themes
Strengths	Uses standards for validity and reliability; relates variables to hypotheses; utilizes unbiased approaches; provides uniform information; can draw correlations between variables and examine changes in variables over time; generalizable and useful for making predictions, particularly when replicated; useful for studying large groups of people	Focuses on concepts, contexts, and settings; allows for exploration and explanation of personal values and experiences using participants’ categories of meaning; can allow for more collaboration with participants; useful for understanding complex phenomena; responsive to local situations and can include in-depth analyses of contexts and environments; flexible and adaptable	Allows for integration of different data at different stages of inquiry; provides context to quantitative findings to supplement findings by allowing individual cases to illustrate larger findings; can add insights and understanding that might be missed with only a single method

(continued)

Table 6.1 (continued)

Characteristic	Quantitative methods	Qualitative methods	Mixed methods
Weaknesses	Susceptible to respondent bias; focus on hypothesis testing may obscure observation of other phenomena (i.e., confirmation bias); researchers' categories may not reflect respondents' contexts; difficult for use with complex or conceptual issues; results may not translate well to specific situations, contexts, or individuals; requires adequate sample size for statistical power	Data collection and analyses can be expensive and/or time-consuming; analyses are subjective and can be more easily influenced by biases and idiosyncrasies; results are not generalizable; difficult to use to make predictions; lack of stringency may not meet acceptability or credibility criteria for some the scientists, community leaders, etc.	Can be difficult for a single researcher to carry out both qualitative and quantitative research, both in terms of workload and skill; can be expensive and/or time-consuming; methodological challenges, e.g., paradigm mixing, interpreting conflicting results

Note. Adapted from Johnson and Christensen (2004)

worked with schools and communities which differed appreciably in geography and ethnic/racial and cultural backgrounds. The multiphase, mixed-methods TAAG formative evaluation research protocol was developed to address these complexities while understanding how to maximize acceptability by schools, parents, and students to enhance potential for program sustainability. The first phase included (a) school surveys to determine physical education (PE) and health education requisites, teaching strategies, physical activity facilities, and after-school programs; (b) surveys of community agencies to identify resources, communication strategies, and the role of staff; (c) a parent survey to determine the parents' and girls' physical activities, access to resources, physical activity barriers, and preferred methods of learning about programs; (d) a girls' activity checklist to determine prevalent and favorite physical activities; (e) in-depth interviews with girls to determine their favorite activities, barriers to being active, social and environmental contexts, and attitudes about PE; and (f) focus groups with boys to understand their perceptions of girls being active. The second phase included focus groups with girls and interviews with PE instructors to refine the development of intervention materials, define meaningful segments for tailoring intervention messages, explore potential channels for delivering intervention messages, and understand the resources and constraints of target school PE departments. By including multiple respondents and data collection methods, the TAAG approach allowed a greater understanding of physical activity in adolescent girls from a variety of perspectives, including teachers, parents, community agencies, boys, and the girls themselves. Thus, the structured modes of data gathering during the formative evaluation phase produced important information that might otherwise not have emerged had representatives of the intended population not been consulted (Gittelsohn, Steckler, et al., 2006).

Similarly, development of a nutrition education program for use in Red Cross chapters throughout the United States went through a multistage process that began with analysis of the program content for technical accuracy and sequencing of materials before having potential instructors and course participants critically examine the program. Formative evaluation research activities then moved into formal pretests of the materials, teaching strategies, and survey instruments, first at 6 sites, then at 10, and finally with a national field test at 51 sites. The program was modified after each stage of the process based on the data obtained before a full-scale implementation was launched on the national level (Dehar, Casswell, & Duignan, 1993; Edwards, 1987). This illustrates two important points: First, there is not always a clear boundary between formative evaluation research methods and the summative methods that are used to assess effectiveness; second, researchers and practitioners can frequently get bogged down in concerns about following rigid rules and making distinctions. This suggests that understanding how underlying processes that are at play may influence the objects of interest in evaluation should be the focus, not allegiance to any one particular method or another.

Other formative evaluation research activities may guide the adaptation or modification of existing programs and resources for new audiences. For example, a behavioral intervention to prevent STDs among minority women was based in part on ethnographic data collected through focus groups; interviews; observations on life and lifestyles, values and beliefs, sexual behavior, knowledge, and risk taking; strategies to motivate behavioral change; and the logistics of implementing a potential intervention. These findings were then integrated into a pre-existing AIDS reduction model to create a new culture- and sex-specific small group intervention (Shain, Piper, et al., 1999).

When utilized most effectively, formative evaluation research is an *ongoing* process that is *integrated* into the development and implementation of a research project, providing assessment information within a feedback loop that identifies the strengths and weaknesses of the project and its intervention approaches as it evolves, informs modifications of measurement instruments, and shapes the evaluative research design and the intervention program (Evans, Raines, & Owen, 1989). Thus, well-designed formative evaluation research will inform monitoring of intervention program delivery as well as the outcomes and process evaluation activities that are used to assess whether efforts and resources are directed as needed and planned and are of sufficient quality and intensity to achieve desired goals for change.

How Was the Intervention Delivered?

Once a program or intervention has been developed and is being implemented, the focus of attention turns to *process evaluation*. This includes evaluating the extent to which the program is being delivered as it was designed (often referred to as *treatment* or *program fidelity*) and the degree to which the program is functioning as designed and achieving the expected goals and objectives. McGraw, McKinlay, et al. (1989) have described five functions common in process evaluation. These include identifying the: (a) extent to which a program reaches the target population; (b) program dose, i.e., frequency of delivery and/or participation in program activities; (c) organizational context or variability within which the program is being implemented; (d) extent to which programs are implemented in line with program goals; and (e) cost of program implementation. Thus process evaluation validates the assumptions made during the program planning stages to ensure that the needs of the intended population as they were identified in the needs assessment and formative evaluation phase are being met and that program activities are being implemented as designed. Seeking discrepancies between the program delivery plan and the reality of implementation allows researchers either to continue implementing the program with fidelity to its original design or modify it appropriately to adapt to the realities or unanticipated barriers encountered during implementation. This is critical because in many studies oriented toward developing and evaluating effective interventions, the planned intervention protocol may need to be adapted in response to the emerging data obtained from process evaluation. Process evaluation can also include a comparison of program plans to actual operation, identification of specific program components that appear to most influence outcomes, and an analysis of the internal dynamics of a program to understand its strengths and weaknesses and the changes in these that occur over time (Dehar, Casswell, & Duignan, 1993). The key to successful process evaluation is making ongoing, careful observations during implementation (especially in the early phase), according critical consideration to the evidentiary weight of these observations, and introducing systematic adjustments in the program or its implementation in response.

It is a mistake, however, to plan evaluation research that focuses solely on the long-term, summative evaluation of program outcomes, and ignore its process, performance, and immediate impact. Thus, two important functions of process evaluation are: (a) assisting in the interpretation of outcomes, and (b) informing future efforts in similar areas. If a program fails to show impact and lacks process evaluations, it will be impossible to know whether the lack of impact is a reflection of failure of theory and program design, failure to implement the program as originally specified, or failure of measurement to detect program impact or effectiveness (Weiss, 1972). If, however, a program is shown to be successful, detailed information about what it consisted of and how it was implemented will be critical for replication and dissemination. Perhaps most common is a combination of the two scenarios: If a program has mixed success achieving its goals, detailed information about program operations will be necessary to identify and adopt in future programs only those features that were successful (Dehar, Casswell, & Duignan, 1993). In short, while summative outcome measures may illuminate which programs perform well and which interventions were associated with a given outcome, it is equally important to know what "key ingredients" (or components) determine a program's success and how those who manage and participate in the program think and behave (Lindsay, 2002).

To illustrate, the "Gimme 5: A Fresh Nutrition Concept for Students" program was a 4-year intervention targeting increased fruit and vegetable consumption by high school students that utilized multiple components: (a) a school-based media campaign, (b) classroom workshops, (c) school meal modification, and (d) parental involvement. For each of these four intervention components, process evaluation strategies were developed to assess program dose, penetration, and utilization, as well as external competing factors. Data collection methods included questionnaires, classroom observations, measurements of student attendance, and assessment of school menus, food offerings, and food use. The process evaluation results not only demonstrated that the intervention was implemented as planned, but also showed how variability in program dose, penetration, and utilization of a multicomponent intervention can influence the outcomes (Nicklas & O'Neil, 2000).

Similarly, a comparison of two variations of a nurse-led psychoeducational intervention to assist oncology outpatients to manage their pain integrated process evaluations via a qualitative study embedded within a RCT of patient outcomes. Using audiotapes of the intervention sessions along with nurse and patient notes to describe the issues, strategies, and interactions experienced during the intervention, the researchers were able to evaluate not only the outcomes of the intervention, but the process of delivering it (Schumacher, Koresawa et al., 2005). In another example, a study of restrictive smoking policies used surveys of employees and supervisors administered before and after the date the policy became effective as primary outcomes measurements. However, qualitative data, including written comments on surveys, focus groups, and structured interviews, were used to elucidate the findings and identify themes and program characteristics which appeared to have the strongest influence on outcomes of the policy (Gottlieb, Lovato, et al., 1992).

Finally, process evaluation research bridges the gap between the intervention design and its impact and outcomes, providing a more comprehensive and well-rounded approach to program evaluation. To illustrate, the SPARK program, a controlled field study of a multicomponent elementary school program to promote physical activity, included a weekly classroom-based self-management program designed to teach behavior change skills such as goal setting and self-instruction to help children generalize physical activity outside of school. An evaluation of curriculum implementation and association between process and outcome was conducted using direct observation of lessons, subjective ratings by teachers and parents, and participation records of students. Investigators found that teachers viewed the self-management curriculum less positively than the physical education curriculum, and teachers were observed implementing the self-management curriculum at an average rate of 65%. Both of these findings may have contributed to the limited outcome effects of the self-management program. The process evaluation thus allowed program coordinators to identify barriers to full program implementation, which could then be used to inform future iterations of the intervention with the goal of improving curriculum implementation by teachers (Marcoux, Sallis, et al., 1999).

Was the Intervention Effective, and Why or Why Not?

The practice of program evaluation research incorporates the systematic collection of data about program characteristics, activities, impact, and outcomes to improve effectiveness, and reduces uncertainty in making decisions regarding what the program does and what it affects (Patton, 1987). If process evaluation has demonstrated how a program has been implemented, an assessment of the impact and outcomes becomes the next step in program evaluation research. *Summative evaluation* is concerned with effects of intervention programming that is both proximal (*impact*) and distal (*outcome*). Moreover, summative evaluation is complicated by the challenges of attributing the causes of behavioral change to intervention (especially in the absence of a control condition or comparison group) and the differing opinions stakeholders will have about what constitutes a successful outcome or how long that outcome must be sustained for the program to be considered a success (Posavac, 2011). In the following sections, we take up concepts of impact and outcome evaluations and provide examples of their application across several settings.

Impact

Much of summative evaluations research focuses strictly on reported changes in attitudes, behavior, or immediate clinical outcomes that are proximal to program implementation.[1] For example, in an STD and HIV intervention program that prioritized female sex workers in China, a women's health clinic was set up near various sites of participants' work (e.g., karaoke bars, massage parlors, and dance halls). Cross-sectional surveys at baseline and postintervention revealed that the rate of condom use with the most recent three clients increased from 55% at baseline to 68% 12 months later, and the prevalence of gonorrhea and chlamydia fell from 26% and 41%, respectively, to 4% and 26%. These results were used to develop national guidelines on sex worker interventions for nationwide replication (Rou, Wu, et al., 2007).

Investigators evaluating an AIDS prevention program for American sex workers found that a mixed-methods approach to evaluation was the most appropriate fit for the impact evaluation of their program. Field staff indigenous to the neighborhood and population was utilized to readily gain access to the community of sex workers; research methods included open-ended interviews with participants and ethnographic field notes, as well as epidemiological questionnaires. This approach allowed respondents to share, in their own words, their feelings about risks for AIDS, which provided primary findings about higher condom-use behaviors with clients versus lower use with husbands or boyfriends. The approach not only addressed research problems endemic to street-based populations but also ultimately provided a more comprehensive assessment of the program's impact than either method could have provided alone (Dorfman, Derish, & Cohen, 1992).

In another example, when Brazilian researchers sought to test the effectiveness of a program designed to improve child growth by training health workers in nutrition counseling, they randomized children to health facilities with trained workers and compared them to those attending facilities with standard care (Santos, Victora, et al., 2001). The research demonstrated that children receiving the intervention had statistically significant weight gain compared to the control group. However, the impact of behavioral programs often depends on factors outside the health system. In this case the researchers had to demonstrate at least six levels of impact, including that it was possible to train many workers in the intervention, that

---

[1] When referring to the effects of intervention, the terms *impact* and *outcome* are used somewhat differently in the behavioral and social sciences than in clinical medicine. In public health, proximal effects are often referred to as impacts, whereas more distal effects are called outcomes. In clinical medicine, however, proximal effects are outcomes and the longer-term effects of treatments are thought of as the impact.

mothers were receptive to and understood the messages they received, and that not only the mothers changed their child-feeding behavior but that the children ate the more nutritious food (Victora, Habicht, & Bryce, 2004).

Other impacts of such evaluative research will include measurements of program information reach to the intended audience in an effort to assess relationships between awareness and behavior. For example, the PSI/PMSC Horizon Jeunes was a youth-targeted social marketing program for improving adolescent reproductive health in urban Cameroon through peer education, youth clubs, mass media promotion, and other behavior change communications. Using preintervention and postintervention surveys at an intervention and comparison site, the investigators found that after about 1 year of intervention, knowledge of the program was nearly universal, and the majority of youth had direct contact with the program. Exposure to the intervention had a significant effect on several proximal determinants of preventive behavior, including awareness of sexual risks, knowledge of birth control methods, and discussion of sexuality and contraceptives, as well as an increase in the proportion of young women who reported using oral contraceptives and condoms for birth control (Van Rossem & Meekers, 2000).

Outcomes

Compared to immediate impacts on variables of interest such as attitudes and behavior, the effort to evaluate the longer-term effects of intervention programs on more distal health outcomes, such as health status or quality of life, can be significantly more challenging, as illustrated in the following examples of outcomes evaluation from three different settings.

Community-Based Cardiovascular Risk Reduction Some of the best examples of evaluation of long-term health effects have emerged from the several historic studies of NIH-funded community-based cardiovascular disease (CVD) risk reduction experiments that have been conducted in North America and in Europe. In North America, studies conducted at Minnesota (Luepker, Murray, et al., 1994), Pawtucket (Carleton, Lasater, et al., 1995), and Stanford (Farquhar, Fortmann, et al., 1990) all utilized a common theoretical basis—social learning theory—in designing a multiple-component intervention approach that included mass media and social marketing, community organization, and direct education of health professionals. All the projects were evaluated using quasiexperimental designs, with intervention cities and comparison cities. In the Stanford Five-City Project, comprehensive community health education whose aims were to reduce community CVD risk factors was conducted in several cities in northern California from 1979 through 1992. The intervention addressed multiple cardiovascular risk factors and was delivered to all residents in two treatment communities from 1980 to 1986, using multiple educational methods. To evaluate outcomes, potentially fatal and nonfatal myocardial infarction and stroke events were identified from death certificates and hospital records abstracted from hospital charts, coroner records, physicians, and next of kin. Over the full 14 years of the study, the combined-event rate declined about 3% per year in all five cities. However, during the first 7-year period no significant trends were found in any of the cities; it was only in the final 7-year period that significant downward trends were found in all except one city. The change in trends between periods was in the hypothesized direction but not statistically significantly greater in the treatment cities than comparison cities. The researchers speculated that some other influence (e.g., secular trends) accounted for the observed change in all the study communities (Fortmann & Varady, 2000).

Similarly, the North Karelia Project, a study of CVD prevention in Finland, encouraged community action that enabled local community health coalitions and public health departments to do whatever they could imagine would make sense to bring about community and individual changes in health-related behavior (Puska, Nissinen, et al., 1985; Puska, Vartiainen, et al., 1998). The program was developed by Pekka Puska and his colleagues in the Department of Epidemiology of the National Public Health Institute with field offices at the level of county departments of health and local advisory boards in North Karelia. Community organization in North Karelia included collaboration with existing official agencies and voluntary health organizations so that the new project activities in CVD prevention could be integrated with ongoing, formal public health activities (Puska, Nissinen, et al., 1985). Like many North American CVD risk reduction projects, the North Karelia project set a strong example for the use of multiple channels and intervention approaches, from mass media to cooperation with agricultural and food merchandising groups, for example, to improve the availability of healthy foods such as low-fat milk and other products (Puska, Nissinen, et al., 1985). Mass media interventions included the production of health education materials and messages that were disseminated through local newspapers and community organizations and campaigns. Training activities included not only doctors and nurses but also social workers, representatives of voluntary health organizations, and informal opinion leaders. Training was organized through county-level or other local organizations. Attention to the health system included reorganizing treatment for hypertension and care following myocardial infarction (MI). This included training and development of treatment guidelines. Cooperation with other local organizations included not only the voluntary health agencies but also the critical food industry (e.g., including dairies and sausage factories) and grocery stores (Puska, Nissinen, et al., 1985). Two characteristics appear critical in the North Karelia community organization: (a) the variety of activities and channels included and (b) the attention in all areas to implementation through and in collaboration with local organizations. In comparison to other parts of Finland, the North Karelia campaign led to impressive reductions both in CVD risk factors (Vartiainen, Puska, et al., 1994) and mortality (Puska, Vartiainen et al., 1998), as well as reductions of cancer risk factors (Luostarinen, Hakulinen, & Pukkala, 1995).

Hospital-Based Change in Patient Perceptions and Behaviors Summative evaluation approaches that permit the researcher to observe the effects of an intervention between or among groups randomized to different experimental conditions (McBurney & White, 2010) are common in clinic-based randomized controlled trials. The design involves multiple baseline measures that are often repeated over time. In such designs, each individual in a group is followed and measurements are collected over the period of the study in order to illuminate between-group changes over time. One of the primary advantages of this design is the increased statistical power afforded by removing subject variance; in short, within-person changes in responses in one condition can be directly compared to within-person changes in responses in another condition (Greenwald, 1976; Stangor, 2007). For example, a study to evaluate effectiveness of a brief intervention designed to alter patients' perceptions about their first MI utilized a prospective randomized design in which patients received the intervention or usual care from rehabilitation nurses. Patients were assessed in the hospital before and after the intervention and at 3 months after discharge from hospital. The intervention resulted in significant positive changes in patients' views of their MI, in feeling better prepared to leave the hospital, in reporting significantly lower rates of angina symptoms, and in returning to work faster than the control group (Petrie, Cameron, et al., 2002).

School-Based Adolescent Health School-Based Adolescent Health Care (SBHC) programs were intended to increase adolescents' access to a range of basic health services, to reduce the prevalence of high-risk behaviors, and to serve as demonstration projects to establish whether centers of that type could be established and run effectively in low-income urban communities. Participating organizations included public health departments, teaching and community hospitals, community health centers, and nonprofit community health agencies that operated SBHC programs in 24 junior and senior high schools in 19 communities with populations of 100,000 or more (Lear, Gleicher, et al., 1991). However, limitations curtailed the extent to which outcomes could be measured using random assignment of students to an experimental or control group. Evaluation options were initially limited by the project timeline, in which the evaluation plan was only designed after the health centers began operation. In this way, the SBHC programs exemplified the tension that often exists between public health program delivery priorities and evaluation research agendas. As Knickman and Jellinek (1997) write, while a formal evaluation had always been planned, “the primary question for program planners was whether school-based clinics were viable on a broad scale: would diverse school districts take the risks necessary to get clinics up and running?” (p. 609). The clinics’ provision of sexual and reproductive health-care services had the potential to be controversial and, as such, the program staff focused mostly on designing an initiative that could be implemented in local communities. Only after the project was launched and the communities attempted to start their clinics were the program staff able to direct resources toward formal evaluation activities.

By that point a random assignment design was not possible since schools had already been selected (nonrandomly) without agreeing to the rigors of randomization. Random assignment of students within schools was also ruled out, both for the ethical concerns regarding withholding care and the practical concerns of spillover and potential contamination effects from intervention to the comparison group of students. Instead, the original evaluation design included a matched comparison sample of schools that had not opened health clinics in the same school districts as the SBHC sites. However, senior program leadership became concerned that student surveys about sexual behavior in the comparison schools could lead to parental backlash and undermine the support of the participating school districts to implement the clinics. This in turn could affect the outcomes of the primary evaluation question regarding the feasibility of the initiative. It was decided that surveys of student behavior would exclude comparison schools within the same district and would instead compare changes in high-risk behaviors among students in the schools with clinics to a national sample of urban youths (Knickman & Jellinek, 1997). To measure these outcomes, the research design entailed two longitudinal surveys: one with the health center school students and the other with a national sample of urban youth in the same grades. These parallel surveys conducted over multiple time points gave the researchers a group with which to compare trends in behavior and outcomes. The primary limitation of this method is that such studies are less likely to detect smaller program effects, given natural variation across sites. However, given the challenges of the research, this approach offered credible (if not entirely conclusive) evidence on other program effects (Kisker & Brown, 1997; Knickman & Jellinek, 1997).

Can the Intervention Outcomes Be Replicated?

A replication study is a deliberate repetition of research procedures in a second investigation for the purpose of determining if earlier results can be confirmed and further supported (Polit & Beck, 2008). Replication of findings is one of the most powerful tools available to validate claims in scientific research. By helping to confirm or dispute findings of an original study, replication studies can also promote the generalizability of the original study or allow unsupported findings to be dropped from practice. In other words, investigators can conduct a replication study to see if the findings from an original initiative are applicable, or generalizable, to their population of interest. Although replication can be incorporated into primary study designs, such as those utilizing multiple baseline measures or replicating an intervention among wait-listed controls after a first wave of outcome evaluations are complete, replication studies typically take one of the following three forms.

Identical Replication

The first is an identical replication study in which the original study is repeated exactly with the same sampling procedures, measurement tools, and analyses. For example, in a replication of the Go Sun Smart program, a behavioral intervention focusing on sun safety behaviors of ski resort employees and guests, the original research protocol was repeated at the sites that served as control groups in the original study. Using the same messages, measurements, and analyses, researchers were able to reproduce the results of the original study, in which greater exposure to intervention messages was associated with greater use of sunscreen, sunscreen lip balm, and face covering, but not gloves or overall sun protection (Andersen, Buller, et al., 2009).

Partial Replication

In the second type of replication study, an original study is duplicated as closely as possible, but not identically. Two major hand hygiene promotion interventions previously demonstrated to induce sustained improvement in clinical settings were replicated along with a passive intervention (soap substitutions and introduction of alcohol-based hand rub, with short-lived promotion of the changes) in selected wards of an 800-bed university teaching hospital. Each intervention used a before-and-after study design to assess results only within, not between, programs; the researchers chose this model because although all three interventions were conducted in parallel, there was no intention to compare them because potential confounders identified by previous modeling could not be controlled in statistical tests of significance. By replicating both successful interventions, the researchers were able to confirm that the programs can improve hand hygiene compliance and that the improvements can be maintained postintervention. However, because the interventions were not delivered identically to the original study (e.g., implementation varied based on departmental engagement and leadership), the investigators were able to use differences in outcomes as compared to the original study to identify institutional support, commitment, and guidance as active ingredients in the success of the program (Whitby, McLaws, et al., 2008).

Systematic Extension Replication

The third kind of replication study is a systematic extension replication, which tests the implications of a study in a new setting to establish broad ecologic validity. For example, the initial investigations into the links between procrastination and health in student samples implicated stress-related and behavioral pathways. Researchers who sought to replicate and extend previous findings among community-dwelling adults found that, consistent with previous work, procrastination was associated with higher stress, more acute health problems, and practicing fewer health-promoting behaviors (Sirois, 2007). Conversely, the positive results of an HIV/STI intervention originally targeting urban African-American males in nonschool settings were not successfully replicated in health classes at urban and suburban schools with diverse student bodies. The replication demonstrated increased knowledge, confidence, and behavioral intention among the intervention group but had no impact on sexual initiation, frequency of intercourse, or condom use, leading the investigators to conclude that the behavioral impact of an intervention may not be easily transferable when the program is taught to different groups and/or outside of the original setting (Borawski, Trapl, et al., 2009).

Challenges in Replication

Replication studies can pose challenges. First, one negative replication does not necessarily invalidate an original positive finding. Interpretation of the results of replication studies must take into account the myriad reasons that attempts to repeat the results might not be successful. Interpretations of failure must avoid the error of affirming the null hypothesis. Even if the failure of replication raises questions about generalizability, it cannot falsify the original finding. For example, if the original effect is small, negative results may arise by chance alone. Additionally, the participants or environment in a replication attempt might differ from those in the original study in a way that becomes significant, or a team might lack the skill or resources to reproduce the study correctly (Yong, 2012). Beyond these, numerous features such as those of settings, organizations, implementation fidelity, and populations addressed may moderate the generality of a finding from its original setting to others. Prudence and parsimony suggest always assuming failure of generalization before concluding lack of validity of original findings.

A second source of challenge of replication studies is that, despite the value they may play in understanding behavioral interventions, it can be difficult to fund and publish replications, primarily because they are viewed as adding few novel findings to the existing literature relative to the time and resources spent on the research (Carpenter, 2012; Jasny, Chin, et al., 2011). In spite of virtually all authoritative writing on the subject identifying replication as essential to scientific progress, support for replication is very rare. This is in fact one of the challenges faced in much dissemination research, which is the systematic study of replications, the subject, in part, of our next section.

How Can the Intervention Be Improved, Scaled, and Disseminated?

A variety of methods and tools have emerged that offer practical assistance to help individuals and organizations make improvements in program delivery and outcomes and set the stage for dissemination and scaling (Duke University Health System, 2018; Langley, Nolan, et al., 1996; Moen, Nolan, & Provost, 1999). One of the most practical approaches utilizes *rapid cycle improvement*, in which the emphasis is on implementing small tests of change. These changes are based on ideas which might come from the process and outcomes evaluations, from the literature, from practices seen in other programs, or from new opportunities that emerge as structures evolve (either specific to the program level, or more broadly, such as the development of new technology and media).

Rapid cycle improvement initiatives often utilize the *Plan-Do-Study-Act* (PDSA) cycle. This begins with the "Plan," which includes assembling a knowledgeable, motivated team to develop an *Aim Statement*. The Aim Statement articulates the specific, measurable goals to guide the improvement effort, as well as stated measurement objectives to determine whether the changes were effective. Aim Statements can often be effectively developed by thinking broadly about change concepts, i.e., generic ideas that can be applied to spark a specific change in the situation. Change concepts might include managing time (e.g., reducing startup, setup, or wait time), avoiding mistakes, improving workflow, or minimizing waste.

Thus in PDSA, the plan emerges from trialing, making numerous small changes, and revising, rather than from a protracted planning exercise designed to arrive at some "perfect" plan. The "Do" phase involves carrying out the plan. The change may be tested with only a small number of patients/staff/program participants, and the test period may be as short as 1 day for small PDSA cycles. The *Study* phase involves examining the results to determine if objectives were met. All PDSA activities should be documented in detail to allow for comparison between different plans. Finally, *Act* uses the results to make decisions, incorporate changes into the workflow, and establishes future quality improvement plans. If the improvements were successful on a small scale, they should be tested on a wider scale to ensure an acceptable level of improvement is achieved. At that point, plans should be made to standardize the improvements. If the change was not an improvement, the team should develop a new theory and test it; often, several cycles are needed to produce the desired improvement (HealthIT.gov).

For example, a Michigan public health department utilized PDSA in an effort to improve its older adult influenza vaccine programs. The Aim Statement was, "Increase older adult (65+) influenza immunizations to achieve an 80% influenza immunization rate by the end of the next flu season" with three improvement outcomes measurements: (a) percentage of eligible persons who receive a vaccine; (b) increase in the percent of ordered vaccine that is administered; and (c) increase in the number of sites offering influenza vaccines to older adults. To understand the current vaccination processes, the PDSA team developed a flow chart of the major steps for the health department and community partners involved in annual influenza vaccinations, including ordering vaccine, scheduling clinics, and distributing and retrospectively evaluating the success of efforts.

This revealed that almost all steps were carried out independently, without coordination among the various entities who delivered vaccinations. Further, some community-wide program elements, like public information, were performed by the health department with no input from other providers. Finally, no one was aware of any process to evaluate what strategies were effective across the community while the flu season was in progress, and there was no mechanism within which to provide data or feedback to providers about their patient and community-wide vaccination rates. The team brainstormed potential solutions to these shortcomings, considering potential costs, potential impact, and feasibility of success of each idea. The most promising solutions were tested at 20 randomly selected providers, data were collected and evaluated, the changes to practice were deemed to increase vaccination rates, and the program was standardized and implemented with the full roster of providers the following year (Tews, Heany, et al., 2012).

Engaging the Community in the Research Process

Having reviewed a broad range of research and program evaluation methods to answer the seven questions from needs assessment to dissemination, we turn to a cross-cutting theme—the engagement of communities in program development, research, and evaluation. Researchers and practitioners are increasingly realizing that improvements in population health and the problems of interest in behavioral medicine require changes in a broad range of social determinants of health. Achieving changes in these challenging areas needs to include working with communities through partnerships between researchers, practitioners, and members of the community. Community-based participatory research (CBPR) has emerged in recent decades as a collaborative research approach designed to bridge the gap between science and practice through community engagement and social action to increase health equity by ensuring and establishing structures for participation by communities affected by the issue being studied (Israel, Schulz, et al., 1998, 2001; Minkler, Blackwell, et al., 2003; Wallerstein & Duran, 2010). Some proponents of CBPR have come to use the term more under an umbrella of community organization approaches to intervention. Here we intend a broader use to describe the close relationship between researchers and communities that seek engaged understanding of the challenges those communities face and collaboration in developing responses to them—ranging from better individual clinical care and health education to broad public policy. (See also accompanying chapter by Ramanadhan & Viswanath.)

CBPR involves a reciprocal transfer of expertise, shared decision-making, power, and mutual ownership over the processes and products of the research (Freudenberg & Tsui, 2014; Viswanathan, Ammerman, et al., 2004). It expands the potential to develop, implement, and disseminate effective interventions across diverse communities through strategies to address power imbalances and facilitate mutual benefit among academic and community partners. Thus, at its best, CBPR can not only lay the foundation for efforts that improve population health, but also create broader community capacities for addressing issues that support improvements in other spheres of community development, including the environment, housing, transportation and economic activity, and in policy changes that create a just and humane society (Freudenberg, 1982; Freudenberg, Franzosa, et al., 2015; Freudenberg & Tsui, 2014). It also allows for practicing health professionals to engage in both an analysis and implementation of solutions unique to the specific setting, in collaboration with those who live and practice in that setting (Livingood, Allegrante, et al., 2011). Perhaps most importantly, CBPR encourages and promotes reciprocal transfers of knowledge (Wallerstein & Duran, 2010) by training community members in research (Minkler, Lee, et al., 2010) and including them in intervention development, e.g., the use of former drug users as "translators" in the design of a program to reduce sexual risk among African-American cocaine users (Stewart, Wright, et al., 2012), and delivery, such as through the use of local community volunteers to provide instruction on a physical activity program in Iran (Pazoki, Nabipour, et al., 2007).

The literature identifies several principles of practice to help community–research collaborations in developing, implementing, and evaluating their partnerships. These include the following: (a) identifying the best processes based on the nature of the issue and the intended outcome; (b) academic and community partners learning from each other; (c) capacity building (e.g., the commitment to training community members in research) (Minkler, Lee, et al., 2010); (d) acknowledging the difference between community input and active community involvement, and emphasizing the latter; (e) developing relationships based on mutual trust and respect; (f) acknowledging and honoring different partners' "agendas"; (g) collaborating not only in applying findings but also in determining the ways in which the findings are produced and thus interpreted (Green & Mercer, 2001); (h) using evaluation strategies that are consistent with the overall approach taken in the academic–practice–community partnership; and (i) engaging in long-term commitments to effectively reduce disparities (Baker, Homan, et al., 1999; Green & Mercer, 2001; Wallerstein & Duran, 2006).

Several examples of CBPR from around the world demonstrate how these principles have guided various community health improvement efforts. The first example is of the Mayisha project, which involved a participatory community-based survey among five migrant sub-Saharan African communities in London. The research plan was guided by a community-based collaborative group selected to encompass broad experience in sexual health and HIV research and in HIV prevention with African communities, including representatives from African HIV forums, Client Care Services, Directors of Public Health, and African Health Promotion teams. Community fieldworkers from the local African community were identified through key stakeholders and local advertising and were responsible for recruiting participants to the study. From a practical standpoint, the use of community-based fieldworkers allowed the investigators to ethnically match interviewers to participants. From a larger public health perspective, the use and acceptability of participatory methods allowed the African communities to demonstrate their commitment toward supporting studies of this nature and improving sexual health (Fenton, Chinouya, et al., 2002).

A second example is that of a project undertaken in Beirut, Lebanon. A 3-year CBPR project involving the testing of a psychosocial intervention to improve the reproductive and mental health of married women in a disadvantaged community of Beirut partnered university researchers with a community advisory committee and a local women's committee. Evaluation of this approach found that the women and the broader community felt ownership of the study and that the CBPR approach gave the women voices and allowed for an improved understanding of the community and surrounding reproductive and mental health issues (Kobeissi, Nakkash, et al., 2011).

A third illustrative of CBPR collaboration in the United States began with a participatory, door-to-door health survey of 1000 households in New Castle, a small municipality located in rural Indiana, that revealed a smoking rate of twice the national average. This finding helped galvanize the community into action to develop and implement a variety of health-promoting environmental and policy changes, ranging from restrictions on indoor smoking to initiatives to promote physical fitness and healthier lifestyles. In this way, the CBPR approach laid the groundwork for long-term sustainable changes in support of community-wide improvements in health (Minkler, Vasquez, et al., 2006).

Finally, a CBPR approach that has been used successfully to address substance use prevention through school community health promotion in Iceland provides a good example of a long-term effort (Sigfusdottir, Thorlindsson, et al., 2009; Sigfusdottir, Kristjansson, et al., 2011). School-based surveys in the early and late 90s showed that substance use among 13–15-year-old adolescents was on the rise in Iceland. This led to development of a CBPR approach where academic and practice-based researchers, policy makers, and field practitioners in adolescent health, municipal leisure services, and education came together and collectively organized a program that continues to the present day. This program, referred to as the *Icelandic Model*, emphasizes the school district as a unit of intervention, analysis, and reporting. Population surveys have been carried out annually, with input from all concerned stakeholders, including school personnel and community-based parent groups, and findings on mutually identified risk and protective factors have been analyzed and disseminated for each school district and municipal community taking part in the program. This approach has contributed to a paradigm shift in norms, values, and perceptions about adolescent health and development throughout Iceland. Moreover, during the 15 years that the approach has been ongoing, substance use among ninth and tenth grade students has dropped over 60% in Iceland (Kristjansson, James, et al., 2010; Sigfusdottir, Kristjansson, et al., 2008). In this case, CBPR has provided an empowering opportunity for communities to define and take ownership of a critical problem and find the practical and feasible solutions to address it.

In addition to benefits for the community, this CBPR effort over more than a decade has produced rich new findings illuminating key issues in the field, as well as advancing substance use prevention. These have included new methodologic innovations in conducting ongoing survey research (Kristjansson, Sigfusdottir, Sigfusson & Allegrante, 2014; Kristjansson, Sigfusson, et al., 2013) and investigating and addressing emerging community health challenges, such as the problem of physical inactivity (Eidsdottir, Kristjansson, et al., 2008) and overweight and obesity (Eidsdottir, Kristjansson, et al., 2010, 2013; Thorisdottir, Kristjansson, et al., 2012). The collaborative research has also increased understanding of the relationship of body mass index and depressive symptoms in adolescents (Eidsdottir, Kristjansson, et al., 2014).

For all of its potential to strengthen the collaboration between researchers, practitioners, and lay members of communities to solve health problems, CBPR also poses some challenges. First, logistically, behavioral medicine investigators who adopt the principles of CBPR in their work with communities can face obstacles in several areas: partnership capacity and readiness, time constraints, funding flexibility, translation, and expansion (Macaulay et al., 2011; Minkler, Blackwell, et al., 2003). Second, CBPR can also require researchers to confront and address a range of thorny ethical issues, including how to obtain participation and community consent, tensions created by differentials in power and privilege, racism and ethnic discrimination, and a range of issues around research for social change (Green, 2004; Wallerstein & Duran, 2006). Finally, respect for the community needs to be combined with an understanding that *all human beings* are often inaccurate in their explanations of their own behavior. For example, individuals entering smoking cessation classes often request dramatic portrayals of the harms of smoking (e.g., photographs of blackened lungs) as an aid in their efforts to quit. The role of such "scare tactics," however, is complicated. They may encourage progress in the early stages of contemplating quitting (Hammond, Fong, et al., 2004) or predict quit attempts (Yong, Borland, et al., 2014), but evidence for their impact on actual cessation is still lacking (Borland, Yong, et al., 2009). In one study of different types of support for adults seeking to lose weight, that which received the highest satisfaction ratings was not that in which participants achieved the greatest weight loss (Gabriele, Carpenter, et al., 2011). It seems that collaboration and mutual respect in program planning need to include recognition of these features of the psychology of self-perception, social influence, and attributional processes along with respect for the perceptions of those involved and evidence regarding effective approaches. Despite these potential pitfalls, familiarity with the concepts and principles and the spirit of CBPR, together with good process evaluation, can help investigators and program planners avoid them.

Translating Research into Practice

An emerging area of concern related to the issues of replication and dissemination is the translation of research findings into actionable practice and what has been sometime referred to as the "gap" between research and practice. For example, in the case of community-level efforts to prevent injury, Hanson, Finch, Allegrante, and Sleet (2012) have identified three principal gaps that separate academic researchers, policy makers, health practitioners, and the communities in which change is being proposed. These include: (a) the research-to-practice gap, (b) the efficacy-to-effectiveness gap, and (c) the injury-prevention-to-safety-promotion gap (Hanson, Finch, et al., 2012). In reviewing over 1200 articles published in 12 leading public health and health promotion journals, Oldenburg, Sallis, Ffrench, and Owen (1999) found that 63% of publications were descriptive, 11% were concerned with method development, and 16% were intervention based; only 5% were concerned with institutionalization or policy implementation research, and less than 1% contained diffusion research. This is important for behavioral medicine because it is not at all uncommon for interventions that have been tested under conditions of high internal validity to be altered when they are implemented into practice settings (Cohen, Crabtree, et al., 2008). The literature has sought to address the challenges of translating research into practice (e.g., see Cohen, Crabtree, et al., 2008; Katz, Murimi, et al., 2011) and several approaches to improving the translation of research into practice have been proposed (e.g., see Glasgow & Emmons, 2007). In the following, we review several of these models.

RE-AIM

One of the most widely respected approaches to improving research translation in behavioral medicine research is the *RE-AIM framework*. The RE-AIM framework is one of the primary tools designed to enhance the quality, speed, and public health impact of efforts to translate research into practice. The goal of RE-AIM is to draw attention to essential program elements, including external validity, which can improve the sustainable adoption and implementation of effective, generalizable, evidence-based interventions (Glasgow, Vogt, & Boles, 1999). The five RE-AIM steps for evaluating the potential health impact of interventions are:

1. ***R***each: The absolute number, proportion, and representativeness of individuals who are willing to participate in a given initiative, intervention, or program.
2. ***E***fficacy or ***E***ffectiveness: The impact of an intervention on important outcomes, including potential negative effects, quality of life, and economic outcomes.
3. ***A***doption: The absolute number, proportion, and representativeness of settings and staff or other people who deliver the intervention (i.e., intervention agents) who are willing to initiate a program.
4. ***I***mplementation: At the setting level, implementation refers to the intervention's fidelity to the various elements of its protocol, including consistency of delivery as intended and the time and cost of the intervention. At the individual level, implementation refers to clients' use of the intervention strategies, consistency, costs, and adaptations made during delivery:
5. ***M***aintenance: At the setting level, maintenance refers to the extent to which a program or policy becomes institutionalized or part of the routine organizational practices and policies. Maintenance also applies to intervention effects at the individual level over time, defined as effects of a program on outcomes after 6 or more months after the most recent intervention contact.

RE-AIM's utility and effectiveness derive in large part from its focus on both individual levels (reach and efficacy) and organizational levels (adoption and implementation) of impact (e.g., maintenance can be both an individual- and an organizational-level impact). It is critical to evaluate both levels because each provides valuable independent information about intervention impact. For example, a clinic-based intervention that has large impact on reach and efficacy but is only adopted, implemented, and maintained at a small number of medical practices with specific resources that are not available in typical "real-world" settings would not have sustainable translation into wider practice. If only the individual dimensions of the intervention were used for evaluation, the intervention would appear to have large potential for impact when in reality it has little hope of resulting in a large public health impact because it could not be adopted, implemented, and maintained in real-world settings. Conversely, if an intervention has potential for wide organizational adoption, implementation, and maintenance, but little reach, efficacy, or maintenance at the individual level, the potential impact of the intervention would not likely be achieved because of the deficiencies at the individual levels.

The RE-AIM website (www.re-aim.org) maintains a substantial searchable library of publications utilizing the framework. Examples include the planned evaluation of the BETTER 2 program, which is designed to expand implementation of a chronic disease prevention and screening intervention in primary care settings. Researchers will evaluate the program using RE-AIM to inform a mixed-methods approach, including a descriptive statistics on patients accepting the intervention, qualitative information on implementation and adaptations of the program, longitudinal measures of provider use of the intervention within their practice, and a composite index to assess quantitatively the effectiveness of the intervention (Manca, Aubrey-Bassler, et al., 2014). Likewise, an evaluation of different versions of an Internet-based diabetes self-management support program provides a clear application and interpretation of the RE-AIM model (Glasgow, Kurz, et al., 2010). A three-arm practical randomized trial was used to compare a minimal contact and moderate contact versions of the online program, compared to an enhanced usual care protocol. Primary behavioral outcomes (e.g., healthy eating, physical activity) and secondary biological outcomes (e.g., hemoglobin A1c, BMI) were compared at baseline and a 4-month follow-up. Interpreting the results through the RE-AIM structure, the intervention met several of the criteria for potential public health impact, including that it was feasible and engaging for participants and was able to reach a large number of people. However, there was mixed effectiveness in improving outcomes, and the authors concluded that further research is necessary to evaluate long-term outcomes, to enhance the effectiveness and cost-effectiveness of the intervention, and to better understand the connections between the intervention's processes and its outcomes. In this way, while RE-AIM is most commonly used to report results or compare interventions, it is also useful as a planning tool as well as a method to review intervention studies.

Utilization-Focused Evaluation

Another approach to facilitating translation of research into practice is what has been referred to as *utilization-focused evaluation*. Evaluation researchers must bear in mind that intended users of research, such as community leaders, program managers, policy makers, and public health-related practitioners, are more likely to use findings from evaluations if they understand the research process, are consulted and engaged, and sense ownership of the findings. This approach is the basis for utilization-focused evaluation, a process for making evaluation decisions in collaboration with an identified group of users, with a focus on their intended uses of the evaluation. By actively involving users in this way, the evaluation researcher can prepare the ground work for the use of evaluation findings and train users in the use of findings, which reinforces the intended utility of the evaluation throughout the process (Alkin, 2004). The approach thus places priority on how the evaluation findings will be applied by people in the real world (Patton, 2008).

Utilization-focused evaluation does not advocate any particular evaluation content, model, method, theory, or use. Instead, it is a process for identifying key stakeholders (Bryson, Patton, & Bowman, 2011; Guba & Lincoln, 1989) and helping these primary intended users to select the most appropriate content, model, methods, theory, and uses for their particular situation. This process has been employed to evaluate a wide range of topic areas, including human services agencies (Greene, 1987), a national AIDS prevention program in Switzerland (Dubois-Arber, Jeannin, & Spencer, 1999), and a Canadian compassionate care benefit (Williams, 2010). Along with several guides and toolkits on the topic (Bryson, Patton, & Bowman, 2011; Fetterman, 2000; Patton, 2008, 2012), investigators interested in the logic of the utilization-focused evaluation approach might find it useful to compare the pretest-posttest control group design used to evaluate a problem-solving skills training for adolescents (Tellado, 1984) to the alternative, utilization-focused research plan proposed for the same program (Patton, 1984).

PRISM

A third promising approach that supports translation of research into practice is the Prevention Impacts Simulation Model (PRISM). Originally designed and developed at the US Centers for Disease Control and Prevention and National Institutes of Health to estimate the impacts of public health interventions on the health of populations, PRISM is a systems dynamic simulation tool that includes 22 categories of policy, systems, and environmental change across several broad areas of interventions (Homer, Milstein, et al., 2008, 2010; Honeycutt, Wile, et al., 2014). These categories address medical care, smoking, nutrition and weight loss, physical activity, emotional distress, and air pollution. PRISM can assist users with decision-making about chronic disease intervention by modeling the likely impact of various prevention strategies for cardiovascular diseases, as well as for cancer and respiratory diseases related to risk behaviors such as smoking, diet, and physical inactivity. Moreover, PRISM is capable of modeling both individual interventions and combined interventions and can be used not only to estimate the short- and long-term population effects of intervention and the future costs averted by prevention but also to forecast future outcomes. By integrating the best available evidence on modifiable risk factors and demonstrated interventions, PRISM thus can provide a robust simulation of the impact of proposed or implemented prevention efforts on both indicators and cost of chronic disease.

Emerging Issues and Challenges

The movement toward evidence-based behavioral medicine practice mirrors one that has evolved in clinical medicine over the past several decades. Encouraged by health-care reform initiatives around the world, this movement has been fueled by a rapidly growing foundation of evidence from outcomes research in clinical medicine, behavioral medicine, and public health. Perhaps the most visible demonstration of the evidence-based medicine movement is embodied in the Cochrane Collaboration (2015), which was formed to organize the burgeoning volume of medical research into a searchable and useable evidence base that could benefit decision-making by health professionals, patients, and policy makers. However, with this growth has come a spirited discussion among practicing interventionists, behavioral scientists, clinicians, evaluators, policy makers, and patients about what kinds of evidence actually constitute “the best available scientific data” to inform decision-making in clinical practice. What evidence is most likely to advance behavioral medicine, clinical care, and public health? What are the ideal channels and practices for the dissemination of new knowledge, and for translating research to best practices in real-world settings? And what ethical obligations does the scientific community have to ensure the widest possible dissemination of the benefits of research? While these questions are neither exhaustive nor limited to the research methods and approaches addressed in this chapter, they are nevertheless illustrative of the kinds of challenges behavioral medicine faces going forward. Thus, this final section of the chapter takes up several of what we believe to be some of the most pressing issues these and other questions raise for the field.

What Constitutes Evidence?

Even if in behavioral medicine we limit our investigations solely to pursuing improvements in health, the objectives of behavioral research range widely from proving that some specific therapeutic event or intervention results in some specific outcome, to showing that a set of community-based activities will reward government support of those activities as a means of preventing disease or promoting health. Thus, the idea that any one approach to research would constitute "the gold standard" by which to answer questions across such a wide and variegated range of potential research objectives is preposterous. One need only ask what Copernicus, Darwin, Galileo, and Watson and Crick—all great scientists—have in common? *None of these great scientists had control groups*!

With growing recognition of the impact of health policies not only on health status, mortality, and quality of life but also on national economic prosperity and security, there is growing interest in using research to inform decisions with broad policy implications on sound evidence. However, concern over the soundness of evaluations and the stakes involved has encouraged some conservatism in ascribing value to the broadest range of available data. For example, a number of reimbursement policies in the United States now use evidence reviews of the U.S. Preventive Services Task Force (www.uspreventiveservicestaskforce.org) as the basis for identifying reimbursable services; however, the task force tends to confer considerable weight on evidence generated from RCTs and discounts the evidence from other equally valuable (but not equally valued) research designs. To illustrate the dilemma, consider a report in *The New York Times* (Kolata, 2013) on recent American Heart Association cholesterol guidelines. The story pointed to how "the drafting committee mistakenly relied only on randomized controlled clinical trials, the gold standard of medical evidence, but ignored other strong data [including a wealth of existing genetic and population data] that would have led to different conclusions." This example demonstrates the risk of limiting the evaluation of interventions best evaluated through methods other than RCTs, and highlights the need to identify practical ways of identifying promising approaches to prevention and improved care in whole populations.

Thus, it is not surprising that a primary criticism of the RCT focuses on the need for realistic, pragmatic alternatives to the dominant paradigm of studies requiring "hard" data and statistical proof utilizing highly homogenous patients in academic clinical settings. Such studies may be high in internal validity but they lack the external validity to support effective translation of research findings into policy and real-world practice (Glasgow, 2008, 2013; Steckler & McLeroy, 2008). Differences in culture, social structure, norms, and functions of communities and their populations, moreover, naturally preclude the highly widespread generalizability of results between populations affected by different social determinants (Livingood, Allegrante, et al., 2011). In addition, application of interventions previously demonstrated to be effective using strict research protocols (where internal validity is highly valued) often fail to produce the desired effect in real-world settings (where external validity is highly valued). In some cases, the intervention is initially delivered by trained professional study staff that is highly supportive of patients and motivated toward the success of the study. However, unless the intervention is one that can be easily replicated or continued in the hands of other staff members, interventions often fail to be maintained once study staff leave (Glasgow, Bull, et al., 2002). Moreover, even when programs are successfully continued by site staff beyond the study period, and the intervention is applied in a rigorous manner with high fidelity to the original study design, practitioners may find that the previously successful program is ineffective and fails to produce significant treatment effects (Hallfors, Cho, et al., 2006).

This problem is now sparking development and rapidly growing respect for innovative research and evaluation designs that allow interventions to gain credence on the weight of converging evidence and without the inherent limitations of the RCT. A good example of this movement toward more innovative thinking in evaluative research is the recent Institute of Medicine (IOM, 2012) study of how best to assess the value of community-based approaches to health promotion that go beyond the RCT

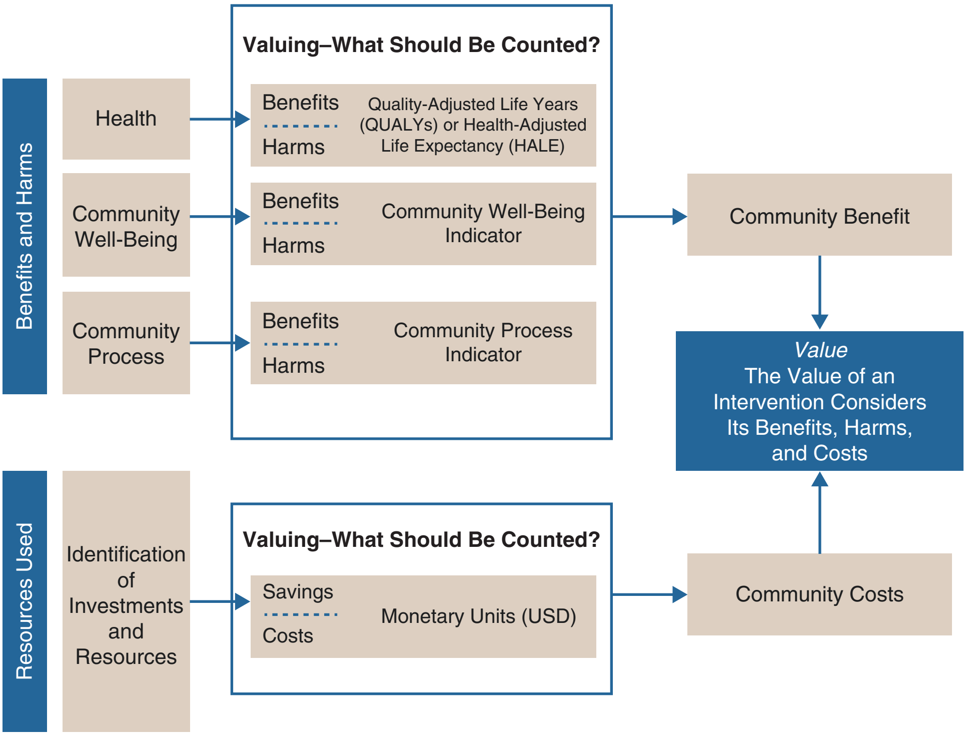

Fig. 6.1 Conceptual framework for assessing the value of community-based prevention interventions (Reprinted with permission from the National Academy of Sciences, Courtesy of the National Academies Press, Washington, DC. A full copy of the report, *An Integrated Framework for Assessing the Value of Community-Based Prevention*, is available at: http://www.nap.edu/catalog.php?record_id=13487)

model of evaluation. The IOM report provides a new conceptual framework (see Fig. 6.1) for assessing the value (which includes the benefits, harms, and costs) of community-based prevention. The report points to the clear need to use constructs beyond individual health in assessing the value of health promotion and public health, including community well-being and community processes, and how public health and health promotion can more effectively assess and incorporate the dimensions of social determinants into programs and interventions. This will require the development of new performance measures, new metrics that will be capable of operationalizing the concepts of community well-being and community process, and ultimately new concepts of community benefit, as well as systematic ways of using the new framework as recommended in the IOM report (Allegrante & Livingood, 2013).

What Are the Objects of Intervention That Explain Variance in the Observed Effect?

A second question of interest has to do with what the objects of intervention (also sometimes referred to as the "active ingredients") that are responsible for and explain the variance in the observed effect. To illustrate, evaluating the effect of a pill that contains a powerful medicine is very different from evaluating a national campaign to reduce obesity and type 2 diabetes. Especially important is that in assessing the effects of the pill, we seek to isolate the effect of the pill from the "confounding" ecologic effects of the context. This is why we conduct RCTs, which allow the investigator to isolate the active ingredient of intervention under highly controlled conditions. For a national campaign to reduce obesity and type 2 diabetes, however, we seek to understand, incorporate, and exploit the effects of context, which interact with intervention components (often synergistically) and will change over time and space, as an integral part of the intervention. Thus, a primary issue for behavioral medicine research concerns the identification of key components of interventions to which outcomes can be attributed and, then, how to disseminate such interventions.

The experience and results of the Diabetes Prevention Program (DPP) illustrate the challenge. The DPP showed that moderate physical activity (150 min per week) and loss of 7% of body weight among those with impaired glucose tolerance significantly reduced conversion to type 2 diabetes in this high-risk group, both in comparison to placebo and to Metformin, a standard medication used to treat diabetes. This "lifestyle" intervention utilized a standard set of materials and a combination of group and individual contacts to promote physical activity and weight loss. However, in the interest of testing the benefits of physical activity and weight loss, *not* any particular way of achieving them, study sites were encouraged to be highly flexible and creative in developing ways that would enable participants to achieve 150 min of moderate activity per week and 7% weight loss. The exciting findings of the DPP, in many respects the greatest impacts identified to date for a fundamentally behavioral approach to a major health problem, raise the question of what precisely should be disseminated. The benefits of 150 min of moderate activity a week and 7% weight loss should lead to diverse efforts to achieve these; however, some voices have called for focus on the particular intervention used in the DPP, "a proven, community-based weight loss program," i.e., "a…program," not multiple approaches to pursuing weight loss and physical activity as the path to saving Medicare $7 billion (Thorpe & Yang, 2011). There is a difference in strategy here: (a) disseminating a "program" that is as well and specifically defined as possible or (b) promoting varied approaches to achieving behavioral impacts, weight loss, and increased physical activity. It is likely that both strategies will have their successes. The difference between them illustrates the challenges interventionists face in recognizing the need for both standardization and flexibility or adaptability in the implementation of programmatic elements of intervention.

What Are the Factors We Need to Study Not Only to Guide Dissemination but Also Adaptation and Implementation? And How Do We Incorporate Them into Research?

Ideally, no investigation should be limited to the researchers completing their project, publishing their manuscript, and moving on to the next project, leaving lessons learned buried in the archives of journals, or worse, not published at all. Finding ways to disseminate effective, affordable, and feasibly scalable interventions that have been demonstrated in research is a major challenge for behavioral medicine as it is for all population health professions. Dissemination should be guided in part toward objectives of sustainability and replicability by communicating to the scientific community not only the results and end point of the project but the explanatory details that drove the findings. This requires proactive consideration of dissemination goals before the program begins as well as meticulous documentation of all steps in the project before it concludes.

In what have come to be called *practical trials*, external validity and replicability are increased through four key features: (a) use of representative patients to represent the range of patients encountered in real-world settings; (b) implementation in multiple settings rather than in those that are expertise- and resource-rich; (c) comparison of conditions that represent current standards of care or alternative treatments (rather than placebo or no treatment) to demonstrate that changes in practice result in significantly better results than current, familiar interventions; and (d) the inclusion of multiple outcomes, such as implementation requirements, costs, and feasibility (Glasgow, 2008). Such trials can provide a much more complete picture of evidence-based practice and strengthen program delivery, but will only do so if the individual study methods and the intervention are reported with sufficient detail and clarity to be fully understood and fully replicated.

In recent years, there has been recognition that translation of evidence into practice will be improved when research design and reporting standards are modified to help quality improvement teams understand both these adaptations and the effort required to implement interventions in practice (Cohen, Crabtree, et al., 2008). Toward this end, and as research knowledge has been accumulated, increased emphasis has been placed on the standardization and comparability of study findings that pertain to practice. A recent example of this is the Transparent Reporting of Evaluations with Nonrandomized Designs (TREND) Statement that provides a proposed 22-item checklist for standardized reporting of behavioral and public health intervention evaluations (Des Jarlais, Lyles, et al., 2004). The goal of this initiative is to increase the utility of nonrandomized study designs by providing a framework within which comparable information across studies can be more easily synthesized and translated into generalizable knowledge (Des Jarlais, Lyles, et al., 2004). It is intended to be a complement to the 25-item CONSORT Statement for randomized trials (Altman, Schulz, et al., 2001; Begg, Cho, et al., 1996) and the CONSORT-SPI (Montgomery, Grant, et al., 2013) that is designed specifically to enhance reporting clarity for social and psychological interventions. While TREND was originally launched to improve public health practice, behavioral medicine also stands to benefit from such transparency in reporting design and methods of quasi-experimental behavioral research. In addition to CONSORT and TREND, similar standards have now been developed for reporting qualitative studies (O'Brien, Harris, et al., 2014) and systematic reviews (IOM, 2011) and meta-analyses (Moher, Liberati, et al., 2009, for the PRISMA Group), along with other ongoing and emerging efforts that have been developed in the last decade to increase the quality and transparency of reporting in health research (Altman, Simera, et al., 2008) and reduce bias in randomized controlled trials (Higgins, Altman, et al., 2011).

Despite such guidelines and "rules," no method of improving rules for gathering and transparency in reporting evidence can eliminate the role of scholarly, professional, or clinical judgment in assessing and applying it. Put simply, there are two broad tasks in this: gathering and assembling evidence and applying it. Perfecting the former does not eliminate the latter. That is, perfecting the evidence does not eliminate the role of human appraisal in judging how and to what it is best applied. Even when we can ensure that policy and practice will be guided by sound evidence, the role of human judgment in applying it remains fundamental.

How Do We Incorporate a System-Wide or Population-Based Approach to Research?

Since the WHO Report on the Social Determinants of Health (Commission on the Social Determinants of Health, 2008) demonstrated the powerful impact of economic, environmental, and social- structural factors on health status, more research effort has focused on these broader determinants. However, much published research has continued to focus on individual determinants of change, largely ignoring the other contexts that shape behaviors (Glass & McAtee, 2006; Golden & Earp, 2012). Broader trials are needed that include impact and outcomes important to decision makers and communities, that address multiple contexts outside the individual level, including the environment in which programs are conducted, and that focus on moderating and mediating factors, economic issues, and social contexts (Glasgow, 2008; IOM, 2012).

Several have called for behavioral medicine and public health to embrace behavioral interventions that are system-wide, population-based, or focused on changes in public policy, which by their very nature require consideration of a broader range of acceptable "evidence" and "outcomes" as well as increased inclusion of the varied contributors to public health (Allegrante & Livingood, 2013; Epping-Jordan, 2004; IOM, 2012; Lieberman, Golden, & Earp, 2013; Livingood, Allegrante, et al., 2011). Limiting the field to individually based, "best practice" interventions for which there is "scientific evidence" from randomized trials not only fails to recognize the key social, policy, media, and other ingredients that actually produce significant results but can also point practitioners in the misguided direction of higher-cost, clinically based interventions (Livingood, Allegrante, et al., 2011). For example, Livingood, Allegrante, et al. (2011) note that, historically, major public health achievements tend to involve a complex and dynamic interaction between society and community rather than following "a linear movement from scientific testing to broad application" of individually focused interventions that have been characteristic of the classic biomedical model. The biomedical model, most notably developed by the US National Institutes of Health, comprises a model of scientific discovery on a continuum that goes from basic and clinical research, to applied research and development, to treatment at the bedside (Levy, 1982). In contrast, key public health achievements of the twentieth and twenty-first centuries, such as the normative changes in tobacco use in many countries, have required attention to a range of individual, social, and institutional factors that influence population health and have been the focus of health promotion (Livingood, Allegrante, & Green, 2016).

Reflecting this "range of individual, social, and institutional factors," recent developments in statistical analysis techniques collectively referred to as *multilevel methods* now allow researchers to design studies that can disentangle individual-level influences from community-level factors such as class, school, work site, residential location, town, city, or county, but still examine all levels at the same time and thus come closer to "clean" effects that may be attributed to different levels (Raudenbush & Bryk, 2002; Snijders & Bosker, 2012). The essential idea with multilevel studies is that findings pertaining to individuals that are close in proximity for any number of reasons (e.g., live in the same neighborhood, attend the same school, and employed at the same workplace) are likely to be caused, at least in part, by similar lifestyles and/or living conditions. Multilevel inquiries thus uphold that research findings are not simply attributable to individuals but also to the social environment and common living circumstances, which in turn may increase the strength of the investigator's interpretation.

The Weight of Evidence and Affirming the Null Hypothesis

Research scientists are by nature skeptical and critical. As a consequence, they are frequently dismissive of propositions with the response that "*there's no evidence for that*". Technically, the refrain, "*there's no evidence for that,*" allows the conclusion of just that, "there's no evidence." However, it frequently leads to an assertion that a particular line of inquiry or endeavor has been shown not to work—this amounts to "affirming the null hypothesis," something most graduate students were taught was not possible. This can grossly constrain development of behavioral medicine and public health interventions of all kinds. The fear of "there's no evidence for that," should not constrain our creativity in developing new and untested approaches (Fisher, 2008).

There are additional problems in weighing the presence and absence of evidence. The law of parsimony, Occam's razor, dictates that science assume the simplest relationship among events until evidence forces more complexity (Fisher, 2008). In light of this, consider, for example, findings of the Guide to Community Preventive Services that sufficient evidence exists for diabetes self-management education in "community gathering places" such as "community centers, libraries, private facilities (e.g., cardiovascular risk reduction centers), and faith institutions" (p. 201) but not if offered through worksites. (Only one study was found reporting self-management education in worksites and it "had design limitations," p. 207). The variability in available evidence from different sites does not constitute evidence that there are significant or substantial differences among them. Parsimony would lead to a conclusion that there is evidence for diabetes self-management education settings in a variety of settings without any strong evidence to differentiate among them in terms of likelihood of success.

Recalling the inebriated individual looking for keys under the streetlight, not because that is where they were lost, but because "the light is better here," we need to be critical of the assumptions we make in assembling evidence (Fisher, 2008). Why disaggregate diabetes self-management education according to community centers, libraries, private facilities, cardiovascular risk reduction centers, faith institutions, and worksites? To what extent do the distinctions among them have a plausible causal role justifying their differentiation? Why not large versus small settings? Daytime versus evening? Clinic- versus community-based? In contrast, perhaps more useful answers would flow from disaggregating by such factors as organizational support for the program, proximity or accessibility to intended audiences, and presence of community resources supporting the program (e.g., safe, enjoyable sites for physical activity). The point here is not just about community sites for diabetes education, but that how we assign evidence to groups or categories and, more broadly, how we manage and categorize evidence will influence the conclusions we draw from it. Parsimony dictates we do not differentiate without evidence. Greater criticality about these processes needs to come before "there's no evidence for that."

Another way to view the dilemmas is to imagine you were in charge of a state department or ministry of health and you were looking for evidence to guide public investment in population-wide prevention of diabetes. In weighing the available evidence to inform your decision, would you prefer to base your decision on 20 RCTs, all of which demonstrated exquisite internal validity showing that a particular approach was effective relative to randomized controls among volunteer samples treated through university research centers? Or would you prefer to base your decision on the findings from practice-based evidence of ten programs testing varied adaptations of an approach and associated community health promotion activities, carried out with urban, rural, and multiethnic community groups, and showing benefits in pre-post analyses and against national norms; associated lessons learned identifying local buy-in from a government or health leader, inclusion of primary care endorsement, and duration of community activities as critical success factors? The point is that evidence can come in many forms and limiting our confidence to evidence generated solely from highly controlled conditions narrows the range of evidence from which we can draw in making decisions about what programs work and under what conditions. Ultimately, the example also points to Green's (2008) notion of the "fallacy of the pipeline" that he argues is implicit in the traditional, unidirectional continuum of translation and dissemination of research into the hands of practitioners who are then expected to implement approaches that have been tested under condition of high internal validity. To counter this fallacy, Green has captured the challenge in what is a now-popular refrain: "If we want more evidence-based practice, we need more practice-based evidence" (Green, 2006, 2008).

Using PRECEDE-PROCEED, RE-AIM, PRISM, and similar models, if we identify needs related to a problem, identify reasonable evidence-based (where pertinent evidence is available) approaches to addressing those needs, implement the program and show it was implemented according to objectives, assess short-term impacts (e.g., reported changes in diet and physical activity), and show objectively measured reductions in the problem relative to appropriate benchmarks, does this not constitute knowledge with utility? This question is of distinct importance for the field of behavioral medicine in light of the urgency with which health disparities must be addressed. For example, in the United States most new HIV infections among youth occur among gay and bisexual males, with a 22% increase in estimated new infections in this group from 2008 to 2010 (Centers for Disease Control and Prevention, 2014). The timeline for an NIH grant to complete a large-scale randomized trial of a behavioral intervention can include 1–2 years devoted to securing funding and 3–5 years (or longer) devoted to conducting the research, completing data analysis and disseminating results, with the potential for the public health impact of the epidemic to increase significantly during that 7–10-year period. Further, this timeframe is particularly inappropriate given the increasing role of new technology as tools for health promotion, for instance the HOPE (Harnessing Online Peer Education) social media intervention which increased HIV testing rates among young men via Facebook outreach and peer education (Young, Cumberland, et al., 2015). Accelerating the discovery, dissemination, and implementation of knowledge is thus a critical imperative.

What Are the Moral and Ethical Obligations of Dissemination?

Finally, no treatment of the topic of the application of research methods from education, applied psychology, and behavioral science to behavioral medicine would be complete without some consideration of the moral and ethical obligations of the researcher. What are our moral and ethical obligations as reflective scientists—whose work is often supported by public funds—to ensure that our scientific work and findings are disseminated? As noted previously, intended users are more likely to accept the utility of research and evaluation results, and more likely to support the dissemination of results, if they understand and feel ownership of the process of the research. This raises two significant issues.

First, beyond publication in peer-reviewed scientific journals, researchers increasingly need to dedicate adequate resources to community-based debriefings, discussion of research findings, and consideration of the implications for practical use. Researchers thus must be prepared to play the role of public intellectual to use their research in affecting change. All partners should be involved in the dissemination of information about the partnership and project findings in forms that all partners can understand and use; this includes reaching multiple audiences (e.g., community members, policy makers, local health professionals, and the lay public) through a variety of communication channels and formats (e.g., radio, newspapers, social media, presentations, handbooks, position papers, testimony, and scientific journal articles), with all partners involved as co-authors and co-presenters to the extent that substantive contribution to the research may require. Thus, it is important to strike a balance between time devoted to the preparation of manuscripts for publication in peer-reviewed scientific journals and developing processes that enable researchers to report results to the broader community and public stakeholders for discussion of the utilities and implications of the research (Seifer, 2006).

Second, many researchers are now considering the ethical implications of publishing in peer-reviewed scientific journals where the published article will be housed behind a "paywall"—accessible only to readers whose academic institutions maintain costly annual subscriptions, or to those who are willing and able to pay a fee for access to a published piece of scientific research. Some critics charge that research funded by public tax funds should be freely available to the public whose moneys have supported the research, while others make the case that open access is a moral issue and that the principle of beneficence obligates scholars to act for the benefit of others. The open-access policies of the US National Institutes of Health (National Institutes of Health, 2014), the Canadian Institutes of Health Research (Canadian Institutes of Health Research, 2014), and the Research Councils, Innovate UK, and Research England of UK Research and Innovation (UK Research and Innovation, 2018) represent notable mandates adopted in the past decade which endorse this philosophy. Nevertheless, the issue of the extent to which the privatization of scientific content undermines the advancement of sciences remains a challenge, with important questions remaining about the system of scientific peer review and publication in which considerable knowledge remains out of reach for much of the general public.

Finally, the argument for open access has also extended to the issue of whether scientific peer review should also be open to broader audiences, including the public, rather than limiting judgments about scientific worth solely to submitting authors, journal editors, and anonymous reviewers. In 2006, the prestigious scientific journal, *Nature*, initiated a trial of *open peer review*. Open peer review is the process of rendering scholarly judgments about the scientific value of research through an entirely transparent process by which the identities of those reviewing the research are disclosed to submitting authors and the public as part of the process. This differs from the traditional peer review process in which the identities of reviewers are anonymous. Despite significant interest in the trial by participating scientists, only a small proportion of those authoring papers chose to participate in the open review. The trial suggests that opening up peer review to broader participation among scientists and the public to comment on the quality and rigor of scientific research may not be as widely popular as believed (*Nature*, 2006).

Conclusion

This chapter has sought to describe and place in context the research approaches of education, applied psychology, and behavioral science and their potential applications to behavioral medicine. We have also attempted to sensitize the reader to the key issues in research and evaluation that will continue to require attention in behavioral medicine. Several final observations are worth making.

First, as we hope the chapter has shown, a wide range of research methods and evaluation designs are available to support the assessment of needs, formulation of intervention approaches, and evaluation of the process, impact, and outcomes of behavioral medicine interventions at the individual, community, and policy levels. Moreover, with the growing recognition of the importance of the broad range of social determinants of health, there is a nexus of complex factors that must be addressed to improve population health. To meet the challenge, more emphasis is now being placed on evaluative designs that value the use of a wide range of methods to assess health outcomes and the clinical, community, and social circumstances that support improvements in health and quality of life. Thus, the focus of this chapter has been on diverse methods in educational, public health, and behavioral science evaluation that may serve a broad range of objectives in order to study and understand complex phenomena and develop effective interventional measures.

Second, there are real and important differences in how interventions are evaluated that have profound implications for what and how much we can learn from the research and programs in which society invests public resources. Simply because research may fail to document a prespecified or a priori outcomes of primary interest, does not necessarily mean a study is not without merit or that something valuable has not been learned. Even “negative” trials of interventions, or studies in which unanticipated outcomes of value have been observed, can yield vitally important insights and new knowledge that can guide others in future work.

Finally, behavioral medicine faces an evolving landscape of issues that will require its scientists and practitioners to work more effectively to engage the community and other stakeholders in designing and conducting investigational studies and program evaluations. Partnerships with other disciplines and with the patients and communities of interest whose health and quality of life we seek to improve promise to strengthen the science of behavioral medicine and the impact it can have through the research and evaluation process.

Acknowledgments We thank Edwin Fisher at the Gillings School of Global Public Health of the University of North Carolina at Chapel Hill and Linda Cameron at the University of California, Merced, for the helpful comments, attention to detail, and expert editorial guidance they provided throughout the writing of this chapter. We also thank Naomi Arbit, Madhabi Chatterji, Alexandra DeSorbo, and Miguel Marshall at Teachers College, Columbia University; Aduragbemi Banke-Thomas at the Liverpool School of Tropical Medicine; and Altyn Aringazina, MD, at the Kazakstan School of Public Health for reading and commenting on drafts.

Theory in Behavioral Medicine

Joost Dekker, Jos F. Brosschot, Ralf Schwarzer,
and Akizumi Tsutsumi

Introduction

Theory gives direction to the development of research questions and facilitates the interpretation and integration of research findings. Theory may contribute strongly to the development of the science of behavioral medicine, provided that the theory meets the requirements of a scientific theory. Empirically well-founded theory may give direction to the development of valid diagnostic and assessment procedures and the development of effective interventions, as well. Theory may contribute strongly to the application of behavioral medicine knowledge in clinical care and public health.

In this chapter we will first make introductory comments on the role of theory in behavioral medicine research and the need for theoretical rigor. We will also introduce an important distinction between *general* and *focused* theories. We will illustrate the role of theory in behavioral medicine by providing an overview of several general theories in behavioral medicine, specifically psychophysiological stress theories and social cognitive theories on health behavior change. We will also describe focused theories, specifically theories on occupational stress and a theory on functional decline in osteoarthritis. In the last section, we will give some final reflections on the role of theory in behavioral medicine research.

The Role of Theory in Behavioral Medicine Research

The scientific method is a cyclic process involving theories, hypotheses, observations, and conclusions (de Groot, 1971; Dekker, 2008). Scientists use theories to develop a specific hypothesis, which is subsequently tested in an empirical study: the observations in the empirical study result in a conclusion on the truth of the hypothesis and the need for adaptation of the theory. In the deductive approach, "theory" is the point of entry into the scientific cycle; development of the hypothesis and designing an empirical study are the next steps. In the inductive approach,

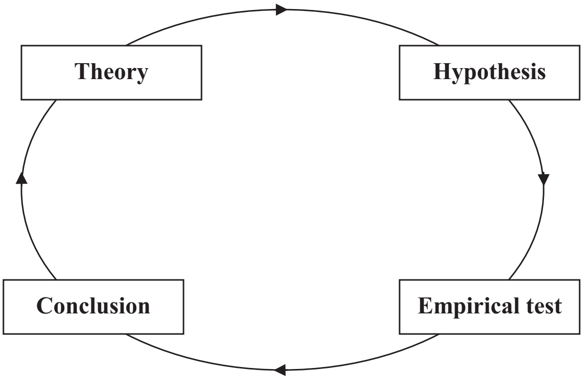

Fig. 7.1 The scientific method: a cyclic process

one starts from empirical data; these observations lead to a theory, which then needs to be tested empirically. The cyclic process, however, is common to both, as is illustrated in Fig. 7.1.

A scientific theory has two main functions, the heuristic function and the integrative function.

1. Heuristic function: Theory gives direction to the development of research questions. Theory provides guidance in developing research questions.
2. Integrative function: Theory facilitates the interpretation and integration of research findings. Theory provides guidance in interpreting empirical facts.

These two functions of theory will be illustrated below. The first function of theory – heuristic function – is to guide the development of research questions. Physical activity has a beneficial effect on cancer-related fatigue. A comprehensive theory on fatigue could lead to the hypotheses that the beneficial effect of physical activity is due to improvement of aerobic capacity (Chinapaw, Buffart, et al., 2012) or due to improvement of mood (Gielissen, Wiborg, et al., 2012). These hypotheses can be tested in a study evaluating whether improved aerobic capacity or improved mood mediates the relationship between physical activity and fatigue. If aerobic capacity, but not mood, is found to mediate the beneficial effect of physical activity, the theory would be revised: physical activity leads to improved aerobic capacity and thereby to a reduction of fatigue (and mood seems to be irrelevant). The further development of the revised theory would focus on exercise physiology (and exclude mood as a pathway). The revised theory would guide the development of the next study, for example, a study on the dose-response relationship between exercise intensity, aerobic fitness, and fatigue reduction. A theory adapted to the most recent empirical findings is conducive to identifying the next step in research. Theory is the point of accumulation of knowledge in a specific field: theory "absorbs" recent empirical findings; the empirically enriched theory guides future scientific research.

The second function of theory – integrative function – is to facilitate the coherent interpretation of empirical findings. Without the integrative framework of theory, empirical research runs a risk of ending up with a set of loose facts which are difficult to interpret. For example, both cognitive behavior therapy and exercise have a beneficial effect on pain in fibromyalgia patients, without substantial differences between these treatment approaches. The lack of a differential effectiveness as such is difficult to interpret. However, it has been theorized that in some patients, cognitive factors (e.g., catastrophizing) perpetuate pain, while in other patients, behavioral factors (e.g., deconditioning) perpetuate pain (van Koulil, van Lankveld, et al., 2010). This theory potentially explains the lack of differential effectiveness: if cognitive factors perpetuate pain, cognitive behavior therapy is likely to be effective (and not exercise); on the other hand, if behavioral factors perpetuate pain, exercise (and not cognitive behavior therapy) is expected to be effective. In a study with a mix of patients (some patients with cognitive factors and other patients with behavioral factors perpetuating pain), both cognitive behavior therapy and exercise will be effective. This explains the lack of a differential effectiveness of these therapies. Thus, theory facilitates the interpretation and integration of empirical findings.[1]

Theoretical Rigor

In current thinking on the science of behavioral medicine, strong emphasis is placed on methodological rigor (e.g., the methodological criteria for conducting and reporting of clinical trials). Much less attention is being paid to the need for "theoretical rigor." This is an unfortunate state of affairs: in order to advance behavioral medicine as a science, theory needs to be developed in a rigorous way. We will shortly discuss the requirements for a scientific theory, and we will give some examples of insufficient theoretical rigor.

A scientific theory consists of a set of concepts and statements concerning a particular domain of reality (de Groot, 1971). Requirements for a scientific theory include (de Groot, 1971; Cramer, 2013):

1. Clear definitions of concepts. Concepts need to be clearly defined.
2. Logical consistency. Statements on the relationship between concepts need to be clearly articulated and logically consistent, meaning that the statements do not contain a contradiction.
3. The theory needs to be falsifiable. Empirical falsification of the hypothesized relationships should be a realistic possibility: the outcome of an experiment must include the option that the theory or hypotheses derived from the theory are wrong.
4. Parsimony, i.e., preference for the least complex explanation for an observation. A parsimonious and sober theoretical explanation is preferred over a complex theoretical framework with more concepts and relationships than are really needed to explain a phenomenon.
5. Restrictiveness. The theory should be restricted to a clearly defined domain of reality.
6. Empirical validity. Empirical observations confirming hypotheses derived from the theory contribute to the empirical status of the theory. The more empirical evidence supporting the theory, the better the empirical status of the theory.

The need for falsification as a realistic possibility has been emphasized by Popper and others (Popper, 1963): it should be a realistic option that in an empirical study, the theory is found to be wrong. That is, one should be able to describe the specific observations that would lead to the falsification or rejection of the hypothesis being tested. The criterion of falsifiable hypotheses is not always met, even in modern science. Confronted with conflicting results, scientists have frequently hypothesized two opposite processes, which are supposed to be operating in different individuals or at different moments in time. In these circumstances, the conditions under which each of these processes is supposed to operate or not to operate need to be clearly specified. Under condition A, process X is operating, leading to an increase in outcome variable O. Under condition B, the opposite process Y is operating, leading to a decrease in outcome variable O. If these conditions (A and B) are not specified, any outcome of an experiment (increase or decrease of O) can be "explained": if the outcome of the experiment is an increase in O, "apparently" process X was operating; if the outcome is a decrease in O, "apparently" process Y was operating. Whatever the outcome of the experiment, there is always an explanation. Unless the conditions under which these processes are supposed to operate are clearly specified, the theory runs the risk of not meeting a crucial requirement for a scientific theory: falsification of the theory should be a realistic possibility.

---

[1] This example provides another illustration of the heuristic role of theory as well: the logical next step would be a 2 × 2 study comparing the outcome of cognitive behavior therapy and exercise in patients whose pain is perpetuated by cognitive factors and patients whose pain is perpetuated by behavioral factors.

In chronic pain, pain-related fear and avoidance are contributing to pain and disability. This has led to the formulation of the theoretical "fear-avoidance" model on chronic pain (Vlaeyen & Linton, 2000, 2012). An opposite theoretical model based on endurance-related responses and physical overuse or overload has been hypothesized as well (Hasenbring & Verbunt, 2010). These two theoretical models have been integrated into the avoidance-endurance model of chronic pain (Hasenbring & Verbunt, 2010). In this theoretical model, both avoidance and endurance are hypothesized to cause pain and disability. In this positing of two opposite processes, it is essential to clearly articulate characteristics of patients in whom avoidance is hypothesized to be operating, and characteristics of patients in whom endurance is hypothesized to be operating.

Furthermore, it has been hypothesized that the outcome of each of these processes (avoidance and endurance) may vary with time (Hasenbring & Verbunt, 2010). This introduces even more degrees of freedom: two opposite processes which each are hypothesized to lead to opposite outcomes at different moments in time. This further complicates the task of specifying the observations that would lead to the rejection or modification of the theory, calling for an articulate definition of the exact role of time in each of these processes, in addition to the definition of characteristics of patients in whom avoidance versus endurance is hypothesized to be operating. In the absence of a clearly articulated theory on patient characteristics and the exact role of time, there is a risk that this theory is not falsifiable: two opposite processes which each have an opposite outcome depending on time leave many options for a fit between theoretical explanation and empirical fact.[2]

The criteria of logical consistency of statements and parsimony are not always met in behavioral medicine theory either. Various theories may be available to explain a certain phenomenon. For example, several theories on the role of psychological factors in the development and persistence of chronic pain have been formulated. These include theories on cognitive coping styles (e.g., catastrophizing), pain-related anxiety and fear, helplessness, self-efficacy, pain coping strategies, readiness to change, acceptance, and illness beliefs (Keefe, Rumble, et al., 2004; de Rooij, Steultjens, et al., 2011). Although each theory may provide a parsimonious explanation, the field as a whole offers a bewildering complex explanation of the role of psychological factors in chronic pain: closely related and overlapping concepts, without a clear demarcation between these concepts, and various conceptualizations of the relationships between these concepts and chronic pain, without a comprehensive theory integrating these various conceptualizations.

Apart from an exceptional (but laudable) attempt at theoretical (Sullivan, Thorn, et al., 2001) or empirical (de Rooij, Steultjens, et al., 2011; Nielson & Jensen, 2004) clarification, the field seems to accept this state of affairs. Obviously, this is an undesirable state of affairs. First, the overall theoretical explanation of the role of psychological factors in chronic pain does not meet two criteria for a scientific theory: logical consistency of concepts and statements and parsimony, i.e., preference for the least complex explanation for an observation. Second, empirical studies on concepts derived from these various theories may lead to confusing and contradictory conclusions, sometimes providing evidence for factor X, sometimes for factor Y, and sometimes for factor Z. Reviews summarizing the available literature are helpful, be it a narrative review (Keefe, Rumble, et al., 2004) or a systematic review (de Rooij, Roorda, et al., 2013). However, in the absence of a comprehensive theory facilitating the interpretation and integration of the various empirical findings, such reviews advance the field only to a limited extent. For this reason, Keefe, Rumble, et al. (2004) have called for clear and understandable definitions of concepts used in the explanation of chronic pain, as well as for a comprehensive theory integrating various conceptualizations and findings on psychological factors in chronic pain. Despite obvious relevance, such an endeavor does not seem to have a high priority: only a few studies have attempted to

---

[2] These comments do not imply that the authors of this theory are not aware of the need for theoretical rigor.

clarify relationships between psychological concepts in chronic pain (de Rooij, Steultjens, et al., 2011; Sullivan, Thorn, et al., 2001; Nielson & Jensen, 2004). There is an urgent need to develop comprehensive theories which meet the requirements for scientific theory: clear definitions of concepts, logical consistency, the theory needs to be falsifiable, parsimony, restrictiveness, and empirical validity.

General Theories and Focused Theories

General theories in behavioral medicine concern the basic and universal mechanisms explaining how psychosocial, behavioral, and biomedical factors interact in health and illness in general. Major general theories in the field of behavioral medicine include the theories on stress and social cognitive theories on health behavior. These general theories cut across phenomena, populations, and settings.

Empirical research on a general theory primarily aims to test basic, universal mechanisms. Do cognitions predict future health behavior? The general hypothesis that cognitions predict health behavior can be tested in various health behaviors, e.g., smoking cessation, physical activity, or sleep hygiene. The specific health behavior which is used to test the theory is not the main focus of interest – the primary aim of the study is to test whether the general hypothesis that cognitions predict future health behaviors is valid. General theories provide understanding in many different situations. This is the major strength of a general theory: a general theory is a universal "tool," which applies to many phenomena, populations, and settings.

A problem with general theories is that they are insufficiently specific to help understand specific phenomena. General theories provide general explanations (e.g., cognitions predict health behavior) but provide less guidance in understanding a specific phenomenon (e.g., sleep hygiene). More focused theories may have much more potential in explaining specific phenomena: in-depth understanding of specific phenomena may require focused theories on each of these phenomena.

Focused theories concern specific phenomena. A focused theory explains how psychosocial, behavioral, and biomedical factors interact with regard to a specific health issue. Examples of focused theories include the explanation of fatigue in cancer patients, the explanation of the impact of depression on cardiac disease, and the explanation of smoking relapse prevention.

Research on a focused theory, by definition, aims to test the explanation of a specific phenomenon. Does low-exercise self-efficacy contribute to fatigue in patients with cancer? The specific health problem (i.e., fatigue in patients with cancer) is the main focus of interest – the primary aim of the study is to test the hypothesis that low-exercise self-efficacy contributes to fatigue in patients with cancer.

Focused theory is frequently derived from one or more general theories: general theory (e.g., on cognitions and behavior) is tailored to the specific health issue (exercise self-efficacy and fatigue in patients with cancer). Specific issues (such as the impact of chemotherapy on fatigue) are added to the focused theoretical model on fatigue in patients with cancer. This results in a comprehensive focused theory of the specific phenomenon. Focused theories have great potential to improve our understanding of specific health issues. This is the major strength of focused theory: it aims to improve our understanding of specific health issues, thereby contributing to finding solutions for these specific health problems.

Focused theory should be distinguished from pragmatic research. Pragmatic research does not use (focused) theory to guide research. Instead, pragmatic research amasses observations and data. Pragmatic researchers rely on research methods to gather data on a specific health issue. Pragmatic researchers do not develop hypotheses, which are subsequently tested, nor do they use theory to integrate research findings. Pragmatic research does not rely on (focused) theory and does not aim to contribute to the development of (focused) theory.

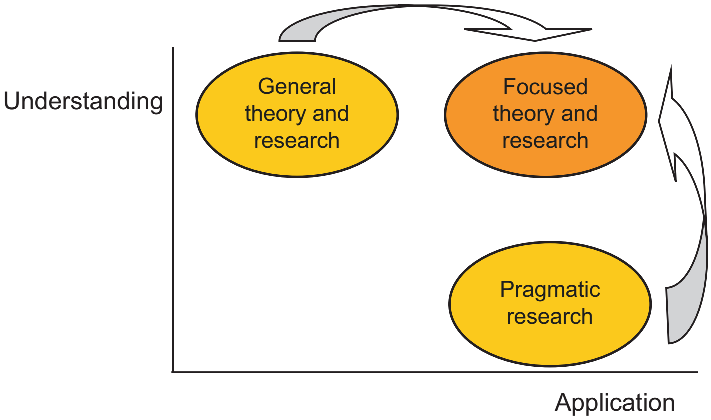

Fig. 7.2 Research based on focused theory: understanding *and* application

It can be argued that shifting from research on general theories to research on focused theories, as well as shifting from pragmatic research to research on focused theories will strongly contribute to our understanding of specific health issues. This shift is illustrated in Fig. 7.2. Research based on focused theory aims *both* to understand *and* solve a specific health issue, as contrasted to research on a general theory (which aims to understand universal mechanisms without attention to specific applications) and to pragmatic research (which aims to gather data on a specific health issue but without attention to theoretical understanding). The approach based on focused theory is expected to strongly contribute to our capability to understand and find solutions for specific health problems.

Summary

In summary, theory has two main functions in science:

- Heuristic function: theory gives direction to the development of research questions.
- Integrative function: theory facilitates the interpretation and integration of research findings.

Theoretical rigor is required, in order to ensure that theory really contributes to the development of science:

- Concepts need to be clearly defined.
- Statements on the relationship between concepts need to be logically consistent and clearly articulated.
- Empirical falsification of the theory should be a realistic possibility.
- A parsimonious theory is preferred over an elaborate theoretical framework.
- The theory should be restricted to a clearly defined domain of reality.
- Empirical observations confirming the theory contribute to its empirical status.

In behavioral medicine, a distinction can be made between:

- General theories which concern general mechanisms explaining how psychosocial, behavioral, and biomedical factors interact in health and illness. A general theory facilitates understanding of many different health issues.
- Focused theories, which concern specific health and illness issues. Focused theories have great potential to further our understanding of specific health issues.

Below, we will first give an overview of two general theories in behavioral medicine, i.e., specifically psychophysiological stress theories and social cognitive theories on health behavior change. These two "grand" theories provide eloquent illustrations of the role of general theory in behavioral medicine. We will then describe two focused theories, i.e., theories on occupational stress and a theory on functional decline in osteoarthritis. These two theories illustrate the potential of focused theories to deepen our understanding of specific health issues.

General Theories on Psychophysiological Stress

During the last 15 years, evidence has been accumulating showing that psychological stress is a risk factor for organic disease, e.g., cardiovascular disease. For example, high levels of overall life stress – a combination of stressors at work and at home, financial stress, and major life events – are associated with a greater than twofold risk for developing a myocardial infarction, which is greater than the risk for obesity and hypertension (Rosengren, Hawken, et al., 2004; Dimsdale, 2008). Work stressors have been found to increase cardiovascular disease risk up to 3.6 times (Bosma, Peter, et al., 1998; Matthews & Gump, 2002) in a dose-response fashion (Chandola, Britton, et al., 2008), with follow-up times between 4 and 12 years, although evidence is not consistent for all types of work stressors and less clear for women (see Backe, Seidler, et al., 2012). Marital conflict appeared to be linked to a nearly threefold risk of recurrent coronary events (Matthews & Gump, 2002; Orth-Gomer, Wamala, et al., 2000). Several other stressors also seem to increase CV risk, such as bereavement or care giving for a spouse with Alzheimer (Dimsdale, 2008; Lee, Colditz, et al., 2003; Vitaliano, Scanlan, et al., 2002). Taken along with similar observations in diseases in areas other than CVD, it seems safe to conclude that stress carries a considerable disease risk. Given the long history of mind and body dualism, a reasonable and important question arises from this literature: how can it be explained that stress, a presumably psychological phenomenon, can have these severe bodily effects? This part of the chapter deals with several of the main developments in general theories that have been employed in the last century to account for the effects of stress on physiology, disease, and mortality.

Early Stress Theories

Historically, there are several general stress theories that have inspired and guided a tremendous amount of research spanning over more than 80 years. Most textbooks start with Walter Cannon in the 1930s, who coined the term *fight or flight* to describe the animal's physiological response to acute threats. This response was characterized by high sympathetic nervous system activation that caused the adrenal medulla to produce adrenaline. Cannon viewed the fight/flight response as part of an organism's striving to maintain a steady physiological state, called homeostasis and in fact defined as early as 1865 by Claude Bernard. Cannon called the external factors that disrupt homeostasis "stress," using this term for what we now like to call "stressors."

The next historical figure, Hans Selye, showed in the 1950s that the bodily response to stress appeared to be a very *general response* to any type of threat to the organism: heat, cold, hunger, thirst, wounds, infections, and last but not least emotional disturbances. Selye developed this finding of a general response into the first formal stress theory, called the general adaptation syndrome (GAS). Typical aspects of the GAS are swelling of the adrenal cortex, increases in glucocorticosteroid release (which is cortisol in primates, including humans), atrophy of the thymus, and development of gastric and duodenal ulcers. Importantly, the GAS consists of three temporal stages, an alarm stage, a resistance stage, and an exhaustion stage, and the latter would finally cause disease and death. Later it became clear that most health damage from stress is due to continued activation (stage 2) rather than exhaustion (stage 3), at least in highly developed human societies.

The notion of the fight/flight response of Cannon is still popular. However, from Selye's findings it became clear that it should be taken metaphorically rather than literally. We do not really "fight" or "flee from" threats such as hunger, cold, or infections. Instead the body's stress response is a general defensive activation response, which is launched whenever there is a threat to the physical or psychological integrity of the organism. Perhaps the greatest insight of Selye was not so much the GAS, but this *generality* of the stress response to a variety of stressors. This generality also implied that the stress response is a phylogenetically very old natural defensive function that humans share with all other vertebrates and many invertebrates. This "old" defense might immediately progress into fight or flight, for example, on the level of intra- or interspecies threat, but it need not. In fact, *actual* fight or flight plays only a minor role in human stress and health.

Biological Stress Responses and Their Psychological Determinants

Biological Stress Responses

These early stress theories have led to a great amount of research, primarily laboratory stress experiments, that have yielded many insights into the physiological and psychological aspects of the stress response. With respect to the physiological aspects, it has become gradually clear that stressors have immediate effects on virtually every aspect of the body: the autonomic nervous system, the cardiovascular system, the immune system, the gastrointestinal system, the endocrinological system, the skeletomuscular system, and so on (Sapolsky, 2004). The biological responses that were the major interest of Cannon (i.e., adrenaline) and Selye (i.e., glucocorticosteroids) were part of two major physiological subsystems involved in the stress response that have become known as the sympathetic–adrenal–medullary (SAM) system and the hypothalamic–pituitary–adrenal cortical (HPAC) system. Together with the autonomic nervous system (ANS), these are still studied as being among the most important "larger" systems involved in the health risk of the stress response, because they govern the activity of the other bodily systems described above. Dysregulation in SAM, HPAC, or ANS has deleterious consequences for the other bodily systems and can lead to disease. A particularly important development in the 1980s and 1990s was research showing that stress can influence immunity and immune-related disease processes, such as wound healing and infections, and that the ANS is anatomically and functionally linked to the immune system. This research was partly triggered by the discovery that severe stressors, such as the loss of a loved one, could lead to immune-related diseases and even premature death. The new field that emerged, psychoneuroimmunology (PNI; Ader, 2007), had a tremendous influence on thinking about stress and health, also in the medical world. Before PNI, the reductionist biomedical model of disease that had been the ruling paradigm in medicine for the larger part of the twentieth century had already been challenged to incorporate psychological and social factors (Engel, 1977). However, it was PNI that made psychological stress truly acceptable in the medical world as a factor influencing bodily health. Rather than one single theory, PNI is a field with many sub-theories and hypotheses. Still, an overall and leading hypothesis has been that stress causes suppression of immune functions, making the body more vulnerable to disease agents, including infectious agents and neoplasia (tumors). Indeed, stress responses appeared to be able to decrease several immune functions, although this is particularly true for chronic and severe stressors. In contrast, mild, brief stressors often have brief immune-enhancing effects, depending on immune parameters (see Ader, 2007).

Psychological Determinants

On the psychological side, several factors were identified to determine the nature and the magnitude of the stress response. These factors involve the objective characteristics of stressors, as well as the perception and interpretation (appraisal) of these stressors. For example, different types of (laboratory) stressors appeared to cause different types of cardiovascular activation. During stressors that are challenging and thus require *active coping*, for example, math-like stressors, cardiac (beta-adrenergic) effects dominate. On the other hand, during frustrating stressors involving *passive coping*, for example, "mirror tracing" or threatening tasks, vascular (alpha-adrenergic) effects dominate (Obrist, 1981; Allen, Obrist, et al., 1987). A more recent theory (Blascovich, 2008) echoes these early findings. According to this theory, the response to stressors that are perceived as "challenging," and thus require active coping, would be characterized by high cardiac output. In contrast, the response to stressors that are perceived as "threatening," and thus requiring passive, vigilant coping, would be characterized by high total peripheral resistance (i.e., "vascular"). The latter is more hazardous when sustained for longer periods, because it mediates the risk of high blood pressure for cardiovascular disease. The contrast of challenge versus threat, either to describe characteristics of stressors or their perception, is a returning concept in stress theories and also a major element in a leading stress theory (Lazarus & Folkman, 1984) that deals in particular with the psychological side of stress.

Another important factor – and obviously related to active versus passive coping – is the *uncontrollability or unpredictability* of stressors. A series of studies in the 1960s and 1970s, by among others Weiss (1970) and Seligman, Maier and Solomon (1971), and coworkers (see Steptoe & Appels, 1989), showed that threatening stimulation such as mild electric shocks in animals led to unhealthy physiological outcomes such as high glucocorticosteroid levels and gastric ulceration. However, this was only the case when the threat was uncontrollable or unpredictable, even when levels of threat were kept equal over conditions. Later it appeared that the *perception* of uncontrollability/unpredictability was enough to yield these deleterious effects (Steptoe & Appels, 1989). Several theoretical models combined uncontrollability with the factor *effort or arousal* involved in coping ("fight or flight") with a stressor. Effort and uncontrollability have also become important factors in leading psychological stress theories, including work stress theories (Karasek, 1979). The effort/arousal dimension and the uncontrollability/ unpredictability dimension were believed to be, to a large extent, independent. For some time (i.e., during the late 1970s and 1980s) the two dimensions were hypothesized to be differentially related to the responses of the SAM and HPAC systems, that is, effort was believed to increase SAM activity, and uncontrollability was believed to increase HPAC activity (Henry & Stephens, 1977; Frankenhauser, 1980). Consequently, some theorists speculated that effort and uncontrollability might also be related to the *diseases* caused by dysregulation in these two systems: cardiovascular diseases (SAM/effort) or infectious disease and cancer (HPAC/uncontrollability) (Fisher, 1986). However, these differential hypotheses concerning physiology as well as diseases never received much empirical support. The biological reality is that the SAM and HPAC systems might be anatomically and functionally too closely connected to allow for these differential relationships. At high levels of activity, such as during stress but also during stress-free physical exercise, both will respond, with the HPAC system (i.e., glucocorticoids) acting slower.

There are numerous other important, more specific psychological factors influencing stress responses, such as previous stressors including early-life stress, gender, social evaluation, social support, individual differences such as self-esteem, neuroticism, and hostility, that can either modulate the stress response directly of by aggravating the stressful events which led to them in the first place. Of particular interest is a new theory of Taylor and coworkers (Taylor, Klein, et al., 2000) that hypothesizes another action tendency in addition to fight/flight, with the equally catchy name "tend and befriend." With oxytocin as biological basis, it holds that affiliation, or coming together in groups, during threatening situations should be taken into account as an important psychological aspect of stress responses.

Theories Linking Stress to Disease Pathways

Action Tendencies and Physiological Preparation

A major challenge for stress theorists has been to explain how psychosocial stress – a psychological phenomenon – can influence the body's systems in such a severe way that it can cause disease. Firstly, why does the body respond to stressors anyway? For this we have to turn to emotion theories. The psychological aspect of the stress response is comprised of negative emotions such as anger, anxiety, and fear. Associations of emotional responses, including the negative emotions, with bodily changes had been studied systematically for a long time, notably in the nineteenth century by Charles Darwin and William James. Most researchers have regarded these bodily changes as a functional part of emotions. The best answer to this first question is provided by more modern emotion theories and is relatively straightforward. These theories make clear that emotions involve action tendencies (e.g., Frijda, 1988), which in turn are associated with physiological activation to *prepare* for these actions. Negative emotions such as anger and anxiety are associated with physiological preparation for fight or flight, that is, vigorous autonomic activity, increasing heart rate, blood pressure, cortisol levels, and suppressing many – temporarily less relevant – biological processes including gastrointestinal, growth, and immune processes (Sapolsky, 2004). In his recent coherent overview of the biology of psychological stress, Lovallo (2005) further clarified and simplified this notion by pointing out that the physiological preparation for fight or flight is basically the same as what happens during preparation for bodily *exercise*. After preparing for exercise, we usually engage in this activity, but we seldom engage in actual fight or flight in modern human society. Still, during the stress response, our body keeps preparing for these actions. This explains the often intense physiological part of the stress response.

Final Pathway to Disease

This brings us to the next question: How does the stress response finally lead to disease or enhance the risk of disease? The link of emotions with disease only started to be systematically studied in the second half of the last century. Until the 1960s, and for some researchers far beyond that decade, the study of emotions and disease was dominated by psychodynamically oriented theories. A core notion was that *specific* kinds of emotional conflicts, when chronically suppressed, would lead to *specific* physiological patterns and diseases (see Nemiah, 1982). For example, intrapsychic conflicts concerning dependence would lead to peptic ulcers. These theories were difficult to reconcile with and did not contribute to growing biological and psychological knowledge. More recent examples are theories about the *physiological costs* of pent-up negative feelings such as anger or anxiety and, conversely, the assumed healthy effects of letting out these feelings in some way or another. However, after decades of research, little evidence has been gathered in favor of these theories (discussed in Vingerhoets, Nyklicek, & Denollet, 2008; Brosschot & Thayer, 1998). In fact, venting one's anger only increases anger and aggressive behavior tendencies as has been shown in numerous experiments (e.g., Bushman, Baumeister, & Phillips, 2001). Also, both habitually expressing anger and suppressing anger appeared to carry serious cardiovascular risks. Their shared "toxic" elements are likely to include the sustained action tendency (i.e., ongoing preparation for fight or flight) and its associated high physiological response (Brosschot & Thayer, 1998).

The intensity of people's physiological responses to stress appeared to be more fruitful as an explanation for the unhealthy effects of the stress responses. This idea was patented in the *reactivity hypothesis*, which has been the conventional hypothesis for over 50 years, and continues to guide many researchers in their research. It states that frequent intense responses to stressors cause biological dysregulation and damage (see Gerin, Pickering, et al., 2000). However, this hypothesis or model of the stress-disease link has received several criticisms. One criticism holds that human physiological responses to real-life stressors are seldom large or intense and are generally as low as physiological responses to regular mild physical stressors, such as walking the stairs (e.g., Halsey, Watkins, & Duggan, 2012), cycling (e.g., Glynn, Christenfeld, & Gerin, 2002), or other types of daily exercise. Another related but perhaps more important criticism is that prolonged physiological activity is far more crucial than incidences of high reactivity (Brosschot & Thayer, 1998; Schwartz, Gerin, et al., 2003; Linden, Earle, et al., 1997). At the same time, it is likely that those who respond intensely during stressors, the high reactors, have longer, more, and exacerbated prolonged activity.

There are exceptions, for example, people who already have a disease are vulnerable to even brief stress responses of low intensity.

Prolonged Physiological Activity

The notion of prolonged activity is also not new; it was already explicit in Selye's GAS theory and emphasized later by Ursin (1978). Surprisingly it did not receive substantial research attention until the 1990s when, rather independently, several research groups suggested new theoretical models of chronic stress. McEwen's allostatic load model explains how prolonged stress causes growing wear and tear on the body that will finally, over time, cause disease (McEwen & Stellar, 1993). Somewhat later, Linden and colleagues (Linden, Earle, et al., 1997) proposed that slow recovery rather than high reactivity explains the health risk of stressors. They also pointed out that particularly *emotional* stressors cause slow recovery and not *non-emotional* stressors such as physical stressors or "threat-free" cognitive stressors, even if the stressor duration is equal. At the same time, Brosschot and Thayer (1998) explicated the role of sustained action tendencies in causing prolonged activation, and they later, together with Gerin, proposed the *perseverative cognition hypothesis* (Brosschot, Gerin, & Thayer, 2006). This hypothesis holds that prolonged activity is caused by the continued mental representation of stressors, independent of the actual presence of these stressors.

Perseverative Cognition

Perseverative cognition is manifested in cognitive phenomena such as rumination and worry. They keep on triggering the fight/flight action tendency and therewith the physiological preparation for that action. The hypothesis emphasizes that prolonged physiological activity does not only occur *after* stressors but also *before* stressors (i.e., anticipatory stress), sometimes even far before them, due to perseverative cognition. This implies that stressors that are feared in the future but never occur can still have strong physiological effects. The more people worry about the future, the more often physiological activation will occur: their bodies are suffering from events that never happen! Conventional stress studies did not – and still often do not – account for perseverative cognition such as worry and rumination, or any other psychological cause of prolonged physiological activation. They also typically fail to measure stressors that have not (yet) happened. By being guided, either explicitly or implicitly, by the reactivity model, they have missed and continue missing a potentially large source of stress responses. As an example, consider a work stressor, such as a bad relationship with one's boss. Actual encounters with that boss may be limited to minutes per day or several hours per week. However, the ruminating about the boss may be constant and causes by far most of the prolonged activity during that period (Gerin, Zawadzki, et al., 2012). The same is true for other chronic stressors, such as racial discrimination, loneliness, low social economic status, care giving, etc. According to the perseverative cognition hypothesis, stressors will not become health risks without sustained worrying or rumination, because there would be no prolonged physiological activation (Brosschot, Gerin, & Thayer, 2006). There is growing evidence in favor of the perseverative cognition hypothesis, specifically with respect to the physiological effects of worry and rumination (Verkuil, Brosschot, et al., 2010).

Finally, the perseverative cognition hypothesis illuminates a special feature of human stress. Worry and rumination are typical human cognitive phenomena. It is safe to assume that other animals' brains are incapable of making cognitive representations of past and future threatening scenarios of such concreteness and vividness that they have physiological consequences. Consequently, chronic stress may truly be called a distinctive human form of stress or a recent "invention" of mankind.

Current Developments

This chapter is far too short to do justice to all other exciting new developments in stress theory and research and can only briefly touch on them. One recent development is the hypothesis that stressors may have consequences even when people are not aware of their own emotional stress response. During the last 15 years, a host of studies has demonstrated that people are not aware of the major part of their cognitive regulation (Bargh & Morsella, 2008). It is likely that emotional cognition is not an exception. People may also not be aware of a – potentially large – part of their stress-related cognition, while this *unconscious stress* might substantially contribute to prolonged activation. Several findings point in this direction, for example, physiological effects of unconscious stress stimuli and prolonged physiological effects of stress during *sleep*, our most important restorative period in life, during which conscious stress-related thought activity is not possible (Brosschot, Verkuil, & Thayer, 2010).

There are several other new developments and challenges of which only five examples will be mentioned and only briefly so. Firstly, there are advances in *genetics*, especially how stress alters gene expression (epigenetics). Secondly, rapidly growing insights from *neuroscience* elucidate brain systems involved in stress, especially the interplay of prefrontal and subcortical areas ("emotional brain"). Thirdly, computer-/Internet-assisted ambulatory (real-life) psychophysiological monitoring is enabling exciting and fast progress, which enables ever more sophisticated testing of prolonged stress processes. Fourthly, there is the increasing and fruitful attention for meditation-based interventions. Finally, evidence is slowly piling up that anxiety disorders and depression are important risk factors for somatic disease. These conditions can easily be understood as prolonged stress responses, with worry and rumination as the core etiological factors in their onset and maintenance (Verkuil, Brosschot, et al., 2010).

General Social Cognitive Theories of Health Behavior Change

This section deals with selected general theories that attempt to explain health behavior change. From a metatheoretical viewpoint, stage models are contrasted to continuum models. This will be illustrated by one example of a continuum model (reasoned-action approach) and one example of a stage model (transtheoretical model), followed by an example of a hybrid model (health action process approach).

Two Approaches to Global Theories: Continuum Models and Stage Models

Models of health behavior change postulate a pattern of factors that may improve motivation and that would eventually lead to sustained behavior change. A distinction is made between stage models and continuum models (Lippke & Ziegelman, 2008). In continuum models, individuals are placed along a range that reflects the likelihood of action. Influential predictor variables are identified and combined in one prediction equation. The goal of an intervention is to move the individual along this route toward action. Such models assume that a person's behavior is the outcome of an intention (e.g., "I intend to run four times a week for at least 30 minutes each time"). Intention forming is seen as being determined by beliefs and attitudes. Therefore, the focus is on identifying a parsimonious set of predictors that includes constructs such as perceived barriers, social norms, disease severity, personal vulnerability, attitudes, or perceived self-efficacy. These are then combined into a prediction equation for explaining behavioral intention and behavior change. The most prominent examples of the continuum model are several theories that have been described as pursuing the reasoned-action approach (see below).

Stage models take the perspective of the clients who reside in different mind-sets while progressing through behavioral phases, whereas continuum models look at theoretical constructs. In the model of action phases, the so-called Rubicon model (Heckhausen & Gollwitzer, 1987), a distinction is made between an initial motivation phase and a subsequent volition phase, an idea that dates back to earlier work by Lewin. Individuals in one phase differ from individuals in the other phase in terms of their goals, readiness to change, and action attempts. The transtheoretical model of behavior change (TTM)

(Prochaska & DiClemente, 1983) makes a distinction among five stages of change, assuming that people are qualitatively different between stages. Based on this assumption, intervention strategies are developed that are tailored to the current mind-set of an individual. Thus, stage theories are mainly put forward with the idea to identify a match between transitory psychological characteristics and suitable treatment components to facilitate behavior change.

Continuum Models: The Reasoned-Action Approach (RAA) Theories

The reasoned-action approach (RAA; Fishbein & Ajzen, 2010) stands for a family of related models, namely, the theory of reasoned action (TRA), the theory of planned behavior (TPB), and the integrated behavior model (IBM). The theory of planned behavior (TPB; Ajzen, 1991) represents a revised version of the theory of reasoned action (TRA; Fishbein & Ajzen, 1975) (for a historical overview, see Head & Noar, 2014). The RAA theories follow a continuum model design that includes distal and proximal antecedents of a given behavior. The core of the model consists of few variables (see Fig. 7.3). Intention reflects a person's readiness or motivation to perform a health behavior. The intention is based on attitude toward the behavior, subjective norm, and perceived behavioral control. Intention mediates between these three factors and the behavior. Attitude toward a behavior is an indicator of the positive or negative value that is associated with the performance of the behavior.

The RAA has become a leading conceptual framework in behavioral medicine over the last four decades, having inspired generations of health behavior researchers. It is illustrated by a simple and intuitive path diagram, with the behavioral intention as the most proximal antecedent of behavior, which mediates between social-cognitive constructs and health behavior. The RAA theories (TRA, TPB, IBM) are very well developed in terms of their formal characteristics of well-defined constructs, hypothesized paths linking them, and falsifiable statements. Another strength of the RAA lies in its parsimony and generality. Together, parsimony and generality designate a broad approach that enables the utilization of the RAA for a large number of research questions. This may be the reason why little has changed since the 1970s, except for minor additions in a more cursory fashion. The main substantial addition was the inclusion of perceived behavioral control in the TPB variant, which later became perceived self-efficacy in the IBM variant. One could see this as an attempt to combine the TRA with the very influential social cognitive theory (SCT; Bandura, 1986). Today, most health behavior theories consider self-efficacy as one crucial component.

The model has been evaluated as being successful in predicting intentions, but less successful in predicting behaviors, which is obvious because the focus is on preintentional variables. In a meta-analysis, Armitage and Conner (2001)

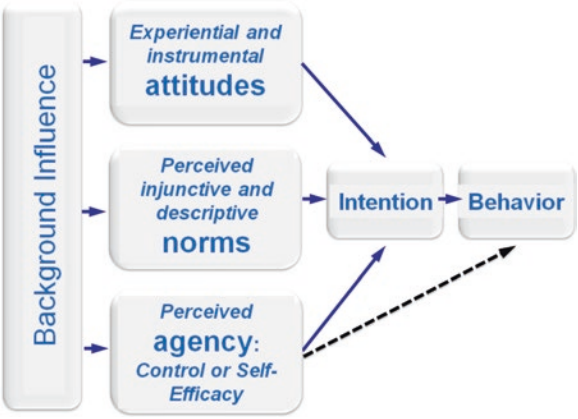

Fig. 7.3 Simplified diagram of the reasoned-action approach theories (RAA; Fishbein & Ajzen, 2010) according to Head and Noar (2014)

reported an average of 39% of explained intention variance, as opposed to an average of 27% explained behavior variance. These percentages are high because many studies in this area are only cross-sectional correlation studies based upon mere self-reports. Due to such basic research designs, the coefficients are often inflated, whereas in longitudinal studies, using objective behavioral outcomes, as well as in experimental studies, the predictive value of the theory is very limited (Sniehotta, 2009). Thus, the RAA theories are mainly intention theories. To transform them into a more powerful behavior change theory, they need to be extended by postintentional predictors that are more proximal to the behavior in question. In the last decade, many researchers have introduced further extensions to the RAA, typically labeled "extended theory of planned behavior." Such useful extensions are postintentional which means that researchers have identified a weak point in the theory, namely, the translation of intentions into action. There seems to be a collective desire to learn more about processes that occur after individuals have formed an intention. In particular, planning (implementation intentions) has become the most prevalent extension of the TPB (for a review see Hagger & Luszczynska, 2014). Such studies that have added planning as a mediator between intentions and behavior, have made a substantial improvement of the utility of the RAA.

Two basic processes in health behavior change can be distinguished, namely, goal setting (motivation, intention formation) and goal pursuit (volition, action). The RAA puts its weight on the initial motivation phase, and this is done very well and in the most general manner, making it a general intention theory for all kinds of behavioral applications. What is also needed in behavioral medicine is an elaboration of the second phase where intentions are translated into action and where one has to deal with initiation, temptation, and relapse. When designing interventions for a particular health-compromising behavior, for example, smoking cessation in already motivated individuals, the RAA is not ideal as it does not account for processes that are involved in such changes. The RAA has, so far, been less convincing as an intervention theory because this would require more treatment-focused experimental work instead of the predominant correlational type of inquiry (Head & Noar, 2014; Sniehotta, Presseau, & Araújo-Soares, 2014).

There are two debatable aspects of continuum models. First, a single prediction rule for describing behavior change implies that cognitive and behavioral changes occur in a linear fashion and that a "one-size-fits-all" intervention approach may be suitable for all individuals engaging in unhealthy behaviors. Consequently, it does not emphasize qualitative changes during the course of time, such as changing mind-sets, phase transitions, or recycling back and forth. According to continuum models, it is not important whether an intervention approach is targeted first toward changing perceived vulnerability, perceived consequences, or perceived self-efficacy. Hence, interventions are not required to be progressed in any certain sequence, but they could be applied in any order, or simultaneously.

Second, traditional continuum models typically did not account for the postintentional phase in which goals are translated into action. This segment between intentions and behaviors is also called "intention-behavior gap" (Sheeran, 2002). It is quite common that people do not behave in accordance with their intentions. For example, unforeseen barriers emerge, and people give in to temptations. In a postintentional phase, various factors can compromise or facilitate the translation of intentions into action. Theorizing about health behavior change should not only emphasize the motivation phase but also consider the subsequent action phase that may be more decisive for behavior change. Advanced continuum models, therefore, need to include factors that help to bridge the intention-behavior gap (e.g., an extended theory of planned behavior). In doing so, it is implicitly assumed that there are at least two phases of behavior change, a motivational one that ends with an intention and a volitional one that peaks in successful performance. Thus, any extension of traditional continuum models into this direction implicitly adopts the idea of distinct processes, stages, or phases in health behavior change. Indeed, this segmentation idea is not foreign to the TPB. Fishbein and Ajzen (2010) argue that one can target unmotivated individuals by changing beliefs and motivated individuals by removing barriers that hinder the translation of intentions into actions. Using the intention as the watershed that divides the audience into two groups, it turns any continuum theory into a stage theory.

Stage Models: The Transtheoretical Model of Behavior Change (TTM)

To overcome the limitations of continuum models, stage theorists have made an attempt to consider process characteristics by proposing a number of qualitative stages. Whereas the focus of continuum models lies in the prediction of intention and behaviors, the major focus of stage models lies in the design of stage-matched interventions. One such approach is based on clinical research on addictions and has become the dominant stage model of health behavior change: the transtheoretical model of behavior change (TTM), also called stages of change (SOC) model (Prochaska & DiClemente, 1983). Its main feature is the implication that different types of cognitions and behaviors may be important at different stages of the health behavior change process. The most common version of the TTM includes five discrete stages of health behavior change that are defined in terms of one's past behavior and future plans (precontemplation, contemplation, preparation, action, maintenance) (see Fig. 7.4). For example, at the precontemplation stage, a problem drinker does not think about quitting in the future. At the contemplation stage, he or she reflects about quitting sometime within the next 6 months but does not make any specific plans for behavior change. At the preparation stage, the problem drinker resolves to quit within the next month and prepares for this step. The action stage includes individuals who have taken successful action for any period of time. If abstinence has lasted for more than 6 months, the person is categorized as being in the maintenance stage. Sometimes a termination stage is added, for example, in the case of smokers who have been abstinent for at least 5 years. The stages are expected to be mutually exclusive and qualitatively different.

People could make multiple attempts to progress from preaction to action stages. However, relapses could occur anytime, resulting in a spiral-like progression through the behavior-change process. In contrast to continuum models, stage models such as the transtheoretical model assume that factors producing movement toward action differ with respect to a person's stage. The identification of stages bears implications for interventions because matching a treatment to the current stage of a target group would lead to better outcomes.

In addition to the described basic stages of change, the TTM also includes ten processes of change, decisional balance (the perceived pros and cons of changing), perceived self-efficacy, and temptation. Processes of change are conceptualized as causes for the transitions between the stages, whereby it is assumed that different processes influence different stage transitions.

A meta-analysis on tailoring interventions pointed to some empirical evidence in favor of stage-matched treatments (Noar, Benac, & Harris, 2007). However, evidence in favor of the TTM and other stage models is mixed. The very nature of stages, their operationalization, the failure to move people from one stage to the next, or the failure to achieve stage-matched effects are points that have been raised (Sutton, 2005).

A major problem that TTM shares with other stage models is the validity of the key constructs. Stage allocation is based on a simple algorithm asking people whether they act or not and if not, whether they intend to do so or not, etc. For example, questions to stage smokers are (1) are you thinking about quitting within the next 6 months? ("No" = precontemplation, "Yes" = contemplation), (2) are you planning on quitting within the next month? ("No" = contemplation, "Yes" = preparation), (3) are you currently quitting? ("No" = preparation,

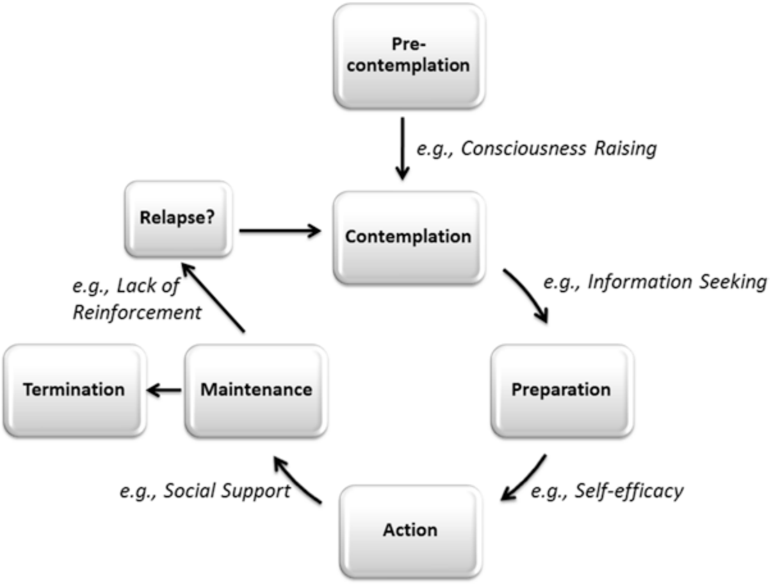

Fig. 7.4 Simplified diagram of the transtheoretical model (TTM; Prochaska & DiClemente, 1983). Stages are within *rectangles*, and transition processes are at the *arrows*

"Yes" = action), and(4) have you quit for at least a month? ("No" = action, "Yes" = maintenance). Sensitivity and specificity need to be addressed to determine the number of false positives, for example. Passage of time might not be the ideal criterion to identify cutoff points in the process of change (Lippke, Ziegelmann, et al., 2009). Self-reports for stages or intentions are subject to intraindividual fluctuation and, therefore, may result in different decisions depending on the time of day, mood, or social influence. For example, one can easily imagine a current smoker fluctuating during the day between a "Yes" (contemplation) and "No" (precontemplation) in response to the question "Are You thinking about quitting in the next 6 months?" Thus, if a particular stage algorithm is not sufficiently valid in a particular health promotion setting, stage-matched interventions may not be successful.

Parsimony in Hybrid Models: The Health Action Process Approach (HAPA)

Developed in 1988 (Schwarzer, 1992), the HAPA was originally an attempt to integrate the model of action phases (Heckhausen & Gollwitzer, 1987) with social cognitive theory (Bandura, 1986). It includes a number of constructs and principles (see Fig. 7.5).

Constructs

Intention In the process of motivation, intention has been regarded as a kind of "watershed" between an initial goal-setting phase (motivation) and a subsequent goal-pursuit phase (volition). When describing health behavior change, it is most helpful to follow this distinction. For example, to gauge the progress of an individual who is supposed to quit smoking and to design therapeutic interventions, the first question to ask should be whether this person is either preintentional or postintentional. To which degree is the person motivated (goal setting), or to which degree is the person making explicit efforts to quit (goal pursuing)? The terms motivation and goal setting pertain to the preintentional phase, whereas the terms volition and goal pursuit pertain to the postintentional phase.

Although the construct of intention is indispensable in explaining health behavior change, its predictive value is limited (Sheeran, 2002). When trying to translate intentions into behavior, individuals are faced with various obstacles, such

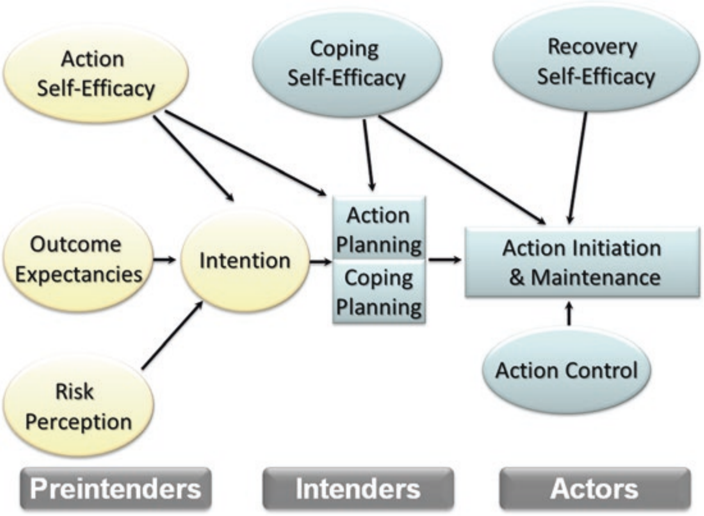

Fig. 7.5 Simplified diagram of the health action process approach (HAPA; Schwarzer, 2008)

as distractions, forgetting, or conflicting bad habits. Godin and Kok (1996), who reviewed 19 studies, found a mean correlation of .46 between intention and health behavior, such as exercise, screening attendance, and addictions. Abraham and Sheeran (2000) reported behavioral intention measures to account for 20–25% of the variance in health behavior measures. If not equipped with means to meet these obstacles, motivation alone does not suffice to change behavior. To overcome this limitation, further constructs are required that operate in concert with the intention.

Risk Perception At first glance, perceiving a health threat seems to be the most obvious prerequisite for the motivation to overcome a risk behavior (e.g., smoking). Consequently, a central task for health communication is not only to provide information about the existence and magnitude of a certain risk but also to increase the subjective relevance of a health issue to focus the individuals' attention on information pertaining directly to their own risk. However, general perceptions of risk (e.g., "smoking is dangerous") and personal perceptions of risk (e.g., "I am at risk because I am a smoker") often differ to a great extent. Individuals could be well informed about general aspects of certain risks and precautions (e.g., most smokers acknowledge that smoking can cause diseases), but, nevertheless, they might not feel personally at risk (Renner & Schupp, 2011).

The adoption of health behaviors should not be viewed simplistically as a response to a health threat. Risk information alone does not help people to change risky behaviors because it does not provide meaningful information about how to manage behavioral changes. Initial risk perception seems to be advantageous in raising awareness and in helping people become motivated to change, but later on other factors are more influential in the self-regulation process.

Outcome Expectancies In addition to being aware of a health threat, people also need to understand the links between their actions and subsequent outcomes. These outcome expectancies can be the most influential beliefs in the motivation to change. The term "outcome expectancies" is most common in social cognitive theory (Bandura, 1986). "Pros and cons" take a similar role in the transtheoretical model (Prochaska & DiClemente, 1983), where they represent the decisional balance in people who contemplate whether to adopt a novel behavior or not. In the theory of reasoned action (Fishbein & Ajzen, 1975), the corresponding term is "behavioral beliefs" that act as precursors of attitudes.

The pros and cons represent positive and negative outcome expectancies. A smoker may find more good reasons to quit ("If I quit smoking, then my friend will like me much more") than reasons to continue smoking ("If I quit, I will become more tense and irritated"). This imbalance in favor of positive outcome expectancies will not lead directly to action, but it can help to generate the intention to quit. Indeed, a key observation of research from the transtheoretical model is the importance of "pros" *more than* "cons" in moving peoples from precontemplation to contemplation and preparation. Outcome expectancies can also be understood as means-ends relationships, indicating that people know proper strategies to produce the desired effects (Hankonen, Absetz, et al., 2013).

The perceived contingencies between actions and outcomes need not be explicitly worded; they can also be rather diffuse mental representations, loaded with emotions. Social cognition models are often misunderstood as being rational models that deal with "cold cognitions." In contrast, health behavior change, to a large degree, is an emotional process that turns into a cognitive one after people have been asked about their thoughts and feelings, thus making them aware of what is going on emotionally. An example of an emotional outcome expectancy is anticipated regret ("If I do not use a condom tonight, then I will regret it tomorrow").

Perceived Self-Efficacy Perceived self-efficacy portrays individuals' beliefs in their capabilities to exercise control over challenging demands and over their own functioning (Bandura, 1997). It involves the regulation of thought processes, affective states, motivation, behavior, or changing environmental conditions. These beliefs are critical in approaching novel or difficult situations, or in adopting a strenuous self-regimen. People make an internal attribution in terms of personal competence when forecasting their behavior (e.g., "I am certain that I can quit smoking even if my friend continues to smoke"). Such optimistic self-beliefs influence the goals people set for themselves, what courses of action they choose to pursue, how much effort they invest in given endeavors, and how long they persevere in the face of barriers and setbacks. Self-efficacy influences the challenges that people take on as well as how high they set their goals (e.g., "I intend to reduce my smoking," or "I intend to quit smoking altogether"). Some people harbor self-doubts and cannot motivate themselves. They see little point in even setting a goal if they believe they do not have what it takes to succeed. Thus, the intention to change a habit that affects health depends to some degree on a firm belief in one's capability to exercise control over that habit. Perceived self-efficacy has been found to be important at all stages in the health behavior change process which led to the development of phase-specific self-efficacy (Ochsner, Scholz, & Hornung, 2013).

Planning Good intentions are more likely to be translated into action when people develop success scenarios and preparatory strategies of approaching a difficult task. Mental simulation helps to identify cues to action. The terms planning and implementation intentions have been used to address this phenomenon. To date, research has accumulated abundant evidence for the effectiveness of planning in behavioral medicine (Wiedemann, Lippke, & Schwarzer, 2012). Meta-analyses have summarized the effects of planning on health behaviors (Gollwitzer & Sheeran, 2006).

One way of planning is the anticipation of barriers and the generation of alternative behaviors to overcome them. This has been called coping planning (Sniehotta, Schwarzer, et al., 2005). People imagine scenarios that hinder them in performing their intended behavior, and they develop one or more plans to cope with such a challenging situation. For example, "If I plan to run on Sunday, but the weather does not permit it, I will go swimming instead," or "If there is something exciting on TV tonight that I do not want to miss, I will reschedule my workout to the afternoon." Coping planning might be a more effective self-regulatory strategy than mere action planning. After people contemplate the when, where, and how of action, they imagine possible barriers and generate coping strategies. Thus, coping planning comes on top of action planning (Wiedemann, Lippke, & Schwarzer, 2012; Scholz, Schuz, et al., 2008). Planning is an alterable variable. It can be easily communicated to individuals with self-regulatory deficits. Quite a few randomized controlled trials have documented the evidence in favor of such planning interventions (for a review see Kwasnicka, Presseau, et al., 2013).

Principles

Principle 1: Motivation and Volition The health behavior change process is divided into two phases. There is a switch of mind-sets when people move from deliberation to action. First comes the motivation phase in which people develop their intentions. Afterward, they enter the volition phase.

Principle 2: Two Volitional Phases In the volition phase, there are two groups of people: those who did not yet translate their intentions into action and those who did. Thus, there are inactive as well as active persons in this phase. In other words, in the volitional phase one finds intenders as well as actors who are characterized by different psychological states. In addition to health behavior change as a continuous process, one can also create three categories of people with different mind-sets, depending on their current location within the course of behavior change: preintenders, intenders, and actors. This is more parsimonious than the TTM (precontemplators and contemplators = preintenders; preparers = intenders; actors and maintainers = actors).

Principle 3: Postintentional Planning Intenders who are in the volitional preactional stage are motivated to change, but they do not act because they might lack the right skills to translate their intention into action. Planning is a key strategy at this point. It serves as an operative mediator between intentions and behavior (for a review see Hagger & Luszczynska, 2014).

Principle 4: Two Kinds of Mental Simulation Planning can be divided into action planning and coping planning. Action planning pertains to the when, where, and how of intended action. Coping planning includes the anticipation of barriers and the design of alternative actions that help to attain one's goal in spite of impediments.

Principle 5: Phase-Specific Self-Efficacy Perceived self-efficacy is required throughout the entire process. However, the nature of self-efficacy differs from phase to phase. This is because there are different challenges as people progress from one phase to the next one. Goal setting, planning, initiative, action, and maintenance all pose challenges that are not of the same nature. Therefore, one can distinguish between preactional self-efficacy, coping self-efficacy, and recovery self-efficacy. Sometimes the terms *task self-efficacy* instead of preaction self-efficacy, and *maintenance self-efficacy* instead of coping and recovery self-efficacy are preferred.

Theory-Based Interventions

When it comes to the design of interventions, one can consider turning the implicit stage model into an explicit one. This is done by identifying individuals who are categorized as preintenders, intenders, and actors. The basic idea is that individuals pass through different phases on their way to behavior change. Thus, interventions may be most efficient when tailored to these particular mind-sets. For example, *preintenders* are supposed to benefit from confrontation with outcome expectancies and some level of risk communication. They need to learn that the new behavior (e.g., becoming physically active) has positive outcomes (e.g., well-being, weight loss, fun) as opposed to the negative outcomes that accompany the current (sedentary) behavior such as developing an illness or being overweight. They also need to develop an optimistic belief that they are capable of performing the critical behavior.

In contrast, *intenders* should not benefit much from health messages in the form of outcome expectancies because, after setting a goal, they have already moved beyond this mind-set. Rather, they should benefit from planning to translate their intentions into action.

Finally, *actors* should be prepared for particular high-risk situations in which lapses are imminent. Interventions help them if they desire to change their routines (e.g., adopting or altering a behavior).

Interventions should not be designed in a pure rational manner because health behavior change is also an emotional process that is being analyzed as a cognitive one only after people have been asked about their feelings. All the theoretical constructs are loaded with emotions in the first place. Thus, treatments need to focus on changes in emotions (for an overview of behavior change techniques, see Michie & Johnston, 2012).

Overviews of leading health behavior theories are provided in some book chapters (health belief model, reviewed by Abraham and Sheeran (2005); protection motivation theory, reviewed by Norman, Boer, and Seydel (2005); social cognitive theory, reviewed by Luszczynska and Schwarzer (2005); transtheoretical model, reviewed by Sutton (2005); and theory of planned behavior, reviewed by Conner and Sparks (2005)). The HAPA is presented in more detail in Schwarzer (2008).

Focused Theories on Occupational Factors in Health and Disease

Occupational Stress Model

Occupational stress has received growing attention as increasing evidence on its role in occupational health has become available. In particular, studies using theoretical models of occupational stress proved to be useful as they identify specific components of the work environment or of the interaction between the work setting and the working person, which adversely affect health. The impact of stressful working conditions on health has been investigated with particular intensity over the past 30 years. A number of theoretical models were developed and tested that identify stressful job characteristics with potentially adverse health effects (Cooper, 1998).

"Stress" is too vague a word to be informative in epidemiologic studies. For example, study participants are sometimes asked whether or not they experience occupational stress. The content may differ according to the individual. One person might perceive occupational stress as a result of time pressure, while another might suffer from a conflict in a personal relationship with a supervisor or colleague. Even if the exposures detected by the answer to such a question predict a health outcome, it would be impossible to intervene because the precise nature of the stressor would be unknown. There have been improvements in the measurement of occupational stress, moving away from the generic idea of stress toward the combination of a few definite concepts based on theories. The introduction of occupational stress models has made breakthroughs in conceptualizing real-life complex phenomena in the workplace. Constructed by a few relevant specific (toxic) components, occupational stress models are applicable to a broad range of occupations. They can be operationalized for experimental as well as epidemiological studies and be useful for the theory-based intervention.

The job demand–control model is one of the most prevailing occupational stress models in the field of behavioral medicine. The job demand–control model includes two components: psychological demands, which tap quantitative and conflicting demands of work, and job control, which measures decision authority and skill utilization over a task. Employees who face high demands and have little control over their work (i.e., job strain) are hypothesized to be at great risk of becoming ill (Karasek & Theorell, 1990). Later, the third component, social support at work, was incorporated (Johnson & Hall, 1988). According to the extended model – the job demand–control–support model – the highest risk of illness is expected in employees with high demands, low control, and low social support.

The predictive validity of the job demand–control (–support) model has been supported by a large number of empirical studies proving the predictions of various health outcomes, particularly cardiovascular diseases (CVD) (Belkic, Landsbergis, et al., 2004; Kivimaki, Nyberg, et al., 2012; Kivimaki, Virtanen, et al., 2006) and depression or psychological distress (Bonde, 2008; Netterstrom, Conrad, et al., 2008; Stansfeld & Candy, 2006). Evidence is accumulating on prospective associations with other health outcomes including musculoskeletal disorders (Rugulies & Krause, 2005) and sickness absence (Suominen, Vahtera, et al., 2007).

Hypothesized Mechanisms Through Which Occupational Stress Leads to CVD

Although several systematic reviews confirmed significant prospective association between occupational stress, including job strain (high demands and low control), and CVD (Belkic, Landsbergis, et al., 2004; Kivimaki, Nyberg, et al., 2012; Kivimaki, Virtanen, et al., 2006), the mechanisms underlying the association between occupational stress and CVD remain still unclear. Exploring the mechanisms is a scientific field providing many research questions (Fig. 7.6).

Much of the figure reflects the general theories on psychophysiological stress reviewed earlier in this chapter. Research however shows the value of articulating this general model among workers and in the specific contexts of work, leading to a focused theory of occupational stress. There are a number of epidemiological studies which address the association between occupational stress and conventional CVD risk factors, including hypertension, type II diabetes, and metabolic syndrome. Job strain (combination of high job demands and low job control) and iso-strain (combination of job strain and low social support at work) have been shown to predict incidence of hypertension (Markovitz, Matthews, et al., 2004; Schnall, Schwartz, et al., 1998), diabetes (Heraclides, Chandola, et al., 2012; Kumari, Head, & Marmot, 2004), and metabolic syndrome (Chandola, Brunner, & Marmot, 2006). Furthermore, sophisticated measurement devices such as ambulatory blood pressure monitoring has made more precise estimation possible rather than static blood pressure measured at clinical settings, and evidence shows consistent associations between job strain and high blood pressure in prospective analyses (Clays, Leynen, et al., 2007; Landsbergis, Schnall, et al., 2003). Recent large-scale pooled analyses also revealed prospective associations between job strain and unhealthy behaviors such as obesity, leisure-time physical activity, alcohol intake, and tobacco smoking (Fransson, Heikkila, et al., 2012;

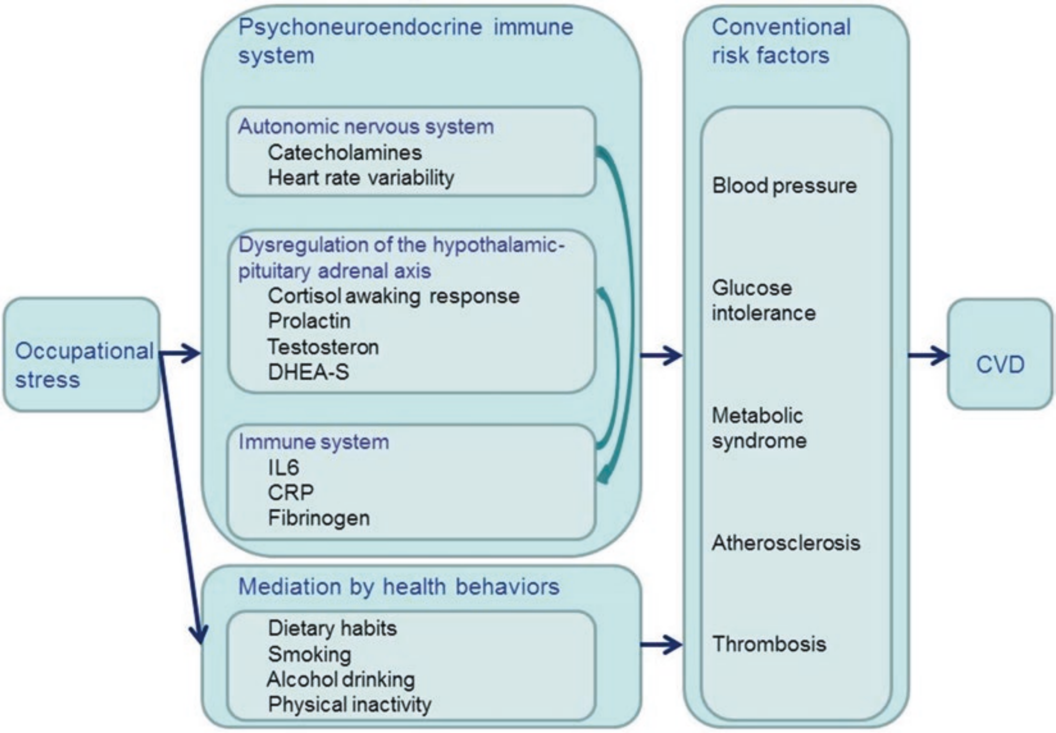

Fig. 7.6 Hypothesized mechanism underlying the association between occupational stress and CVD

Heikkila, Fransson, et al., 2013; Heikkila, Nyberg, et al., 2012; Nyberg, Heikkila, et al., 2012). Although confirmed, the associations seem weak so that hypothesis of an association between occupational stress and unhealthy behaviors are only modestly supported (Siegrist & Rodel, 2006).

Research interests are focusing more on pathophysiological mechanisms. Occupational stress is considered as chronic stressor, and its pathophysiological mechanisms are thought to be in accordance with rapidly accumulating knowledge regarding cardiovascular effects of the stress response (Brotman, Golden, & Wittstein, 2007). Occupational stress may affect CVD through direct activation of neuroendocrine and inflammatory responses to stressors. One of the main axes of neuroendocrine stress responses is the autonomic – sympathetic and parasympathetic – nervous system. Furthermore, occupational stress may affect dysregulation of the hypothalamic–pituitary–adrenal axis. Changes in sympathetic–parasympathetic balance and the tone of the hypothalamic–pituitary–adrenal axis may negatively affect the cardiovascular system. There may be acute effects, such as precipitating myocardial infarction, left ventricular dysfunction, or dysrhythmia, as well as chronic effects, such as accelerating the atherosclerotic process (Brotman, Golden, & Wittstein, 2007). In addition, evidence is accumulating that inflammatory cytokines production is associated with psychological stress.

Several studies investigated cardiovascular activity in response to perceived occupational stress. Strong evidence has been observed in blood pressure elevation in response to job strain (Steptoe & Willemsen, 2004; Theorell, Perski, et al., 1988). Association of occupational stress with repeated activation of the sympathetic nervous system, characterized by high heart rate, lowered heart rate variability, and reduction in high frequency power, has also been explored in occupational settings (Collins, Karasek, & Costas, 2005; Rau, Georgiades, et al., 2001).

Studies on the associations of occupational stress with hormonal measures have produced less consistent findings. Catecholamines such as adrenaline and noradrenalin are relevant biomarkers of sympathetic nervous system arousal. Since adrenaline and noradrenalin have a short half-life in the circulation, urinary catecholamines are often measured in occupational stress research. Some studies showed elevated urinary catecholamine levels among workers with job strain (Evans & Carrere, 1991; Harenstam & Theorell, 1988; Pollard, Ungpakorn, et al., 1996) but some did not (Brown & James, 2000; van der Beek, Meijman, et al., 1995). Interesting findings are associations of job strain with sustained activation of catecholamine (i.e., after work) suggesting slow unwinding of sympathetic nervous activity (Fujiwara, Tsukishima, et al., 2004; Lundberg & Frankenhaeuser, 1999).

The release of corticosteroids represented by cortisol is part of the systematic arousal of the hypothalamic–pituitary–adrenal axis initiated by release of corticotropin-releasing hormone by the hypothalamus. Normally, cortisol release shows clear circadian rhythms and appears to peak at early morning hours, with a low point around midnight. Studies of cortisol regulation in workers with job strain suggest that the regulation is disturbed, but the patterns of cortisol release appeared different by studies. Some studies indicated that morning saliva cortisol levels increased in job strain (Steptoe, Cropley, et al., 2000) or remained lower in low job strain (high job control and low job demands) groups (Alderling, Theorell, et al., 2006), while several others showed reduced rather than heighten cortisol responses among strained group (Fujiwara, Tsukishima, et al., 2004; Rystedt, Cropley, et al., 2008; Steptoe, Wardle, et al., 1998). The latter finding is explained by an inhibited elevation of morning cortisol induced by prolonged stress. In an experimental study which employed a simulated work–office environment allowing for manipulation of job demands and job control in a strict orthogonal fashion, Hausser, Mojzisch, and Schulz-Hardt (2011) found that participants in the high strain condition showed a significantly higher cortisol response compared to participants in the non-strain conditions and that higher demands led to a higher cortisol response in the conditions when participants had low job control but no such increase was found when job control was given.

So far the observed associations of job strain and hormonal responsiveness are not consistent. But literature suggests that clearer overall pictures are expected to be found by introducing into the analyses personal characteristics and histories of the workers, such as anger expression (Steptoe, Cropley, et al., 2000) or exposure to adversity in adolescence (Westerlund, Gustafsson, et al., 2012). Similarly, clearer overall pictures are expected to be found by taking into consideration how long the workers are exposed to job strain (Fujiwara, Tsukishima, et al., 2004; Rystedt, Cropley, et al., 2008) or restricting the study participants to employees whose regulatory system (circadian rhythm) is intact (Alderling, Theorell, et al., 2006). Responsiveness of hormone release can be more clearly distinguished by employing independent manipulations of job demands and control in a laboratory (Hausser, Mojzisch, & Schulz-Hardt, 2011).

A recent systematic review suggests that occupational stress is associated with disrupted immune responses: Nakata (2012) identified 56 studies on the research question. Of those studies, 12 tested whether job strain was associated with immune parameters and five tested the effect of the effort-reward imbalance (ERI) model, another established occupational stress model (Siegrist, 1996). Seven out of 12 job strain studies and all ERI studies showed significant associations between occupational stress and immune parameters. However, many other studies that focused on certain type of jobs that were considered to be inherently stressful and other quantitative workload features such as overwork and self-reported mental demand produced inconsistent or insignificant associations between the stress measurements and immunoglobulin markers and/or cellular immune indicators. Nakata attributed the inconsistent findings to measurement issues of occupational stress, such as the difference in intensity, length, acute, or chronic, along with other methodological shortcomings, including lack of prospective studies with sufficient sample size, residual confounding, and measurement methods of immune indicators with much to be improved. Nakata also pointed out the importance of careful selection of stress measures because some job stress measures may not be suitable for certain occupations and jobs. Well-established occupational stress measures which cover various and broad aspects of working conditions and with high validity and reliability would overcome these shortcomings on stress measurement.

New technologies such as neuroimaging have been incorporated to untangle the complex interactions of risk factors. Functional associations between brain, neuroendocrine, immune, and cardiovascular reactivity were examined in experimental settings (Isowa, Ohira, & Murashima, 2006; Ohira, Fukuyama, et al., 2009) in which researchers manipulated controllability (controllable vs. uncontrollable), while subjects performed a stochastic learning task. Their regional cerebral blood flow, cardiovascular, neuroendocrine, and immune indices were measured simultaneously. The studies showed that immune responses were most directly associated with cardiovascular activities under the uncontrollable condition and that the dorsolateral prefrontal and orbitofrontal cortices are involved in both evaluation of the controllability of a stressor and regulation of immune function. More specifically, redistribution of NK cells as well as mediating autonomic and endocrine responses to a stressor was attenuated or downregulated when the stressor was uncontrollable. These findings that uncontrollability of an analog stressor in an experimental situation inhibits adaptive regulation of immune, cardiovascular, and neuroendocrine responses to stress have obvious relevance to the focused area of occupational stress, given its major emphasis on job controllability.

In summary, epidemiological studies utilizing the demand–control model have revealed prospective associations of job strain and its components (demand/control/support) on conventional CVD risk factors, such as hypertension, diabetes, metabolic syndrome, and health behaviors. Naturalistic and laboratory studies in which high demand-low control situations are manipulated have been uncovering the pathophysiological mechanisms through which job strain lead to CVD. This demand–control model constitutes, then, a focused theory, articulating in the specific features of occupational stress, the broad relationships of general theories on psychophysiological stress.

Lessons from Interventional Research

Stress-reduction approaches in the workplace would be improved by focused theories that might provide useful tools for dealing with real-life complex phenomena in the workplace. Intervention effect could then be evaluated based on the theory.

There are three levels of psychosocial intervention at workplace: individual level, interpersonal level, and organizational level. Of these, organizational intervention is of particular importance because more permanent and efficient effects are anticipated (Burke, 1993; Karasek, 1992). However, the three levels are not mutually exclusive. A strong participatory element is especially important when the organizational intervention study focuses on work organization, communication, or interpersonal relations (Kompier, Geurts, et al., 1998) so that it is necessary to improve not only work environment but also workers' empowerment (Kompier & Kristensen, 2001). Successful participatory organizational interventions would be expected to work in two main ways: (1) by modifying objective stressful conditions in the psychosocial environment and (2) through the active learning that workers experience in direct participation and successfully affecting positive change. The former is based on occupational stress theory that primarily focused on environmental improvement or job redesign rather than behavioral change in symptoms of ill-health. The latter is due to enhanced perceptions of control and influence, development of skills based on organizational learning theory, and self-esteem and social support enhanced by participation, dialogue, and workplace democracy (Mikkelsen, Saksvik, & Landsbergis, 2000).

A team-based, problem-solving intervention was conducted based on active employee involvement, shared work-related goals, and action planning to improve the work environment for stress reduction (Tsutsumi, Nagami, et al., 2009). The theoretical concept that provided the basis for the study was the job demand–control–support model. As introduced in the former section, the job demand–control–support model identifies three psychosocial factors at work whose effects on physical and mental health are the most frequently documented. It was hypothesized that implementing an intervention targeting the theory grounded psychosocial work environment should bring about beneficial effects on workers (a decrease in mental health problem or improvement of job performance) through a decrease in three adverse psychosocial factors – high psychosocial demands, low decision latitude, and low social support.

Exposure to psychosocial job conditions was measured before the intervention as prior hazard identification and at the end of the intervention in order to evaluate implementation of the intervention. For this, the Job Content Questionnaire (JCQ) was employed. The JCQ is based on Karasek's demand–control–support model (Karasek & Theorell, 1990). The results of pre-intervention stress surveillance based on JCQ was visualized to compare Japanese national data and then used as a reference for hazard identification and an index of improvement (Kawakami & Japan Industrial Safety and Health Association, 2001). In addition, a checklist was introduced for organizing workplace-level discussion to identify immediate, low-cost improvements in the workplace. The checklist was developed through a review of related references and the collection of examples of workplace improvements to produce a concrete action plan (Yoshikawa, Kawakami, et al., 2007). Using these tools, workers listed and prioritized issues to be improved in their workplace based on the results of their stress surveillance, then started to improve their work conditions based on the action plans.

Scores on the General Health Questionnaire during the follow-up period improved in the production lines where the intervention was implemented, whereas the score deteriorated in the production lines of the control groups, with a significant intervention effect. In addition, scores for self-reported job performance increased in the intervention group, but decreased in the control groups, yielding a significant intervention effect (quantitative outcome evaluations). According to the job demand–control–support model, these results would be attributable to the improvement of three psychosocial work environment, i.e., decreasing job demands and increasing of job control and/or workplace social support.

Process evaluation examines whether the intervention was properly conducted and then whether the theory underlying the hypothesis was supported. Theoretically, stress-related outcomes can be improved by increasing workers control or social support at work and decreasing job demands. Some studies examined the hypothesis by investigating the mediating effects of job control–demands–support statistically (quantitatively) (Bond & Bunce, 2001; Jackson, 1983). As qualitative methods are useful to examine the richness and significance of people's (context-dependent) experience (Griffiths, 1999), we evaluated the implementation of the intervention by employing qualitative method (post-intervention interviews with those involved in the intervention).

Post-intervention interviews revealed that psychosocial job conditions (job control and social support at work) improved in most intervention lines and that meaningful actions resulted from these improvements. For example, at a line, where job control was improved, the workers dealt with a variety of small parts, and the tasks had not been standardized. The work involved the workers thinking for themselves, and the small units they worked on were formulated according to the specific task. In another line, the workers proposed many improvement plans by mutual agreement. For example, dust was a problem in the line, so they decided to clean up their workplace regularly with all members of the group carrying out the plan (coworker support increased). At the other line, the preparatory table was moved nearer to the task table so that frequently used materials and tools would be placed within easy reach, thus substantially shortening preparation time. Manuals for working procedures were revised by marking specific places, so that workers could refer to them more easily (job control increased). A line leader produced several improvement plans such as labeling materials, inventory control, and gauge instrument improvement, which were then executed. Supervisor support was substantially improved in this line.

Post-intervention interviews also revealed some of the reasons why psychosocial job conditions did not improve in the intervention lines. These reasons included low workers' self-esteem, resistance of veteran workers who were near retirement, and poor human relationships in line, which the line leaders attributed to the poor commitment of the workers, leading intervention not to be effective. The information was considered useful for redesigning the intervention (Griffiths, 1999).

The above example shows the implementation of a participatory intervention for workplace improvement by addressing three adverse psychosocial work factors (high psychological demands, low decision latitude, and low social support) grounded in a focused theory of the job demand–control–support model and their effects on workers' mental health and job performance. Further, the theory guided process evaluation by both quantitative and qualitative methods that provided rich information on how the intervention was implemented and whether the hypothesized mediating effects of psychosocial work factors were valid. Both successful and failed intervention will provide a step forward in occupational stress research as well as further strengthen the theory's validity. Scrutinizing the process will facilitate the interpretation and integration of research findings.

Focused Theory: Functional Decline in Osteoarthritis[3]

Avoidance of Activity in Osteoarthritis of the Knee

Osteoarthritis (OA) of the knee is associated with pain and instability of the knee and leads to activity limitations, such as limitations in walking and climbing stairs. Activity limitations may translate

---

[3] This section describes only part of the theory. A full description of the theory is given in Dekker (2014).

into restrictions in social participation, for example, problems with housekeeping and traveling.

The course of functioning in knee OA is highly individual and variable: functioning has been found to improve in some patients, to remain stable in others, and to gradually worsen in still others (Dekker, van Dijk, & Veenhof, 2009; Holla, van der Leeden, et al., 2014). One of the risk factors for functional decline is psychological distress. Psychological distress, i.e., an anxious and depressed mood, predicts future functional decline (Dekker, van Dijk, & Veenhof, 2009; van der Leeden, Veenhof, et al., 2014).

This empirical observation led to the question: how does psychological distress contribute to future functional decline? There is no direct link between psychological distress (i.e., an anxious and depressed mood) and future decline (e.g., limitations in walking and climbing stairs). Thus, the question arises how psychological distress contributes to functional decline. In other words, a theory is needed on how psychological distress contributes to future functional decline. This can be stated more generally. A risk factor provides information on prognosis. Unless the risk factor has a direct impact on prognosis, the risk factor does not explain prognosis, however. Risk factors are part of complex causal mechanisms which determine prognosis. A risk factor in itself is just an observation, not an explanation. Explanation requires theory on the complex causal mechanisms which determine prognosis, as is illustrated below.

It has been theorized that avoidance of activity explains the impact of psychological distress on future functional decline in knee OA. According to this explanation, pain may cause subjects to avoid activity: in knee OA, pain is frequently related to activities such as walking. Avoidance of these activities reduces pain. In the short term, this is beneficial: avoidance of activity causes less pain. In the long term, however, avoidance of activity causes muscle weakness and thereby activity limitations. Physical activity and exercise are required to maintain muscle strength. Avoidance of activity causes muscle weakness, which is an important cause of activity limitations (see Fig. 7.7).

Psychological distress is thought to enhance the tendency to avoid activity, resulting in muscle weakness and activity limitations (see Fig. 7.7). Psychologically distressed patients, i.e., patients with an anxious and depressed mood, lack motivation to exercise or to perform physical activity and avoid such activities. Thus, psychological distress is hypothesized to strengthen the tendency to avoid activity, leading to muscle weakness and activity limitations.

This theory was introduced as an explanation for the observation that psychological distress predicts worsening of activity limitations. Avoidance

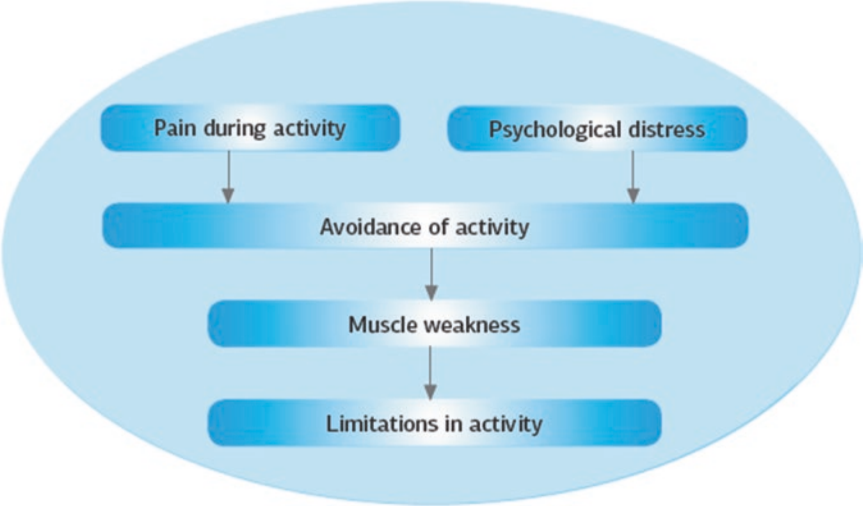

Fig. 7.7 Behavioral explanation of activity limitations: Avoidance of activity

of activity was introduced as an explanation of this phenomenon in 1992 (Dekker, Boot, et al., 1992). Although terminology and some details of the theory have evolved, the basic theoretical model has remained the same over the years.

This theory was tested in a series of studies, generally confirming the validity of this focused theory and illustrating the interplay between theory and empirical findings (Dekker, Tola, et al., 1993; Steultjens, Dekker, & Bijlsma, 2002; Holla, van der Leeden, et al., 2012; Pisters, Veenhof, et al., 2014; Holla, Pisters, &, Dekker, 2014). (i) The first hypothesis derived from the theory stated that muscle weakness mediates the relationship between psychological distress and activity limitations. This hypothesis was tested and confirmed (Dekker, Tola, et al., 1993), which encouraged further research. (ii) The next study focused on avoidance of activity, as this is a central concept in the theory. The hypothesis derived from the theory stated that avoidance of activity induces muscle weakness which results in activity limitations. In other words, muscle weakness mediates the relationship between avoidance of activity and activity limitations. The hypothesis was tested and confirmed (Steultjens, Dekker, & Bijlsma, 2002). (iii) Subsequently, hypotheses were formulated on the impact of pain and psychological distress, as the role of pain and psychological distress had not yet been tested. It was hypothesized that pain induces avoidance, resulting muscle weakness. In other words, avoidance of activity is a mediator between pain and muscle weakness. This hypothesis was tested and confirmed (Holla, van der Leeden, et al., 2012). In addition, it was hypothesized that psychological distress enhances the impact of pain on avoidance (moderation). This hypothesis was rejected (Holla, van der Leeden, et al., 2012). Instead, evidence was found that psychological distress induces avoidance directly, not as mediated by pain, resulting in muscle weakness (see Fig. 7.7). The hypothesis that muscle weakness mediates the relationship between avoidance of activity and activity limitations was tested once again and confirmed (Holla, van der Leeden, et al., 2012). This was a replication of the earlier confirmation (Steultjens, Dekker, & Bijlsma, 2002). Finally, a longitudinal study confirmed the findings from previous cross-sectional studies: in a 5-year follow-up study, the mediating role of muscle weakness between avoidance of activity and activity limitations was confirmed (Pisters, Veenhof, et al., 2014). Thus, starting with cross-sectional studies, the empirical status of the theory gradually became stronger as also a longitudinal study supported the theory.

This progression of findings illustrates *the heuristic function of theory* (see section “The Role of Theory in Behavioral Medicine Research”). The theory has driven a series of studies, gradually deepening our understanding of functional decline in knee OA. The theory indicated which studies needed to be done, in order to understand functional decline in knee OA.

Neuromuscular Exercise in Osteoarthritis of the Knee

Neuromuscular factors other than muscle weakness are known to be associated with functional decline in knee OA. This includes proprioception (the sense of joint motion and position), laxity (the passive range of motion in the frontal plane), and varus–valgus motion (movement of the knee in the frontal plane during walking). These factors are hypothesized to interact with muscle weakness causing instability of the knee and thereby leading to activity limitations. This theory is illustrated in Fig. 7.8. Evidence to support this theory has been summarized elsewhere (Van der Esch & Dekker, 2014).

Based on this neuromuscular theory, a neuromuscular exercise program was developed. It was argued that muscle strengthening exercises may not be sufficient to improve the performance of activities. Exercise therapy may need to target instability and may need to improve neuromuscular control, in addition to muscle weakness. Thus, an exercise program was developed, comprising neuromuscular exercises, in addition to the strength training. Neuromuscular exercise consisted of balance and agility training, aiming at improved perception of knee position and motion and at improved control of the knee.

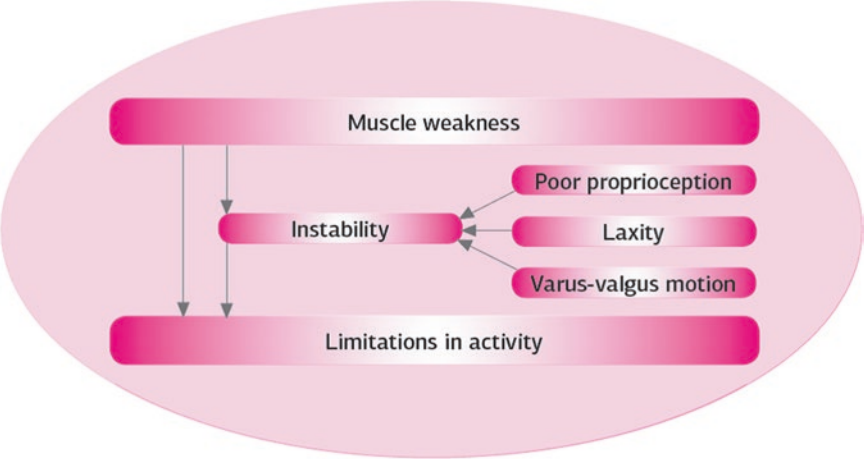

Fig. 7.8 Neuromuscular factors and activity limitations

This approach was tested in a randomized clinical trial comparing an exercise program consisting of neuromuscular exercise (aiming at improved stability of the knee), strength training and functional exercise (aiming at improved performance of activities) with a program consisting of strength training and functional exercise (aiming at improved performance of activities) only. It was expected that the first program would be more effective in improving the performance of activities of knee OA patients than the second program. Unexpectedly, there was no evidence of differential effectiveness of these programs: both programs were highly effective in improving muscle strength, stability, and the performance of activities; but there was no significant difference in effectiveness of these programs (Knoop, Dekker, et al., 2013).

The neuromuscular theory provided guidance in interpreting this unexpected result (see Fig. 7.8). A likely explanation for the negative result of the trial is that muscle weakness has a much stronger impact than the other neuromuscular factors. If muscle weakness is the most important determinant of activity limitations, improvement in other neuromuscular factors is not likely to improve outcome. Another explanation of the negative results of the trial is that strength training not only improved muscle strength but also other neuromuscular factors: if strength training improves both muscle strength and other neuromuscular factors, additional training of the other neuromuscular factors is unlikely to improve outcome (Knoop, Dekker, et al., 2013). Both explanations point to the importance of strength training in knee OA: strength training seems to be the most important modality of exercise therapy in knee OA.

This example illustrates *the integrative function of theory* (see section “The Role of Theory in Behavioral Medicine Research”). The focused theory on neuromuscular control in knee OA was instrumental in developing the tentative explanation of the dominant role of exercise aiming at muscle strengthening. The theory facilitated interpretation of the unexpected, negative result of the trial. Of course, the tentative conclusion that strength training is the most important modality of exercise therapy in knee OA needs further empirical testing.

The Power of Thought

We have summarized two major general theories in behavioral medicine, specifically psychophysiological stress theories and social cognitive theories on health behavior change, as well as two focused theories, specifically theories on occupational factors in health and disease, and on functional decline in osteoarthritis. These theories have several features in common:

- First, the development of these theories shows a cyclical process. The original version of the theory is stated. Empirical observations then indicate the need for adaptation of the original theory. The revised theory is subsequently subjected to further empirical testing. This cyclical process is a key feature of the development of scientific theory.
- Second, the authors of these theories are strongly committed to maintain theoretical rigor. The theories are characterized by clearly defined concepts and logically consistent relationships between these concepts.
- Third, these theories are falsifiable: the theories have been repeatedly shown to be wrong, indeed. Negative empirical findings led to adaptation and further development of the theories.
- Fourth, in revising theories, authors have aimed to maintain parsimony. The health action process approach (HAPA) is a good example of this as described in section "General Social Cognitive Theories of Health Behavior Change" of this chapter. The degrees of theoretical freedom are limited, i.e., parsimony is a distinct characteristic of this theory.
- Finally, each of these theories is restricted to a clearly defined domain of reality. The general theories are restricted to the impact of psychological stress on disease and to health behavior change, respectively. The focused theories are restricted to the impact of occupational stress on health and disease and to functional decline in osteoarthritis, respectively.

Most important, perhaps, each of these fields shows the power of thought. Theory gives direction to the development of research questions – the heuristic function of theory and theory facilitates the interpretation and integration of research findings – the integrative function of theory. Theoretical analysis is vital for the development of behavioral medicine as a scientific discipline.

Advancing Implementation: Toward an Inclusive View of Research in Behavioral Medicine

Dean L. Fixsen, Renée I. Boothroyd,
Karen A. Blase, Amanda A. M. Fixsen,
and Allison J. Metz

Introduction

In the early years of this millennium, having made a major investment in the development of evidence-based innovations, policymakers and others in health and social services were expecting to see dramatic improvements in outcomes for children, families, and individuals in the population. Disappointing results led to examinations that pointed to a growing science to service gap (Institute of Medicine, 2000, 2001; U.S. Department of Health and Human Services, 1999). Evidence-based innovations were slow to be used in typical service settings when they were used at all (Nembhard, Alexander, et al., 2009). Estimates suggested about 14% of the evidence-based innovations were used in practice after about 17 years (Balas & Boren, 2000; Green, 2008). These and other reviews provide clear indications that evidence is not enough to produce socially significant outcomes (Rangachari, Rissing, & Rethemeyer, 2013). The success of an evidence-based innovation is not measured by its effectiveness alone, but needs to take into account the ability to bring the full, intended experience of the innovation into the lives of children, families, and communities.

The science-to-practice gap is being addressed across multiple fields, disciplines, and settings, including education, public health, criminal justice, child welfare, and other social service sectors. A variety of terms, from "diffusion" and "adoption" (Rogers, 1962, 1995) and "dissemination" and "implementation" (Brownson, Colditz, & Proctor, 2012) to "knowledge translation" (Graham, Logan, et al., 2006), "knowledge to action" (Wilson, Brady, & Lesesne, 2011), "knowledge transfer and exchange" (Kiefer, Frank, et al., 2005), and "translational research" (Kelly, Somlai, et al., 2000; Waldman & Terzic, 2010), are commonly used – often interchangeably – to describe inquiry along this continuum of getting from science to practice. Dissemination and implementation (D&I) are sometimes combined as if they refer to a shared approach for getting research evidence into practice (Rabin, Brownson, et al., 2008).

The question "what does it take?" to get evidence into practice is critical so that what can help improve health reaches those it is intended to help. For the sake of clarity, "implementation" includes diffusion (passive spread of innovation knowledge) and dissemination (distribution and transfer of

information and innovation material), but is not defined by them. Implementation is an active and outcome-oriented endeavor (Fixsen, Naoom, et al., 2005) that is focused on how to support full and effective use of an evidence-based innovation as intended in typical service settings (Fixsen, Blase, et al., 2013a, b; Greenhalgh, Robert, et al., 2004). Implementation remains the missing link in the science to service chain, although the quality chasm may be narrowing.

The Need for Attention to the Process of Implementation

While experimental medicine had been under way for a long time (Bernard, 1865), it was the call for evidence-based medicine (EBM) by Sackett, Rosenberg, Gray, Haynes, and Richardson (1996) that raised expectations of the benefits to be derived from investments in innovation. Shortly thereafter, the Society of Behavioral Medicine established an Evidence-Based Behavioral Medicine (EBBM) Committee that was supported by the National Institutes of Health (NIH) Office of Behavioral and Social Science Research (OBSSR) to explore how core principles of EBM were applied to research on behavioral (non-drug, non-device) interventions (Davidson, Goldstein, et al., 2003). By 2006, the US health-care crisis had arrived and, along with it, the need for a better integrated system of care and coordinated approach to evidence-based behavioral medicine. OBSSR sponsored the Council on Evidence-Based Behavioral Practice, who, from an interdisciplinary approach across medicine, nursing, psychology, social work, public health, and information sciences, developed an evidence-based practice model in evidence-based behavioral medicine (EBBM). In contrast to the sole emphasis of evidence-based medicine (EBM) on research evidence, the EBBM model of research to practice added two parameters: resources (i.e., practitioner expertise) and client/population characteristics (Satterfield, Spring, et al., 2009). This model acknowledged that the translation of research to practice required some degree of client engagement in shared decision making and resources such as trained interventionists and accessible community facilities. The model also acknowledged that EBP occurs in particular organizational and environmental contexts that will influence implementation.

Given the power of EBM advocates expecting that people benefit from investments in innovation, the research budget for the National Institutes of Health (NIH) in the United States doubled between 1995 and 2010 (www.nih.gov). The challenges inherent in this idea came to light when Clancy (2006), then the head of the federal Agency for Healthcare Research and Quality, noted that the $100 billion annual investment in research had very little impact on the $1.6 trillion spent on health-care services. She speculated the lack of impact may be due to federal funding choices through which NIH spends over 99% of its budget to produce evidence-based innovations and less than 1% on how to use those innovations effectively in practice. Perl (2011), a longtime leader in the National Institute on Drug Abuse, cited similar experiences and suggested we are "addicted to discovery." Woolf and Johnson (2005) reviewed innovations and health outcomes and observed that any new innovation would have to be three times more powerful than anything yet produced to realize the same public benefit that would be derived from using already known innovations as intended. With all this in mind, Kessler and Glasgow (2011) suggested a moratorium on funding to produce innovations. They recommended investing heavily in implementation science so that the health-care system could learn to use the innovations already established and available for use.

All of these issues are strong arguments for investing in implementation science, practice, and policy. Hundreds of articles on the topic have been published about implementation strategies, including "one-off" ideas, measures, and approaches with methods and findings varying from one investigator to the next (Tinkle, Kimball, et al., 2013); yet there is little discernable progress that integrates what we are learning and knowing in implementation science in health. Why is that? Answers to this and other questions about what we currently know in implementation science – and how we know it – are the topic of this chapter.

Implementation Science: A Brief History

Looking Across Disciplines

Implementation science, as a self-conscious field of study, has been developing since the 1950s (Fischer, Miller, & Sidney, 2006; Pressman & Wildavsky, 1973; Saetren, 2005; Van Meter & Van Horn, 1975). The interest in implementation was born in analyses of policy outcomes. In the United States, the 1950s and 1960s saw major federal laws providing funds to achieve ambitious goals. The Eisenhower System of Interstate and Defense Highways (passed in 1956), the National Aeronautics and Space Act (passed in 1958), Kennedy's pledge in 1961 to put astronauts on the moon and return them safely to earth by 1969, and Johnson's Great Society programs (passed in 1965) encountered many difficulties even with massive input of federal funding and intervention.

Policy analysts began looking at policy implementation. It is not enough to have enabling legislation that funds departments to administer funds and contracts. The funds have to be administered in ways that assure implementation activities are in place to produce the desired outcomes. McNichol (2006) has a fascinating account of how the Federal Highway Administration had to encounter and overcome obstacles in society (routing based on racism), administration (contracts based on corruption instead of building roadways), and supply (lack of consistency and quality among contractors) to meet the goal of building 50% of the envisioned interstate highway system by 1966 (10 years after passage of the legislation). The National Aeronautics and Space Administration (NASA) was formed as a new agency to administer contracts and fund innovations to accomplish the seemingly impossible task of safely going to the moon and back. Landing on the moon in 1969 dramatically accomplished the vision in the 1958 legislation but not before engineering problems were overcome (e.g., strong metals, heat shields), and many innovations (e.g., silicon-based integrated circuits, lightweight computers) were developed. The highways and moon landings were mission driven, and problems were viewed as opportunities to create solutions to accomplish the goal.

The Great Society programs did not fare so well. The war on poverty, urban renewal, Medicaid, head start and follow-through education, VISTA volunteers, and others were heavily funded and backed by federal authority. By 1982 President Reagan eliminated nearly all of the funding for Great Society programs. Rossi and Wright (1984) provided a retrospective view of the "Golden Age" where science was intended to guide changes in social programs to achieve a Great Society. Unlike the highway and space programs, the effects for Great Society programs were close to zero. The conclusion was that the implementation was the culprit (Pressman & Wildavsky, 1973; Rossi & Wright, 1984; Van Meter & Van Horn, 1975). The intentions of the legislation and federal and state department administrators rarely were actualized in practice and, therefore, could not produce the intended benefits.

The next "Golden Age" for science began with the initiation of the evidence-based movement in the 1990s (Backer, 1992; Roberts, 1996; Sackett, Rosenberg, et al., 1996). The evidence-based movement has rekindled interest in implementation as the missing link in the science to service chain. Networks of researchers and practitioners have galvanized around implementation at state, national, and global levels (e.g., Colorado Implementation Collaborative (CIC), http://www.coloradoimplementation.com/; the European Implementation Collaboration (EIC) http://www.implementation.eu/; and the Global Implementation Initiative (GII), http://globalimplementation.org). Since 2010, the US federal government has invested in a number of evidence-based social policy programs. But without support for quality implementation, they too run the risk of not delivering promised outcomes. Reviews of the literature have documented growth and gaps in knowledge about diffusion and dissemination (Brownson, Colditz, & Proctor, 2012; Greenhalgh, Robert, et al., 2004) and implementation (Fixsen, Naoom, et al., 2005). More recent reviews of numerous frameworks have been conducted to guide diffusion and dissemination (Tabak, Khoong, et al., 2012) and implementation (Meyers, Durlak, & Wandersman, 2012) research and practice. Results from these remarkable advances in implementation science will inform the discussion in this chapter.

Implementation Science in Behavioral Medicine

In EBBM, translational behavioral medicine (TBM) is an approach that concerns the transfer of knowledge from the psychosocial and biomedical sciences in order to develop behavioral interventions to improve health, evaluate the effectiveness of those interventions, and study and improve their implementation in practice and policy. The overarching objective of TBM is to advance, integrate, and actualize knowledge from the research, practice, and policy arenas to improve the health of individuals and communities. Since 2011, implementation-related studies have been reported in *Translational Behavioral Medicine: Practice, Policy, Research*, a scholarly professional journal devoted to the topic that was established by the Society of Behavioral Medicine.

The research-to-practice gap is being addressed from multiple facets. Training institutes for dissemination and implementation research (Meissner, Glasgow, et al., 2013) and knowledge translation (Straus, Brouwers, et al., 2011) have been designed to influence the research itself and make it more relevant and actionable for generating the kind of evidence that can enhance what we know about the research to practice process (e.g., www.ebbp.org). The International Society of Behavioral Medicine (ISBM) has facilitated satellite forums on dissemination and implementation and formed a global network on D&I research (Chan, Oldenburg, & Viswanath, 2015). Some national programs have required applicants to adopt one or more evidence-based strategies that have been specified in a prescribed menu of effective practices (Hawkins, Wilson, & Rodriguez, 2011). Methodologically, professionals are recommending use of alternative research designs and approaches to recast the nature or conduct of research itself to identify and understand the factors that facilitate implementation of behavioral medicine programs, e.g., mixed-methods approaches (Green, Duan, et al., 2015), pragmatic trials (Glasgow, 2013), qualitative comparative analysis (Kane, Lewis, et al., 2014), systems science methods (Burke, Lich, et al., 2015), and effectiveness-implementation hybrid designs (Curran, Bauer, et al., 2012). Others are calling for the need to establish critical evaluation and reporting elements that are relevant to and can assist the situations and decisions of practitioners and policymakers seeking to put research into practice (Neta, Glasgow, et al., 2015). A 2015 Special Issue of the *International Journal of Behavioral Medicine* on *Advancing the Science of Dissemination and Implementation in Behavioral Medicine* outlines evidence and progress from the application of many and varied theories and research methodologies to bridge research to practice (Chan, Oldenburg, & Viswanath, 2015).

Other studies along the evidence-to-practice continuum are examining how to best disseminate and implement evidence-based interventions and integrate them within clinical and community settings. In many cases, studies utilize and test a particular "implementation strategy" to deliver and increase uptake of an evidence-based program; researchers then evaluate changes in client or population outcomes. For example, investigators examined use of a peer-led approach to translate use of a proven, clinic-based diabetes prevention program in a community mental health organization (Schneider, Sullivan, & Pagoto, 2011). In another study, investigators tested the use of commercial smartphone-based devices and applications to improve chronic disease health monitoring behaviors (Vashist, Schneider, & Luong, 2014). Despite some positive results (much like an efficacy trial), such studies often fail to operationalize "what it takes" to support full and effective use of the innovation (also known as the process of implementation). Instead, investigators continue to report the need to understand and then actually address what turns out to be a complex set of factors for how to get evidence-based interventions into practice (Dolcini, Catania, et al., 2014; Spoth, Rohrbach, et al., 2013).

In contrast to "implementation" as its own intervention strategy to deliver an evidence-based innovation (and then measuring client or population outcomes), other researchers are focused on understanding, addressing, and improving factors related to the "how" of implementation. Most real-world practice occurs in complex organizations and contexts, suggesting that successful implementation may necessitate the use of an array of strategies to be effective at multiple levels of an organization or system (e.g., clinician-level competence, organizational culture). Herein, studies use discrete (e.g., training), multifaceted (e.g., training plus reminders), and comprehensive approaches that incorporate multiple implementation strategies or systematic processes to integrate evidence-based innovations into routine care or services (Powell, McMillen, et al., 2012). The comprehensive bundles of implementation strategies align with taking more of a systems thinking approach to implementation, one that understands and embraces the real features of community, organizational, and other contexts (Best & Saul, 2011; Chaudoir, Dugan, & Barr, 2013). These more comprehensive approaches may complicate the task of operationalizing implementation methods in complex, yet typical environments. Doing so, however, may offer greater coverage of potential barriers to change and also build a range of strong and relevant bridges from science to practice that are based in the realities of lower-resourced settings.

Taking an Inclusive Look at What We Are Learning in Implementation

The Case for Universal Thinking in Implementation

What *do* we know about the conditions that affect implementation? Implementation science has a long history based on the experiences of those who are attempting to put evidence-based innovations, legislation, mandates, and good ideas into practice so that they produce intended benefits to individuals and society. The health sector has not paid attention to the broader developments in implementation science, preferring to "stick with their own" and consider only evidence-based innovations and implementation in health. For example, the 121 references in a summary of the need for better theory to encourage better implementation in public health behavior programs (Glanz & Bishop, 2010) included only six citations related to developments outside of health.

The premise of this chapter is that implementation principles are universal. This is a parsimonious assumption, an assumption proven useful to guide advances in science (Thorburn, 1915). In mathematics the methods for computing a mean are the same in health, education, social services, engineering, business, and so on. Why a mean needs to be computed and the meaning of the mean that is derived may vary widely, but the principles are the same. The methods for calculating a mean may vary (e.g., adding and dividing manually, or with a calculator, or using a high-powered computer), but the operations to compute the mean are the same across the various methods. After years of experience, we now can be reasonably sure there is no "health mean" that is different from, say, a "child welfare mean" or a "manufacturing mean."

Instead of looking inward at "health only" information about implementation, health sciences can benefit from implementation science as it has evolved with contributions from a wide variety of fields. A review and synthesis of the implementation evaluation literature (Fixsen, Naoom, et al., 2005) summarized information from agriculture, business, child welfare, engineering, health (including global and public), juvenile justice, manufacturing, medicine, mental health, nursing, and social services. Valuable information also was obtained from complexity and chaos theories, computer science, political science, and organizational sciences. Like statistics, implementation is universal, because it is derived from each of and all these fields. The generalizable principles have much to offer each field, including health and behavioral medicine. By turning to counterparts in other domains, health and behavioral medicine can learn how they are approaching problems, identifying areas of common interest and challenges, and sharing insights and ideas for the mutual benefit and advancement of evidence to practice from each domain.

The remainder of this chapter will discuss why and how the health sector can benefit from a more inclusive view of implementation science. First, human service (including health) settings are complex, the variables interact among various levels of practice and organizations, and the time frames for detecting outcomes are long (Hawe, 2015). This means useful implementation data are difficult to produce in any domain, and a better understanding will evolve from accumulating research data from all domains, including complexity science (Leykum, Pugh, et al., 2007) and improvement science (Ovretveit, 2011). Second, variations in settings and complexity of innovations produce greater exposure to a range of potentially important implementation variables. Variability in other domains can inform effective implementation practices in the health domain. Third, measures of implementation variables have been slow to develop. The lack of common assessments inhibits the development of accumulated knowledge within and across domains. Measures developed in one domain can be helpful in other domains and can advance the science more rapidly.

Frameworks to Guide Implementation

The complexity within human service systems and the well-documented interactions among variables at practitioner, organization, and system levels (Novins, Green, et al., 2013; Lobb & Colditz, 2013) have led to the development of implementation frameworks. The frameworks are designed to organize thinking and guide research and practice when the use of innovations is attempted. They are also intended to offer "incrementally actionable" guidance for leveraging change where other broad frameworks have been less clear (Rangachari, Rissing, & Rethemeyer, 2013). Recently, two reviews of frameworks have been published to guide our understanding of how to get evidence into practice. Tabak, Khoong, et al. (2012) documented 61 frameworks related to diffusion, dissemination, and/or implementation. Of the 61 frameworks, 12 were categorized as specific implementation frameworks. Meyers et al. (2012) outlined the key features of 25 implementation frameworks. Of the 37 specific implementation frameworks documented in these two reviews, only 5 appeared on both lists. The developmental nature and trajectory of implementation science can be seen in the little overlap among the frameworks in these two reviews published in the same year. Also, as outlined in Table 8.1, the date of publication is an indication of the recent expansion of interest in implementation science and practice. Only 4 of the 45 source documents cite frameworks developed before the current millennium, and 22 were published after 2005. More publications about implementation frameworks (20+) have been published in the 6-year period from 2006 to 2012 than in the 15-year period from 1989 to 2005.

Table 8.1 Source documents for 32 implementation frameworks summarized by year of publication

Publication year	Number of source documents
1989–2000	4
2001–2005	16
2006–2012	22
No date (web citations)	3

Amidst the growing number of implementation models, some are well known and applied in health. In particular, frameworks such as RE-AIM (Glasgow, Vogt, Boyles, 1999), PRISM (Homer, Milstein, et al., 2010), CFIR (Damschroder, Aron, et al., 2009), and PARIHS (Rycroft-Malone, 2004) are often cited as important conceptual frameworks for understanding translational processes and interrelated factors that facilitate implementation.

- RE-AIM (reach, effectiveness, adoption, implementation, and maintenance) is a framework that focuses primarily on characteristics of the intervention with some attention to the organization context. It was classified by Tabak, Khoong, et al. (2012) as a framework equally focused on dissemination and implementation and is a frequently used approach (Park, 2015). Reach is the percent and representativeness of individuals willing to participate in receiving the intervention; effectiveness is the impact of the intervention on targeted outcomes and quality of life; adoption is the percent and representativeness of settings and intervention staff that agree to deliver the intervention; implementation is the consistency and skill with which various intervention elements are delivered by the staff (i.e., fidelity); and maintenance is the degree to which intervention benefits are sustained for individuals as well as how long the intervention is sustained for organizations delivering it.

- The Prevention Impacts Simulation Model (PRISM) is designed to estimate trajectories for health and cost outcomes for the entire US population from 1990 to 2040. PRISM includes heart disease, stroke, diabetes, hypertension, high cholesterol, and obesity and accounts for cancers and respiratory diseases related to smoking, obesity, poor nutrition, and physical inactivity. The model includes 14 interventions that are influenced by factors such as access, price, promotion, and regulation. The model reports summary measures of mortality and years of life lost as well as the consequent medical and productivity costs of the chronic diseases and conditions modeled. PRISM represents an interesting approach to modeling interventions in whole systems to maximize public benefit. (It should be noted that another common model of implementation within organizational settings (Feldstein & Glasgow, 2008) also goes by the acronym "PRISM," the practical, robust implementation and sustainability model. This latter-named framework is included in the two major reviews of implementation frameworks as referenced in subsequent parts of this chapter.)
- The Consolidated Framework for Implementation Research (CFIR) is composed of five major domains: intervention characteristics, outer setting, inner setting, characteristics of the individuals involved, and the process of implementation. The intervention is defined in terms of the strength and quality of the evidence. The outer setting refers to patient needs and resources. The inner setting is defined by organization culture and the extent of leadership engagement. Individual characteristics include knowledge and beliefs, self-efficacy, and identification with the organization. The process of implementation includes planning, execution, evaluation, and reflection.
- Promoting Action on Research Implementation in Health Services (PARIHS) is a framework that emphasizes evidence, context, and facilitation factors related to an innovation and its implementation in practice. High-quality evidence that fits patient experiences and expectations is desirable. Context emphasizes organization culture, leadership, and the use of data for improvement in a learning organization. Facilitation is noted as a critical function to ease the tasks related to using an innovation in the midst of existing practices and organization structures.

With these four health-oriented implementation frameworks in mind, what can be learned from looking across implementation syntheses from other fields (e.g., Fixsen, Naoom, et al., 2005) and other, more recent frameworks? What do we know about conditions that affect implementation of any innovation? How can we create, improve, and replicate conditions for effective implementation in real-world settings and systems based on what we know and what we are learning about factors that contribute to effective implementation? (Metz & Albers, 2014; Nichols, Martindale-Adams, et al., 2014; Pagoto, 2011). Answers from such inquiry can guide implementation research and practice across behavioral medicine and other disciplines.

Looking Across Implementation Frameworks

The modest overlap among the implementation frameworks (5 of 37) in two major reviews published in the same year provides a glimpse into the complexity of this work. It also highlights the conundrum facing implementation researchers and potential users of evidence-based innovations: 32 views of implementation. In this regard, they offer information about a range of perspectives from a variety of human service and business fields and can suggest components considered important to the process of using research evidence in human services.

The 32 distinct implementation frameworks identified from Tabak, Khoong, et al. (2012) and Meyers, Durlak, and Wandersman (2012) are listed alphabetically in Table 8.2. As noted in Table 8.2, the frameworks are drawn from work in a number of fields, such as mental health, health care, business, substance abuse, education, violence, drug use, and injury prevention. Source documents are noted in Table 8.2 with a designation indicating whether documents were available in a form suitable for further qualitative analysis. Source documents were not available or suitable for data entry and further analysis for seven (7) frameworks.

The number of frameworks presents a challenge for implementation researchers and potential users of innovations supported by research evidence. Frameworks developed in individual sectors add confusion to a field that has lacked coherence and definition. In their reviews of the literature, Brownson et al. (2012), Greenhalgh, Robert, et al. (2004), and Fixsen, Naoom, et al. (2005) point out the difficulties encountered in the review process. Researchers in different fields with different traditions and interests use different languages to describe a common concept or use common language to describe different concepts. The lack of agreed-upon language for concepts and commonly used measures of implementation variables hinder reviews and prevent quantitative meta-analyses. A similar problem now can be seen in frameworks tailored to particular fields. Winter (2006) states, "The implementation sub-discipline has been characterized by many different approaches representing different research strategies, evaluation standards, methodologies, concepts, and focal areas for research. … The highly fragmented character of implementation research is not very conducive to theory accumulation" (p. 163).

Fixsen and Fixsen (2016) conducted a qualitative content analysis across the 32 specific implementation frameworks to provide guidance for the next generation of research, practice, and theory development. Data from source documents were entered into *Atlas.ti*, the software used to code aspects of each framework. An initial set of codes, themes, and categories was developed based on a prior review and synthesis of the implementation evaluation literature (Fixsen, Naoom, et al., 2005) and based on the open coding and categories developed in the Model Programs Study (Naoom, Blase, et al., 2010). The prefigured categories, themes, and codes were used initially to code the primary source documents in order to narrow the scope of data analysis (Creswell, 2007). While the typological analysis provides a place to begin, there was room for novel themes to emerge from the data. Thus, the codes and illustrative quotations reflect the initial set of codes as well as novel content that did not fit the prefigured coding categories.

The initial results are summarized in Table 8.3. The coding process that examined the source documents noted in Table 8.2 resulted in over 600 pages of coded "quotations." Nearly all of the codes that emerged from the examination were readily grouped into the key components of the Active Implementation Frameworks (Fixsen, Blase, et al., 2015; Metz, Bartley, et al., 2014) – effective innovations, enabling contexts, implementation drivers, implementation stages, implementation teams, and improvement cycles. For example, the codes for capacity assessment, community involvement, organization/system alignment, capacity for change, context, implementation policy, and system intervention are aspects of enabling context in the Active Implementation Frameworks. Quotations associated with those codes were grouped under this column in Table 8.3.

Two additional coding groups emerged that were heavily emphasized by many framework authors – codes for "fit" and "recipients." In particular, in many of the frameworks (Aarons, Hurlburt, & Horwitz, 2011), the psychological makeup of recipients or intended beneficiaries of innovations and the culture and climate of organizations attempting to use innovations are postulated to be important determinants of readiness of "recipients" and "fit." These codes were included in the Active Implementation Frameworks where they are

Table 8.2 The 32 frameworks in the sample and source documents as cited in the reviews of Meyers, Durlak, and Wandersman (2012), of Tabak, Khoong, et al. (2012), and of both reviews

postulated to play a key role in staff selection (one of the implementation drivers) and organization exploration processes (one of the implementation stages). However, in the Active Implementation Frameworks, fit and recipients were not given the same central and independent role in determining implementation and innovation outcomes.

Integrating Implementation Frameworks

For current purposes, it is apparent that the health-related frameworks are not unique in some way – the concepts and operations described by Damschroder, Aron, et al. (2009), Kitson, Harvey,

Table 8.3 A summary of the number of quotations coded in 31 source documents related to 25 implementation frameworks. The quotations are organized into categories related to the Active Implementation Frameworks

	Active implementation (Impl.) frameworks						
Reviewed frameworks	Effective innovation	Enabling context	Impl. drivers	Impl. stages	Impl. team	Improvement cycles	Totals

et al. (1998), Kitson, Rycroft-Malone, et al. (2008), and Feldstein and Glasgow (2008) are very similar to the other frameworks and fit equally well into the key components of the Active Implementation Frameworks. As noted in the totals at the bottom of Table 8.3, the frameworks overall included more coded information related to implementation drivers, enabling contexts, and implementation stages. Implementation teams, improvement cycles, and effective innovations also were well represented, although there were fewer coded quotations related to these three components.

The summary presented in Table 8.3 is important for advancing implementation science, practice, and theory. The Active Implementation Frameworks are based on a thorough review of the implementation evaluation literature (Fixsen, Naoom, et al., 2005), analysis of best practices as described by expert purveyor and user groups (Blase, Fixsen, et al., 2005; Blase, Naoom, et al., 2015), and evaluations in organization and system change efforts (Fixsen, Blase, et al., 2013a, b; Metz, Naoom, et al., 2015; Sullivan, Blevins, & Kauth, 2008). The research base and best available practice evidence base provide a comprehensive foundation for the Active Implementation Frameworks. As a comprehensive and evidence-based framework, the Active Implementation Frameworks offer a comfortable fit with the 25 frameworks subject to review and a way to begin to integrate core elements of implementation across disciplines and fields of study in health and other human services.

Effective Innovation

Nearly all of the 32 frameworks point to the use of effective innovations as the goal of implementation science. Effective innovations may be supported by evidence obtained from a range of methods beyond randomized group designs (US Government Accounting Office, 2009). They also emphasize the need to define the core functions and operationalize those functions, so innovations are clear and can be learned, used, assessed, and repeated in practice. The clarity of the core functions is important, so the degree of "adaptation" can be assessed during the adoption process, and so the fidelity of use of the innovation can be assessed in practice. Additionally, clarity of key functions can serve to provide an important level of coherence across similar approaches applied in different settings that are necessarily contextualized based on local culture, resources, and other organizational features (Leerlooijer, Ruiter, et al., 2011).

Implementation Drivers

Implementation drivers attend to the confidence and competence of those delivering the innovation and the organizational context in which they are being delivered. Nearly all of the frameworks direct attention to developing the competency of practitioners, so they know about and are able to use an innovation in practice. Staff training and some form of coaching are seen as essential to developing relevant competencies. The Active Implementation Frameworks include fidelity assessment as a key component of developing competency and an essential outcome of selecting, training, and coaching practitioners to use an innovation. The frameworks in the review were not so clear, and several expressed a tension between assuring fidelity and assuring fit with existing therapies and organizational routines.

Organizational factors were common features of the frameworks with an aim to support practitioners and support necessary training and coaching. Organization factors included data collection and the use of data to help inform decisions by managers and leaders. In behavioral medicine, researchers are noting the role of "data liquidity" – ensuring the availability and free flow of data at the local, "on-the-ground" level – as critical to facilitate implementation (Abernethy, Wheeler, et al., 2011). Leadership was seen as essential to any change process related to the use of innovations in practice. There is good agreement that organizations need to change to accommodate and support the use of effective innovations in practice and that leadership has an essential role in initiating and managing change within the organization and within the broader system in which it operates. Such emphasis on the demonstrative role of leadership in implementation can also be found in behavioral medicine. In particular, a case study of implementation of behavioral interventions for HIV prevention in resource-limited settings identified active program leadership, commitment, and support at the provincial level as essential for program uptake and to ensure program continuity (Jones, Weiss, & Chitalu, 2015).

Implementation Stages

The frameworks varied in the emphasis given to stages or phases of activities, although nearly all of them advised that implementation processes take time. Nearly all of the attention in the frameworks was focused on what the Active Implementation Frameworks refer to as the exploration, installation, and initial implementation stages of implementation. That is, what are the considerations for arriving at a decision to adopt an innovation, what resources are needed to get started and how can they be obtained, and how can practitioners be hired or approached then prepared to begin to use an innovation with appropriate recipients for the innovation. Related research in behavioral medicine has explored the type and timing of individual, organization, sociopolitical context, and innovation factors that influence the adoption, continuation, and continuation of interventions in different settings (Huijg, van der Zouwe, et al., 2015).

As mentioned earlier, the frameworks emphasized the psychological readiness of individuals and the cultural and climate readiness of organizations as critical to the exploration and installation processes. The Active Implementation Frameworks give some attention to these factors but not to the same degree. For the Active Implementation Frameworks, readiness can be created during the exploration and installation processes, and organization culture and climate are seen as outcomes of implementing innovations with fidelity and good outcomes. Thus, beyond some minimal amount, they are viewed as products and not prerequisites.

Implementation Teams

The question of who does the work of implementation was given scant attention in the frameworks. Engaging in exploration activities, providing training and coaching, assuring leadership for change, and so on are actions requiring expertise in order that they be conducted effectively and efficiently. The AIF explicitly include expert implementation teams in organizations and systems as essential to implementation processes. An unplanned, "do it yourself" approach likely will be inconsistent and difficult to improve from one innovation to the next and one organization to the next. Without implementation teams as a key aspect of an implementation framework, other elements become prerequisites since there is no component of the framework to produce what is not already present (e.g., readiness, culture, climate, informed beneficiaries). In behavioral medicine, some researchers are noting the important role of intervention development teams to address a series of structural decision points (e.g., addressing environmental barriers, creating strategies for sustainability) (Rotheram-Borus, Swendeman, et al., 2011). An important distinction here is the composition and function of the team: it is not a team focused on project execution framed by funding parameters, but a team of people with competencies and specific roles to ensure implementation strategies.

Enabling Contexts

The frameworks place considerable emphasis on organizational and system contexts that are needed to support the adoption, use, and sustaining innovations in practice. Such emphases on context are acknowledged as translational behavioral medicine explores how to address and overcome barriers to global implementation. Depending on the framework, the lists vary but often include factors related to referrals, funding, monitoring, rules and regulations, and leadership for changing the features of current organizations and systems that are not conducive to the use of effective innovations and effective implementation methods. Low- and middle-income countries (LMIC) not only suffer from a double burden of disease, but often less available and limited resources, supports, and infrastructure (e.g., size and training of health workforce, public sector system supports) (Oldenburg & Absetz, 2011) that frameworks emphasize as critical for effective implementation. Amidst tremendous resource challenges, practical insights from those working in LMICs demonstrate important ways forward (Baumann, 2011; Baumann, Frederick, et al., 2015). While there is broad acknowledgement of the critical role of context, the frameworks are often silent on who might be accountable for creating contextual readiness or improving contextual fit over time. In the Active Implementation Frameworks, the implementation teams are accountable for these functions and work with leaders at various levels to create alignment and fit where needed.

Improvement Cycles

Little attention is given to improving innovations, implementation methods, organization functioning, and contextual fit after an innovation is put into practice. The AIF make the assumption that the process of getting started will produce many opportunities to get better. It also is assumed that the longer an innovation is in use in an organization, the more it will impact organization and system functioning. Thus, change is expected and improvement cycles are embedded in organizations in the same way training and coaching become standard functions in organizations using EBPs and other innovations. Some investigations in behavioral medicine note relationships between high levels of fidelity and high levels of readiness (contextual factors), suggesting a possible paradox that an intervention may work best for those who need it least. Rather than only selecting for levels of readiness, the field is acknowledging the need for implementation activities to improve factors associated with high fidelity and to measure and monitor fidelity and moderating factors over time (Augustsson, von Thiele Schwarz, et al., 2015).

Applying What We Are Learning: Case Examples

Fall prevention among the elderly presents compelling implementation challenges. The life-threatening consequences for individuals and costly outcomes for society are well documented (Gillespie, 2004; Scott, Wagar, et al., 2010). The research evidence has been so compelling that it has led to updated clinical practice guidelines limiting patient restraints and new policies emphasizing the use of alternative interventions to fall prevention (http://www.law.cornell.edu/uscode/42/1395i-3.html). Despite the evidence and efforts to change practice, the overuse of physical restraint remains common at approximately 5% in the United States (Agens, 2010) and 31% in Canada (Feng et al., 2009). The rate of chemical restraint is estimated at 34% in long-term care facilities in the United States (Agens, 2010), far higher than the recommended rates of 0–5% required for optimal resident care (Guttman, Altman, & Karlan, 1999). Evidence-based alternatives to the use of restraints include lowering beds, using hip protectors to reduce fall-related hip fractures, adding Vitamin D supplementation to enhance muscle strength and bone density, increased supervision, and regular toileting to address incontinence (Cameron et al., 2010; Scott, et al., 2010; Shimada, Tiedemann, et al., 2009). Integrating these into daily practice presents implementation challenges that can be overcome with the purposeful use of implementation supports (Fixsen, Scott, et al., 2011).

In another case example, Metz, Bartley, et al. (2014) used the implementation frameworks to guide the development of a county child welfare program to keep children with their families and out of the foster care system. An implementation team was formed, a usable intervention was developed, and staff were hired, trained, and coached to execute the new ways of work with children and families. Data were collected on the performance of the implementation team and the fidelity with which the intervention was delivered to families in daily practice. Higher scores on implementation team performance (from 1.10 to 1.83 on a 0–2 scale) were related to higher fidelity scores for caseworkers (from 18% to 83%). The purposeful use of evidence-based implementation strategies makes a socially significant difference in outcomes for the intended beneficiaries of behavioral health programs.

In another study, investigators report a successfully translated behavioral intervention (SMART/EST Women's Program) which aimed at reducing distress, improving health, and decreasing risk behaviors for disadvantaged women living with HIV/AIDS in the United States (Weiss, Tobin, et al., 2015). The study translated evidence to clinical practice by using community health center staff (versus research staff) to conduct the intervention. Authors reported equivalence of outcomes between the research-led and community health center staff-led groups. Paradoxically, such outcome data can distract from trying to understand and be able to support the processes for using the innovation elsewhere. Qualitative data on the process of implementation is as essential as quantitative data on endpoints, given the complexity of real-world settings and the challenges encountered. Authors outlined implementation strategies that focused on developing staff competency and confidence, building organizational infrastructure and leadership support, and paying attention to core elements and fidelity at the same time as adapting to local context. Such information about strategies to support both practitioners and organizations in implementation are necessary for the kind of "transferring ownership" that is required to be effective.

Summary, Conclusions, and Future Directions

Advancing implementation science in behavioral medicine is critical for addressing the evidence-implementation gap and corresponding, urgent need for intentional support of evidence-based and public health interventions. With the advent of frameworks, the field of implementation science is moving from making lists to making sense (Nilsen, 2015) and is moving toward mid-range theories of implementation (ICEBeRG, 2006). The compilation and comparison of frameworks provides an inclusive view of implementation research and dependable guidance for those who intend to support the use of evidence-based programs in typical behavioral health settings. In terms of understanding, addressing, and improving factors related to the "how" of implementation, recurring themes include (a) a defined set of an innovation's core components that can guide parameters for necessary adaptations based on context, (b) building the competence and confidence of those delivering the innovation, and (c) developing and strengthening organizational infrastructure to create culture, climate, practices, and policies that support implementation activities. Other themes addressed the nuanced difference between applied research to identify factors influencing implementation and approaches that actively address and improve – rather than try to control – those factors with an eye toward ongoing quality improvement of implementation.

Moving forward, advancing implementation in behavioral medicine will require a combination of evidence from different fields, different perspectives, and different research designs. After all, the evidence-to-practice question herein is not "does this innovation work under ideal conditions?" Evidence from formal trials along with case studies, network analyses, systems thinking, assessments of local context, and other approaches will provide information and improve the evidence flow from multiple perspectives relevant to implementation (Yamey & Feachem, 2011). In addition, most real-world settings for implementation involve complex, multifaceted, existing, and sometimes overlapping programs rolled out by a variety of organizations; and many approaches to effective implementation are multicomponent (Hawe, 2015). Many types of evidence are needed to make research findings more relevant and actionable for implementation, which calls for innovative study designs (e.g., rapid learning designs, simulation modeling) (Rabin & Glasgow, 2015). Learning from and in parallel with other fields such as quality improvement research and empowerment evaluation can also advance implementation in behavioral medicine (Olds & Øvretveit, 2013; Wandersman, Alia, et al., 2015).

The need for many types of evidence in implementation also calls for innovative measurement science (e.g., development of context-relevant measures, longitudinal measures). In particular, agreement about core constructs that affect implementation success and identifiable measures of them will strengthen the coherence and understanding of implementation research. These may include organization, provider, structural, and innovation- and patient-level constructs and demonstrated a reliable association with implementation outcomes (e.g., fidelity) (Chaudoir, Dugan, & Barr, 2013). Examples of implementation measurement include the Seattle Implementation Research Conference Measures Project (www.seattleimplementation.org/) and the Grid-Enabled Measures developed by the National Cancer Institute (http://cancercontrol.cancer.gov/brp/gem.html), both of which are initiatives to compile, enhance, and help harmonize dissemination and implementation measures.

Behavioral medicine and a number of other fields are also giving prominent attention to the issue of community or stakeholder engagement throughout the process of implementation. A number of case studies describe the process of relationship building – between community and academic partners, between professional and community support organizations, and between scientific and community priorities (Pagoto, 2011). Evidence-to-practice efforts at national and global scales will require the leadership and ownership of community and organizational partners. Such participatory approaches – in exploring fit of an innovation, assessing fidelity, sensemaking about socially significant outcomes – have been associated with enhanced buy-in, support of, and momentum in implementation efforts (Huijg, van der Zouwe, et al., 2015; Pinto, Waldemore, & Rosen, 2015).

As implementation science progresses, federal and state agencies are changing to take advantage of the knowledge base. Service dollars are being spent and accounted for, but, without realizing the improvement in service outcomes expected from evidence-based programs, attention now is turning to the fidelity with which evidence-based programs are being used in practice. Data showing poor fidelity associated with poor outcomes (Sanetti & Kratochwill, 2014; Schoenwald, Garland, et al., 2011) has led to increasing interest in implementation methods to consistently produce high-fidelity performance among populations of practitioners. Integrating frameworks will expedite this process and guide funding, quality assurance, and provider organization operations for generations to come.

Part III

Key Influences on Behavior and the Relationships Among Behavior, Health and Illness

9

Behavioral Medicine's Roots in Behaviorism: Concepts and Applications

Howard Rachlin, Leonard Green,
Ariana Vanderveldt, and Edwin B. Fisher

The conceptual and empirical approaches of behaviorism in western psychology of the twentieth century provided an important foundation for the development of behavioral medicine. Many key areas of behavioral medicine have their roots in behavior therapy which in turn arose from behaviorism and learning theory (Wolpe, 1969) to address issues of mental health and psychotherapy. Neil Miller, a pioneer in the application of behaviorism to complex behavior and psychotherapy (Dollard & Miller, 1950), was a major figure in the development of behavioral medicine. Biofeedback (Cox, Sutphen, et al., 1998), stress management interventions featuring relaxation and active coping with stressors (Bishop, Kaur, et al., 2005; Levenkron, Cohen, et al., 1983; Penedo, Dahn, et al., 2004; Surwit, van Tilburg, et al., 2002), and group and individual interventions for weight management and smoking cessation (Lichtenstein, Harris, et al., 1973; Stuart, 1967) are all grounded in behavior therapy. These interventions were integral to the early development of the 1960s' self-control and self-management approaches (Bandura, 1969; Goldfried & Merbaum, 1973; Kanfer, 1970) that laid the groundwork for much of behavioral medicine that followed.

The present chapter provides an introduction to contemporary behavioral theory and research. It reviews basic concepts of reinforcement, choice, and stimulus control and, then, their extension in behavioral economics. Extended discussion of smoking cessation and weight management illustrates the application of these concepts to complex patterns of behavior and health. Contemporary behaviorism provides a comprehensive basis for understanding such complex and dynamic behavioral patterns and, at its base, is congruent with broad social and ecological approaches that have emerged in global behavioral medicine and public health.

Consequences of Behavior

Reinforcement

The most fundamental principle of learning theory is that behavior is a function of its consequences. A reinforcer is any outcome that follows a behavior that increases the frequency and likelihood of the behavior in the future. There are two

broad categories of reinforcers – positive and negative reinforcers. When a behavior results in an outcome that increases the frequency of the behavior in the future, the outcome is said to be a *positive reinforcer*. For example, people who experience a "runner's high" are more likely to go for a run again than those who do not experience that consequence. The behavior of running is followed by some outcome (a "runner's high"), and as a result, that behavior is more likely to occur. In contrast, when a behavior results in the avoidance of or escape from something, and this increases the frequency of the behavior in the future, that outcome is said to be a *negative reinforcer*. Many people put on sunscreen before going outside in order to avoid being sunburned. If they fail to do so and get a burn, they might apply aloe in order to relieve the pain. In the former case, putting on sunscreen is followed by the avoidance of a painful outcome and in the latter case, applying aloe reduces a painful situation. Both fit the definition of negative reinforcement: avoidance or reduction of an outcome (e.g., sunburn) that makes the behaviors more likely to be repeated in the future.

That a reinforcer is defined by its effects on behavior is central to behaviorism. Colloquially, a positive reinforcer often is used interchangeably with the word "reward" or is said to be something "good" or "pleasant." In practice, however, it is important to evaluate the consequence in terms of its effect on the future likelihood of behavior, rather than on one's intuitive notion of what is "good" or "pleasant." Something pleasant does not always reinforce a behavior (e.g., social attention), and something not typically viewed as pleasant can sometimes reinforce a behavior (e.g., yelling and time-out; see Durand, Crimmins, et al., 1989).

All else being equal, a larger or higher-quality reinforcer typically will generate a higher rate of responding (e.g., Trosclair-Lasserre, Lerman, et al., 2008). The delay to when a reinforcer is received also is critical and can sometimes surpass the effects of the amount or quality of a reinforcer. The effectiveness of and preference for a reinforcer, however, is not a stable, inherent characteristic of a reinforcer. An outcome's effectiveness, for example, may be augmented by depriving the individual of the resource and may be diminished by satiation (Raynor & Epstein, 2003). In this sense, then, whether and to what extent an outcome is reinforcing depends on the context within which it occurs. Throughout the chapter, we will return to this central tenant of behaviorism, that the characteristics of behaviors and their relationships with the stimuli and consequences that surround them are dependent on their contexts.

Schedules of Reinforcement

The behavioral requirements for obtaining a reinforcer markedly affect both the rate and the pattern of responding. Schedules of reinforcement determine when a reinforcer is delivered based on the behavior being emitted (for a review, see Murphy & Lupfer, 2014). The simplest schedule of reinforcement is a continuous schedule: Every time the targeted behavior is emitted, it is followed by a reinforcer. Most behaviors, of course, are not reinforced every time they are emitted; rather, behaviors are reinforced intermittently. There are two broad categories of intermittent schedules of reinforcement – ratio schedules and interval schedules. Under ratio schedules, the delivery of a reinforcer depends on the number of responses emitted. Many customer loyalty programs, for example, require that the customer make a fixed number of purchases (e.g., ten) before the next (eleventh) purchase is free. The timing of the purchase is irrelevant; the only contingency determining the delivery of the reinforcer (i.e., the free item) is the number of previous purchases made. Under interval schedules, in contrast, the delivery of a reinforcer depends on the passage of time before a response produces a reinforcer. Checking one's mailbox operates on an interval-like schedule. Mail is dropped off approximately every 24 h. It does not matter how many times the response of checking the mailbox is emitted; the mail will not be received any sooner. On interval schedules, a certain amount of time must elapse before the response will be reinforced.

In general, ratio schedules of reinforcement produce higher rates of responding than do interval schedules. Unlike interval schedules, reinforcement is dependent on the number of responses emitted under ratio schedules. Therefore, the greater the rate of responding, the greater the number of reinforcers earned on ratio schedules. In addition, the faster the responding, the sooner the reinforcer is delivered. In contrast, on interval schedules, higher rates of responding will not markedly increase the number of reinforcers earned.

Schedules of reinforcement can be made more complex than simple ratio or interval schedules by varying the predictability of the reinforcer. On fixed schedules of reinforcement, the response requirement (i.e., fixed-ratio schedule) or time requirement (i.e., fixed-interval schedule) is consistent. In the customer loyalty example, a person must always make ten purchases before the next response is reinforced. Often, however, response requirements are not consistent, and behavior is reinforced after a variable number of responses have been emitted or a variable amount of time has elapsed. Some businesses have instituted variable-ratio schedules on purchases. In these cases, customers are reinforced with a "surprise" free item after they make a number of purchases. The exact number of purchases required to obtain the free item changes each time: Occasionally a person might make 15 purchases before getting a free item whereas on another occasion the item is presented after only a few purchases. Similarly, on variable-interval schedules, the precise amount of time that must pass before a response is reinforced varies with each reinforcer delivery. Checking one's email follows a variable-interval-like schedule in that opening your inbox to check for a message occasionally is "reinforced" by a message, and the time between messages received in one's inbox varies. Checking more frequently does not affect the rate at which emails arrive in one's inbox. Rather, an amount of time must elapse and that amount of time varies – sometimes an email arrives shortly after receiving the last one, whereas other times hours might pass before a new email is received.

Under fixed-ratio and fixed-interval schedules, a *post-reinforcement pause* often is observed in which responding ceases for a period of time after the reinforcer is received. If a rat were required to press a lever 50 times for each food pellet, it would not continuously press the lever. Rather the rat would tend to press the lever 50 times quickly, consume the food pellet when it is delivered, and then wait for a period of time before beginning to press the lever another 50 times. The length of the post-reinforcement pause varies with the ratio requirement: The greater the response requirement, the longer the average post-reinforcement pause. A similar pause in responding following receipt of a reinforcer is observed with fixed-interval schedules, and its length varies with the interval requirement. In contrast, variable-ratio and variable-interval schedules – in which the next response might yield a reinforcer – typically produce reasonably steady rates of responding, with few post-reinforcement pauses.

Alternative Reinforcers

In addition to the amount and quality of a reinforcer and its schedule of delivery, the availability of alternative reinforcers markedly affects the effectiveness of a reinforcer. In rats, for example, plain water (especially when the rat is liquid-deprived) functions as a very effective reinforcer for lever pressing. When rats also are given the opportunity to lever press for sucrose water, however, the effectiveness of the plain water as a reinforcer declines substantially (e.g., Freed & Green, 1998). It is not something within a stimulus that makes it a reinforcer; rather it is the context, which includes the availability of alternative stimuli, that determines whether and the degree to which something is reinforcing. This principle has substantial practical importance. In order to determine whether something is a reinforcer, one must evaluate its effect on behavior within a specific context.

Punishment

Like reinforcers, a punisher affects the future frequency and likelihood of the behaviors that it follows. Whereas reinforcers increase the likelihood of a behavior, punishers decrease the likelihood of the behavior.

Punishment is ubiquitous in everyday encounters. Failing to pay one's taxes can result in a fine or even jail time; talking during class can result in a reprimand or angry glance from the instructor. Skinner (e.g., 1953, 1971) argued for the limited use of punishment and even questioned its long-term effectiveness in behavior change. Punishment reduces the frequency of an undesired behavior, but often it is accompanied by unwanted side effects such as negative emotions and aggression (for a review, see Lerman, Kelley, et al., 2002). Of likely even greater concern is that punishment alone does not directly encourage or teach desired behaviors. If a parent wants a child to play quietly in the playroom, punishing the child for running around does not directly increase the likelihood of playing quietly. Punishment will decrease the likelihood of running around, but it also might increase the likelihood of alternative behaviors, some of which may include other undesired behaviors like fighting with playmates.

Another important consideration is the effect of punishment on behaviors that surround it. Punishing students for being noisy in school may decrease the frequency of noise, but also may punish coming to school in the first place. That is, avoidance of punishers becomes a reason to skip school, whereas reinforcers for appropriate classroom behavior become a reason to attend school. Despite these concerns, mild punishment is effective in reducing many serious problem behaviors and usually will have an even greater effect when combined with reinforcement of desired behaviors (Mayhew & Harris, 1979). It is critical, however, that the overall density of punishment within a situation does not overwhelm the density of positive reinforcers. Otherwise, the response may well be avoidance rather than engagement.

Negative Reinforcement Is Not Punishment

A common point of confusion is the distinction between negative reinforcement and punishment. Recall the definition of a reinforcer as something that, when made contingent on a behavior, *increases* the likelihood of that behavior. A negative reinforcer is "negative" in that its *removal* increases the likelihood of a behavior. A parent might often give in to a child's demands (e.g., asking for candy at the grocery store) or misbehavior so that the child stops engaging in that behavior (e.g., whining). In this case, the child's whining is being positively reinforced. That is, the child's whining results in the parent's giving in (e.g., giving the child candy). In contrast, the parent's behavior of "giving in" is being negatively reinforced: By giving in, the parent escapes from the aversiveness of the child's whining. Both the behaviors of whining and giving in are being reinforced, and thus both behaviors have an increased likelihood of occurring again. A punisher, on the other hand, *reduces* the likelihood of the behaviors that lead to it. A parent might ask that the child shares toys with another child. If the child whines and complains, this might function as a punisher for the parent's asking the child to share. That is, the parent might be less likely to ask the child to share in the future because asking often leads to whining and complaining by the child.

Stimulus Control

Consequences affect the future likelihood of a behavior but, as we emphasize throughout this chapter, behaviors and consequences occur within a context. *Stimulus control* refers to the extent to which a particular environmental context (which may be termed the antecedent) exerts control over the likelihood of behaviors within that context. Antecedent stimuli gain control of a behavior when they predict that some outcome will be more or less likely following that behavior. If a pigeon's key pecking is reinforced in the presence of a green key light, but pecking is not reinforced in the presence of a red key light, the pigeon then will come to peck when the key is green and not peck when the key is red. Traffic signals similarly influence one's driving behavior so that one is more likely to stop at a red light and go at a green light. A sign on the door reading, "Please do not disturb," is a clear indication that knocking will be ineffective or may even lead to an unpleasant response.

Over time, strong stimulus control of a behavior occurs when an individual has learned in which contexts engaging in a particular behavior produces reinforcement (e.g., talking with friends before the class begins) and in which contexts it does not (e.g., talking with friends during class when the instructor is lecturing). As a result of the differential reinforcement, discrimination will be evident and behavior will be more likely to be emitted in contexts that signal reinforcement and less likely to be emitted in contexts that signal either punishment or no reinforcement.

Stimulus control helps explain much of the complexity and sophistication of human behavior. One can see much of child development and high-level adult functioning as the result of a process involving greater and greater stimulus control and finely discriminated behavior. Consider, for example, the highly skilled teacher or coach who somehow seems to know just the "right thing" to say to help an individual feel motivated and confident. Such "emotional intelligence" entails highly nuanced responding to myriad cues in the environment. Interestingly, the highly skilled individual might be unable to explain such fine judgment or instead refer to vague descriptions (e.g., "I just had a sense," "You know it when you see it," etc.). Similarly, the star athlete may be at a loss to answer questions such as, "What made you realize you had the opening to score that goal?"

Unhealthy behaviors often can be considered as reflecting poor or inappropriate stimulus control. For example, cultures with low rates of alcoholism tend to have highly ritualized norms for drinking alcohol in which alcohol typically is consumed only with meals, with family, and during holidays. These rules establish stimulus control over alcohol use within a culture. In contrast, the "obesogenic" food environment in the United States (Brownell & Horgen, 2004) includes a number of unhealthy features, including norms for eating in almost every situation: on meeting, on departing, to celebrate, to mourn, at the start of a work meeting, upon entering an office with a jar of candy at the receptionist's desk, etc. Stuart's (1967) landmark work on behavioral weight control, which is still the basis for much of contemporary approaches (e.g., Johnston, Foreyt and colleagues, *infra*), includes restrictions on the time, place, and even the plates and utensils for eating, in order to reduce the number of stimuli associated with unnecessary caloric consumption.

Although discrimination is critical (i.e., responding differently in the presence of different stimuli), so, too, generalization is essential. Typically, when a behavior-consequence contingency is learned in one context, generalization to other similar, albeit untrained, contexts will occur. In a classic experiment, Guttman and Kalish (1956) observed generalization when they trained pigeons to peck at a key for food when the color of the key was a specific wavelength (e.g., yellow, 580 nm; Guttman & Kalish, 1956). During test trials in which food was not delivered, they presented different wavelengths and measured how much the pigeons responded to each test color. Pigeons responded most to the wavelength that had been presented during training but also responded to similar, untrained wavelengths. Response rates decreased as the wavelengths became increasingly different from that in training, producing a generalization gradient around the original, trained wavelength. Generalization of behavior to untrained contexts clearly is an adaptive mechanism because organisms rarely encounter the exact same context in which they learned a behavior-consequence contingency.

Extinction

We have emphasized that behaviors followed by a reinforcer are more likely to occur in the future and that behaviors followed by punishers are less likely to occur in the future. In addition to punishment, extinction reduces the frequency of a behavior. In extinction, a previously reinforced response no longer is followed by the reinforcer that was maintaining it. The discontinuation of reinforcement leads to the eventual decrease in the frequency of that behavior.

An often worrisome but predictable side effect of extinction is that behavior shows an initial increase in its occurrence, a phenomenon termed an *extinction burst*. A child whose nagging during a shopping trip has often been reinforced in the past with candy will likely nag during future shopping trips. If the parent then institutes extinction by withholding this reinforcement, an immediate outcome is likely to be an increase in the amount of nagging.

In addition to the initial increase in the originally reinforced behavior, extinction leads to an overall increase in *operant variability*. Eckerman and Lanson (1969) studied the variability in topography of a pigeon's keypeck response and observed that variability increased when extinction was instituted (Eckerman & Lanson, 1969). If a complex set of behaviors is extinguished, then variations in the set also will occur in extinction. Consider a study by Neuringer, Kornell, and Olufs (2001) in which rats received food reinforcement after engaging in a particular sequence of behaviors (left lever press, then a key press, and then a right lever press; referred to as LKR; Neuringer, Kornell, & Olufs, 2001). After this behavior set was well established, extinction was instituted in which the rats no longer received food for the LKR response sequence. In addition to the initial increase in the originally reinforced behavior (i.e., extinction burst), Neuringer et al. found that the rats were much more likely to engage in novel behavior sequences (e.g., RRK).

In other cases of extinction, *resurgence* occurs, in which responses that previously had been reinforced but then were extinguished, reappear during the process of extinction of a more recently learned behavior (e.g., Winterbauer & Bouton, 2010). Suppose the parent from the grocery store, for example, successfully extinguished the child's nagging and reinforced polite asking. When the child politely asked for candy, the parent gave her candy. If the parent now decided to completely stop giving candy to the child while at the store (i.e., polite asking is placed on extinction), the previously reinforced but since extinguished response of nagging is likely to reappear during this extinction period.

Even after extinction has been implemented successfully, there will be cases of *spontaneous recovery*: After a period of time following extinction of a behavior, exposure to the context that once had been associated with reinforcement may trigger a reemergence of the behavior. Using the example from above, suppose that after the child's nagging behavior has been extinguished, the parent does not take the child shopping for a few weeks. If then one day the parent takes the child shopping, the child may again start nagging. Fortunately, spontaneously recovered responding typically is less intense than responding observed prior to extinction and is extinguished more quickly. Often, reoccurrence of a previously extinguished behavior (i.e., spontaneous recovery) is mistaken for relapse or as evidence that extinction is ineffective. Spontaneous recovery is a typical outcome of any extinction procedure and should be planned for when implementing a treatment program. Especially important is that inadvertent reinforcement during spontaneous recovery may cause renewed vigor and reinforce a pattern of occasionally testing whether a reinforcer may or may not be available for the behavior.

This takes us back to the important topic of schedules of reinforcement. Depending on the schedule, some behaviors will be more "resistant" to extinction than other behaviors. One might think that a behavior reinforced on a continuous schedule of reinforcement would be more thoroughly "stamped in" or learned and therefore would be more resistant to extinction. However, less consistent and predictable schedules of reinforcement produce behaviors that are more resistant to extinction, a phenomenon termed the *partial reinforcement extinction effect*. A behavior previously reinforced on an intermittent schedule will continue to occur longer after it is placed on extinction than a behavior that was previously reinforced on a continuous basis. Furthermore, variable schedules of reinforcement typically produce behavior that is more resistant to extinction than fixed schedules of reinforcement.

One way of thinking about extinction following different schedules of reinforcement is the ease with which extinction and reinforcement can be discriminated. If the schedule of reinforcement is so unpredictable that it is hard to tell whether reinforcement no longer is available or whether a long break between reinforcers is part of the schedule, then behavior is more likely to continue in extinction.

Coda: Why Basic Behavioral Principles Matter for Health Promotion

Understanding the complexity of reinforcement and extinction is critical for behavioral medicine and health management. If a desirable behavior is not reinforced, then it will eventually decrease. Maintenance of healthy behaviors is not achieved by somehow making behaviors persist in the absence of reinforcement, but rather by finding naturally occurring consequences to reinforce the behavior. If there are insufficient reinforcers for healthy behaviors in an individual's environment, then an individual is unlikely to engage in those behaviors; any attempt in trying to "fix" the individual may prove fruitless and often leads to "victim blaming." Rather, such circumstances call for addressing the lack of reinforcers in the individual's environment, as through community or organizational approaches to health promotion (Fisher, Auslander, et al., 1992).

One way of connecting the reinforcers introduced to initiate behavior change with naturally occurring reinforcers is through extending treatment so that the naturally occurring reinforcers overlap with those used during initial interventions. Consistent with this, the duration of intervention appears to be a major feature of successful health-behavior interventions. In a meta-analysis of self-management programs for diabetes, the only predictor of improved blood-sugar control was the length of time over which contact was maintained (Norris, Lau, et al., 2002). In a study of psychosocial interventions for depression, patients who stayed over 3 months reduced their depressive symptoms and improved their quality of life the most (Forsman, Nordmyr, & Wahlbeck, 2011). Similar results have been reported in studies on weight loss (Wadden, West, et al., 2009; Wing & Hill, 2001; Wing, Tate, et al., 2006) and smoking treatments (Fiore, Jaén, et al., 2008). Furthermore, increasing the variety of reinforcers and contexts in which treatment is delivered will increase the similarity of the intervention with natural contexts. Kottke, Battista, and DeFriese (1988, p. 2888) put it well when characterizing results from one of the first meta-analyses of interventions for smoking cessation: "Success was not associated with novel or unusual interventions. It was the product of personalized smoking cessation advice and assistance, repeated in different forms by several sources over the longest feasible period."

Reinforcers in one's daily life often are delivered on schedules that are like variable-ratio and variable-interval schedules. Moreover, behaviors are maintained by a large number of different reinforcers, each according to a different schedule. This nexus of different consequences that maintain behaviors provides a model for making healthy behaviors more resistant to extinction. Consider approaches for encouraging the eating of fruits and vegetables in an individual who consumes very few of either. Among those for whom eating fruits and vegetables has become routine, a number of reinforcers are likely at play, including daily energy and alertness; maintained healthy body weight; the occasional praise of a doctor, nurse, or spouse; and reminders of health benefits in government reports or other media. The objective for the individual who does not eat fruits and vegetables, then, is twofold: (1) encouraging the initial development of eating fruits and vegetables and (2) transitioning the new habits to control by the incentives that will maintain them in the natural environment.

For the first objective, frequent and clear monitoring, reminders, and reinforcers are helpful. For example, one could set a weekly objective and monitor progress daily. If the achievement of the objective is not a sufficient reward, one could schedule an enjoyable activity as a reinforcer, such as sharing the success in a group meeting or a night out at the movies. After the behaviors have become frequent, the second objective, transitioning to the naturally occurring reinforcers, becomes the priority. To achieve this objective, one could monitor daily mood and energy to make these consequences more salient, share positive experiences with family and friends, or weigh oneself daily, a habit noted as important among those who have maintained appreciable weight losses (Wing & Hill, 2001).

Choice and Behavioral Economics

All behavior involves a choice between engaging in a particular behavior and engaging in some other behavior. We sometimes study individual behaviors without reference to choice or to the context in which the behaviors occur, but the fact remains that all behavior entails choice. If a context has strong stimulus control over a behavior, it may make the behavior highly likely to occur, but there still is a choice. Even with those behaviors that we may experience as somewhat involuntary, like leaving a building upon hearing a fire alarm, the person chooses to leave (as opposed to staying and finishing a phone call or an email) and by doing so, the response of leaving the building is negatively reinforced (the unpleasant alarm is no longer heard). Understanding choice is central to understanding learning and behavior.

Behavioral economics emphasizes the choice context within which behavior occurs. Behavioral economics conjoins the axioms and models of microeconomics and the behavioral principles of psychology and behavior analysis. Despite their distinct origins, the fields of economics and behavior analysis both seek to understand behavior by identifying the consequences of that behavior. In behavior analysis, the consequences are reinforcers. In economics, the consequences of behavior are the commodities that are provided to the individual. Because these are very similar concepts, we will use the terms “reinforcer” and “commodity” interchangeably in the discussion that follows.

The synthesis of economics and behavior analysis has led to a wealth of research on choice behavior with substantial implications for health, including how to arrange incentives to encourage healthy behaviors (Bickel & Vuchinich, 2000). The following section is a brief review of fundamental behavioral economic concepts in the study of choice.

Price and Elasticity of Demand

As already noted, the reinforcing value of a commodity is not a fixed attribute of the commodity. Rather, its value will vary depending on several aspects of the situation, including what other commodities are available. One way of assessing the value of a commodity is in terms of the demand for that commodity. Demand refers to the amount of a commodity purchased at a given price. In behavioral terms, price can be thought of as the amount of responding required to obtain the reinforcer. For example, with rats, the price of sucrose pellets might be ten lever presses per pellet. Demand can be determined by measuring the amount consumed as the number of presses required to obtain a sucrose pellet (its price) is varied. A demand curve plots the relation between price and consumption of a commodity. Figure 9.1 plots the demand for two commodities, electrical stimulation of the brain (ESB) and food, as a function of their increasing price.

Consistent with the law of demand, if the price of a commodity increases, the consumer should buy less of it; if the price decreases, the consumer should buy more. However, consumers are differentially sensitive to changes in price. Demand for a commodity is said to be elastic when consumption (the number of obtained reinforcers) decreases more than proportionally to price increases and is said to be inelastic when consumption decreases less than proportionally to

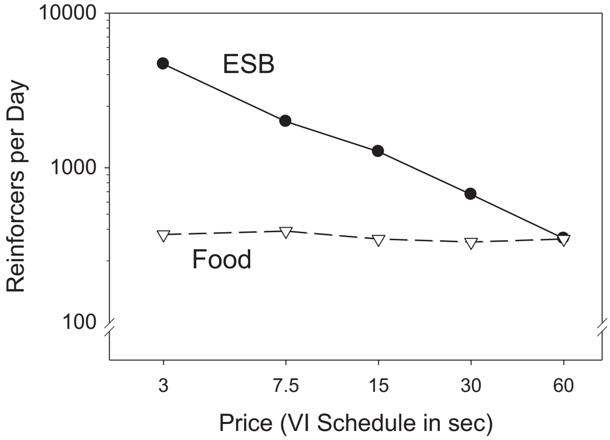

Fig. 9.1 Demand for food and electrical brain stimulation (EBS) in rats as a function of price. The demand for ESB is elastic: as the price increased, rats' demand for ESB decreased substantially. In contrast, the demand for food is inelastic: as the price increased, rats' demand for food remained relatively constant (Data are plotted on log-log coordinates and are from Experiment 2 of "Electrical brain stimulation and food reinforcement dissociated by demand elasticity," by S. R. Hursh and B. H. Natelson, 1981, *Physiology & Behavior*, *26*, p. 280)

price increases (e.g., Hursh & Bauman, 1987). The degree of elasticity can be observed by the slope of the demand curve. As can be seen in Fig. 9.1, as the price of ESB increased, rats' consumption decreased markedly, indicating that demand for ESB was elastic. In contrast, as the price of food increased, rats' consumption remained relatively constant, indicating inelastic demand. Elasticity is one way in which we can understand health behaviors. For example, addiction may be characterized as a relatively inelastic demand for a commodity such as nicotine or alcohol.

Alternatives and Patterns of Choice

Elasticity of demand is not an inherent characteristic of a commodity and its price. Rather, choice of a commodity is influenced by the context and, in particular, what other commodities are available in the situation. Manipulating the price of one commodity affects not only the demand for that commodity (own-price demand) but also the demand for other commodities (cross-price demand).

When offered the choice between two different commodities, an individual may have a strong preference for one over the other. An individual may prefer chocolate to vanilla ice cream but likely will not always choose chocolate ice cream when given that choice. Distributing choices among several alternatives clearly is adaptive in exposing individuals to alternatives in their surroundings, some of which may become advantageous if conditions or challenges change and require new responses and skills.

The allocation of behavior across alternatives is well described by the matching law (Herrnstein, 1961, 1970). Specifically, behavior allocation depends on the reinforcement earned from one alternative and on the reinforcement obtained from other alternatives available. One formulation of the matching law is as follows:

$$\frac{B_1}{B_2} = \frac{R_1}{R_2} \tag{9.1}$$

where B_1 and B_2 are the response rates for two different behaviors, and R_1 and R_2 are the reinforcement earned from each of those behaviors. As is evident from Eq. 9.1, the matching law predicts that a particular behavior (B_1) will occur in proportion to the reinforcers obtained from that behavior (R_1) and in inverse proportion to the reinforcers obtained from alternative behaviors (R_2). That is, the distribution of responses tends to match the distribution of reinforcers obtained from those responses. A pigeon may have the choice between pecking the left key, which produces food reinforcement on average after 1 min (variable-interval 1-min schedule), and pecking the right key, which produces reinforcement on average after 2 min (variable-interval 2-min schedule). The left key has a rate of reinforcement that is twice that of the right key. On average, the pigeon will obtain twice as much food for responding on the left key as for responding on the right key. As a consequence, the pigeon will match that rate, responding twice as much on the left key as on the right.

Notice that the matching law predicts that behavior allocation will be a function not only of the reinforcement earned from a given behavior but also a function of the reinforcement earned from alternative behaviors. If two available behaviors (e.g., eating spaghetti and eating pizza) provide the same amount of reinforcement for an individual, each will be chosen approximately equally, assuming no others are available. If the rate, amount, immediacy, quality, or other feature of the spaghetti is enhanced to make it twice as valuable as the pizza, then choice of spaghetti will increase and choice of pizza will decrease, even though the reinforcement produced from the pizza has not changed.

Clearly, then, our choices do not occur in a behavioral vacuum. It is essential not only to focus on the reinforcement earned from the targeted behavior but also to consider the reinforcement earned from alternative behaviors. It is evident from the matching law that there are two ways to modify a targeted behavior: Change the reinforcement contingency for the target behavior itself (R_1), *or* change the reinforcement contingency for alternative behaviors (R_2). Often the reinforcement earned from a behavior is difficult to modify, but the frequency of the behavior still can be modified by adjusting the reinforcement contingencies for alternative behaviors. In a study by Epstein, Smith, Vara, and Rodefer (1991), for example, overweight children played a game in which they earned two kinds of points, either those that could be exchanged to engage in a highly liked sedentary activity (e.g., watching videos) or those that could be exchanged to engage in a moderately liked vigorous activity (e.g., riding an exercise bike) (Epstein, Smith, et al., 1991). When the reinforcement schedule for earning each point type was identical, the children overwhelmingly spent their time earning sedentary activity points. When the game changed to require more effort to earn sedentary activity points, however, the children switched to spending more of their time earning vigorous activity points. That is, making it more difficult to earn points for one alternative (sedentary activity) increased time and energy directed to the other alternative (vigorous activity). Thus, Epstein and his colleagues were able to promote vigorous activity in overweight children not by adjusting the reinforcement contingency for this activity directly but by manipulating the reinforcement schedule for the sedentary activity.

Economists make a distinction between substitutable and complementary commodities or reinforcers. If a person usually buys broccoli because it is less expensive than asparagus, that person may nevertheless *decrease* consumption of broccoli (even when its price has not changed) and purchase more asparagus if asparagus is in season and its price has declined. Asparagus is economically substitutable for broccoli. Substitutable reinforcers are those that are functionally similar and fulfill similar needs. In many cases of economic substitutability, there is an apparent physical resemblance between the two commodities, but physical resemblance is not necessary. For example, most purchasers will choose among brands of gasoline based on price or convenience, assuming near equivalence among the products. In other cases, however, there may be little apparent physical resemblance between the two commodities. Watching television and playing outside with friends are to a degree substitutable. Commodities are substitutable because of shared, functional characteristics (Green & Freed, 1998). They share common functions but not necessarily common physical characteristics. Substitutes have positive cross-price elasticity: As the price of a commodity increases, consumption of that commodity will decrease while consumption of its substitute will increase. As the ticket prices of movies in theaters increase, people become more likely to watch movies at home.

Complementary commodities, in contrast, are those that are used jointly and thus are consumed in a fairly constant proportion to each other. Complements have negative cross-price elasticity: As the price of a commodity increases, consumption of both it and its complement will decrease. For example, gasoline and automobiles may be considered complements. Increasing the price of gasoline not only will reduce the purchase of gasoline but also will reduce the purchase of automobiles that are inefficient in their use of gasoline. The degree of cross-price elasticity varies because few commodities are perfect substitutes or complements for each other. In the example above, although gasoline is to an extent a complement of inefficient automobiles, it has alternative functions other than driving that might motivate people to purchase it (e.g., motor boats, lawnmowers, etc.). Sometimes two commodities are unrelated: The price of one has little or no effect on the consumption of the other. In cases like this, these commodities are said to be independent.

The effect of price increases on consumption of substitutable and complementary commodities has significant implications for public health policy. For many people, alcohol consumption and cigarette smoking are complementary reinforcers and often are consumed concurrently. Although excessive consumption of either contributes to health problems, in the last few decades public policy has focused more on curbing cigarette consumption by increasing taxes and instituting bans on smoking in many places. Krauss, Cavazos-Rehg, Plunk, Bierut, and Grucza (2014) reported that in the United States, the sale of beer and hard alcohol showed a decrease in those states that significantly increased taxes on cigarettes or instituted much stricter smoke-free air policies (Krauss, Cavazos-Rehg, et al., 2014). States with the largest increases in the price of cigarettes showed a decrease of 26% in the sale of alcohol compared to only a 5% decrease in states with the smallest cigarette price increases. Interestingly, consumption of wine was not affected by changes in cigarette prices or smoke-free air policies, suggesting that wine is independent of smoking. By understanding the interactive nature of price, complements, substitutes, and demand, public health efforts can be better targeted and more effective.

It also may be noted that the behavioral-economic approach has demonstrated that initial degree of preference is not necessarily a predictor of the degree or ease with which a behavior might be modified. Consider, for example, that when rats were given the choice between different reinforcers, Freed and Green (1998) found that the rats had an extreme preference for a high-fat reinforcer (a corn oil solution; Freed & Green, 1998). Nonetheless, consumption could be markedly reduced when its price was increased, but only if there were a palatable substitute available (i.e., a reinforcer of similar value, a mineral oil or a sucrose solution). A healthier but less-palatable alternative (plain water) had little effect on the rats' consumption of the high-fat corn oil solution. These results counter the long-standing belief that very strong preferences necessarily are difficult to change and further emphasize the importance of considering available alternative reinforcers when attempting to modify behavior. They also show that preference is not a fixed characteristic of the individual or of the commodities chosen but is much determined by the context in which they are presented.

Taken together, these findings suggest that the matching law understood within a behavioral-economic framework has broad applicability to human behavior: Humans allocate their time and effort to different behaviors, and they do so according to the relative value of the reinforcers those behaviors produce. Consider, for example, the circumstances of low-income, ethnic minority adolescents and young adults in many settings around the world. The value of reinforcers contingent on education and pursuit of jobs may be compromised by uncertainty, ethnic prejudice, and other disadvantages. In contrast, some criminal behavior may have clear and immediate payoffs. The matching law suggests that the allocation of time and effort to these two types of behaviors will vary according to the relative outcomes of each. Along with the earlier discussion of punishment and reinforcement, the matching law can provide an important strategic perspective: Reducing criminal behavior might be achieved more effectively by increasing the value associated with alternatives (e.g., education or jobs) than by aggressive policies focusing on criminal behavior itself.

Discounting

Discounting is a rich area of research that examines how the delay to a reinforcer (delay discounting) or the likelihood of obtaining a reinforcer (probability discounting) influences choice for that reinforcer. (For a review, see Madden & Bickel, 2010). When alternatives differ along only one dimension, choosing between them can be relatively easy: People generally will prefer rewards that are larger rather than smaller, immediate rather than delayed, and certain rather than uncertain. Choosing between alternatives can be substantially more difficult, however, when they differ along two or more dimensions. Consider the choice between $100 now and $200 in 1 year. Although the larger amount is preferred over the smaller amount, receiving a reward sooner is preferred to getting one later. Because these dimensions (amount and delay) are pitted against each other, choice becomes substantially more complex and difficult.

When offered the choice between the immediate $100 and the delayed $200, many people would choose the immediate $100 despite $200 being objectively twice as much. In cases like this, it is said that the immediately available $100 has greater subjective value than the delayed $200. Subjective value is directly proportional to the magnitude of the reward and inversely proportional to the delay to or odds against receipt of the reward. The way in which subjective value varies by amount, delay, and probability of reward is quite orderly and well-described by a hyperboloid function (for reviews, see Green & Myerson, 2004; Green, Myerson, & Vanderveldt, 2014). Figure 9.2 shows the subjective values of a $200 hypothetical monetary reward plotted as a function of the delay until its receipt (left panel) and the odds against its receipt (right panel). The curves represent the fits of the hyperboloid model to the obtained subjective values.

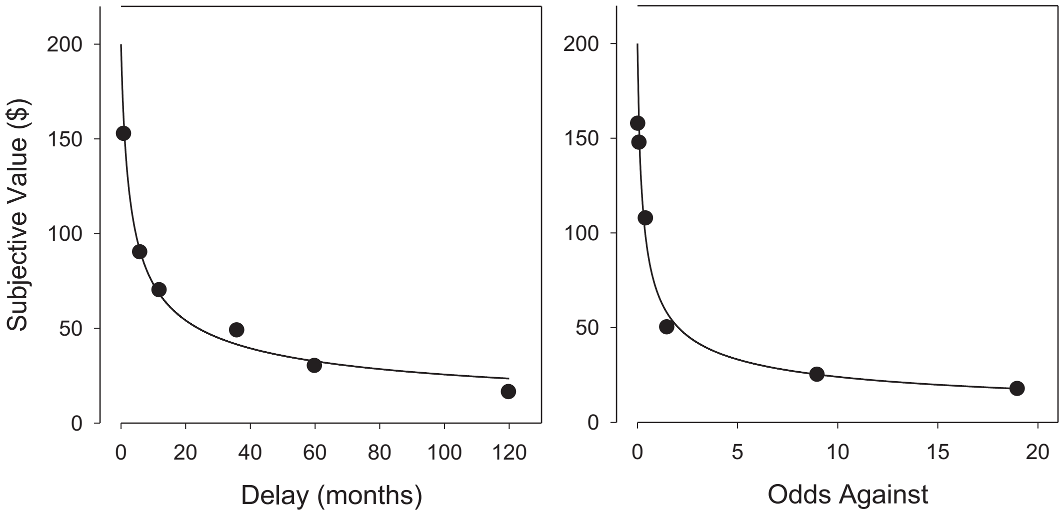

Fig. 9.2 Subjective value of a hypothetical $200 monetary reward as a function of time until receipt (*left panel*) and odds against receipt (*right panel*). The *curves* represent the best-fitting hyperboloid functions (Data are from Experiment 2 of "Amount of Reward has Opposite Effects on the Discounting of Delayed and Probabilistic Outcomes," by L. Green, J. Myerson, and P. Ostaszewski, 1999, *Journal of Experimental Psychology: Learning, Memory, and Cognition*, *25*, p. 423)

The rate of discounting, or the degree to which subjective value declines with increases in delay or decreases in probability, is not necessarily a stable aspect of the reward or of the individual. An individual's rate of discounting varies, for example, depending on the magnitude of the outcome (Green, Myerson, & Ostaszewski, 1999; Kirby, 1997), its quality (Freeman, Nonnemacher, et al., 2012), and whether the reward is consumable (e.g., food, music, etc., Charlton & Fantino, 2008). A common finding, called the magnitude effect, is that rewards of different magnitudes lose subjective value at different rates. With delayed rewards, a larger amount is discounted proportionally less steeply than a smaller amount, whereas with probabilistic rewards, a larger amount is discounted proportionally more steeply than a smaller amount. As can be seen in the left panel of Fig. 9.3, at a delay of 12 months, the $5000 reward is subjectively worth approximately 56% of its undiscounted value. In contrast, at the same delay, the $200 reward is subjectively worth only 35% of its undiscounted value; the $200 is discounted more steeply (i.e., it loses subjective value more quickly) than the $5000 reward. Interestingly, amount has an opposite effect on the rate of discounting probabilistic rewards: At an odds against of 1.5 (a probability of 40%), a $5000 reward is subjectively worth 15% of its undiscounted value, whereas a $200 reward is subjectively worth 25% of its undiscounted value (see Fig. 9.3, right panel).

The relations among subjective value, amount, delay, and probability of reward have substantial implications for health behavior. Consider a worksite program in which all employees who succeed in quitting smoking are entered into a lottery, the winner of which will receive a large reward such as an attractive vacation. Depending on the number of employees, the probability of winning may be extremely low, making this a low-probability but large reward, and so the subjective value of this reward may be steeply discounted. Such a program may be less effective than giving highly probable or certain smaller rewards, (e.g., being able to leave work one hour early at the end of the week) for all who report no cigarette smoking during the week.

Differences in rate of discounting also are apparent across individuals, and often these dif-

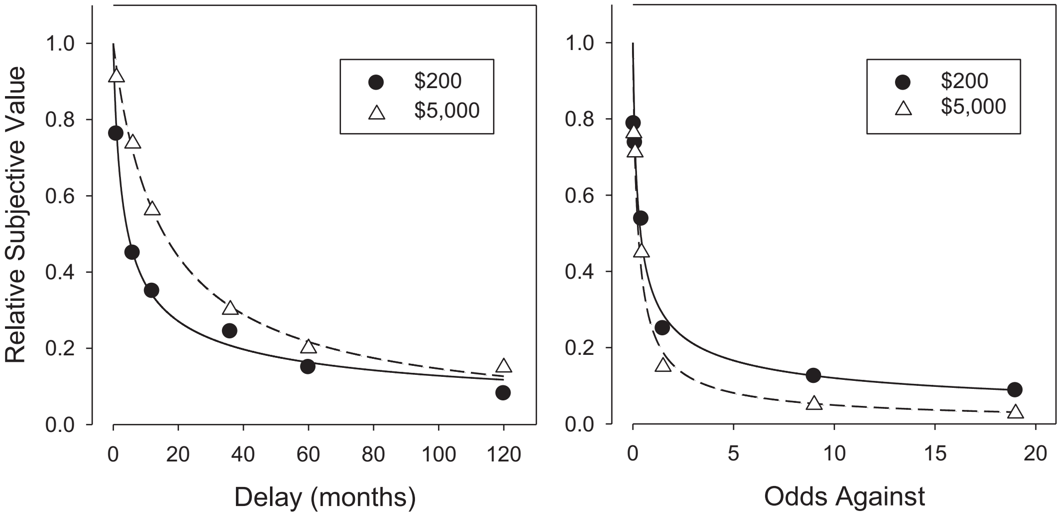

Fig. 9.3 Relative subjective value of $200 and $5000 rewards as a function of time until receipt (*left panel*) and odds against receipt (*right panel*). Larger delayed rewards are discounted less steeply than smaller delayed rewards, but larger probabilistic rewards are discounted more steeply than smaller probabilistic rewards. The *curves* represent the best-fitting hyperboloid functions (Data are from Experiment 2 of "Amount of Reward has Opposite Effects on the Discounting of Delayed and Probabilistic Outcomes," by L. Green, J. Myerson, and P. Ostaszewski, 1999, *Journal of Experimental Psychology: Learning, Memory, and Cognition*, *25*, p. 423)

ferences are related to what are termed impulse-control disorders. One might expect that those who are dependent on a substance would not discount that substance at all. For these individuals, we might expect that it would not matter how delayed or improbable receipt of the substance might be, but that merely the possibility of receiving their substance of choice would compel their behavior. Interestingly, however, nicotine-, alcohol-, cocaine-, and opioid-dependent individuals discount delayed monetary rewards more steeply than controls and discount their drug of abuse even more steeply than monetary rewards (see Fig. 9.4; for a review, see MacKillop, Amlung, et al., 2011). Similar findings have been found with other groups with impulse-control problems, including habitual gamblers (Petry & Madden, 2010) and obese women with binge-eating disorder (Manwaring, Green, et al., 2011).

Discounting applies not only to the direct reinforcers involved in various impulse-control problems but also to the delayed and probabilistic negative consequences of those behaviors (e.g., lung cancer, liver disease, financial insecurity, poorer family interactions, etc.). Because those negative outcomes are delayed and probabilistic, as are the positive consequences of giving up the behaviors (e.g., improved health, financial security, etc.), the problem behavior may remain and treatment interventions may be less effective. For example, cigarette smokers make decisions between smoking now with the increased chance of poorer health later on and experiencing nicotine withdrawal now with an increased chance of better health in the long run. Baker, Johnson, and Bickel (2003) reported that both smokers and nonsmokers discounted delayed health gains (e.g., improving one's health) more steeply than delayed health losses (e.g., making one's health worse). These findings suggest that public health efforts may be improved by framing decisions in terms of avoiding future health losses (e.g., losing the ability to live independently) rather than accruing better health.

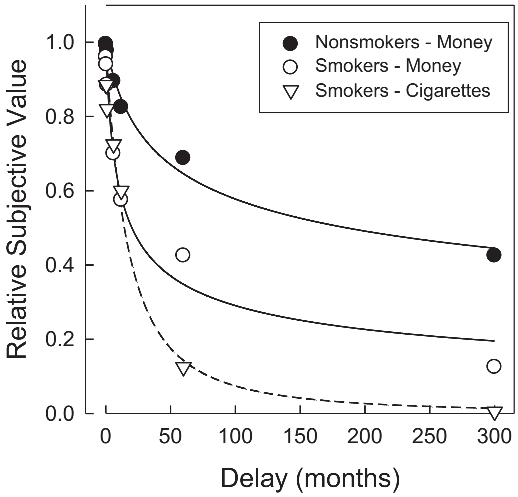

Fig. 9.4 Relative subjective value of cigarette and monetary rewards as a function of time until receipt. The *curved lines* represent the best-fitting hyperboloid function. Cigarette smokers discounted money more steeply than nonsmokers and discounted the value of cigarettes more than money (Data are from Figs. 1 and 2 of "Impulsivity and Cigarette Smoking: Delay Discounting in Current, Never, and Ex-Smokers," by W. K. Bickel, A. L. Odum, and G. J. Madden, 1999, *Psychopharmacology*, *146*, p. 451)

The relation between rate of discounting and impulse-control disorders has been the basis for the argument that discounting may be an underlying trait reflecting an individual's "impulsivity." In this view, impulsivity is choosing the smaller, sooner reward (e.g., an immediate $100) over the larger, later reward (e.g., $200 in 1 year), whereas, in contrast, self-control is choosing the larger, later reward over the smaller, sooner reward. In fact, there is evidence suggesting that degree of discounting is a predictor of later self-control problems (Audrain-McGovern, Rodriguez, et al., 2009; Carroll, Anker, et al., 2010; Yoon, Higgins, et al., 2007). For example, Yoon et al. studied pregnant women who were abstaining from smoking and found that steep delay discounting of monetary rewards was a significant predictor of postpartum relapse at 24 weeks. Similarly, Audrain-McGovern et al. measured delay discounting of monetary rewards in adolescents over several years and found not only that patterns of discounting were relatively stable but also that the initial measurement of the adolescents' discounting predicted onset of smoking in later years.

These results suggest that steep discounting (i.e., relatively strong preferences for more immediate rewards) may be a stable individual difference that can identify those at risk for future impulse-control problems (Odum, 2011). Operating early in life or even prenatally (e.g., El Hajj, Schneider, et al., 2014), social, economic, and developmental factors that may lead to such steep discounting are important topics for future research. For example, it has been reported that people of lower socioeconomic status (SES) tend to discount delayed rewards more steeply than people of higher SES (e.g., Green, Myerson, et al., 1996; Sweitzer, Halder, et al., 2013), suggesting that childhood SES may be an important factor that contributes to impulsive decision making later in life. In particular the relative unpredictability of delayed outcomes that accompanies low SES (see Sherlaw et al. and Siddiqi et al., *infra*) may have a role in shaping such propensities around discounting.

One might expect, then, that steep discounting is a characteristic of individuals and thus explains impulsive behavior problems; the situation, however, is far more complex. Research has shown that delay and probability discounting involve different underlying processes and therefore reflect different "types" of impulsivities rather than a unitary trait (Green & Myerson, 2010). Yi and Landes, for example, found that brief periods of smoking abstinence in cigarette smokers led to an increase in delay discounting but that such abstinence had no effect on probability discounting (Yi & Landes, 2012). As researchers and practitioners further develop models of impulse-control disorders, their efforts may be better served by considering the role of "multiple impulsivities" rather than treating impulsivity as a unitary construct (Green & Myerson, 2013).

Finally, it is important to consider the addictive substance in light of individual propensities around discounting. In this context it is worth noting that research on cigarette smoking and nicotine addiction has long emphasized the remarkable rapidity of the uptake of nicotine with smoking (Henningfield & Keenan, 1993; Pomerleau & Pomerleau, 1987; U.S.D.H.H.S., 1988). It takes only seven seconds from inhaling a cigarette for nicotine to reach the brain. In contrast, nicotine delivered by patches or gum yield much slower uptake. Smokers report considerably more pleasure from smoking than from other modes of nicotine delivery, accounting for relapse to cigarettes from other modes of nicotine delivery which may, over the course of a day, match the total amount of nicotine delivered. This sensitivity to the rapidity of uptake of nicotine appears to parallel the steep discounting of delayed drugs of choice among smokers and individuals dependent on other drugs. Thus, at least in the case of smoking, addiction may require both an individual's propensity for steep discounting and the necessary pharmacokinetics of the drug and its mode of delivery.

Discounting and "Self-Control"

We can see the challenge of many self-control problems such as weight management as a competition between short-term payoffs such as eating enjoyable food and long-term consequences such as healthy body weight. In the 1970s, George Ainslie along with several of us (HR, LG) showed that discounting of short- and long-term reinforcers can provide a model for self-control. Remarkably, they demonstrated this with a series of experiments with pigeons examining choices among long-term goals and the intrusion of more immediate temptations.

For the pigeons, the long-term goal was not that of losing weight or quitting smoking but rather getting 4 s of access to grain (Ainslie, 1974). To get the 4 s access to grain, pigeons had to wait 15 s. To complicate things a little, the pigeons were occasionally presented a red "temptation" key after 12 s. If they pecked this key, they then would get immediate access to the grain, but for only for 2 s. They were in a classic self-control situation: Yield to the temptation key and get an immediate but lesser reward (2 versus 4 s' access to grain), or resist the temptation, wait an additional 3 s, and get access to the larger reward.

Ainslie added one more complication: At the beginning of the 15 s of waiting, a green "self-control" key was presented. If the pigeon pecked it, then the red temptation key was not presented on that trial and the 4 s access to grain was simply presented after 15 s with no temptations along the way. The result? Ainslie showed that some pigeons came to "exert self-control" by pecking the green key, thereby avoiding the temptation, and thus went on to receive the greater, delayed reinforcer.

Pecking the green key to keep the 2-second temptation from ever occurring is similar to setting one's alarm clock. When we go to sleep, we set the clock for when we intend to get up, knowing that otherwise our preference may well be different the next morning when the alarm goes off. We may even set the clock across the room so that the intention at bedtime will be more strongly enforced in the morning.

A subsequent experiment by Rachlin and Green (1972) applied discounting to understanding pigeons' self-control. Figure 9.5 depicts the discounting over time of a larger, more delayed reward (represented by the solid curve) and a smaller, but sooner reward (represented by the dashed curve). Well in advance of either reward (at time T_1 in Fig. 9.5), the relative subjective value of the larger, more delayed reward (LL) is greater than that for the smaller, sooner reward (SS); thus, preference is for the larger, more delayed reward. However, as time to the smaller, sooner reward approaches, its relative value becomes greater than that of the larger, more delayed reward (at time T_2 in Fig. 9.5), and preference reverses to that of the smaller, sooner reward. Such preference reversals follow from the hyperbolic discounting of rewards and have been shown in pigeons, rats, and humans (e.g., Ainslie & Herrnstein, 1981; Green & Estle, 2003; Green, Fisher, et al., 1981; Green, Fristoe, & Myerson, 1994). Because one's good intentions at T_1 fall prey to immediate temptations at T_2, how might one increase the likelihood of ensuring receipt of LL in the face of such preference reversals? Relying on such "ghost-in-the-machine" concepts as willpower or ego strength provides little guidance.

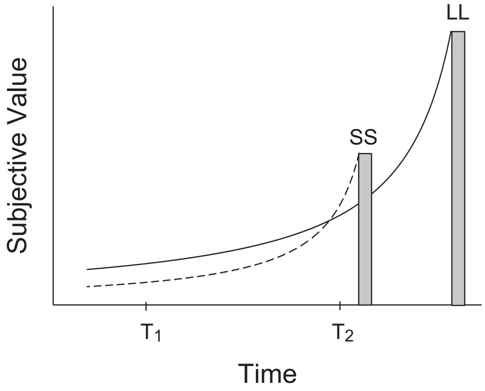

Fig. 9.5 Discounting of a larger, later (*LL*) reward and a smaller, sooner (*SS*) reward. The heights of the *bars* represent the nominal amount of reward, and the *curves* show how subjective values change as a function of delay to each reward. At T_1 the larger, later reward has a higher subjective value, but this preference changes at T_2, at which time the smaller, sooner reward has a higher subjective value

In the Rachlin and Green (1972) experiment, at T_2 pigeons were offered a choice between SS and LL, and invariably chose SS. However, at T_1, the pigeons were offered a choice between making a commitment or not. By pecking a commitment key, only the LL option would then be offered later at T_2; pecking the noncommitment key led to the choice between SS and LL at T_2. In this case, the pigeons that otherwise would choose SS at T_2 had a way to preclude this option and ensure receipt of LL. Indeed, Rachlin and Green found that when the pigeons were allowed to make a commitment response well in advance of when preference would otherwise reverse, all the pigeons came to "exert self-control" by pecking the commitment key at T_1 and thus obtain LL.

The pigeons' behavior is consistent with the view that we do better if we exercise our "willpower" far in advance of temptations rather than waiting for them to become close at hand. The pigeons pecked the key that prevented the temptation from even becoming available more often when the key appeared well in advance of the temptation than when it appeared closer to the time the temptation was to occur. So efforts at self-control will be more successful if we act early, well before temptations are liable to lure us out of our strategy than if we wait for the temptations to be just about to occur. If we wait until the tempting dessert is on a plate in front of us, it will be difficult to resist. But if we shop for food so that no tempting desserts come into our homes, they will be far easier to resist.

The pigeons in the research just described had only one way to exercise self-control. They could simply keep the temptation from happening. Humans have a far wider range of strategies available to them. They can keep the temptation from becoming available, for example, by bringing their own lunch to work and not even going to the cafeteria where seductive desserts lie in wait. But they also can do things like decreasing the attractiveness of the temptations, for example by thinking about all the diseases that cigarettes cause so that, when tempted, the cigarette is not just a reminder of the pleasures of smoking but also a reminder of its perils. Humans also can make their long-term goals more effective in motivating their current behavior. Buying some clothes that you would like to fit into may help elevate the discounted value of the long-term weight loss and thereby help maintain a diet. Working out a schedule of milestones along the path to the long-term goal also may raise the perceived likelihood of the delayed goal as well as provide some reinforcement for meeting the milestones along the way. Being social, humans also can use their friends and family to help them achieve their long-term goals. For example, telling your friends about your plan to achieve some goal adds an incentive of not wanting to be embarrassed among them should you fail to achieve it.

Across all of these plans and strategies, long-term goals, and immediate temptations, two points appear critical in understanding self-control. First is that self-control or yielding to temptation is determined by the *relative* value of the discounted greater, delayed reward and the discounted lesser, sooner reward *at the time* a choice is made. Second, the "secret" to self-control is not some kind of mental energy applied to resisting temptation but rather that of making choices when our preference is for the delayed reward (e.g., at time T_1 in Fig. 9.5), so as to avoid a situation in which the value of the temptation is greater than that of one's long-term goal (e.g., at time T_2 in Fig. 9.5).

Coda: Classical Conditioning

The reader may be wondering why, after a lengthy review of behavioral psychology, the name Pavlov and research in classical conditioning have yet to be mentioned. Unquestionably, classical conditioning is a fundamental area within which behavior and behavior change must be understood. Moreover, interactions between operant and classical conditioning are ubiquitous, and thus one must be aware of contemporary research and theory in each area. The focus of the present chapter is on the interrelation between behavior, its consequences, and patterns of behavioral choices. These, in large part, are not the focus of research on classical conditioning. Nonetheless, in the next section on cigarette smoking, some understanding of classical conditioning processes is needed. Therefore we provide a brief review here.

In classical conditioning, a neutral stimulus is presented such that it predicts an unconditioned stimulus (US). The US is a stimulus that produces an unconditioned response (UR), that is, a response that is not dependent on prior learning. Suppose a bell (neutral stimulus) is periodically presented preceding food (US), which causes an animal to salivate (UR). Because the bell regularly predicts the food, the bell comes to elicit a conditioned response (CR), in which presentation of the bell by itself causes the animal to salivate. That is, over time, given the predictive association between the originally neutral stimulus (bell) and the US (food), the bell, now a conditioned stimulus (CS), comes to elicit conditioned responses (salivation) that precede the unconditioned stimulus. Similarly, as people sit down to enjoy a nice meal, their salivary glands begin secreting saliva in anticipation of the food that is to come. (For presentations of fundamental aspects of contemporary research and theory in classical conditioning, see Gottlieb & Begej, 2014 and Schachtman & Reilly, 2011).

Two features of classical conditioning that have a direct and significant relation to behavioral medicine are highlighted here. The first feature is the extinction of classically conditioned responses. If one often has the urge to smoke a cigarette when drinking with friends at a restaurant, one might think that the way to extinguish this behavior is to avoid the conditioned stimuli (i.e., avoid drinking with friends at a restaurant). However, extinction occurs when the conditioned stimulus is presented without the unconditioned stimulus. Staying with the example then, one must have the drink with friends, but not smoke. Extinction is central to the treatment of fears and phobias, in which one must learn to experience the circumstances associated with anxiety (e.g., entering an elevator) without feeling great distress. Avoiding the feared situation does not extinguish the classically conditioned fear. Rather, experiencing the feared situation (e.g., entering the elevator) without the feared events (i.e., the US; perhaps the elevator breaking down) leads to extinction. An appreciation of extinction also is important in other areas of health behavior, such as learning to watch television or spend time with friends without those being the occasion for unhealthy eating.

The health practitioner should be aware of extinction-related phenomena that may lead to relapse, and thus design interventions with full knowledge of these phenomena. These include spontaneous recovery (the recovery of a CR that occurs when a CS is presented after a period of time has elapsed following extinction), renewal (the recovery of a CR that occurs when the CS is presented in a context different from that in which extinction took place), and reinstatement (the recovery of a CR that occurs after extinction following reexposure to the US), any one of which increases the likelihood of relapse. (For an excellent discussion of mechanisms involved in extinction and for an understanding of phenomena related to relapse, see Vurbic & Bouton, 2014).

A second feature of classical conditioning that is of critical importance to behavioral medicine is the wide range of responses, response systems, and situations to which classical conditioning applies. Many bodily processes are conditionable, including insulin regulation in response to cues associated with ingestion of glucose or with the injection of insulin and regulation of the immune system (e.g., Ader, Felton, & Cohen, 1991; Kyriazis, Soundarapandian, & Tyrberg, 2012; Matysiak & Green, 1984; Szczytkowski & Lysle, 2008). Classical conditioning is also important for understanding substance use and abuse, drug tolerance, drug overdose, and withdrawal. Unconditioned responses to drugs may become conditioned to the circumstances surrounding drug-taking. These may then contribute to troublesome urges and cravings when individuals try to stop drug use but are exposed to circumstances that have been associated with it. Effective treatments should address these conditioned responses to help individuals sustain abstinence (e.g., Cunningham, 1998; Siegel, 1990).

A particularly troublesome impact of the wide range of things that can be conditioned involves the conditioning of *tolerance and opponent processes*. As strong or unusual substances are consumed, the body mobilizes “opponent processes” that resist their effects (Siegel, 1976). Opponent processes in turn reduce the value of a fixed amount of the commodity, requiring more and more to achieve the same effect. Even the casual drinker or smoker experiences some reduced effect with continued use. For the individual heavily dependent on alcohol, nicotine, opioids, or narcotics, this “tolerance” effect is magnified. Those dependent on opioids, for example, may regularly consume amounts of opiates that would kill nonusers.

The opponent processes underlying tolerance may themselves become conditioned responses to whatever environmental stimuli (conditioned stimuli) are present when the addictive substance is habitually taken. An individual addicted to heroin, for example, tends to build up resistance to the primary narcotic effect of the heroin in situations in which the drug is habitually taken. If heroin is taken only in one situation (in one way, in one room, at one time of day, with one other person or set of people present), that situation becomes a conditioned stimulus for tolerance (opponent processes that act against the pleasurable effect of the addictive substance). Then, if the same dose is taken in a new situation, the conditioned stimuli that trigger opponent processes will be absent, and the effect of that very same dose will be much stronger than before – strong enough in some cases to be fatal (Siegel, 1988a, b).

Complex Patterns of Behavior

The previous sections of this chapter have reviewed fundamental concepts of behaviorism and how they may be applied to complex patterns of behavior of health significance, such as addictions. In this, behavioral economics has contributed valuable understanding of how different behaviors may be linked by the common functions they serve, such as in substitution, or by the opportunities and consequences that accompany them, such as in the effects of altered prices of one behavior on the likelihood of others. We turn now to examples of how these principles can be extended to a major health behavior, cigarette smoking, and to a major health condition, obesity.

Conditioning of Smoking

Smoking is an addiction, and the powerful reinforcing properties of nicotine are central to that addiction (Grunberg, Shafer Berger, & Starosciak, 2012). As noted previously, nicotine from cigarette smoking reaches the central nervous system in about seven seconds (Pomerleau & Pomerleau, 1987). In contrast, most disincentives for smoking are subtle or delayed, thus reducing the likelihood of their discouraging smoking. In addition to the immediately direct reinforcing effect of nicotine, smoking involves a complex array of associated stimuli. On the surface, smoking a cigarette seems very simple: The cigarette is lit and placed in one’s mouth, inhalation of the smoke follows, the smoke is exhaled, and so on. However, smoking and inhaling are frequently repeated – over a million times for the individual who has smoked a pack a day for 20 years (Fisher, Jr. & Rost, 1986). As a result, a large range of discriminative and conditioned stimuli come to signal the occasion for reinforcement by nicotine and to elicit conditioned responses that can, themselves, reinforce actions in the “simple” sequence of smoking a cigarette.

Discriminative stimuli alter the likelihood of a response by signaling the relation between the behavior and its reinforcement. In addition, through classical conditioning the circumstances surrounding smoking (the CSs) come to elicit conditioned responses. The complexity of these conditioning effects is increased by the fact that smoking is not a single response but rather a sequence of behaviors. Behaviors in the middle of the smoking chain play many roles. Taking a cigarette out of its package may (1) elicit conditioned responses resembling the pharmacological effects of nicotine that reinforce previous behaviors that led to it, (2) be reinforced itself by the conditioned responses it elicits, and (3) serve as a discriminative stimulus for subsequent behaviors, signaling the likelihood of their reinforcement by nicotine. Each inhalation provides an opportunity to increase “…the thorough interweaving of the smoking habit in the fabric of daily life” (Pomerleau & Pomerleau, 1987). As another example, a stress-producing phone call may serve as a discriminative stimulus, signaling a situation in which the anxiolytic pharmacologic effects of nicotine would be especially reinforcing. The stressful call may result in the behavior of reaching for a cigarette. In turn, reaching for a cigarette may serve as a conditioned stimulus that elicits conditioned responses that resemble those anxiety-reducing, reinforcing effects of nicotine. These conditioned responses may then reinforce reaching for the cigarette. Each action in the chain may both evoke conditioned responses reinforcing earlier actions and serve as a discriminative stimulus for subsequent actions.

The conditioning of smoking is further complicated by the varied reinforcing effects of nicotine. Nicotine can reduce anxiety, improve one’s mood, and function as a stimulant. The same individual may smoke to “get going” in the morning, to feel better after a stressful interaction at work, and to improve his or her mood after a long day. Each of these – getting going in the morning, stress at work, relaxing at the end of the day – can come to serve both as discriminative stimuli for smoking and, following cessation, as conditioned stimuli for withdrawal symptoms or cravings. Furthermore, the circumstances that give rise to such states, such as the time of day, work demands, family conflict, etc., come to signal the occasion for smoking or to elicit conditioned withdrawal symptoms.

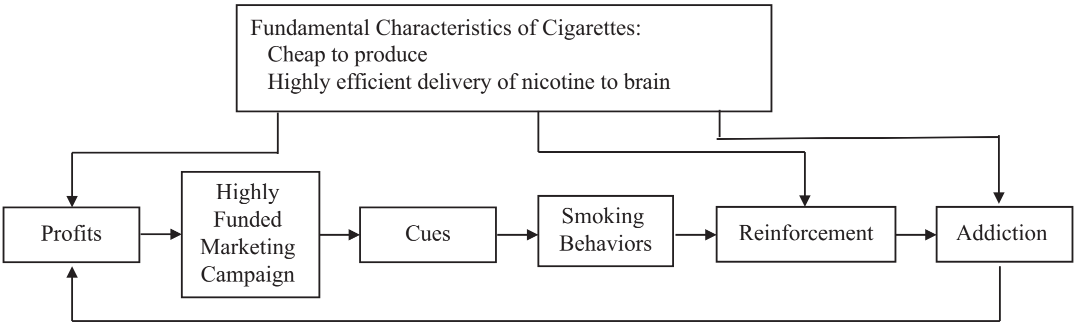

Fig. 9.6 Relations among fundamental characteristics of cigarettes, profits from cigarette sales, marketing of cigarettes, and key processes in smoking behavior and nicotine addiction

From the perspective of conditioning, cravings or urges are conditioned responses to circumstances that have been associated with nicotine delivery (the unconditioned stimulus). Consistent with this perspective, nicotine replacement appears to reduce withdrawal symptoms but does not reduce the desire to smoke (Henningfield & Nemeth-Coslett, 1988). This finding suggests that desires and cravings are dependent on the cues and circumstances associated with previous smoking and not only on nicotine. Simply providing an alternative source of nicotine, then, might not fully diminish those conditioned urges. Similarly, smokers report greater withdrawal symptoms if they quit in their home environment rather than in novel environments such as a residential smoking-cessation treatment program. Presumably, this is because the home environment contains far more conditioned and discriminative stimuli associated with prior smoking (Hatsukami, Hughes, & Pickens, 1985). Quitting away from one's home environment may be a beginning for quitting smoking, but it is unlikely to be the full answer. Given the extinction-related phenomena noted earlier, renewal and reinstatement would be expected upon return to the home environment, thereby increasing the likelihood of relapse.

Multiple Determinants and the Persistence of Smoking

In addition to the reinforcement and conditioning influences discussed, other environmental influences on smoking are well-documented (e.g., Borland, *infra*, Fisher, Brownson, et al., 2004). These include advertising and other marketing approaches, exploitation of social and economic adversity, social and peer influences on smoking among adolescents as well as adults, and the profitability of selling cigarettes over other consumer products. Furthermore, these influences on smoking interact among themselves. For example, the profitability of cigarettes leads not only to the ubiquity of cigarette marketing but in turn to the conditioned responses to cigarette advertisements and promotions and the biological and psychological responses that they trigger (see Fig. 9.6). Reciprocally, success in addicting a large number of individuals and keeping them addicted drives the profitability of cigarette marketing. The multiplicity of determinants of smoking and the many interactions among them can account for much of the persistence of smoking – a persistence otherwise inexplicable in light of smoking's risks. The fundamental concepts of conditioning, reinforcement, and stimulus control help explain how broad environmental influences such as advertising influence smoking at the individual level.

Substitutability of Social Support and Nicotine in Cigarette Smoking

A major theme of this chapter is how behaviorism and behavioral economics help us understand the influence of environmental and contextual influences on behavior. An interesting example is the relation between the behavioral economics concept of substitutability previously discussed and the complex relation between social support and health, characterized most broadly by findings that the absence of social support, namely, social isolation, is as lethal as smoking cigarettes (Holt-Lunstad, Smith, & Layton, 2010; House, Landis, & Umberson, 1988). Social support can provide incentives for life-enhancing behaviors (e.g., exercising) as well as offset the effects of stressors that might otherwise lead to emotional upset. For example, "having much to live for" because of satisfying social relationships may provide incentives for exercising, managing diabetes, and quitting smoking. Furthermore, the presence of social contact and support may guard against depression by offsetting depressed mood in a way that may substitute for mood-elevating effects of nicotine.

If social support is a commodity (i.e., a reinforcer) in and of itself, then it may serve as a substitute for other commodities. Consider, for example, that both social support and smoking appear helpful in coping with difficult life circumstances. Family difficulties, stress at work, or other stressors might increase the probability of choosing to spend time with friends *or* choosing to smoke. If social support were substitutable for nicotine, it might explain the relation between social support and success in smoking cessation (Fisher, Jr., 1997). More specifically, if social support and nicotine are substitutes, then when supportive relationships are limited, the probability of choosing cigarettes would be expected to increase. If companionship provided by a spouse substitutes for nicotine, then it would be expected that widowhood would be associated with increased smoking. Indeed, widowhood (as well as divorce, separation, and single marital status) is associated with greater prevalence of smoking, increases in rate of smoking, and likelihood of relapse among former smokers (Fisher, 1996; Fisher, Jr., 1997).

The benefits of social support while it is available are significant, but economic substitutes lose their power when they are no longer available. Thinking of social support this way may explain why interventions that provide support are effective in encouraging smoking cessation while they are available but lose their influence after they are terminated (Etringer, Gregory, & Lando, 1984; Fisher, Jr., 1997; Lichtenstein, Glasgow, & Abrams, 1986). The fundamental roles of reinforcement and extinction are clear; behavior increases with reinforcement and declines in its absence.

Social behavior, however, may sometimes facilitate smoking rather than substitute for it. Recent quitters frequently relapse while they are socializing. Fluctuations in the frequency of smoking from one day to the next often are associated in a complementary way with socializing so that, for example, going out to a nightclub or bar with friends on a weekend might be associated with increased smoking. Thus, in addition to social support and smoking/nicotine being substitutes, they may also be complements, that is, increases in one will lead to a corresponding increase in the other. Which function these behaviors take, complements or substitutes, may be context-dependent. Stress may lead to substitutability whereas socializing may lead to complementarity. These observations point again to a key theme of this chapter. How behavior is influenced by the events that surround it is not an intrinsic characteristic of the behavior or those events, but, rather, determined by the contexts in which they occur.

Extension to Other Health Behaviors

We have spent a substantial portion of this section discussing the implications of behavioral concepts to smoking behavior, in part, because of its prevalence. However, behavioral concepts also have significant implications for other health behaviors. For example, Vuchinich and Tucker articulated a behavioral economic model of alcoholism that frames choice for alcohol as determined by factors in the environment of the individual dependent on alcohol, such as the availability of social support or contact (Vuchinich & Tucker, 1988, 1996, 2003). The substitutability of social support or contact and of alcohol consumption is a central part of this model. Parallel to the previous discussion of efforts to promote nonsmoking, Vuchinich and Tucker direct attention to the provision of appealing and inexpensive substitutable sources of support and socialization in efforts to promote alcohol abstinence or controlled drinking. Behavioral models also have been helpful in understanding other health behaviors (e.g., diabetes) and in the development of incentive programs (Long, Jahnle, et al., 2012). In the next section, we focus on another major health concern, obesity, and again show how behavioral psychology and behavioral economics help inform understanding of this complex health behavior.

Obesity, Patterns of Behavior, and Teleological Behaviorism

This chapter has detailed ways in which behavior is shaped and sculpted by its contexts, the availability of other behaviors, the economics of their costs and consequences, the circumstances that surround individuals, and their behavioral histories (e.g., over a million puffs linking cigarette smoking with numerous cues in daily life). We now turn to another immense global health problem, obesity (see also Chapter by Johnston et al*.*, *infra*). In our discussion of obesity, we illustrate the application of another behavioral approach, *teleological behaviorism* (Rachlin, 1994), that focuses on *patterns* of behavior.

You might say that there is a difference between a man who intentionally swings a hammer and a man who accidentally swings a hammer, even though the two men are behaving in the same way at a given moment in time. You might suggest that the difference lies inside them, in their intentions. It could be argued that something inside of people must mediate behavioral differences, but the difference between intention and accident is behavioral. The difference between a man purposely swinging a hammer and a man accidentally swinging a hammer can be resolved not by looking inside him, but by looking at more of his behavior. A man accidentally swinging a hammer will not be hammering a nail or building a floor.

Teleological behaviorism focusses on patterns of behavior extended over time rather than on isolated actions. The question of why one of us (HR) is writing this paragraph cannot be broken up into the question of why he is writing this sentence, why he is writing the next sentence, and so forth. Rather, you have to look at why he is working on the chapter as a whole. If he had to decide whether to write each sentence individually he'd have writer's block – since there is no reinforcement for writing each sentence individually. Correspondingly, in the area of weight control, there is no reinforcement for each act of unhealthy food refusal and healthy food choice. It is sometimes said that the reinforcement for such acts is delayed; however, refusal of a single candy bar tonight does not make one suddenly a slimmer, healthier, and happier person 3 weeks later. A single act of self-control is not reinforced – now *or ever*. Reinforcement of acts such as refusing a candy bar is to be found not in particular acts themselves but in the value of a pattern of acts strung out over time. This value may be extrinsic to the pattern (e.g., social approval) or more closely linked to the pattern itself (e.g., the pleasure of playing a favorite piece of music).

Two things need to be emphasized. First, in teleological behaviorism, the unit to be explained is not the individual act or behavior, but a pattern of behavior that extends over time. Consider this in contrast to the criticism that behaviorism looks only at isolated stimuli and responses without considering things like the goals or purposes of the individual. A second key point will emerge in this discussion: Patterns of behavior may be shaped and sustained in themselves – as patterns – without reinforcement of their particular component acts. In fact, patterns may be reinforced and sustained even despite a negative value of their component acts. After all, every discrete act of an organism, even a pigeon's peck, is itself a complex pattern of sub-acts. A peck nevertheless may be reinforced without explicit reinforcement of its components. A third key point is that the events and consequences that signal the occurrence of and reinforce patterns of behavior may change over time. The cues, reinforcers, and behaviors that lead to weight loss are not the same as those that sustain a substantial weight loss over a number of years.

Readers may be surprised that the language in the pages that follow sounds more mentalistic than they may have expected. Teleological behaviorism accepts mental terms such as perception, imagination, and even willpower, although it defines those terms strictly as patterns of behavior (see Rachlin, 1994, 2014). Their validity in describing a given act (e.g., refusing a candy bar) does not depend on the existence of internal events at that moment in time (e.g., activity in some place in the brain), but on external, observable events (the past performance and consequences of the behavior) spread out over time. A pattern of refusing, say, a second croissant with morning coffee is under the control of external stimuli – a pattern of what one sees when stepping on the scale or looking in the mirror, medical reports, compliments from friends, and so forth – and not some interior muscle-like substance in the brain called "willpower" that the individual somehow squeezes whenever she or he wants to do something not immediately rewarding.

The following observations about obesity and weight loss come from this teleological, behavioral viewpoint. In addition to suggesting new ways of addressing obesity, they serve as examples of teleological ways for thinking about behavior in health and in general.

Economics and Reinforcement: The Escalating (Relative) Joys of Obesity

Teleological behaviorism and behavioral economics have much in common. Both specify the relation between behavior and consequences, and the key to both is the maximization of favorable consequences (Kagel, Battalio, & Green, 1995). Economic theory assumes that people behave so as to maximize utility under any given set of constraints (prices and budgets in economic language and reinforcement contingencies in behavioral language).

Looking at maximization over time introduces a key issue. Often, behavior that maximizes utility in the short run does not maximize utility in the long run. The immediate pleasures of overeating are clear. Millions of years of food scarcity in the history of humankind have developed a tendency to eat whenever food is available. For many of those living in upper-income societies food is virtually always available, and so we tend to overeat. However, although overeating may maximize utility in the short run (e.g., it produces immediate pleasure), it negatively affects health and social acceptance in the long run.

Eating has many reinforcers, but what are the consequences of patterns of eating? If each act of eating is reinforcing and the individual eats more and more, then too often the consequence of this pattern is weight gain. Each act of eating is reinforced, but the aggregate effects are negative. Patterns have both short- and long-term consequences and each must be considered.

If overeating leads to weight gain, then weight gain, itself, may start to affect other behaviors. We could say, oversimplifying, that as weight is

Behavior ≠ Behavior ≠ Behavior

"Accidentally" and "intentionally" swinging a hammer are distinguished not by characteristics of the behaviors, per se, but by the patterns of which they are a part, their settings and contexts. The details of the patterns of behavior and their settings are critical; swinging a hammer ≠ swinging a hammer.

In contrast to this emphasis on behaviors being defined by the patterns of which they are a part and the settings and contexts in which they occur, we often read about "medical decision making," "treatment adherence," or "self-management" as if they were unitary behaviors or homogeneous sets of behaviors. To say that adherence = adherence = adherence, regardless of whether the adherence is to a daily aspirin, to a 10-day course of antibiotics, or to a plan to use epi-

continued

nephrine to control anaphylaxis, is similar to saying that swinging a hammer = swinging a hammer, regardless of whether the hammer swinging is part of hanging a picture on a wall or tearing down a wall.

Adhering to daily dental hygiene, taking one's blood pressure pill daily, and adhering to a regimen of stretching before exercise may each fall within some broad category of adherence. However, they are very different patterns of behavior and are carried out in very different contexts with very different discriminative and conditioned stimuli and incentives guiding their performance. If we summarize knowledge about adherence or self-management or other behavioral objectives as if they were unitary actions divorced from their contexts, our knowledge and consequently our interventions will fail to address important characteristics and nuances of them. In behaviorism, this emphasis on the specificity of behavior and its contexts is absolutely fundamental. There may be a few things that different types of decisions have in common, or different types of adherence, or different types of self-management. This, however, cannot be assumed. Rather the determinants of a behavior need to be verified within the particular circumstances in which it is to occur. (See introductory chapter by editors, *infra.*)

gained, the probability of reinforcement from eating is generally maintained, but the probability of reinforcement from other activities declines (e.g., it becomes harder to move about, fatigue may increase, and some social opportunities that depend on feeling comfortable about one's body or being viewed as attractive, may be lessened). Moreover, the more weight is gained, the more this gap increases. Returning to the matching law described earlier, we can substitute the terms eating (E) and other activities (OA) into Eq. 9.1:

$$\frac{B_{\mathrm{E}}}{B_{OA}} = \frac{R_{\mathrm{E}}}{R_{OA}} \tag{9.2}$$

As R_{E} becomes increasingly greater than R_{OA}, the frequency of B_{E} relative to B_{OA} also will increase. This leads to greater weight gain, which further decreases R_{OA} and thereby increases R_{E} relative to R_{OA}. This cycle may then continue in a classic positive feedback loop. Sadly, individuals may reach a point where eating becomes their most valued and one of only very few pleasurable activities, putting them on a very distressing course.

Superimposed on this dynamic evolution of relative incentives for eating and doing other things, there may accrue additional positive and negative reinforcers for being overweight. First, there may be physical tasks that cannot be performed. If mowing the lawn becomes a major undertaking, then someone else in the family is likely to be mowing the lawn, negatively reinforcing the pattern of obesity. Inactivity or sloth is strongly disapproved in many societies. But a thin, able-bodied teenager doing little all day but watching television is likely to be perceived as more socially deviant or even hostile than an obese teenager doing the same thing. For obese people of any age, along with social disapproval, many cultures may provide a certain measure of social accommodation. If sufficient weight is lost and it changes the reactions and expectations of others, then a formally obese person might feel the loss of that accommodation.

Another source of negative reinforcement may stem from the social effects of obesity. Nearly every teenager is nervous about the introductions to the opposite sex provided by their culture, whether dances at schools or meetings arranged by families. But there often are sufficient social forces to overcome that obstacle. For an obese teenager, however, such countervailing forces may be relaxed, the dance missed, and the evening spent watching television. Additionally, in cultures in which physical attractiveness is endorsed as a contributor to romantic choices, obesity may reduce attractiveness, thereby reducing the long-term consequences of romantic relationships but, in the short run, negatively reinforcing obesity by providing escape from the stressors of early negotiation of such relationships. Turning to possible positive reinforcement, the obese teenager, boy or girl, is less of a threat to other teenagers of the same sex and therefore may find it easier than would a non-obese teenager to develop same-sex friendships.

Weight Control Should Precede Weight Reduction

As noted earlier, there is a natural tendency among pigeons, rats, and people to increase behavioral variability when things are not going well (e.g., during extinction). This tendency serves us well in most real-life situations – as it has served our ancestors. The general term for such a strategy, built into all of us, is "win-stay, lose-shift" (Levine, 1959, 1994). As long as things go well, keep doing what you were doing; as soon as things start going badly, increase the variability of your behavior by trying something else. Reinforcement determines which behaviors survive and which are extinguished. In order for reinforcement to work, however, behavior has to vary.

This tendency toward variable responding extends to eating. If things start going badly in life (as they inevitably do for all of us at some time), our natural tendency will be to increase the rate of other valued acts that, for many of us, include eating. This propensity toward variability in responding may explain an important characteristic of the literature on weight loss. People seem much more adept at weight loss (restricting their eating for relatively limited periods of time), than they are at weight maintenance (minimizing variability in their eating over extended periods of time).

The problem with losing weight first and then trying to maintain it is that reaching one's goal weight is the most vulnerable point of weight control. One must increase caloric intake modestly so as to stop losing weight, but not so much more as to gain weight. If one waits until a goal weight has been achieved, it is likely that weight regain will happen before a pattern of weight-maintenance eating is established. The result may then be "win-stay, lose-shift" with frustration, further weight gain, etc. Focusing first on the relatively easy weight loss and then regaining during the relatively more difficult weight maintenance leads to the "merry go 'round" of weight loss, weight regain, weight loss, and so on that is indeed a common pattern.

Weight reduction and weight maintenance constitute a sequence, much like a chain schedule of reinforcement. Usually it is a good idea to begin training with such schedules with the final link first. If you want to train your dog to fetch your slippers and then drop them in front of you, you should first train your dog to drop the slippers, and only after that has been learned, to fetch them. Similarly, after individuals have learned to maintain their weight within a given range, it will be easier for them to reduce their weight and then maintain it within the new range than it would be to learn to maintain their weight only after reducing it. In fact, once having developed reliable patterns of weight maintenance, the individual can titrate these strategically, generally maintaining regular consumption around, perhaps, cultural or religious holidays and then reducing consumption to lose a few pounds that may have been gained. This is reflected in studies of those who have maintained weight loss for extended periods of time. They tend to report regular monitoring of their weight and quick response to weight gain (Wing, Tate, et al., 2006).

The essence of this message is not to add or take away behaviors, but to reduce their variability. Dietitians assert that "anything can be built into a diet," including highly preferred treats or sweets. The problem is not eating some of such foods, but eating highly varying amounts such as in binges. Research with both human and nonhuman subjects (Allen Neuringer, 2004) has found that a pattern of reduction in variability of behavior may be explicitly reinforced. So, we can look at low variability itself as a feature of patterns of behavior to be reinforced.

Weight Maintenance Is a Lifetime Project

The plentiful availability of food in many segments of society, together with our inheritance of eating patterns appropriate for the environment of scarcity faced by our ancestors, impose problems for all of us. Let us again consider the differences between maintaining one's weight and maintaining nonsmoking. The individual who has not had a cigarette for over a year or so (for some it can take considerably longer) is usually able to relax about smoking in day-to-day activities. This person may need to be careful around high-risk situations, such as a stressful interaction at work or perhaps celebrating with alcohol and with friends who smoke, but most hours of most days, there is little need to do very much to stay off cigarettes. In contrast, maintaining weight loss requires many choices of the right food throughout the day for the rest of one's life. The decisions may eventually become almost automatic, but they still need to be made, and the unhealthy choices (e.g., eating too much, poor food choices, etc.) are almost always present and occasionally reintroduced such as on holidays, birthdays, and family celebrations.

Habits, Both Bad and Good, Are Situation Bound

Heroin addiction was very common among American soldiers in Vietnam. When the war ended, officials became concerned that the returning soldiers would bring their drug habits home with them, but, surprisingly, this did not happen (Robins, 1993). For most soldiers, the contexts (e.g., stimulus control, reinforcement contingencies) provided by army life in Vietnam and life in the United States were very different.

In the area of weight control, it is common that people who may have trouble controlling their eating under normal conditions nonetheless control it on religious fast days such as during Yom Kippur, Lent, or Ramadan. The special conditions of the holiday isolate it from the rest of life, and reinforcement differs in different contexts signaled by different discriminative stimuli. In weight control, this specificity of reinforcement to discriminative stimuli is both a disadvantage and an advantage. The advantage is that, by following rules for a time, we can change the relations between cues and eating and establish patterns of healthy eating. This can be done in two ways. First, by practicing healthy eating at regular meal times and in a room for eating (and not, for example, in front of the television set), those cues come to be associated with healthy eating. Second, by eliminating eating from other situations (such as while working or perhaps driving in a car), those situations are extinguished as cues for eating, and desires to eat in them are lessened. By following such rules for a few weeks, the healthier eating habits become conditioned and the patterns they comprise become increasingly more automatic. As a wise dietitian, Dr. Ruth Brennan, once put it to EF, “It's not what you eat between Christmas and New Year's; it's what you eat between New Year's and Christmas.”

In addition to the situational cues for eating, we carry around with us a set of cues from one environment to another within our own bodies; sooner or later we get hungry wherever we are. For many of us, “junk food” is almost always available. Eating unhealthy food in response to such hunger cues may then carry over into new situations under the discriminative control of those hunger cues.

Negative and Positive Addictions

The economists Stigler and Becker (1977) distinguish between negative and positive addictions (Stigler & Becker, 1977). Negative addictions are often the ones we identify as addictive or unhealthy, such as smoking cigarettes, drinking alcohol, taking heroin or cocaine, or overeating. Beyond a certain point, the more you smoke, drink, take heroin, overeat, etc., the worse your health gets, the more you feel disapproval from others, the worse your social life gets, the worse your job performance gets, and, as we have discussed in terms of the matching law, the more you may have to rely on the negative addiction as a source of pleasure. There is another crucial theoretical property of negative addictions: As their rate increases, tolerance builds up. The defining property of a negative addiction is that the higher its rate, the less reinforcing or valuable each marginal unit of consumption. The more you drink, the less reinforcing a single drink.

Positive addictions, on the other hand, are activities that many people spend a lot of time doing but usually do not identify as addictions. Positive addictions such as physical exercise, social activity, reading serious literature, listening to classical music, stamp collecting, or doing crossword puzzles are generally considered to be good for an individual. For Stigler and Becker (1977), the crucial property of positive addictions is the opposite to tolerance: The more one engages in the addictive activity, the more satisfying it becomes. The more proficient we become at playing a musical instrument, the more satisfying each "unit of consumption" is each time we play a song. The healthier one becomes, the more a morning walk or yoga becomes enjoyable.

Imagine Ralph existing in a world where the only activities available are positive and negative addictions. To make the illustration still simpler, let us represent the group of negative addictions by a single one, overeating, and the group of positive addictions by a single one, exercising. Ralph's world is so constrained that during his waking hours, when he's not eating, he's exercising, and when he's not exercising, he's eating; if he spends 90% of his time eating, he must spend 10% exercising; if he spends 60% of his time exercising, he must spend 40% eating.

For this hypothetical situation, let us stipulate that at every combination of eating and exercise, from 20:80 to 50:50 to 90:10, the marginal value of eating (the value of the very next unit of it) is higher than the marginal value of exercise. This immediate preference applies all of the time, whatever the overall ratio.

Because eating is a negative addiction, as it increases, the value of each unit of food decreases. To keep the total value of eating at a high level, Ralph has to eat more and more. If he eats more and more, he will be exercising less and less. Compounding this, because exercising is a positive addiction, as he exercises less and less, the value of each unit of exercise decreases. The less

Setting and Following Rules

Several times, we have talked about how people can commit themselves to following a particular rule or plan. The reader may wonder whether this is really behaviorism. It seems to suggest that, independent of all the conditions influencing their behavior, people can just decide to do something and proceed with it, determined only by that decision.

We can think of rules as discriminative stimuli that emerge in our own behavior. Recall the complex chains of behaviors and stimuli we discussed in the case of cigarette smoking in which, say, the behavior of sitting down to relax becomes, itself, a discriminative stimulus for reaching for a cigarette. From a teleological behavioral perspective, the patterns of behavior under the control of discriminative stimuli like rules, commitments, or to-do lists are patterns of behavior that some of us have learned better than others. That is, some of us have learned to conform our behavior to the "do list" we write in the morning, just as almost all of us have learned to conform our driving to a red light. That we wrote the "do list" and the government installed the red light does not alter the fact that, once they exist, both influence behavior by their relationship with overall probabilities of consequences, even though a single violation of either may often have no immediate consequence. That setting and following our own rules is something we learn can be seen in the fact that different people are better at different rules and commitments. The accountant may be very good at abiding by commitments to update records before the end of each business day. The professional athlete who extends her career past the age of 40 may be very good at keeping the commitment to daily conditioning, sleep, and healthy diet. So, returning to the example, some of us may have learned to do things like "not letting myself take a break until I have worked for 1 h." The difference here is not one of internal fortitude, but of what patterns we have learned.

time Ralph spends playing basketball, the worse his fitness and skill, the more effortful and the less fun playing basketball becomes. Thus, the more Ralph eats, the worse both eating and exercise become. Not only does his long-term health and happiness decrease, but the immediate pleasures he gets from both eating and exercise decrease as well – going down in parallel.

Although the hypothetical example for Ralph is extreme, one can easily imagine similar patterns in real life as eating commands more and more time and attention, leaving less time for other reinforcing activities, which then become less and less pleasurable. A similar dynamic may play out in drinking alcohol, as drinking more becomes necessary to gain pleasure, resulting however in less time and attention devoted to other, positive addictions which then become less and less pleasurable.

You may well ask: If this theory is true, why are we not all addicts? If the marginal utility of the negative addiction is always higher than that of the positive addiction, then how can positive addictions gain a foothold in competition with negative addictions? The answer is that if we have grown up in environments in which longer-term rewards are reliably delivered and in which we have been constrained by parents and other social influences from choosing the immediate pleasure, our choices have become patterns under the control of the overall ratio of good to negative consequences they yield. To some extent, we all have developed such patterns. Otherwise we might never get out of bed in the morning. But, as beneficial options become more and more abstract and spread out over time, they become less likely to gain control over our choices.

Economic Substitutability and Positive and Negative Addictions

Are there positive addictions that substitute for negative addictions? Surprisingly, there are. Considerable evidence exists that, as discussed earlier, social support may substitute for cigarette smoking and heroin and cocaine consumption (Green & Fisher, 2000). Another likely candidate for a substitute for overeating is exercise. That is, overeating and exercising may share some common reinforcers that support one substituting for the other. From this perspective, the effectiveness of exercise in weight control may lie not so much in the calories exercising consumes but in its economic substitutability for overeating.

Exercise has the further advantage over social activity as a substitute for eating in that our social system does not impose a degree of complementarity on exercise and eating. It is easy – in fact almost necessary – to eat while socializing in our society, but difficult to eat while swimming, riding a bicycle, or playing basketball. This constitutes some theoretical support for the common wisdom that an exercise program should be an important part of any weight control program. But if the effectiveness of exercise lies more in its substitutability for eating than directly in calorie reduction, there is a reason to include training in other positive addictions (music appreciation, playing a musical instrument, reading literature, collecting stamps or baseball cards, playing chess or computer games, calligraphy) as well as social skills as part of weight control programs.

Most weight loss or weight management programs begin with people monitoring their eating and looking for ways to eliminate harmful patterns, while learning key features of a healthy diet and trying to increase these. The ideas outlined here suggest a very different way of beginning a weight management program. Because of the need to find economic substitutes for highly pleasurable eating patterns, often those that are especially pleasurable in circumstances of stress or distress, the Teleological Weight Management program might begin by assigning participants the task of developing a new or cultivating an existing positive addiction that would substitute for eating. This would be a primary resource for circumstances in which unhealthy patterns are provoked by the stressors of (most people's) daily life. The criteria for selecting such a substitute would be that it will be reliably pleasurable to the individual and not harmful or unhealthy. It would not need to be especially healthy but, so that it might work as a substitute for unhealthy eating, it would need to be convenient in most all circumstances of daily life.

Also, as a first step and recognizing the centrality not of weight loss but of weigh maintenance, participants would monitor their diet and learn how to maintain their weight. With that skill in place, it may be *relatively* easy to reduce consumption for a period of time so as to lose some weight and then return to maintenance. This combination of positively addictive substitutes for harmful eating patterns and weight maintenance punctuated by periods of caloric restriction to reduce weight might offer new approaches for long-term patterns of healthy eating and weight maintenance.

Conclusions: From Behaviorism to Behavioral Medicine to Public Health

There is a fundamental compatibility between the behavioral perspective that is so important to and essential in the origin of behavioral medicine, and an ecological perspective that has achieved prominence in much of behavioral and social science and public health. As depicted in Fig. 9.7, both behavioral and ecological perspectives share an emphasis on contexts, be they termed "stimuli," "reinforcers," "setting events," "experience," "learning history," "ecological layers," or "social, cultural, community, economic, and policy influences."

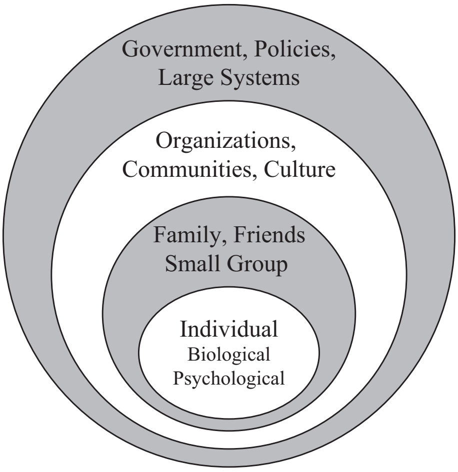

Fig. 9.7 Ecological model of health behavior

In ecological approaches (McLeroy, Bibeau, & Steckler, 1988; Stokols, 1992), the behavior of the individual is viewed as guided by layers of influences, including the family, proximal social influences such as social networks and neighborhoods, organizational influences such as worksite and community systems and healthcare systems, and larger social influences such as government, policy, and large economic structures. Different models may specify different layers of influence and different components of each, but they share two important emphases: (1) that the behavior of the individual reflects the influence of all the layers and (2) that the layers interact in their influence so that, for example, communities may influence families and families may also influence communities.

Both behavioral and ecological perspectives share an emphasis on how experience across a wide array of settings shapes behavior. Ecological perspectives add attention to how organizational and policy levels provide structure to the more immediate settings – the stimuli and reinforcers – that organize individual experience. Both also share the assumption that the same approaches to analyzing individual behavior can be applied to the behavior of larger social units such as groups or organizations and the ways they are influenced by *their* environments.

There is a practicality to the emphases placed by both behavioral and ecologic perspectives on the contexts that surround individuals. Both focus interventions on that which can be directly measured and manipulated. Whether it is the social network or community-based organization and health campaign, or individual coaching to establish patterns of self-control around diet, programs driven by ecological and behavioral perspectives focus on things that are "actionable." For behaviorism, this reflects the philosophical rejection of inferred, intraindividual constructs like intention and willpower. For ecological perspectives, it may be more of an emphasis on the contextual rings around the individual rather than inferred psychological structures within the individual.

Both reject the "victim blaming" attribution of chronic, harmful patterns of behavior to some stable, psychological characteristics of the individual without reference to the contexts that led to the development of those behavior patterns.

In *Science and Human Behavior*, Skinner (1953) addressed the broader influences on individual behavior that the ecological perspective emphasizes (Skinner, 1953). There he extended the fundamental principles of behaviorism to the understanding of large patterns of behavior like religion and the behavior of social groups. For example, in talking about how environmental influences shape the god/father metaphor in religious practice, Skinner argued that the emphasis on god/father as the source of protection reflected reinforcement contingencies operating on religious organizations. He argued that the financial support and loyalty of adherents to a religious group reinforces its development of effective metaphors for gaining influence over those adherents. The metaphor of god/father persists because it works, because this behavior of the organized religion is reinforced by the support of the adherents it draws. Without using the term "ecological," Skinner clearly wrote in its spirit, showing how events at different ecological levels might reinforce each other.

Many who embrace an ecological perspective nevertheless reject behaviorism as mechanistic, suggesting it treats individuals as objects. (For examples of misrepresentation and misunderstanding of behaviorism's and Skinner's views, see, e.g., Dinsmoor, 1992; Todd & Morris, 1983, 1992). This may rest on rhetorical confusion rather than substantive disagreement. In his provocatively titled book, *Beyond Freedom and Dignity*, Skinner (1971) argued that the "myths" of "freedom" and "dignity" as intrinsic human characteristics encourage policies that hold the individual responsible for her or his behavior, an attributive tendency much akin to victim blaming. At the same time, Skinner argued that these myths distract our institutions, government, and culture from more effective approaches to promoting healthy and adaptive behavior. From the perspective of creating interventions to advance human progress and quality of life, Skinner argued that we must recognize that humans are not intrinsically free and autonomous. The key issue then is not assuming that freedom and autonomy are automatic, but providing interventions and developing environments that promote the skills and behaviors that make people feel free and dignified. Perhaps rapprochement lies in shared objectives of people being treated with dignity and feeling free, not an assumption that freedom and dignity are guaranteed by human nature.

"Control" is sometimes the sticking point. Skinner talked about being able to control behavior for the good of the individual and the group and society. The usage, even in work intended to emphasize the role of the individual (such as the book title *Self-Control: Power to the Person*; Mahoney & Thoresen, 1974), seems, from the perspective of twenty-first-century empowerment, to impose something of an authoritarian cast on what we more commonly now refer to as "self-management." In their early extensions of Skinner's work to clinical and community applications, Krasner and Ullmann (1973) recognized that all control is partial and multiply determined, and so they titled their book *Behavior Influence and Personality: The Social Matrix of Human Action*, anticipating much of the integration of behaviorism with broad social influences and patterns of behavior, as emphasized here. From all these perspectives, "control" appears to be just an oversimplification. We are talking about very complex varieties of "influence."

In the twentieth century, behaviorism provided concepts for understanding how the circumstances that surround the individual shape and guide behavior, including behaviors of great significance for one's health. Evolution of behaviorism into behavioral economics and teleological behaviorism of the late twentieth and twenty-first centuries emphasize the relationships among patterns of different behaviors and the contexts that surround them. Key among these are the ways in which different behaviors and contexts – sometimes very different behaviors and contexts as in the case of cigarette smoking and social support – may interact and how understanding these relations can inform prevention and improve care. The concepts and findings of behaviorism and behavioral economics are fully compatible with the contextual emphases of ecological perspectives. Indeed, behavioral models may be thought of as providing the fundamental building blocks from which ecological models emerge. Key to both models, and for a humane practice of behavioral medicine, is recognizing the essential functionality or rationality of an individual's behaviors when understood in the contexts from which the behaviors have arisen.

Finally, behavioral economics and teleological behaviorism emphasize a number of linkages. Finite resources, whether dollars, Euros, RMB, or hours in a day, link behaviors so that allocation of resources to one at some point limits allocation to others. Substitutability and complementarity help us understand how some behaviors promote each other and others may tend to lessen each other. The matching law along with concepts of positive and negative addictions help us understand how investments of our time and energy in one pattern of behavior may influence opportunities in other areas of our lives. The patterns of behavior that are the focus of teleological behaviorism help us understand how coherence among the many actions that comprise playing the piano, conducting a community meeting, or writing a chapter may be shaped by the molar consequences of those patterns. So, too, ecological perspectives help us understand the linkages among policies, organizations, communities, families, and individuals, how working at any one of these levels is likely to influence and then, reciprocally, be influenced by the others. Recent developments such as in epigenetics and environment X gene interaction emphasize further the failure of essentialist or reductionist models in illuminating the complexity of lives. The integration of behavioral and ecological approaches, encouraged by their shared emphases on contexts and connections among contexts, may provide an ecological behaviorism to guide future work in behavioral medicine and public health.

Genetics, Behavior, and Behavior-Genetic Interactions in Health Risk

10

Jana Strahler*, Anett Mueller-Alcazar*, and Urs M. Nater

Knowledge about the genetic determinants of both health and disease has the potential to improve the diagnosis, treatment, and prevention of many illnesses. While the role of heredity has long been recognized in the study of illnesses, current research is aiming to gain a better understanding of the human genome. This first section of the chapter reviews key features of modern genetics and its development. Table 10.1 provides key definitions and terminology. Included terms are underlined at their first mention throughout this chapter.

Modern genetic research essentially began in 1866, and mainly focused on Mendel's law (after Gregor Mendel, the "father of modern genetics") and the so-called Mendelian diseases, which, according to Mendel's laws, are regulated by a single gene and passed on from one generation to the next. In particular, geneticists attempted to correlate Mendelian diseases (examples of these are Huntington's disease, cystic fibrosis, or sickle cell anemia) with genetic variants or markers with the help of so-called linkage analyses. Linkage studies basically illustrate the co-inheritance of marker alleles and specific traits within families. In 1869, the physician Johannes Friedrich Miescher successfully isolated nucleic acids – the active ingredient of the then unknown deoxyribonucleic acid (DNA). A further milestone was reached in 1875, when Francis Galton conducted the first twin studies. In 1941, the geneticists Edward Tatum and George Beadle published a work revealing that genes[1] code for proteins, explaining for the first time how genes are able to direct metabolic processes in cells. Shortly thereafter, in 1944, Oswald Theodore Avery discovered the material from which genes and chromosomes are made: DNA. In a major development of this history, James Watson and Francis Crick were the first to describe the iconic double helix shape of the DNA in 1953, which was based on the work of Rosalind Franklin and other scientists. In 1962, they received the Nobel Prize in Physiology or Medicine, jointly with Maurice Wilkins, for this discovery.

The next aim of many scientists was then to completely decode the human genome. Beginning

---

*Jana Strahler and Anett Mueller-Alcazar authors contributed equally.

[1] The most recent gene definition is conceptualized as follows: "The gene is a union of genomic sequences encoding a coherent set of potentially overlapping functional products" (Gerstein, Bruce, et al., 2007).

Table 10.1 Key definitions and terminology

Term	Short description	An example	Cross reference
Additive genetic component	The effect of one allele on another allele at the same genetic locus	If two alleles are codominant, then the heterozygote is exactly intermediate in phenotype relative to the two homozygous types	Allele; locus (include cross reference to other terms in the table)
Allele	One of several alternative forms of a gene or DNA sequence at a specific chromosomal location (locus); produce variations in a genetically inherited trait	Different alleles produce different hair colors (brown, blond, red, black, etc.)	DNA; locus
Allele frequency	The proportion of a particular allele among the chromosomes carried by individuals in a population	In Caucasian populations, the frequency for the serotonin transporter polymorphism (5-HTTLPR) is about 40% for the L allele and about 60% for the S allele, respectively	Allele; chromosome
Autosome	Any chromosome other than the sex chromosomes (X and Y)	Humans have 22 pairs of autosomes, which are numbered according to their sizes, i.e., the higher the number of genes the lower the number. Chromosomal anomalies typically result in miscarriage early in pregnancy. One exception is, e.g., Down syndrome (tripling of chromosome 21)	Chromosome
Base pair	Two complementary nucleotides joined by hydrogen bonds	Base pairing occurs between A and T and between G and C	Nucleotide
Candidate gene	Due to its location on a chromosome that was found to be associated with a disease, this gene is assumed to cause the disease	The 44 base pair insertion/deletion polymorphism in the promoter region of the serotonin transporter gene associated with altered transporter expression and serotonin uptake	
Carrier	An individual who has one nonfunctioning gene for a recessive disorder can transmit that gene to his or her offspring	The human blood type AB presents an example of allele codominance because the allele IA and IB are both expressed and contribute to the phenotype (blood group AB)	Gene; recessive
Chromatin	The complex of DNA, RNA, and proteins that makes up uncondensed eukaryotic chromosomes		Chromosome; DNA; RNA
Chromatid	One of the two halves of a duplicated chromosome; each chromatid contains a complete double helix, and the two are exact copies of each other		Chromosome; double helix
Chromosome	Structures within the nucleus of eukaryotic cells composed of chromatin and visible at cell division (condensed chromatin)		Chromatin
Codon	A nucleotide triplet that specifies an amino acid or a translation stop signal	Examples for start codon: AUG, ATG Examples for stop codon: UGA, UAG	Nucleotide; triplet
Crossover or crossing over	The breaking and rejoining of homologous chromatids during early prophase I of meiosis, resulting in recombination		Chromatid; recombination

Deletion	The removal of one or more nucleotides from the DNA	ABC → AC Williams syndrome [neurodevelopmental disorder, "elfin" face] results from a deletion of medium size on chromosome 7. Other examples are cystic fibrosis or certain bowel cancers	DNA; nucleotide
Dizygotic or fraternal twins	Derived from two separate ova, thus not identical twins		
Deoxyribonucleic acid (DNA)	Carrier of the genetic information of organisms, usually double stranded DNA consists of a class of nucleic acids identified by the presence of deoxyribose, a sugar, and the four nucleobases		Nucleic acids; nucleobase
Dominance	The interaction of genes that are on the same allele, with one gene being dominant	Allele "A" is dominant over the "a" allele	Epistasis
Dominant	(In human genetics) Describes any trait that is expressed in a heterozygote	For a dominant disorder, one gene functioning abnormally is sufficient to cause the disorder, as in Marfan's syndrome or Huntington's disease. The dominant eye color is brown	Heterozygote
Double helix	The shape that two linear strands of DNA assume when bonded together		DNA
Endophenotype	Endophenotypes are internal phenotypes that can be discovered by a biochemical test or microscopic examination and have emerged as an important concept in the study of complex neuropsychiatric diseases	An endophenotype may be neurophysiological, biochemical, endocrinological, neuroanatomical, cognitive, or neuropsychological in nature such as the stress response measured by cortisol	
Epigenetics	Changes in gene expression that can also be inherited transgenerationally (from mother cell to daughter cell, or sometimes from parent to child), but are not produced by a change in DNA sequence	DNA methylation is the best understood epigenetic mechanism. Acetaldehyde, the conversion product of ethanol, has the potential to interrupt the methylation of histones relevant for gene expression. This might have implications during early prenatal organ development	DNA
Epistasis	The interaction of genes that are not alleles, in particular, the suppression of the effect of one such gene by another	Influence of gene B over gene A Two genes are responsible for the coat color of Labradors. One gene controls the color, and the other gene determines whether the color is expressed (i.e., the pigments are deposited in the coat)	Allele; gene
Gene expression	The process by which the information from a gene is translated into a functional gene product. The sequence is read in groups of three base pairs (codon) that correspond to one amino acid		Codon; nucleotide; nucleic acid; methylation
Gene mapping	Determination of the relative positions of genes on a DNA molecule (chromosome or plasmid) and of the distance, in linkage units or physical units, between them	Maps guide research to hypothesized genes impacting common disorders like diabetes, heart disease, and psychiatric conditions	DNA; chromosome; linkage

(continued)

Table 10.1 (continued)

Term	Short description	An example	Cross reference
Genome	All the genetic material in the chromosomes of a particular organism For the human genome, the set of different DNA molecules comprises 25 different DNA molecules	The first complete human genome was published after 13 years of work in 2003 by the Human Genome Project (today it takes only 1 or 2 days)	Chromosome; HGP
Genome-wide association studies (GWAS)	Platforms to genotype individuals for very large numbers of variants across the whole genome	GWAS (>100,000 SNPs) are recorded in the Catalog of Published Genome-Wide Association Studies of the National Human Genome Research Institute (http://www.genome.gov/gwastudies/)	Genome; genotype
Genotype	The genetic constitution of an individual, either overall or at a specific locus as characterized by its physical appearance or phenotype		Allele; locus; phenotype
Haplotype	A series of alleles found at linked loci on a single chromosome that tend to be inherited together This term can also refer to a cluster of single nucleotide polymorphisms (SNPs) that are generally inherited together	The International HapMap Project aims to identify patterns of SNP groups (= haplotypes or haps) describing patterns of genetic variation in human disease and response to pharmaceuticals	Allele; chromosome; SNP
Heredity	The transmission of characteristics from one generation to the next	E.g., the ability to curl the tongue	
Heritability	The proportion of the causation of a character or trait that is due to genetic causes	Highest heritability estimates have been found for body mass index (0.6–0.9)	
Heterozygote	An individual is heterozygous at a locus if he/she has two different alleles at that locus	Aa	Allele; locus
Homozygous	An individual is homozygous at a locus if he/she has two identical alleles at that locus	AA or aa	Allele; locus
Human Genome Project (HGP)	Scientific research project to identify all of the approximately 20,000–25,000 genes in human DNA and, furthermore, to determine the sequences of the three billion chemical base pairs that make up human DNA		Base pair; DNA; gene
Insertion	Adding of one or more extra nucleotides into the DNA	ABC → ABDC The fragile X syndrome and Huntington's disease are caused by a mutation in which a certain DNA segment is repeated	DNA; nucleotide
Linkage	The tendency of genes or other DNA sequences at specific loci to be inherited together as a consequence of their physical proximity on a single chromosome	A classic example of linkage-analysis-based disease gene identification is the gene responsible for cystic fibrosis	DNA; chromosome; locus
Linkage disequilibrium	Particular alleles at two or more neighboring loci show allelic association if they occur together with frequencies significantly different from those predicted from the individual allele frequencies	While linkage describes the physical linkage of two or more loci, LD describes the statistical association between two or more loci	Allele; locus; linkage
Locus	The specific physical location defining the position of an individual gene or DNA sequence	The chromosomal locus of the serotonin transporter gene (SLC6A4) is 17q11.2, with 17 indicating the chromosome number, q indicating the long arm, and 11.2 representing the position on the arm: region 1, band 1, sub-band 2	DNA; gene

(Genetic) marker	A genetic marker is a gene or short sequence of DNA used to identify a chromosome or to locate other genes on a genetic map	Two genetic markers associated with sensitivity to estrogen alterations after birth predict postpartum depression with high accuracy	DNA; gene mapping
Mendelian principles/laws	Gregor Mendel described three principles/laws, which he summarized from his extensive experiments studying the patterns of heredity for acquired characteristics	Three Mendelian principles: Law of uniformity, law of segregation, law of independent assortment	
Methylation	DNA methylation is one of several epigenetic mechanisms that cells use to control gene expression. During methylation, a methyl group is added to a substrate. This generally leads to silencing of the gene's transcriptional activity; the gene is "switched off"	Methylation of tumor suppressor genes has been linked to heightened tumor activity due to their transcriptional silencing	DNA; epigenetic
(DNA) Microarray	Thousands of genes (in known locations) are placed on a glass slide called a gene chip. A DNA or RNA sample is added, and complementary base pairing produces light that can be measured	Affymetrix, Agilent, Exiqon, Illumina (in alphabetical order)	Pathway analysis
Monozygotic or identical twins	Derived from a single ovum, thus identical twins		
Mutation	A permanent, heritable change in the DNA sequence of a particular gene	A substitution in the beta-hemoglobin gene causes sickle cell anemia	DNA; gene
Nonallelic genes	Genes located at different loci on the same chromosome or on different chromosomes. Altogether, they influence the phenotype	Individuals lacking a protein called the H antigen (absent fucose transferase) appear to have blood group O even if they have the A and/or B genes, the Bombay phenotype	Epistasis
Noncoding DNA	Sequences of DNA that do not code for amino acids lying either between or within (introns) genes	The ENCODE project, which started in 2012, looks into this "junk DNA" constituting about 98% of human DNA	DNA
Nucleic acid	A large molecule composed of nucleotide subunits	Deoxyribonucleic acid (DNA), ribonucleic acid (RNA)	Nucleotide; DNA; RNA
Nucleotide	A unit of nucleic acid composed of phosphate, ribose or deoxyribose, and a purine or pyrimidine base	Nucleoside + phosphate group → nucleotide	Nucleic acid
Pathway analysis	A set or network of genes that is actually expressed at a specific time point		
Phenotype	The observable characteristics (physical or chemical expression) of an organism's genes, including the result of any test that is not a direct test of the genotype	E.g., the color of eyes and hair	Genotype
Pleiotropy	The production by a single gene of two or more apparently unrelated effects	Mutations in the gene coding for phenylalanine hydroxylase result in phenylketonuria characterized by mental retardation, reduced pigmentation of skin and hair, and seizures	Gene
Polygene	A gene whose individual effect on a phenotype is too small to be observed but which can act together with others to produce observable variation	Testosterone regulates the development of what are referred to as secondary sexual characteristics (e.g., a lion's mane); however, testosterone also relates to behavioral traits like aggression	Gene; phenotype

(continued)

Table 10.1 (continued)

Term	Short description	An example	Cross reference
Polygenic	Of, relating to, or determined by polygenes	E.g., height, skin color	Polygene
Polymorphism	Genetic variations in DNA sequence among individuals occurring in more than 1% of a population	E.g., Single nucleotide polymorphism (SNP), copy number variations (CNV), insertion/deletion, variable number of tandem repeats (VNTR)	DNA; SNP; copy number variations
Protein	A large molecule composed of one or more chains of amino acids in a specific order, which is determined by the base sequence of nucleotides in the gene coding for the protein Proteins are required for the structure, function, and regulation of the body cells, tissues, and organs, and each protein has unique functions	E.g., enzymes, hormones	Nucleotides
Quantitative trait loci (QTL)	A locus important in determining the phenotype of a continuous character	QTL analysis links genotypic and phenotypic data	Locus; phenotype
Recessive	A character is recessive if it manifests only in the homozygote	E.g., Cystic fibrosis, sickle cell anemia. Recessive eye colors are blue, grey, and green	Homozygote
Recombination	The exchange of genetic material between chromosomes during meiosis	The construction of immunoglobulin genes is the result of recombination	Chromosome; mutation; crossover
Ribonucleic acid (RNA)	A chemical found in the nucleus and cytoplasm of cells, which plays an important role in protein synthesis, and other chemical activities of the cell. The structure of RNA is similar to that of DNA but only consists of one strand with its main function of translating DNA into protein	There are several classes of RNA: messenger RNA (mRNA), transfer RNA (tRNA), ribosomal RNA (rRNA), and micro RNAS (miRNA), each serving a different purpose	DNA
Sex chromosome	Sex chromosomes (humans have two: X and Y) determine sex. A fetus with two X chromosomes becomes a biological female, while male fetuses have both the X and Y chromosome in their cells	Anomalies in the number of sex chromosomes are typically associated with sterility and infertility, and underdevelopment of sexual characteristics, e.g., the Klinefelter syndrome (XXY) or the Turner syndrome (X)	Autosome
SNP (single nucleotide polymorphism)	Any polymorphic variation at a single nucleotide, which make up about 90% of all human genetic variation. SNPs occur every 100–300 bases along the human genome	In addition to the variants (S and L alleles) of the serotonin-transporter-linked promoter region (5-HTTLPR) of the serotonin transporter gene (SLC6A4), there is also an A > G SNP upstream of the repetitive region that comprises the 5-HTTLPR, which shows a functional significance of this marker	Genome; nucleotide
Transcription factor	Proteins that recognize specific DNA sequences and control the transcription of these sequences to messenger RNA, i.e., controlling which genes are turned on or off. Approximately 3000 transcription factors are expressed in humans	Heat shock factor, transcriptions factors regulating the expression of the heat shock proteins that are involved in the cells' response to elevated temperatures	DNA; RNA
Triplet	A unit of three successive nucleotides (or nucleotide bases) in a molecule of DNA or RNA that codes for a specific amino acid and forms our genetic code, called codon	There are 64 different codon combinations (4 nucleobases) but only 20 amino acids; some code for the same acid, and some code for "start" and "stop" signals	DNA; nucleotide; RNA
Zygote	The fertilized egg cell		

in 1990, the Human Genome Project finished the first complete sequencing of the human genome in 2003. Interestingly, this project determined only 20,000 protein-coding genes, constituting only 2% of the total genomic sequence. The remaining 98% are not protein coding and are part of a complex network of transcription factors including, for example, long noncoding ribonucleic acid (RNA; Mercer, Dinger, & Mattick, 2009) or miRNA (see below). Not long after the Human Genome Project, the International Haplotype Map (HapMap) project of the human genome began, aiming to identify and catalogue genetic similarities and differences in human beings. HapMap was conceived to serve as a resource for researchers, enabling them to find genes that affect health, disease, and individual responses to medications and environmental factors. The complete data set was published in 2009. The ENCODE project, which began in 2012, investigates "junk DNA," i.e., the noncoding regions of the genome outside the genes which might also play a role in our genetic makeup.

The genome-wide association (GWA) study approach is currently very popular as researchers are able to identify genes, or genetic variations, for complex traits and diseases. With the help of GWAS, markers across complete sets of DNA, or genomes, can be scanned rapidly. Using this approach, participants with a specific disease and those without are investigated to find certain genetic variations that occur significantly more often in people with the disease and can thus be considered "associated" with this particular disease. These are recorded in the Catalog of Published Genome-Wide Association Studies of the National Human Genome Research Institute (http://www.genome.gov/gwastudies/).

All of these latest developments of meaningful tools and contemporary methodological approaches have contributed to the exploration of disease susceptibility genes and have thus impacted the field of behavioral medicine. Despite the accumulation of knowledge on genetic factors in health and disease over the past 150 years, however, a detailed understanding of how genes impact human behavior and experience remains elusive. A critical issue for behavioral medicine is that the field still lacks in-depth knowledge regarding the extent of how variations in specific genes (e.g., polymorphisms) are responsible for individual differences in behavioral characteristics that may be associated with health and illness. As an example, six key observations in genetics can be identified, which may help to further advance behavioral medicine research.

First, identifying genetic determinants of psychological traits may improve our understanding of how such traits develop and manifest. Most conceptualizations of, for example, personality traits are not rooted in biology: For neuroticism, one of the best-researched personality traits, it is shown that about 50% of the variance is attributed to genetics (Loehlin, 1992). Nevertheless, there is evidence that some genes are associated with some personality traits. For instance, Zuckerman's (2005) psychopharmacological model suggests associations of dopamine, serotonin, and noradrenalin with sensation seeking. Second, studies of intelligence and stress illustrate that multiple genes with small effect sizes, so-called quantitative trait loci, may affect any one trait. Thus, any one gene may participate in more than one trait (such as the serotonin polymorphism that has been associated with depression, anxiety, and neuroticism; Caspi, Sugden, et al., 2003; Hariri, Mattay, et al., 2002; Lesch, Bengel, et al., 1996). This kind of polygenic determination of behavior or health states by thousands of genes is much more the norm than the simple models of genetic influence first identified by Mendel. Thus, "finding *the* gene for" some disease is unlikely to be a successful search. Third, environmental variables, for instance, (early) life experience, have the potential to regulate gene expression. The mechanism behind this may involve epigenetic or other regulatory processes, which are still poorly understood. The term epigenetics describes heritable changes in the gene expression, which are not due to any alterations in the DNA sequence. The best-known epigenetic marker is DNA methylation and will be described more detailed later (*see* section "Epigenetics"). Fourth, research suggests that the scale of these epigenetic changes may be very large, thus affecting many hundreds of genes that participate in complex molecular signaling pathways (such as for cancer). Fifth, recent observations on the role of genetic markers in medication responsiveness have the potential to improve individualized treatment of illnesses. Sixth, the observation that there is an extensive range of variations in genes will influence research on protection against and susceptibility to illness and, ultimately, improve prevention.

These observations illustrate the potential impact of genetic findings on research questions relevant for behavioral medicine. This chapter will describe past and current research and highlight starting points for future research in the area of behavioral medicine. The first part of this chapter, which will introduce the key concepts in genetics, will be followed by a second, more extensive part on genetic findings in health research.

The aim of this first section is to provide an overview of the key concepts and approaches in genetics. Individual differences in the development of physiological systems determining our behavioral dispositions are partially dependent on the variation in the genetic code stored in the deoxyribonucleic acid (DNA) molecules of all cell nuclei and mitochondria. In parallel, exposure to various environmental factors such as intrauterine environment (e.g., prenatal stress), early-life development, diet, peer and family attachment, or illnesses influences our behavior as well, particularly when we are genetically susceptible to a specific response to such environmental factors. Genetic and environmental factors may either have independent main effects on the variation in behavioral traits or interact with each other (i.e., gene-environment interaction; see below). The DNA between any two human genomes is almost exactly the same (99.9%), but a difference in the sequence can be detected every 1000 or 1500 base pairs. This difference of 0.1% in the sequence of the DNA is the source of all genetic variation in humans and is responsible for hair color and blood group but also for susceptibility to disease. The human DNA consists of 22 autosomal chromosomal pairs and one pair of sex chromosomes, and both together are termed the *human genome*. In the following, we will discuss genetic variation and behavior with regard to monogenetic vs. polygenetic trait variations, approaches of quantitative vs. qualitative/molecular genetics including gene-environment interaction and epigenetics, and more recent concepts such as genomics and proteomics.

Most human genetic traits, i.e., habitual patterns in an individual's behavior, emotions, and cognitions, can be classified as either monogenetic – that is, determined by only a single gene – or polygenetic (and, thus, complex). While useful, this distinction between monogenetic and complex traits can, however, be overly simplistic. Traits that appear to be monogenetic can also be influenced by a variation in multiple genes, while complex traits can be predominantly influenced by variation in a single gene. Both concepts will now be explained in more detail. We also introduce the terms pleiotropy, which describes the effect of one single gene affecting multiple traits, and quantitative trait loci (QTL), which explains how phenotypic data (such as traits) and genotypic data (such as biological/molecular markers) are linked together via statistical methods.

Basics of Behavioral Medicine

Monogenetic and Polygenetic Trait Variations

Variations in *monogenetic traits* are strongly influenced by variation within a single gene and recognized by their classic patterns of inheritance within families. Monogenetic traits formed the basis for "classic" genetics, and prominent examples are Huntington's disease, cystic fibrosis, and hemophilia. However, it has become clear that this very strict single factor inheritance conforming to Mendelian principles is relatively rare, due to the fact that any genetic variation can result in different isoforms (protein variants with altered functional efficiency). The importance of such variation for the protein function often depends on the position of the variation in the base triplet. A single base substitution (SNP, single nucleotide polymorphism) is the most abundant form of

DNA variation in the human genome. It has been estimated that the entire human population harbors approximately 10 million so-called "common" SNPs, with a minor allele frequency (i.e., the percentage of all living humans that have the rarer nucleotide for this SNP, as opposed to the other, more frequent, nucleotide) of greater than 5% in the human population. A base pair substitution in the first or second position is usually more significant than in the third position of the triplet and can lead to considerable consequences: (1) occurrence of a stop codon (termination of translation), (2) mutations which lead to a shift in the reading frame (disruption of the complete polypeptide sequence after the occurrence of the variation), and (3) insertions or deletions of several base pairs or repeat expansions, which do not have any "normal" function to sequence variability but may lead to the absence of a protein (e.g., as is the case with phenylketonuria, PKU) or the formation of dysfunctional or toxic proteins (e.g., Huntington's disease).

Although functional variation based on protein isoforms is clearly important, it accounts for only a small proportion of the total variation caused by genetic differences. A much larger share of the total variation leads to significant differences in the regulation of gene expression (the synthesis of a functional gene product); this type of variation does not result in a different protein but in an increased or reduced expression of the same protein.

Unlike monogenetic traits, *polygenetic* and, of course, most complex traits do not follow patterns of Mendelian principles and are believed to result from variation within multiple, nonallelic genes and their interaction with behavioral and environmental factors. Usually, these nonallelic genes cannot be precisely localized in the genome or identified. Moreover, these genes typically have a small effect but are large in terms of quantity. Polygenetic traits usually characterize continuous traits such as height or hair color. In contrast, polygenetic examples apply to disruptions in, for example, blood pressure or insulin resistance, leading to hypertension and type 2 diabetes.

Pleiotropy and Quantitative Trait Loci (QTL)

Polygenetic traits should not be confused with the concept of pleiotropy, which occurs when a single gene has an effect on the expression of two or more phenotypic traits. For instance, testosterone controls the development of what are referred to as secondary sexual characteristics, but testosterone is also associated with behavioral traits such as aggression. A gene that controls the levels of testosterone would have a pleiotropic effect, i.e., on the expression of many secondary sexual traits, which can be morphological as well as behavioral in nature. The basic principles of monogenetic effects still apply for polygenetic effects in an extended manner. However, there are numerous traits that are under the influence of a variety of genes, with different allelic effect sizes and allele frequencies. Moreover, nonadditive genetic effects, which are due to dominance and epistasis (the latter describing the event that the expression of one gene is affected by the expression of one or more independently inherited genes) as well as a range of environmental influences, also need to be considered here. In terms of environmental influences, intrauterine environment, diet, climate, parenting style and attachment, peers, diseases and accidents, traumatic events, chronic stress, and many more play a pivotal role for all human traits.

Robert R. Plomin, who set up one of the earliest molecular genetic experiments to look at normal variation in human traits, was the first to describe the principle of quantitative trait loci, a model which attempts to explain the genetic basis of variation in complex traits (Plomin, Owen, & McGuffin, 1994). With this model, he tried to explain variation in human intelligence and outlined the concept of genome-environment correlation (see section "Gene-Environment Interaction").

Quantitative traits refer to phenotypes (or characteristics) that show a discrepancy in terms of degree; they can be ascribed to polygenetic effects and are thus the product of two or more genes and their specific environments. The genetic impact on the development of several personality traits (e.g., neuroticism) has been suggested to reflect the interaction of many common alleles. A single phenotypic trait is generally settled on additive effects of many different single traits; on the other hand, several quantitative trait loci (QTL) are associated with a single trait also. One advantageous methodological tool for statistical genetics is QTL mapping, which is necessary to determine the complexity of the genetic architecture underlying a phenotypic trait. This method requires two strains of organisms that differ genetically regarding a trait of interest. Furthermore, genetic markers that distinguish between the parental lines are needed. QTL mapping can be used to examine whether a phenotype is shaped by many independent loci, or by a few loci, and whether those loci interact. This can provide information on how the phenotype may be evolving. In the latest methodological development, classical QTL analyses are combined with gene expression profiling by DNA microarrays.

Approaches of Quantitative and Molecular Genetics

While quantitative genetics is the study of continuously measured traits (e.g., height or weight) and their mechanisms, the field of molecular genetics makes use of methods of both genetics and molecular biology in order to study the structure and function of genes at a molecular level. Both approaches will be explained in detail below.

Quantitative Genetics

Estimation of Heritability in Humans

A central question in behavioral medicine is whether observed variation in a particular trait is due to environmental or to genetic factors, which is often expressed as the "nature vs. nurture" debate. As we now know that genetic variation in a population can result from a variety of factors, such as mutations in the genome (i.e., variations in the order of bases in the nucleotides) or selection, how can we estimate trait heritability?

Heritability, which is often abbreviated as h^2, is the relative contribution of genetic variation to phenotypic variance due to all additive and dominant genetic factors. It is the proportion of the variance in a trait among individuals, which is attributable to differences in genotype among them. Often, this term is also applied in reference to the resemblance between parents and their offspring. Within this framework, high heritability implies a strong resemblance between parents and offspring regarding a specific trait, while low heritability implies a low level of resemblance between them. Heritability can range between 0.00 (no genetic contribution) and 1.00 (all differences in a trait reflect genetic variation) but can also be described in percentage terms. For human behavior, there is no predetermined number to estimate heritability, but most estimates of heritability are found to lie in a moderate range of 0.30 to 0.60.

Family Studies

One approach to examining heritability is the use of family studies. Such studies serve as a methodological tool for understanding the well-being and healthy development of individuals within their families as well as regarding internal family relations across the whole lifespan. For instance, they examine the familial aggregation of quantitative traits such as blood pressure or insulin resistance and usually include dynamic relations within the family (such as hierarchy dynamics or gender roles) as well as the family's interactions with broader social institutions such as school, university, or workplaces. However, family studies are unable to identify whether an aggregation of a trait or disorder is due to genetic or environmental factors. For example, a high correlation of blood pressure readings among a family may be due to shared genetic characteristics, shared food and exercise patterns, or shared stress patterns, to name only a few.

Twin Studies

Twin studies, which, by definition, study family resemblance, have been and remain a powerful tool in genetics. Monozygotic twins (MZ) develop when a fertilized egg divides before it nestles into the mother's uterus. MZ twins are thought to inherit identical genetic material (i.e., 100% shared genetic material), with the exception of imprinting patterns, i.e., differentially methylated maternal and paternal alleles. By contrast, if there is more than one egg released from the ovaries during the woman's menstrual cycle and different sperms fertilize each egg, the result would be nonidentical twins, also known as dizygotic twins (DZ) or fraternal twins. DZ twins are like regular siblings and, on average, share 50% of their genetic material. When twins are raised together, they share parts of their environment, presumably to the same extent for MZ and DZ. In line, as early as 1869, Sir Francis Galton already pointed out a major shortcoming of such studies: The degree of genetic relatedness can be confounded with the degree of shared family environment. For example, monozygotic twins not only share the same set of genes but may be treated more similarly than dizygotic twins or siblings and may share more features of family environment than siblings born several years apart. A shared environment includes potentially important factors such as parental socioeconomic status (SES), neighborhood, school, sports club, family diet, or parental attitudes and child-rearing style. Galton's solution for separating the genetic and shared environmental effects on the trait resemblance of family was as follows: He set up a study (which he called "a unique experiment of nature") in which he compared monozygotic and dizygotic twins with the goal of looking at both the impact of genes and the impact of environment on human traits. By observing monozygotic twins who are reared together, the impact of environment on interindividual differences is reduced to a minimum, and thus the impact of genes can be calculated accordingly using linear equations. The classical twin study is based on the above-mentioned specific assumptions regarding MZ and DZ twins, and, thus, four possible components and interactions as well as correlations can contribute to the total variance in a specific trait: "unique environmental factors" (such as prenatal exposure to hormones, friends, diet, sleep patterns, exercise), "shared environmental factors" (such as SES, diet, family, household, and neighborhood environments), "additive genetic factors" (i.e., the contribution of several genes for one trait, such as the interaction of allele A1, A2, and A3 which promotes neuroticism independently), and "dominant genetic factors" (i.e., the effect of a dominant allele compared to the recessive allele, such as the short allele of the serotonin transporter polymorphism, which produces less serotonin transporter than the long allele). See Table 10.2 for summary of differences among groups commonly used in this line of research. Shared, environmental, additive, and dominant genetic factors can cause twin resemblance, while unique (thus non-shared) environmental factors cannot resemble each other. The contribution of additive genetic, shared, and unique environmental influence to the total variance can be estimated by comparing correlations between MZ and DZ twins, when there is no proof of dominance found. Furthermore, twins who are reared apart or are fostered/adopted together and raised by foster/adoptive parents offer yet another possibility to identify the heritability of human traits. Finally, discordant monozygotic twins, who share the same genome but differ at the phenotypic level, offer the possibility to identify gene expression-relevant events that took place

Table 10.2 How different groups compared in heritability studies differ in the extent of influence by additive genetics and shared environment

	Additive genetics	Shared environment
MZ reared together	↑	↑
DZ reared together	→	↑
Siblings reared together	→	↑
MZ/DZ reared apart	↑/→	–
MZ/DZ reared together by foster parents	↑/→	↑
Siblings reared apart	→	–
Non-related reared together	–	↑
Non-related reared apart	–	–

MZ monozygotic, *DZ* dizygotic
↑ Large effect
→ Medium effect
– No effect

post-zygotically in prenatal and early postnatal development (see section "Epigenetics" below).

Adoption Studies

In 1876, the first researcher to undertake adoption studies was again Sir Francis Galton, and many researchers have conducted such studies ever since. Adoption studies are used to compare adopted individuals with non-adopted individuals in a general or clinical population. Generally, adopted adults or children are compared to adults or children in their birth family who were not adopted. Adoption studies open up the possibility to illustrate the impact of both environment and heredity on a variety of issues. Given that adopted children are not reared by their biological parents, it is possible to compare similarities and differences to the birth family since the impact of heredity and environment on individual personality traits can be calculated. One of the earliest adoption studies was conducted by Heston (1966) in which they investigated 47 adopted children whose biological mothers suffered from schizophrenia and compared these children to 50 adoptees whose mothers had not been diagnosed with schizophrenia in order to look whether schizophrenia has genetic disposition. They found that schizophrenia may have a strong genetic component, as 10% of the children became schizophrenic themselves. A multitude of even larger studies on this question followed and confirmed a strong genetic basis for the development of schizophrenia (e.g., Kendler, Gruenberg, & Kinney, 1994). This approach is not, however, without room for error or confounding. Researchers often fail to differentiate between individuals who were adopted as healthy infants and those who were not healthy at birth. Moreover, frequently, no distinction is drawn between individuals who were adopted as infants and those who were adopted at a much later age. Age plays an important role, as some children who are adopted later on in their lives have already been subject to environmental influences and, in a few cases, might have been victims of abuse, neglect, or abandonment. A study in Romanian children adopted in the United Kingdom confirms this by showing lower cognitive scores, such as verbal, perceptual, or memory competencies, in children adopted at older ages and being institutionalized compared to young and non-institutionalized adoptees (O'Connor, Rutter, et al., 2000). The data shows that the most important factor in gaining cognitive competencies (as measured by using the McCarthy Scales of Children's Abilities, McCarthy, 1972) was moving in an adoptive home. However, individual differences were better explained by the duration of separation, i.e., the group of children who were adopted between the age of 0 and 6 months were scoring significantly higher than those children who were adopted between the age of 6 and 24 months.

While there are obvious advantages inherent in quantitative genetics, such as estimating heritability in the "natural population" and large sample sizes, there are also some shortcomings. For instance, heritability estimations are often based on samples from different countries and are thus subject to the influence of culture and society. Moreover, excluding shared environmental influences (e.g., shared time before/after the separation) and ensuring the reliability of measures are complicated. For instance, it is difficult to validly and reliably operationalize antisocial behavior, as both the social environment and social desirability play a role in terms of this construct, and both of these factors are often confounded with the questionnaire and interview measures.

Molecular Genetics

Molecular genetics bears the potential to explore the molecular basis of human behavior and psychological illnesses. Individual differences in the genetic makeup and their manifestation (e.g., via the expression of a receptor in the human brain) can have an impact on our behavior. As mentioned above, genetic research has grown enormously over the last years. Differences in phenotypes among individuals are, to a considerable extent, due to genetic variation, which is "saved" in molecules of our DNA. The branch of molecular biology that is concerned with the structure, function, evolution, and mapping of the entire human genome is called genomics. In the following, we will briefly review different methodological approaches, which enable the location in the genome of genes that are responsible for various physical characteristics and behavioral traits to be determined.

Methodological Approaches

Linkage Studies

Linkage studies illustrate the co-inheritance of marker alleles and traits within families. Genetic linkage describes the tendency of genes to be inherited together during meiosis if they are located near to each other on a chromosome. Genes whose loci are nearer to each other are less likely to be separated onto different chromatids during chromosomal crossover. For this reason, these genes are described as "genetically *linked*." Linkage analysis is often used to map genetic loci by the use of observations of related individuals.

Association Studies

Association studies constitute another approach to search for genes that have a functional impact on human behavior. While linkage analysis looks at the association between parts of the DNA and physical or behavioral traits (linkage signal = candidate genes), association studies compare subjects with and without this trait in order to identify their distinctive genotypes. The goal of association studies is to search the genome for small variations, which are called single nucleotide polymorphisms (SNPs). With this approach, researchers look at hundreds or thousands of SNPs at the same time and search to identify (vulnerability) genes that may contribute to the development of a certain disease or may be related to a high-risk trait (such as neuroticism, which is related to the onset and relapse of major depression).

Genome-Wide Association Studies

Due to rapid technological progress, *genome-wide association studies (GWAS)* nowadays represent a promising method to study complex, common diseases in which many genetic variations contribute to a person's risk of developing an illness by examining SNPs across the whole genome. Large-scale GWAS have become viable as a result of the development of high-throughput genome-wide genotyping arrays or chips. It is known that the entire human genome consists of 10^9 base pairs and, moreover, that one of 1000 base pairs contains a polymorphism. The genetic basis of several diseases has already been successfully identified as a result of the GWAS approach, including diabetes, Parkinson disease, and Crohn's disease. It is believed that future GWAS will not only identify more SNPs associated with chronic diseases but will also shed light on the variations that affect a person's response to certain drugs and influence interactions between a person's genes and the environment. With the help of more sophisticated approaches such as functional and behavioral genomics, researchers are able to describe gene functions and interactions and observe effects of the genome on human behavior.

Candidate Gene Approach

GWAS screen the entire genome to identify genetic markers of risk. This approach is therefore non-candidate gene driven, similar to the association and linkage study approaches. By contrast, by knowing the frequency of the allele and distribution of the trait in a population, candidate gene studies test whether a particular allele in a so-called candidate gene and a trait co-occur above chance level. For these studies, biological candidates or candidates due to location (genetic linkage) are selected a priori and based on specific hypotheses. This selection is based on assumed or empirically validated causative biological or physiological roles of genes. While the indirect candidate association approach employs presumably functional variants that are associated with the outcome/trait of interest, in the indirect candidate association approach, only the tagSNPs are targeted, and hence, genotyping costs can be tremendously reduced. A very prominent functional example is the 44 base pair insertion/deletion polymorphism (5-HTTLPR) in the promoter region of the serotonin transporter gene (*SLC6A4*). This polymorphism results in an altered transcriptional efficiency and thus in altered transporter expression and serotonin uptake in the presynaptic cell (Lesch, Bengel, et al., 1996).

Case-Control Studies

Case-control studies involve a group of cases with a disease of interest and well-matched controls. These studies investigate subjects who already have a disease or trait and thus enable the determination of characteristics of these patients that differ from those who do not have this specific disease or trait. In genetic case-control studies, the frequency of alleles or genotypes is compared across cases and controls by means of statistical analyses. To enable this comparison, controls need to be unaffected by the disease of interest and need to be well matched for ethnicity, age, sex,[2] and similarity of previous environmental exposures. A difference in frequency of an allele or genotype of the polymorphism between the two groups indicates that the genetic marker may increase the risk of the disease or likelihood of the trait or may be in linkage disequilibrium with a polymorphism.

Concepts of Molecular Genetics

Gene-Environment Interaction (GxE)

Studying individual differences in behavioral medicine has the power to increase our knowledge of phenotypic variance, and thus of psychological traits, in human behavior. These individual differences are due to variations in multiple genes, environmental factors, and gene-gene as well as gene-environment interactions. The nature-nurture debate, one of the oldest arguments in psychology and biology, deals with the question of whether a person's development is predisposed in his or her DNA or whether it is influenced by life experiences and environment. The current state of knowledge indicates that both play important roles in human development. There are examples of pure genetic effects (such as blood group, hair color, or Huntington's disease), pure environmental effects (such as speech/language), or combined effects (such as weight or skin color) on physical and biological characteristics and human behavior.

Differences in genetic factors cause people to respond differently to the same environmental exposure. In the very first molecular genetic study to report such a gene by environment interaction (GxE), Caspi and colleagues (2002) discovered that a common variation within the gene that codes for monoamine oxidase A (MAOA) moderates the effects of childhood maltreatment on aggressive behavior later in life. Almost in parallel to these findings on early adversity, the same work group was able to demonstrate that the effects of life stress on later depression are moderated by the 5-HTTLPR genotype, insofar as carriers of the short allele showed twice the level of depressive symptoms, frequency of a diagnosis of depression, and probability of suicide ideation/attempts than non-carriers. Another GxE interaction for the 5-HTTLPR genotype was reported in an imaging study (Canli, Qiu, et al., 2006), in which carriers of the short allele exhibited greater brain activation in the amygdala (serving as an *endophenotype*, see below) as a function of life-stress experience. In these same individuals, more life stress also correlated significantly with higher levels of rumination, which is known as a risk factor for depression, while non-carriers exhibited the opposite pattern: Here, more life stress was associated with reduced amygdala activation and less rumination.

Importantly, the interaction between genes and environment can be just as validly considered as environmental modification of genetic influence or as genetic modification of environmental influence (Fisher, 2008). For example, Pima Indians in the United States show "the highest prevalence of type 2 diabetes mellitus … of any population in the world." Yet, Pimas living in Mexico have relatively low levels of diabetes. Ample evidence links genetics to diabetes *within* the Pima population (Pratley, 1998). Thus, the relationships among genes, environment, and diabetes among the Pimas can be stated in either of two ways:

- Genetic factors associated with membership in the Pima population have a strong influence on prevalence of diabetes among a population exposed to the obesogenic environment of US diet and food distribution.

---

[2] Even though differences between men and women cannot be attributed solely to biological differences, we will use the term *sex* throughout this chapter.

- The obesogenic environment of the United States has a strong influence on prevalence of diabetes among a population genetically predisposed to high rates of diabetes.

Gene-Gene, Gene-Age, and Gene-Sex Interactions and Gene-Environment and Gene-Gene Correlation

Besides an interaction between genetic and environmental factors, genetic, aging, and gender factors might also be interrelated*:* *Gene-gene interaction* can contribute to the initiation and maintenance of protective and risk behaviors, which in turn decrease and increase the risk of poor health outcomes. *Gene-age interaction* and *gene-sex interaction* describe the impact on variance components by genetic and environmental variance due to the effects of age and sex. Several studies have already investigated the likelihood of heterogeneity in genetic effects by age and sex. This field of research is able to specify how different genetic and environmental factors may be influential in both sexes and in different age cohorts. The investigation of gene by sex interactions, for example, is necessary to explain differences in terms of genetic susceptibilities and regarding the sexual dimorphism of complex traits.

The model of *gene-environment correlation* aims to strengthen the argument that environment and genetics are dependent on one another. This notion further indicates that the genetic impact may overcome environmental experience. There are three kinds of *gene-environment correlation:* (1) *passive gene-environment correlation*, (2) e*vocative (or reactive) gene-environment correlation, and* (3) *active gene-environment correlation.*

Endophenotype Principle

Endophenotype (such as brain activation in the amygdala mentioned above) is a term from the field of genetic epidemiology, which refers to phenotypic expression endogenous to the individual as opposed to exogenous. Thus, focusing on endophenotypes is intended to keep investigations closer to clear genetic connection. Bernard John and Kenneth R. Lewis first expressed this concept in 1966, when they claimed that the geographical distribution of grasshoppers cannot only be described by "exophenotype" (e.g., interactions between genotype and environmental characteristics such as climate and food sources) but, more essentially, needs to be explained by the individuals' internal "endophenotype." Endophenotype is a versatile measure for investigating and explaining individual characteristics. Typical examples are abnormalities in cognitive-affective processes, which are related to differences in sustained attention, executive function, event-related potentials, or localized brain measures, but also endocrine measures such as differences in the stress response (as measured by the stress hormone cortisol). Note that endophenotypes like differences in attentional processes might be related to exophenotypes such as differences in ease of learning a new language, given exogenous exposure to it. The contribution of genetic variation shows a considerably larger effect size when it is mapped onto the endophenotype, which is closer to the level at which a gene operates, compared to more distal exophenotypes which are subject to a broader range of influences in the environment. The power of the endophenotype approach is demonstrated by a fast-growing body of literature on functional brain imaging studies of individuals genotyped for the 5-HTTLPR polymorphism. This research tradition began with a study by Hariri et al. (2002), who reported a significant association between the short allele of the 5-HTTLPR polymorphism and an increased amygdala activation (serving here as endophenotype) in response to negatively valenced faces.

Epigenetics

An interesting and increasingly popular explanation for some complex patterns of environmental influence on genotypic expression is "epigenetic programming." Epigenetic programming triggers changes in gene activity (such as turning genes on or off and altering their expression levels) and does not involve DNA sequence alterations. One of these epigenetic mechanisms is DNA methylation, in which methyl groups are added to the cytosine bases on DNA (folate, for example, is a methyl donor molecule). A groundbreaking study showing an association of early maternal behavior and

DNA methylation moderating the stress response in rats in later life has been published by Weaver and Meaney (Weaver, Cervoni, et al., 2004). This study shows evidence of "epigenetic programming," which potentially might be reversible. This modification is thought to be more stable than other histone modifications and might possibly lead to lifelong changes. The functional consequences of methylation are a reduction or silencing of gene expression. A rather more complex mechanism involved in the manipulation and expression of DNA is posttranslational histone modification (e.g., methylation, phosphorylation, acetylation, and ubiquitination), with molecular evidence culminating in the "histone code" hypothesis proposed by Strahl and Allis (2000). This hypothesis assumes that these modifications provide marks where chromatin-associated proteins bind in order to change (i.e., activate or repress) the chromosomal state and thus to regulate access to DNA. The general process contains the alteration of the ability of histones to attract DNA via chemical modification, which is generally assumed to be in a constant state of change. A third mechanism of epigenetics is RNA interference, which involves smaller RNA molecules such as micro-RNA (miRNA) and small interfering RNA that are binding on messenger RNA, and thus either increase or decrease messenger RNA activity.

As a consequence of the mechanisms described above, epigenetic changes complicate any precise predictions of the phenotype based on structural DNA. The view regarding some of what were previously considered to be "hard" facts of genetics needs to be revised: For many decades, scientists believed that everything in our genome was written in stone. It is now quite clear that genes are still important but that they definitely do not function solely on their own. Genes can be turned on and off by various sophisticated mechanisms in the exogenous environment (e.g., maternal nurturing) or in the cell itself and through the lifelong variability of epigenetic modification patterns. The observation of the latter calls into question the long-held notion that "genes cannot be changed." In fact, it is not only the sequence of base pairs that regulates the human organism and its cellular mechanisms; there are also numerous processes influencing gene expression and thus life. Can it still be assumed that an environmental event is unable to leave a mark in our genome? Current research indicates not, as event-induced epigenetic changes can be passed on from one generation to the next (soft inheritance). This has been observed, for example, in the Dutch Famine birth cohort study (http://www.dutchfamine.nl). This cohort comprises individuals who were prenatally exposed to the Hunger Winter of 1944/1945 in the Netherlands. When the third generation of this cohort study is examined, it will be possible to investigate whether epigenetic changes can also be inherited transgenerationally. Findings of this cohort study also show that individuals are perhaps most vulnerable to epigenetic influences during prenatal and early postnatal phases but that epigenetic changes can occur at any age (Rakyan et al., 2010). Finally, it is known that even an individual's family lifestyle matters, e.g., the diet of our parents and even grandparents, or what they have experienced during their lives (see also below; e.g., the Överkalix study, Lalande, 1996). Recent knowledge regarding epigenetic mechanisms illustrates the far-reaching effects of health-related behavior (i.e., quitting smoking, changing our dietary habits) on our genes and possibly also the genes of our children and grandchildren. For a more in-depth discussion of the concept of epigenetics and findings relevant for behavioral medicine, see the following sections.

Gene Expression

Gene expression is the process by which the information that is encoded in the gene is translated into the products, which are present and operating in the cell (either proteins or RNAs). The cell reads the sequence of the gene in groups of three bases (codon), which correspond to one of 20 different amino acids used to build a protein. DNA sequences where cytosine (C) is directly followed by guanosine (G) and both C and G are linked by a phosphodiester (called CpG dinucleotides), are prone to methylation, i.e., the addition of a methyl group ($-CH3$). This addition leads in general to reduced transcriptional activity, whereas low-methylated DNA shows increased activity. Thus, the level of methylation and therefore gene expression determines which genes are currently "readable" and which specific gene products (proteins) are expressed.

Gene expression has been the focus of several recent studies on micro-RNA (miRNA), i.e., small non-peptide-coding RNAs, which regulate gene expression and are partially complementary to messenger RNAs (mRNAs). miRNAs were first targeted in animal studies (Lee, Feinbaum, & Ambros, 1993; Weaver, Cervoni, et al., 2004). Besides regulating genes, these miRNA also play a role for other important functions in the cell, such as cell proliferation, differentiation, and apoptosis. Emerging data suggest that, for example, stressful experiences can alter biogenesis of miRNAs, but can also impact the expression of mRNA targets, and the activities of miRNA-protein complexes (Leung & Sharp, 2010). While miRNAs usually suppress the expression of target transcripts, some researchers have suggested that miRNAs can also turn into activators during the cellular stress response (Leung & Sharp, 2007). Despite conflicting views within the field, miRNA seems to play multiple key roles in mediating diseases as well as the consequences of stress (Hunsberger, Austin, et al., 2009; Leung & Sharp, 2007).

Following this introduction of the most relevant terms (an overview of other important concepts, such as genomics and proteomics, can be found in Table 10.3 *Recent Concepts*), approaches, and key concepts in genetics, this

Table 10.3 Recent concepts

Term	Short description
Genomics	Genomics is a discipline in genetics that aims to determine the DNA sequence of the entire human genome and fine-scale genetic mapping including heterosis, epistasis, and pleiotropy. Contrary to the static approach of genomics, functional genomics concentrates on the dynamic aspects such as gene transcription, translation, and protein-protein interactions
Functional genomics/ behavioral genomics	Functional genomics is a field of molecular biology that attempts to make use of the vast wealth of data produced by genomic projects (such as genome sequencing projects) to describe gene (and protein) functions and interactions
Proteomics	Proteomics can be used as an experimental approach to describe the information contained in genomic sequences in terms of the structure, function, and control of biological processes and pathways. Proteomics aims to study biological processes comprehensively by a systematic analysis of the proteins expressed in a cell or tissue. Mass spectrometry is currently used as an important tool in proteomics
Deep sequencing	Deep sequencing provides not only the sequence but also frequency of RNA molecules that are present at any particular time in a specific cell type, tissue, or organ. The numbers of mRNAs that are encoded by individual genes are known to be an indicator of protein-coding potential and thus a major contributor to phenotype
Fine mapping	Fine mapping seeks to allocate the sequence of genes and their relative distances from one another on a specific chromosome. Fine mapping entails the identification of markers that are tightly linked to a targeted gene
Next-generation sequencing	DNA sequencing is used to determine the precise order of nucleotides within a DNA molecule. Next-generation sequencing is a group of high-throughput sequencing technologies that parallelize the sequencing process in order to produce thousands or millions of sequences at once
Metabolomics	Metabolomics is the study of biochemical processes that involve metabolites of an organism. These small molecules can function as catalysts such as enzymes or have interactive effects such as pheromones. In contrast to proteomics or genomics, metabolomics provides more detailed information of the biology and chemistry in a living organism. Moreover, as there is a strong connection between the metabolome and the genotype of an organism, its physiology, and environment (such as diet), metabolomics offers a unique opportunity to look at genotype-phenotype as well as genotype-envirotype relationships
Pharmacogenetics/ pharmacogenomics	Pharmacogenetics is the study of how an individual's genetic inheritance affects the body's response to drugs in terms of therapeutic but also adverse effects. It is thus the intersection of pharmaceuticals and genetics and offers beneficial effects on detailed knowledge about, e.g., medication, disease screenings, and health care

chapter now continues with an overview of the broad and substantial genetic influences on behavior and health risk. At the same time, interactions with behavioral and environmental factors necessary for phenotypic expression of genetic influences will be reviewed. Given this chapter's aim of providing the reader with an overview of behavior-genetic interactions in terms of health risk from a behavioral sciences perspective, it is not possible to provide an extensive review here. Therefore, suggestions on where to find further, more detailed information will be made.

The Role of Genetics in Health

As outlined above, only a small number of diseases and behavioral traits are caused by a single gene (e.g., Huntington's disease or cystic fibrosis). The majority of diseases (and behavior in general) are influenced by multiple genes (polygenetic), and it is known that one gene may affect more than one trait (pleiotropy) and also that genes interact to form phenotypic variance (epistasis or gene-gene interaction). This complexity is further increased by the effects of environment (environmental risk factors such as early-life stress, attachment style, social norms, or influence of peer and family behaviors), the interaction of genes and environment, and changes of gene expression throughout human life (epigenetics). The following section will provide a summary of past and more recent research in this context.

In the last years, increasing attention has been paid to the interaction between environmental factors and individual characteristics, such as personality traits. To provide just one example of this, research was able to show that novelty seeking (a personality trait that describes behavior of increased exploration of novel and unknown situations, objects, or stimuli) may increase susceptibility to the effects of advertising of tobacco (and possibly other substances) or that it increased the likelihood of exposing oneself to environments where tobacco is more readily available (Jamner, Whalen, et al., 2003).

Genetic susceptibility and its functional consequences (such as the 5-HTTLPR polymorphism and serotonergic function) play a major role in the explanation of health and health-related behaviors. It will be shown that there is substantial evidence from behavioral genetics research using twin and adoption studies, as well as from molecular genetic approaches looking at candidate genes, and that there are strong effects of genetic influences on variations in health and health risk behaviors. Different aspects of health and behavior are influenced by genetics. This section will discuss genes whose variations may increase susceptibility toward the initiation of health risk behavior and disease. Furthermore, genes involved in the progression and exacerbation of risk behavior, or genes involved in the sensitivity and responsivity of individuals to environmental risk factors, will be reviewed and summarized. In addition, genes that may interact with genes (epistasis or gene-gene interaction) known to predispose an individual to risk behavior and disease, and which are thus associated with protection against these outcomes, will also be mentioned.

This section will also describe how genes and environment do not influence health and health-related behavior independently but rather interact synergistically, i.e., genetic susceptibility factors may only constitute a risk under specific adverse environmental circumstances (see, e.g., interactions between polymorphisms, traumatic childhood experiences, and depressive mood in the abovementioned Caspi study (Caspi, Sugden, et al., 2003; for an overview of gene–environment interplay, see Rutter, Moffitt, & Caspi, 2006)). We will highlight that future research needs to consider the impact of many interacting factors (e.g., family and school environment) that act simultaneously and are in turn dependent on other factors (e.g., socioeconomic status). Importantly, there are also covariates and potential moderators of genetic effects that constitute more essential features of human identity such as race/ethnicity, sex/gender, and age. We will place a particular focus on the first two aspects, i.e., the modifying effect of ethnicity and sex on the relationship between genes and environment.

This chapter will not go into detail with respect to animal research, in which molecular geneticist is able to map genes that are involved in the behavior of, for example, mice, rats, flies, or even worms by simply removing (or "knocking out") the respective gene. In this regard, we refer the reader to Flint and Mackay (2009), who reviewed the genetic architecture of quantitative and complex traits in different species and discussed the difficulties in identifying genes that are responsible for complex traits. Laboratory studies in rodents, especially mice, mirror findings from human studies and show small-sized effects of multiple genes.

Sex/Gender and Race/Ethnicity

In the following, two key factors that might have an impact on health or health-related behavior and their genetic underpinnings will be discussed: sex/gender and race/ethnicity. On average, women have a higher proportion of body fat and lower blood pressure than men. Eating disorders are more prevalent in women. On the other hand, alcoholism and smoking are more prevalent in men, although the frequency of alcoholism and smoking in women has been increasing in the last years. These are just a few of the well-recognized differences between men and women in terms of behavior and health. Similarly, significant health disparities between African-Americans and Caucasians are well recognized, with higher rates, for example, of hypertension, stroke, or diabetes in African-Americans, ultimately resulting in a life expectancy gap of more than 4 years. Interestingly, breast cancer may be more common in Caucasian women, but African-American women have a greater risk of dying from breast cancer (Cronin, Richardson, et al., 2012). This is attributable to the fact that African-American women more often have aggressive tumors (genetic factor) and are less likely to receive adequate breast cancer screening (environmental factor). However, grouping individuals according to their race/ethnicity can only explain a small proportion of genetic variation, with only 10–15% explained variance due to differences between members of different groups (Ioannidis, Ntzani, & Trikalinos, 2004). This section will briefly introduce sex/gender and race/ethnicity as moderators of genetic impact on specific phenotypes.

The Behavioral-Genetic Investigation of Sex Differences

This first part will describe the effects of sex on genes and how sex moderates the effects of genes on behavior. First, the terms *sex* and *gender* need to be clarified. While sex is a classification based on biological differences, gender is a classification originating in the social construction of cultural distinction (i.e., behaviors, lifestyles, and environment) between men and women. The biological difference not only evolves from the presence or absence of the Y chromosome or different primary reproductive hormones but also from highly coordinated physiological systems that serve sex-specific functions. A simple example is the role of insulin in fat metabolism, which functions as a negative feedback signal on energy homeostasis and reduces body fat in men, while in women, it serves to keep the fat stored (necessary during pregnancy and lactation).

Some conditions like hemophilia and color blindness are more prevalent in men because the gene that causes the condition is recessively inherited and located on the X chromosome. As a further example, a condition called androgen insensitivity syndrome often garners public interest.[3] This is a condition in which chromosomally male individuals with a genetic variant of the androgen receptor (which results in an inability of the cell to respond to androgens) have testes and high androgen levels, while their genitalia, secondary sexual characteristics, and musculature are differentiated as women. By the time of the Atlanta Olympic Games in 1996, when sex testing became mandatory during Olympic Games, women with this condition

---

[3] Androgen sensitivity seems to be overrepresented in female athletes. For a recent discussion on sex verification and performance of athletes, see (Tucker & Collins, 2010).

had to compete as men. In 2012, before the Summer Olympics in London, the International Olympic Committee released new regulations that now follow a hormonal definition of sex (abandoning the requirement of a genetic screening). Women are now tested for their individual testosterone levels and their body's response to testosterone.

Both examples illustrate what are called *sex-limited genetic effects*, which means that a genotype is expressed (= the phenotype) in one sex but not in the other. Genetic influences may also play different roles in men and women, the so-called *sex-modified genetic effects*. There is good evidence that genes contributing to vulnerability differ between men and women. From twin studies, the genetic correlation[4] between the sexes can be estimated, i.e., the degree of similarity of genetic risk factors that influence a particular trait. As an example from psychiatry, different genetic risk factors seem to predispose men and women to developing major depression, with values of +0.55 and +0.63, respectively (Kendler, Gardner, et al., 2001; Kendler, Gatz, et al., 2006). In line with this finding, alcohol dependence was found to show correlations of less than 1.00, indicating only partially overlapping disease-related genes between men and women (Prescott, Aggen, & Kendler, 1999). Taking into account the effects of environment and gene-environment interactions, twin study data on smoking initiation reveal that the magnitude of genetic and environmental factors differs between the sexes and that this is also dependent on cultural background. Regarding the risk of smoking initiation, shared environmental effects are more important in women, while genetic factors seem to be of greater importance in men (Heath, Cates, et al., 1993). In sum, to fully understand genes with a potential to impact health risk behavior, one must consider this sex-specific expression of genes.

The Study of Ethnicity in Behavioral Medicine

In some ethnic minorities, there are higher prevalence rates of chronic diseases such as diabetes and cancer, and some diseases seem to be regionally distributed. For instance, hemochromatosis, a disorder in which the body absorbs too much iron from the diet, is most common in Northern Europeans. This observation led to increased attention being paid to racial/ethnic disparities in health across different countries. Furthermore, a discussion on the definition of the term race was also initiated. In anthropology, *race* refers to a group of people who share specific hereditary and observable physical (skin color, hair type, etc.) or biological (blood group, metabolism) characteristics. However, this description is controversial since a person who is categorized as black in one society might be considered non-black in another. In contrast, *ethnicity* is used for a group of individuals of the same geographic origin, religion (ideologies, common beliefs, religious mores), language, and culture (laws, regulations, problem-solving, structural and institutional forces). All of these common characteristics shape an individual's perception and view of reality. Since the concept of race defined as genetically distinct subspecies of humans is no longer accepted due to modern genetic information (genetic ancestry and geographic ancestry are correlated, while race do not correlate well with genetic ancestry, Bamshad, 2005), this chapter will use the more accurate term of ethnicity or ethnic group.[5]

A prominent example of a genetic effect being moderated by ethnicity (and sex) is the level of the serotonin metabolite 5HIAA in cerebrospinal fluid, which is affected by the short and long serotonin-transporter-linked polymorphic region (5-HTTLPR) genetic variant of the serotonin transporter gene (see above). Besides a higher

---

[4] A correlation coefficient of 1.00 means that the same genes influence a trait, while a value of 0.00 indicates absolutely no relationship, i.e., the same trait is influenced by completely different genes in men and women.

[5] To assess race/ethnicity, most studies simply ask "What is your race?" Since there is no biological or genetic test (assuming that race is defined by means of biological and genetic differences), participants' answers are mainly a cultural and subjective construct.

frequency of the long allele in Europe (and Africa) and a lower frequency in America (and Asia), the short allele variant (resulting in lower serotonin transporter mRNA transcription) is associated with high values of 5HIAA in African-Americans (and women) but low values in European Americans (and men) (Williams, Marchuk, et al., 2003). That is, ethnicity appears to moderate the effect of genotype in the case of the serotonin transporter gene. Thus, ethnicity and sex need to be taken into account when determining the functional effects (here serotonergic functions) of such polymorphisms. This is an example of how historic events, migration patterns, selection pressure, and geographic origin result in the occurrence of very different genetic allele frequencies and thus also contribute to the different presence of disease-related alleles.

Historically, research in the area of interethnic differences has always been a matter of controversy and debate. Apart from obvious ethical and political considerations, one of the most important shortcomings in this regard is of a methodological nature. Great caution must be taken when employing measures and scales that were designed and validated in one ethnic group (often Caucasians) and then applied to other groups (e.g., cognitive tests). Thus, a possible ethnic bias needs to be taken into account in these measures. Furthermore, research has also been biased by a lack of attention to within-group variability. For instance, among 25 other subgroups, Mexicans, Puerto Ricans, and Cubans constitute the Hispanic/Latino group, and yet each is genetically and ethnically different from the others. In line with this, the abovementioned analysis of 134 meta-analyses of studies using genetic association designs found that within-group variability accounts for 85% of genetic variation and not, as assumed, differences between groups (Ioannidis, Ntzani, & Trikalinos, 2004). Importantly, the effects of genes might differ due to the presence of other genes (gene-gene interaction) or specific environmental circumstances (gene-environment interaction). Hence, predicting differences in disease risk is complicated across different ethnic groups but also within these groups. This heterogeneity of genetic and environmental sources of variability is well illustrated in the observation of the geographic variation[6] of chronic diseases such as cancer, coronary heart disease, and stroke, despite similar behavioral risk factors (unhealthy diet, physical inactivity, obesity, alcohol use and smoking, unemployment). Why do the same risk factors lead to differences in chronic disease patterns in different regions? Behavioral genetics studies are beginning to identify the sources of variability by differentiating both genetic and environmental factors.

One of the most studied variables in the context of ethnic disparity in health outcomes is socioeconomic status (SES), which will be discussed in more detail in the next section. Differences in SES (e.g., higher income, higher level of insurance, and lower poverty rates in Caucasian households) substantially account for health inequalities between ethnic groups. However, adjusting for SES status does not completely eliminate ethnic disparities. Other contributing factors, genetic or environmental, also need to be considered. Future research will need to face the challenge of incorporating genetic factors, i.e., a biological susceptibility to disease, complex environments, and their interaction in the examination of health inequalities. Whether a functional polymorphism might be considered a harmful (vs. risk/vulnerability) or protective factor in the development of disease is generated and/or shaped by environmental factors (gene-environment interaction). A better understanding of these intricate relationships is also critical for risk-prevention programs. As already discussed in the context of cognitive ability tests, a risk-prevention program that is designed for and proven to be effective in one ethnic group might be less effective or completely fail in another. Thus, it is also essential to consider the environment as a modifying factor when designing and testing future intervention strategies.

---

[6] The Division for Heart Disease and Stroke Prevention of the Centers of Disease Control and Prevention offers constantly updated maps that document mortality and hospitalization rates including ethnic disparities.

Environmental Risk Factors: Chronic Stress, Low Socioeconomic Status, and Lack of Social Support

Although genes partially determine interindividual differences in susceptibility to many diseases, an increasing number of studies suggest that environmental factors and especially gene-environment interactions play a pivotal role in the etiology of various psychiatric conditions (Caspi, Sugden, et al., 2003; Kendler, Kuhn, et al., 2005; Neumeister, Konstantinidis, et al., 2002). This section will present some of the most intriguing findings regarding environmentally based factors and their interaction with genetic factors on health and disease, with a specific focus on psychiatric conditions. We will focus on three highly relevant environmental factors: chronic stress as one of the major health risks in modern societies, SES as one of the most studied variables associated with health disparities among groups, and lack of social support as a factor which interacts with and worsens the effects of chronic stress and low SES.

It is well known that early-life stress has a major impact on an individual's well-being. The first years of life are crucial for physiological and psychological development as well as behavior (Nater & Skoluda, 2013). Stressful experiences during this critical period may increase vulnerability to psychiatric conditions later in life (Kaufman, Yang, et al., 2004). One pathophysiological mechanism underlying this relationship might be an effect of chronic stress on gene expression, the process of protein production from a gene's coding sequence. In studies in which chronic stress was operationalized as social loneliness and chronic threat of losing a loved one or close person, analyses indicated that these stressors were able to upregulate the activity of inflammatory genes and downregulate the activity of immune-restricting pathways (Miller, Chen, et al., 2008). Theoretically, the ultimate effects of being chronically exposed to such stressors may be inflammation-related diseases such as obesity, cardiovascular diseases, or mood disorders.

Another landmark study, which demonstrated the interaction of genes and environment in shaping our behavior, was published in 2003 in the journal Science and has already been reviewed above. In short, the 5-HTTLPR polymorphism had no effect on depressive symptoms in the absence of stressful life events but showed a very large effect when individuals experienced four or more stressful life events. Findings of this study provoked a still ongoing debate about the gene-environment interaction between stressful life events, 5-HTTLPR genotype and depression, and led to a multitude of replication studies. As is often seen in research on molecular mechanisms in psychiatric conditions, the likelihood of replication was 50%, with higher-quality studies being more likely to detect a relationship (Risch, Herrell, et al., 2009). Interestingly, most recent research indicates an effect of sex, with a positive replication in women.

Moreover, it was shown that in Caucasian samples, the short allele of the 5-HTTLPR polymorphism not only predicts vulnerability in the face of negative experiences but also resilience in the case of positive experiences. Therefore, current research also includes potentially positive effects of "risk" genes, which are accordingly called "susceptibility" or "plasticity" genes (genes that seem to make individuals more susceptible to environmental influences, potentially both in a positive and negative way). One might wonder whether there might also be genetic effects on individual differences in terms of exposure to risk factors. Twin studies suggest a surprising heritability of exposure to life events, of about 40% (Plomin, Lichtenstein, et al., 1990).

But how is it possible that life events, which are supposed to be entirely environmental, turned out to be not entirely environmental? Indeed, it appears that some people select an environment that increases their likelihood of experiencing stressful life events. This environmental niche-picking is termed gene-environment correlation. Usually, researchers distinguish between independent and uncontrollable events, such as car accidents, and dependent and controllable stressors, such as quitting a job. According to this theory, a higher heritability is hypothesized for controllable events, and only modest heritability is hypothesized for uncontrollable events. Most studies provided support for this notion (40–50% for controllable events vs. 20% for uncontrollable ones) and found, in general, similar scores for men and women.

Importantly, the abovementioned effect of chronic stress on the activity of inflammatory genes was even more pronounced in individuals with low SES backgrounds, who seem to perceive more threat in stressful situations (Chen, Miller, et al., 2009). Besides these moderating effects of SES – i.e., how much money we make, what educational level we achieve, etc. – it has been suggested that SES is also in our genes. In quantitative genetic studies, income was shown to be moderately heritable (possibly accounting for 10–30%), with greater effects for men (Björklund, Jäntti, & Solon, 2005; Taubman, 1976). Higher estimates of about 50% have been found for educational background (Behrman & Taubman, 1989; Tambs, Sundet, et al., 1989). It may be reasonably assumed that the genetic factors underlying monetary income and educational level are similar (Rowe, Vesterdal, & Rodgers, 1998). However, given the notion of complex gene X environment interaction, direct effect of genes on variations in SES is quite questionable. It is more likely that these influences are mediated via genetic effects on intelligence and personality. In this context, personality traits have been shown to explain a significant part, for example, of SES variance (Chapman, Fiscella, et al., 2010). Future studies will have to examine the pathways by which genetic factors pave the way from predisposition to behavioral differences in different areas of social life.

It also seems reasonable to assume a significant impact of genetic factors on our social environment, e.g., how much social support we receive from others or how much social support we perceive ourselves to receive. It is well documented that both received and perceived social support are associated with physical and mental health. This association may be mediated by a potential buffering effect on the negative consequences of chronic stress. The question whether social support underlies genetic factors has been examined using twin studies. Results of these studies showed moderate heritability but, at the same time, also highlighted the importance of shared environment (e.g., Kessler, Kendler, et al., 1992). Twins share many environmental characteristics that comprise social support (relatives, friends), accounting for a considerable amount of environmental contributions to social support. Another important factor in the context of social support is the quality and quantity of social networks, i.e., the number and subjective evaluation of social interactions and relationships. While the quality of social networks was associated with clear genetic effects, the quantity of social relationships was not found to be heritable. Notably, a sex difference emerged for the relative contribution of genetic and shared environmental factors to the quality and quantity of social networks (Agrawal, Jacobson, et al., 2002): Only in women was the support of relatives (constituting a qualitative aspect of social support) influenced by genetic factors, and shared environmental factors played a significant role for the number of confidantes (the quantitative aspect).

Research on possible candidate genes that may be relevant in the context of social support is still in its infancy. However, initial evidence from molecular genetic studies looking at the neuropeptides oxytocin and vasopressin is very promising: Gene association studies focused on variations in the arginine vasopressin receptor 1A (AVPR1A) gene which have been associated with altruism, partner bonding, marital problems, and perceived quality of social relationships but have also been implicated in autism. Additional functional experiments examining neurophysiological correlates of these genetic variants showed a link between AVPR1A polymorphisms and amygdala activation (for a review see Donaldson & Young, 2008). In brief, the shorter repeat alleles are associated with reduced transcriptional activity of the AVPR1A gene, and this seems to be related to heightened amygdala activity. Increased amygdala activity might, in turn, be related to heightened fear responses in social situations and phobic and avoidance behavior, while decreased amygdala activity has been associated with aggression and hypersociability. Another promising candidate gene is the oxytocin receptor (OXTR) gene. Studies looking at the functional consequences of variants in this gene provided first evidence of a modulating effect of OXTR on the stress-buffering effects of social support (for a discussion on molecular genetic studies focusing on OXTR, see Kumsta & Heinrichs, 2013).

These genetic variations exert their phenotypic effects through their effects on gene expression. The underlying genomic mechanisms of the effects of social environment on health can be explored via the assessment of genome-wide transcriptional activity. Transcriptional activity was shown to be altered in subjects suffering from chronic social isolation, with especially heightened activity of inflammatory pathways (Cole, Hawkley, et al., 2007). This study was one of the first to show an association between a social environmental risk factor (social isolation) and increased pro-inflammatory activity and thus elevated disease risk.

Whether epigenetic inheritance also plays a role, i.e., whether social stress-induced modulations of transcriptional activity are stable and transmitted to the following generation, remains an open question. Research in animals provides evidence for a transgenerational effect of chronic social stress: Stress-induced heightened corticosteroids seem to impact behavior throughout the lifespan but also across generations (Hunter, 2012). In humans, behavior and attachment have been shown to be transferable between generations (Benoit & Parker, 1994; Hautamaki, Hautamaki, et al., 2010; Kim, Capaldi, et al., 2009), but specific molecular mechanisms remain unknown.

Overall, this brief overview of three selected environmental factors shows that these are at least partially heritable. At the same time, the findings also highlight the notion that genetic and environmental factors are closely related in shaping how we, and possibly our children, perceive and respond to our environment.

Health Risk Behaviors

This section describes behavioral genetics studies dealing with genetic and environmental effects and their interaction on typical health risk behaviors. Examples of those health risk behaviors will be alcohol and tobacco use, unhealthy eating behaviors, and physical inactivity.

Alcohol Use

In most prevalence studies on alcohol use, behavioral definitions established by the Centers of Disease Control and Prevention were used. This includes “having at least one drink of any alcoholic beverage in the past 30 days” for alcohol use and “having five or more drinks at one time in the past 30 days” for binge drinking. To address recent progress in research, more refined definitions also include trajectories of alcohol use initiation and progression. Harmful use is defined as abuse that is causing physical (liver cirrhosis, cardiovascular diseases), mental (depressive symptoms after heavy drinking episodes), and social (family and marital conflicts) damage. Harmful use should be distinguished from dependence. Alcohol dependence, also known as alcoholism or alcohol addiction, is a chronic condition characterized by a strong craving for alcohol, inability to limit drinking, and continued use despite related harmful consequences. According to the WHO, harmful use of alcohol results in more than two million deaths each year, making excessive alcohol consumption the third highest cause of preventable disease and disability (after tobacco and lifestyle factors, such as poor diet and physical inactivity). The highest consumption levels are found in Western and Eastern Europe, while abstinence levels are especially high in countries with large Muslim populations. Risky drinking (defined as drinking alcohol to the point of intoxication) was shown to be lowest in Western European countries and highest in the Russian Federation. This pattern of drinking was also shown to occur more frequently in Southern Africa and Mexico. As a further example of ethnic differences, Hispanic adolescents (8th grade) have the highest prevalence of risky and heavy drinking (defined as having consumed more than five drinks in a row in the last 2 weeks) in the United States (Johnston, O’Malley, et al., 2013). The lifetime risk for alcohol dependence ranges between values below 2% for individuals living in African countries and about 15% for men and

8% for women living in Western countries. Prevalence rates of alcohol dependence lie at about 4% in the general population. Thus, alcohol dependence is very common, and differences between countries and ethnic groups need to be kept in mind.

Due to the harmful consequences of alcohol abuse and dependence, the study of the causes of alcohol dependence, including genomic mechanisms, is of pivotal importance. Historically, illuminating the causes of alcohol dependence by studying families of alcoholics was complicated by the fact that alcoholics often have no family by the time they are identified as alcoholic; many individuals no longer have identifiable family ties. As described above, alcoholism has detrimental social consequences, and alcoholics often have broken family relationships, like higher divorce rates (Waldron, Heath, et al., 2011), making it difficult to obtain data from family members. Hence, the more attractive approach was to study twins and adoptees and ask them as well as a third party (e.g., their doctors) about their alcohol-related behavior. Data from one of the largest twin registries (Swedish twin registry, which includes information from the Swedish Temperance Board registration for alcohol abuse[7]) showed a concordance rate of 47.9% in monozygotic twins compared to 32.8% in dizygotic twins regarding Temperance Board registrations (Kendler, Prescott, et al., 1997). Following these initial findings, twin and adoption studies provided further evidence for the substantial effect of genes on alcohol use, misuse, and dependence. The heritability of the latter was estimated to lie at about 40–60%. Findings from adoption studies revealed that adopted-away sons of parents with alcohol problems have a four-fold increased risk of developing alcohol dependence compared to adopted-away sons of parents without this problem. Having a first-degree relative with alcohol dependence leads to a seven-fold increased risk of also developing alcohol dependence. Looking at sex differences in heritability, estimates regarding early alcohol-related behavior, including early onset of alcohol dependence, did not differ significantly between women and men. With respect to late-onset alcohol dependence, heritability was found to be higher in women.

In contrast to the study of other psychiatric disorders (such as schizophrenia), molecular genetic studies in the context of alcohol dependence have the advantage of being able to examine good candidate genes. Hypotheses on such candidate genes have been derived from the obvious differences between people in terms of their immediate response and sensitivity to the effects of alcohol. Enzymes involved in the conversion of ethanol to toxic acetaldehyde and benign acetic acid are therefore perfect physiological candidates. One of these enzymes, acetaldehyde dehydrogenase (ALDH), is quite prominent: About 43% of people in East Asian populations have a scarcely working form of the ALDH gene, resulting in high levels of toxic acetaldehyde and the typical flushing reaction (red skin, headache, feeling awful) when drinking alcohol. Therefore, individuals with this gene variant are rather unlikely to develop alcohol dependence. However, candidate genes have not been restricted to alcohol-metabolizing enzymes. Other candidate genes that have been examined are involved in processes mainly located in brain structures related to the reward circuits and corresponding neurotransmitters, such as dopamine, serotonin, and norepinephrine. Genetic mutations in these systems may also result in interindividual differences in different alcohol-related behaviors including use of alcohol, responses to alcohol, craving, and dependence. Subjects with a particular genotype of the dopamine transporter (which stops the action of dopamine through blockade of presynaptic reuptake) were shown to develop strong withdrawal symptoms, such as seizures and delirium tremens. This effect can be explained by the effect of dopaminergic neurotransmission on GABAergic and glutamatergic pathways (for a review of the role of GABA receptors in alcohol and nicotine dependence, see Cui, Seneviratne, et al., 2012). Genetic predisposition can thus result in an imbalance of excitatory and inhibitory neurotransmission.

---

[7] This register records all subjects who were arrested due to drunkenness or committing a crime under the influence of alcohol.

Although a vast knowledge base on candidate genes has been gathered, little work has been undertaken in terms of testing the effects of environmental factors and gene-environment interaction. The few studies which tested these relations concentrated on sociocultural context (such as educational attainment, family factors, marital status) and adversity (such as early trauma, e.g., childhood abuse and maltreatment and stressful life events). Summing up these studies, the initiation of drinking seems to be mainly determined by environmental factors, while genetic factors seem to play a more important role in the development of alcohol dependence given initial exposure. It can also be concluded that the magnitude of genetic effects varies considerably between different environments: genes play a four- to fivefold more important role in an environment that is characterized by more peer role models, greater neighborhood instability, and higher rates of alcohol sales. By contrast, environmental factors are more important, and genetic influences are more modest in communities characterized by higher social stability and structure. For instance, the gene pool of US Mormons is probably rather similar to the rest of the Euro-American population, but given their environmental influences, those genes are likely to have a lower impact on phenotype.

One may assume that an urban environment, with its greater mobility potential (to move into and out of different regions), would provide an adolescent with more potential friends and activities and thus allow a higher probability for risk genes to be expressed (gene-environment interaction). Marital status seems to moderate the magnitude of genetic influences on alcohol dependence, with greater risk in single or divorced compared to married carriers of a risky gene variant. It might be hypothesized that marriage may buffer the effects of risky genes for alcohol dependence, for instance, through heightened social support and stability. Besides this effect of environmental factors on the expression of risky genotypes, there might also be an effect of genes on the subjects' response to the environment. For instance, genes known for their involvement in the psychophysiological response to environmental stressors (sensitivity to environmental risk factors, i.e., gene-environment interaction) have also been implicated in alcohol use. It is hypothesized that stressors are more strongly related to alcohol use in subjects with certain gene variants. Consistent findings were shown for the corticotropin-releasing hormone receptor 1 gene (CRHR1), indicating that the high-risk allele was only associated with higher alcohol consumption when subjects were also exposed to early-life stress and negative life events. Far less consistency can be summarized for the length polymorphism in the promoter region of the serotonin transporter gene (5-HTTLPR). Individuals with the less functional short allele who experienced more stressful live events or maltreatment were at greater risk of more frequent and heavier drinking. However, there is also evidence that the long variant is the risky genotype, while some studies found no gene-environment interaction at all. For a summary of gene-environment interaction studies in alcohol dependence and a critical review of the limitations of these studies, we refer the reader to Young-Wolff, Enoch, and Prescott (2011).

In sum, the impact of genetic factors on potentially addictive behaviors such as alcohol consumption is well researched. More current research also highlights that genes may also influence the exposure to risky environment, i.e., drugs. This example of a gene-environment correlation (in contrast to the abovementioned response to the environment as an example of a gene-environment interaction) describes the phenomenon that individual variability in, for example, the exposure to drugs and regular drug use is partly genetically determined. For instance, adolescents with genotypes associated with propensity to risk-taking behavior tend to have friends with greater substance use and select lifestyles that lead to higher exposure to environmental risk. Other moderators of the genetic risk for alcohol disorders, with evidence from different studies, are availability of a substance, deviant behavior within the peer group, poor parenting style, financial problems, and a lack of pro-social behaviors such as volunteering or helping others. Future research should focus on these gene-environment correlations while interpreting findings of gene-environment interactions. Furthermore, research needs to clarify whether an unknown third variable may account for the observed interaction. Additionally, examining gene-gene interactions (epistasis) and environment-environment interaction and genetic susceptibility will also enhance our understanding of risk factors for alcohol misuse and dependence. Moreover, looking at (endo-) phenotypes that are more closely related to distinct aspects of alcohol dependence such as withdrawal, tolerance, and mediating traits like cravings will help to integrate and replicate studies in this context.

There is also plausible evidence for an involvement of epigenetic mechanisms in the context of alcohol dependence. As we have learned above, folate levels are an important regulator of DNA methylation, and changes in these levels might impact normal development. Here, alcohol plays an important role: One effect of ethanol is reduced folate activity, which results in altered DNA methylation and thus altered gene expression. Other ethanol-induced effects are functional changes during the processes of acetylation, methylation, and phosphorylation of histones (Shukla, Velazquez, et al., 2008). Furthermore, the abovementioned conversion product of ethanol, acetaldehyde, has the potential to interrupt the methylation of histones relevant for gene expression. Besides these direct effects of ethanol on gene expression, there are also more indirect and distant effects. During gastrulation (i.e., the early phase during pregnancy when organs are developing), alcohol seems to be related to lower levels of DNA methylation, which are known to retard this process of differentiation and development. Several studies provide evidence for the involvement of miRNAs in alcohol dependence, with ethanol decreasing their expression. This, in turn, might be related to apoptosis in certain cells. Current knowledge about these processes mainly stems from investigations with rodents, and the ethanol-related regulation of gene expression in humans still needs to be addressed in future studies.

To sum up, alcohol use and dependence are influenced by (1) genes related to how alcohol is metabolized and the rewarding effects of alcohol; (2) the environment in which we live (family factors, stressful life events), (3) epigenetic mechanisms that can be directly related to the effects of ethanol on acetylation, methylation, and phosphorylation of histones; and, perhaps most important, (4) interactions among all of these such as in genetic influences on behaviors leading to exposure to more risky environments or environmental influences on expression of genes related to experience of stress and its impact on alcohol use. The next section will summarize quantitative and molecular genetics findings for another substance with high addictive potential: nicotine.

Smoking

It is important to point out that there are many parallels between smoking and alcohol use in terms of gene-environment interaction. At the beginning of the twenty-first century, the prevalence of tobacco use ranges from above 30% in Eastern European countries and Chile to values below 10% in Asian and African countries. Nevertheless, low- and middle-income countries have the highest prevalence rates (about 80%). In 2004, 5.4 million deaths worldwide were attributable to tobacco, again with higher rates in low-income countries. Among tobacco-attributable diseases, cardiorespiratory diseases and cancer are the most prevalent. Thus, reducing the rates of smoking or even preventing people from starting to smoke in the first place is of great interest to public health. Most smokers begin their smoking career during adolescence or early adulthood. Interestingly, one fifth of young adolescents (aged 13–15 years) worldwide have already taken up smoking. The rate of young adolescent smokers is especially high in countries with fewer prevention efforts and less politically based intervention (such as increasing prices, raising legal age for the purchase of tobacco, or banning vending machines and tobacco advertising). In line with this, research shows that the motivation to start smoking is strongly influenced by the environment. In fact, such diverse environmental factors as smoking habits of peers or family, being exposed to family conflict, or tobacco industry marketing and advertising campaigns have been related to an increased likelihood of becoming a smoker.

However, there is also evidence that genetic factors play a role. Genes might predispose an individual to smoking initiation via their impact on psychological traits such as novelty seeking and impulsivity (Audrain-McGovern, Nigg, & Perkins, 2009). These traits have been shown to be significantly hereditary and to not only increase the risk of initial smoking but also to influence how people respond to initial nicotine exposure and their likelihood of further nicotine use (see also below). In line with this, research highlights the importance of individual differences in the psychophysiological effects of nicotine, nicotine tolerance, the effects of nicotine on cognition, the rewarding effects of nicotine, and the effects of nicotine deprivation. Thus, once initiated, genetic factors play a major role in the maintenance of smoking and the development of nicotine dependence. Results from quantitative genetic studies show that there is an inherited susceptibility to the rewarding value of nicotine. About 60% of the variance of nicotine dependence can be attributed to genetic factors (Kendler, Thornton, & Pedersen, 2000). Summarizing the findings from twin studies, the risk of being a current smoker is mainly hereditary, with about 55% of the risk being due to genetic factors, about 24% due to shared environmental variance, and about 21% due to individual-specific variance. These studies further showed a significant impact of genetic factors on different aspects of smoking such as initiation, persistence, and ability to quit (for a detailed review of the literature, Li, Cheng, et al., 2003; Sullivan & Kendler, 1999). Interestingly, heritability estimates (expressed as % variance) were not consistent across age groups, which is not surprising given the emergence of other factors that, over time, explain more or less variance. As well, an age by sex interaction emerged, showing decreasing heritability with age in men and increasing heritability with age in women. Moreover, this literature and more recent genome-wide linkage scan analyses support the notion of ethnic differences in terms of genetic factors contributing to nicotine dependence. African-Americans and European Americans differ in their loci of chromosomes, which have been associated with nicotine dependence. In African-Americans, a region on chromosome 5 has been identified, while chromosome 7 was found to be of particular importance in a European American sample (Gelernter, Panhuysen, et al., 2007).

Studies analyzing different gene variants have looked at specific candidate genes in the context of neurobiological pathways involved in nicotine metabolism as well as in the reinforcing and addictive effects of nicotine. These studies provided evidence for an effect of genetic variations in the dopamine, serotonin, and opioid pathways and the nicotinic acetylcholine receptors (for a summary of selected findings from the tobacco genetic literature, see Swan, Lessov-Schlaggar, et al., 2009). Dopamine transporter and receptor polymorphisms have been repeatedly associated with nicotine dependence: It was shown that smokers who have a genetic variance associated with lower basal dopamine exhibited an enhanced dopamine release in response to nicotine (Brody, Mandelkern, et al., 2006), which indicates a higher rewarding effect of nicotine in these subjects. Another enzyme involved the dopaminergic reward circuit that might have a role in the etiology of nicotine dependence is catechol-*O*-methyltransferase (COMT), which is involved in the degradation of catecholamines. Genetic variation in the COMT gene associated with reduced activity of this catecholamine-degrading enzyme (*Met* allele) reduces the likelihood of developing a nicotine dependency (Beuten, Payne, et al., 2006). In this context, a gene-sex-ethnicity interaction might be relevant: Beuten et al. also showed that some gene variants were protective in African-American women, while others were protective in European American men only. It is further well known that nicotine intake increases brain-derived serotonin and, conversely, that nicotine withdrawal decreases serotonin levels. Consequently, the serotonin transporter gene polymorphism (5-HTTLPR) was also studied in the context of nicotine dependence. Research shows that subjects with the short allele genotype of the 5-HTTLPR were less likely to quit smoking (Hu, Brody, et al., 2005). Additionally, these subjects also had higher values of neuroticism. Thus, the short form of this polymorphism has been associated with a temperament trait that might predispose the individual to feelings of anxiety, irritability, and depressed mood as well as exaggerated emotional responses to external stimuli, all of which may be mitigated by the pharmacologic effects of nicotine. It is therefore assumed that the association between the 5-HTTLPR genotype and smoking behavior is mediated via personality, stress responses, and the consequent heightened reward value of nicotine.

Research has also focused on genetic polymorphisms involved in the metabolism of nicotine. Prominent examples are cytochrome P450 isozymes, which are responsible for the biotransformation of different endogenous and exogenous substances including nicotine. Variations in these isozymes have been implicated in the variance of the amount of smoking and nicotine levels between individuals. Research is focusing on genetic variations in two isozymes: CYP2A6 and CYP2D6. Mutations in these genes result in a reduced production and activity of the isozymes or, under homozygote conditions, in a complete absence of this metabolic pathway (in this case the nicotine-metabolizing pathway) (Malaiyandi, Sellers, & Tyndale, 2005). Subjects with gene variants associated with normal metabolization smoked significantly more, had higher rates of nicotine dependence, as well as a higher risk of lung cancer compared to those with reduced metabolization. Molecular genetic methods (using GWAS) confirmed these previous results and showed strong associations between smoking and nicotine dependence and some other genetic variants: In particular, the involvement of the different alpha subunits of the nicotinic acetylcholine receptor gene, especially the CHRNA5-CHRNA3-CHRNB4 gene cluster, has been studied quite often. A group of genetic variants (i.e., SNPs) of this gene complex increased the risk of heavy compulsive smoking and craving, measured via cigarettes smoked per day (e.g., Stevens, Bierut, et al., 2008). This provides clear evidence that variants in the CHRNA5-CHRNA3-CHRNB4 gene cluster are functional.

Results of these GWAS studies can provide further guidance for more specific candidate gene association studies in the future, suggesting the inclusion of previously unanticipated risk genes for nicotine dependence. Furthermore, one of the latest innovations in this context is the inclusion of other methodological approaches that examine the functional significance of these variants and associated neurobiological phenotypes. These intermediate phenotypes, such as nicotinic acetylcholine receptor availability, are more closely related to specific genes and might provide a solution to the limitation of even large GWAS studies, which at best explain only 1–2% of a specific phenotype. For instance, there are several reports showing associations between specific genes and smoking behavior, although some studies failed to replicate these associations. One reason for this might be the failure to include the aforementioned intermediate phenotypes or to take into account environmental factors.

While family, twin, and adoption studies of the last two decades clearly demonstrated the existence of gene-environment interactions in smoking behavior and nicotine dependence, studies which examine these associations directly are surprisingly rare. In line with the assumption that environmental factors might play a larger role during adolescence, the school environment was shown to moderate genetic influences on smoking behavior. As an example, one study found that the highest heritability estimates were observed in schools in which the most popular students were smokers (Boardman, Saint Onge, et al., 2008). This supports the assumption that individuals may have specific genetic characteristics, but the environment enables or limits the effects of these characteristics. An enabling effect of environmental factors also explains the sometimes large differences in heritability estimates between studies. It is highly unlikely that heritability estimates will remain constant when there is actually no constant environment. As already noted above, environmental factors change over time explaining more or less variance. One should keep in mind that there are never more than 100% variance to explain by both heritability and environmental factors. Another study found that lower heritability estimates were observed in schools with mainly non-Hispanic and Caucasian students, a finding which emphasizes the role of ethnicity. Ethnic groups may differ, for example, in their behavioral norms (such as whether and how much they smoke) or availability of financial resources, which in turn might constrain the effects some genes might have. One further example of the large impact of environment-related factors is religiosity, which was shown to be related to lower prevalence rates of smoking initiation and to attenuate the additive genetic component for smoking initiation (Timberlake, Rhee, et al., 2006). The additive genetic component for smoking initiation in this study ranges from about 80% in subjects with low self-reported religiosity to less than 10% in subjects who described themselves as being religious and as considering religious faith as very important. The inhibitory effect of environmental influence on genetic factors was also reflected in a twin study, which showed a smoking prevalence rate of less than 1% in Chinese women, while about 60% of Chinese men were smokers (Lessov-Schlaggar, Pang, et al., 2006). The authors explain this discrepancy through the reduced access of Chinese women to social contexts in which smoking is common. This study clearly demonstrates the existence of gene-environment interactions in smoking behavior, i.e., cultural factors that may prevent women from smoking. Parental monitoring seems to be another moderator of genetic vulnerability to smoking and smoking initiation. In a twin study, high parental monitoring was shown to decrease genetic effects, while low parental monitoring appeared to fundamentally promote genetic effects on adolescent smoking (Dick, Viken, et al., 2007). Thus, the degree of genetic effects on adolescent smoking behavior varies depending on parental behavior (gene-environment interaction).

As noted earlier in this chapter, parental behavior is not only important during childhood and adolescence. Even before contraception, predisposition to a number of diseases can be preprogrammed by parental smoking behavior. Experimental studies investigating transgenerational effects are impossible in humans, so research has to rely on observational findings. Besides evidence for epigenetic modifications in smokers, paternal smoking was shown to be associated with altered miRNA expression in sperm (Marczylo, Amoako, et al., 2012). This provides evidence for a mechanism of epigenetic modulations that can be passed on to the next generation (transgenerational inheritance). Furthermore, maternal cigarette smoking during pregnancy has been related to higher DNA methylation (i.e., lower gene expression levels) in the BDNF gene of their adolescent offspring, suggesting a downregulation of this key regulator of brain development (Toledo-Rodriguez, Lotfipour, et al., 2010). There is also first evidence that epigenetic modifications might be predictive for future disease. A study on childhood asthma showed effects of maternal and grandmaternal smoking on the offspring's risk of asthma (transgenerational inheritance) (Li, Langholz, et al., 2005) Furthermore, long-term effects of smoking on methylation levels and thus expression of genes known to be involved in, for example, coagulation have been found in cancer patients (Shenker, Polidoro, et al., 2013).[8]

Similar to studies on alcohol dependence, future studies should include more intermediate and sophisticated phenotypes that are more closely related to specific characteristics of smoking behavior, such as measures of cognitive function, craving, impulse control, motivational measures, or biological abnormalities (e.g., alterations in specific brain regions). To address the question of the extent to which environmental factors influence genetic properties, studies are in need of reliable measures of the environment. The latter in particular requires interdisciplinary research,

---

[8] EPIC (European Prospective Investigation into Cancer and Nutrition) is a well-designed genome-wide epigenetics study and shows a pattern of DNA methylation that was able to distinguish between smokers who developed cancer and those who did not. This might offer the possibility to screen for cancer risk by means of DNA analysis.

including knowledge from social psychology, economics, politics, and cultural studies.

In sum, smoking is influenced by (1) genes involved in nicotine metabolism as well as in the reinforcing and addictive effects of nicotine; (2) the environment, which enables or limits the effects of genetic characteristics (peers in school who smoke, religiosity, parental monitoring); and (3) epigenetic mechanisms such as maternal and grandmaternal smoking via their impact on methylation levels in the offspring. To complement these points (which mirror knowledge in alcohol dependence), interactions among genes, environment, and epigenetics become more and more evident as, e.g., cultural influences that prevent some groups from smoking and the phenotypic expression of risky genes, or protective gene variants that differ between ethnic groups depending on sex (a gene-sex-ethnicity interaction).

Paradoxically, decreased smoking rates were introduced as one factor in the occurrence of higher obesity rates. The suppressing effect of nicotine on appetite was discussed as a possible mechanism for this. The next section will deal with obesity and unhealthy eating behaviors and their genetic and gene-environmental causes.

Obesity

With its easily accessible and palatable diet and motorized mobility, modern society strongly contributes to increasing rates of obesity. Until the late nineteenth century, obesity was a rather rare phenomenon. One century and related industrialization was enough to completely change this picture. According to data from the WHO and the Organization for Economic Cooperation and Development (OECD), current obesity rates (BMI $\geq$ 30 kg/m^2) vary from less than 5% in Korea and Japan to values above 30% in Mexico and the United States. Across all countries, the childhood obesity rate is about 20%, with the highest rates in the United States (≈35%) and Greece (≈41%). There seem to be differences between different ethnic groups with respect to criteria of obesity and obesity-related health consequences. Some nations had to refine the diagnostic criteria of obesity, since, for example, population studies in Asians show associations between BMI and obesity-related chronic diseases at a much lower BMI level. In this context, Japan defines obesity as having a BMI $\geq$ 25 (The Examination Committee of Criteria for 'Obesity Disease' in Japan, 2002) as there is evidence for a progressive increase of hypertension, hyperglycemia, and dyslipidemia in Japanese individuals at even lower BMI values. Comparable with estimates in smokers, severely obese people are hypothesized to die 8–10 years earlier compared to slim people. Excess body weight has been linked to impaired physiological functions, including deficient immune function and increased cortisol secretion, potentially leading to altered responses to stressors which in turn might lead to disease. Adipose tissue is known to be a major source of inflammatory cytokines and prothrombotic factors. Obesity is therefore a major risk factor for chronic diseases such as coronary heart disease, diabetes, cancer, or depression. The development and perpetuation of obesity is the result of a complex interplay of social, emotional, motivational, and also genetic factors. A significant proportion of the risk of developing obesity is attributable to changes in lifestyle in modern Western societies, which favors unhealthy diets involving the consumption of high energy/caloric food and supports a sedentary lifestyle.

For this reason, and owing to the increased obesity rates that have arisen in such a short period of time (from an evolutionary perspective), genetic causes may be assumed to be rather unlikely, meaning that environmental factors would then explain most cases. In contrast to this assumption, however, numerous studies estimating heritability of susceptibility to obesity-related phenotypes range from 6% to 85%, depending on the population under study (Yang, Kelly, & He, 2007). Estimates for individual differences in BMI or body fat range between 45% and 85% (Silventoinen & Kaprio, 2009). Importantly, these estimates depend on the population examined. For instance, research indicates that children's total body fat is related to a higher heritability estimate compared that of adults. There are also risk factors of obesity related to medical conditions (such as insulin resistance) and psychiatric disorders (e.g., depression is associated with poor diet quality and low physical activity levels) or single gene disorders (e.g., Prader-Willi or Bardet-Biedl syndrome), in which obesity constitutes part of the illness. However, such major genetic effects on obesity are rare, accounting for only a minor proportion of obesity-related morbidity, and their functional consequences (such as abnormal resistance to insulin) remain to be elucidated.

Normally, common forms of obesity are polygenetic. Molecular genetic studies reveal a large number of vulnerability genes that are related to obesity phenotypes such as BMI, appetite, and diet. Hence, various studies examined the effects of genetic variations related to lipid and glycometabolism as well as hunger and satiety (as discussed below). It is generally believed that genetic factors influence obesity via their contribution to (1) the susceptibility to a generally unhealthy diet in a particular social environment and (2) an individual's likelihood of developing obesity in response to a particular level of energy intake and caloric consumption. Most recent advances in our understanding of genetic susceptibility to obesity and unhealthy eating behaviors come from genome-wide association studies. So far, 30 distinct fat-regulating genes have been discovered (Willer, Speliotes, et al., 2009),[9] with different effects between ethnicities. Among other things, a risky genotype was found in the fat mass and obesity-associated (FTO) gene, the first and most robust gene shown to be associated with obesity and obesity-related phenotypes.[10] Various studies and meta-analyses support the role of the *FTO* gene in obesity in Europeans and Asians, an effect that could not be confirmed in African populations. Additionally, specific variants of the melanocortin 4 receptor, brain-derived neurotrophic factor (BDNF), agouti signaling peptide, leptin and leptin receptors, or cholecystokinin A receptor genes are important factors in obesity[11] (summarized in Comuzzie & Allison, 1998; for a meta-analysis see Willer, Speliotes, et al., 2009). Influencing the rewarding value of food and food preferences, mutations in the dopamine transporter and dopamine 2 receptor have been associated with obesity. It is hypothesized that obese individuals show a heightened reward expectation from viewing and smelling food but otherwise show a weak dopamine-related signaling. This attenuated signaling may then result in a deficit in delivering the reward, which is then compensated by eating more to achieve the expected reward level. However, studies confirming this hypothesis remain to be conducted.

Results from family, twin, and adoption studies further suggest that eating behaviors (satiety responsiveness, enjoyment of food, eating rate, slowness of eating) are not only genetically influenced but are also influenced by environmental factors. Heritability estimates indicate that the contribution of genetic factors lies in the range of 50–60% and around 10–20% for shared or unshared environmental factors, respectively. Interestingly, physical activity is able to switch off the effects of the FTO gene. Physical activity was shown to result in a two-point lower BMI among homozygous carriers of the risk allele variant of the FTO gene, which is normally associated with higher BMI (Kilpeläinen, Qi, et al., 2011). This modifying effect of physical (in) activity also occurs in the insulin-induced gene 2.

---

[9] It should be kept in mind that even when all of these genes are combined, they only account for 2% of the disease state (Speliotes, Willer, et al., 2010).

[10] The FTO gene is expressed in the brain, especially in the hypothalamus, which is known to be involved in reward. Subjects who have two copies show a 70% chance of being obese. Variants of this gene have been associated with an altered chosen diet, the total intake of fat and calories, and the release of oxytocin.

[11] All of these factors are involved in pathways of energy intake and/or metabolism, with FTO being involved in regulation of cell respiration in adipocytes; MC4 increasing body temperature and suppressing hunger; BDNF being involved in the central processing of satiety/hunger signals; agouti signaling peptide antagonizing melanocortin 4 receptor function, downregulated during acute stress what might result in inadequate behavioral responses as, e.g., binge eating; leptin and the leptin receptor regulating adipose-tissue mass as well as satiety/hunger; and the cholecystokinin A receptor being involved in the regulation of satiety, the release of beta-endorphins and dopamine, and the contraction of smooth muscles in the gallbladder and stomach.

Thus, physical (in)activity may increase the phenotypic effect of a risky genetic makeup or, conversely, is able to dampen negative effects (Andreasen & Andersen, 2009). Established in 2007, the "MuTHER" ("Multiple Tissue Human Expression Resource") project collected different tissue samples from more than 850 twins and was able to detect what the authors term a "mastery" gene for obesity: KLF14. This gene is known for its direct influence on behavior. KLF14 influences the activity of many other distant genes known to be involved in BMI and blood sugar levels (Small, Hedman, et al., 2011). The KLF14 gene is also a good example of a process called imprinting. In general, the offspring receives the same genes from both parents, but with respect to the KLF14 gene, the father's gene is switched off. Thus, activity of the KLF14 gene is inherited from the mother.

On the other hand, obesity is not only a consequence of fat-regulating genes but also of these genes regulating our dietary patterns, i.e., choice of food. Twin studies showed a surprisingly high heritability of 30–40% regarding whether individuals prefer vegetables and salad; meat, fried food, and chocolate; or coffee and alcohol (Breen, Plomin, et al., 2006; de Castro, 1993). As already mentioned above in our discussion on alcohol use, there is also evidence of gene-environment correlations in the context of obesity. The frequency of fast-food restaurant visits was shown to be substantially heritable in adolescents. However, it remains unknown whether this factor (fast-food restaurant visits) is a moderator (the strength of the effect of genes on obesity depends on fast-food restaurant visits) or a mediator (genes only have an effect on obesity in the presence of fast-food restaurant visits). This finding clearly demonstrates the need to keep in mind that there might be a third variable involved in gene-environment interactions. Findings show that our genes, together with factors and habits related to ethnicity (like beliefs or values), form our food choices. As seen for other health risks, ethnicity was shown to have a strong impact on dietary patterns: Influences on child-feeding behavior not only differed between ethnic groups (e.g., greater food restrictions in African-American mothers), but ethnicity was also shown to be differentially linked to fat mass, weight, and energy metabolism in the offspring. To illustrate this, African-Americans gain a higher percentage of energy from fat compared to European Americans (Weyer, Snitker, et al., 1999). However, these differences cannot be explained by ethnicity alone. Importantly, the confounding effect of SES needs to be acknowledged. See Fig. 10.1 for a schematic of the many relationships among genes, other biological influences, environment, behavior, and sociocultural factors in obesity.

Another interesting finding is that obesity not only runs in families, but having a mother who is obese during pregnancy increases the offspring's risk of obesity. The mechanism that is discussed to underlie this finding may be an effect of fetal nutrition on gene expression. This is an example of the thrifty phenotype hypothesis (also called Barker's hypothesis, after Hales and Barker (1992) who were the first to publish this hypothesis), which states that adult diseases originate in fetal experiences. The fetal nutritional situation results in adaptations, also on the molecular level, that might predispose an individual to obesity in later life. In animal studies, it was shown that these adaptations can be transferred from one generation to another. Epigenetic research in humans is still in its infancy, but initial findings are promising: Results suggest that even genetically identical twins show considerably different gene expression patterns shortly after birth, which might explain the difference in risk for later disease in this group. Not only fetal nutrition, but also nutrition during adulthood, might affect gene expression levels. It has been shown that a diet low in folic acid can decrease overall DNA methylation (Shelnutt, Kauwell, et al., 2004).

One of the most valuable cohorts for our understanding of the effect of prenatal and early postnatal experiences on adult disease is the Dutch Famine birth cohort (see above). For instance, the insulin-like growth factor 2 (IGF2) gene of individuals who were prenatally exposed to malnutrition was shown to be less methylated (Heijmans, Tobi, et al., 2008), providing first evidence for transient epigenetic changes due to

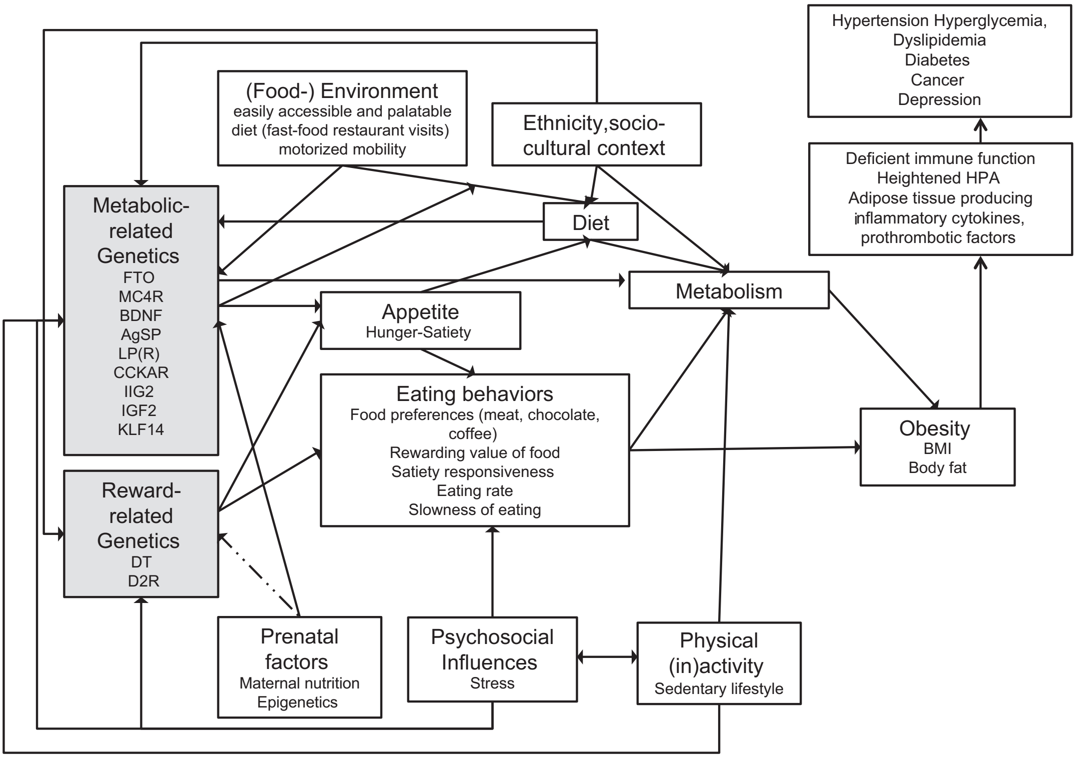

Fig. 10.1 Schematic representation of the kinds of complex relationships among genes, other biological influences, environment, behavior, and sociocultural factors in obesity

early hunger experiences. This altered (higher) transcriptional level of the IGF2 gene might be translated into later disease, since elevated circulating levels of IGF2 have been shown to be associated with obesity (Frystyk, Vestbo, et al., 1995). This cohort will also offer the possibility to study the question of whether it also matters what our grandparents ate at critical times in their lives. With the investigation of the third generation, scientists will be able to determine whether the observed epigenetic changes are also transmitted transgenerationally (Kaati, Bygren, & Edvinsson, 2002). If the food choices of our (grand)parents can alter the offspring's genome, one might wonder whether it is also possible to switch our genes on and off by certain substances in order to live a healthier and longer life. While no conclusions can be drawn at this point, there is intensive research on the effects of nutrients and other substances on the activity of genes involved in metabolism (and possibly obesity) and the stress response (Maurice, Haiser, & Turnbaugh, 2013).[12] Future research will have to show how these changes result in disease and how environmental influences and nutrition can be adapted accordingly.

To sum up this section, obesity is influenced by (1) genes operating in the pathways of energy intake and metabolism, (2) what we choose to eat (and its impact on gene expression), (3) environmental factors (psychosocial stress, cultural factors, but also prenatal factors like maternal nutrition), (4) epigenetic mechanisms such as shown by transgenerationally inherited effects of

---

[12] This study, published in the high-ranking journal *Cell*, shows the effects of xenobiotics, environmental toxins, on gene expression levels of human gut microbes.

hunger experiences, and (5) interactions of, e.g., both values/beliefs and genes forming our choices of food. In the next section, one of the most prominent causes but also forms of treatment of obesity will be discussed: physical (in) activity.

Physical (In)activity

In this section, the terms exercise and physical activity will be used according to their distinct meanings, with (1) *physical activity* being considered as any movement that results in energy expenditure (including window cleaning, gardening, going to work by bike, or activities of daily living) and (2) *exercise* being defined as structured and planned movements with the intention to increase physical fitness. Physical fitness comprises cardiovascular fitness, musculoskeletal strength, lean body mass and fat, endurance, and flexibility (Caspersen, Powell, & Christenson, 1985). To improve physical fitness and reduce the risk of noncommunicable diseases[13] and depressive symptoms, adults aged 18–64 years are advised to do at least 150 minutes of moderate-intensity aerobic physical activity (such as brisk walking, running, and bicycle riding) per week, performed in bouts of at least 10 min. For additional health benefits, adults should double this recommended time (WHO, 2010). Nevertheless, less than 50% of people worldwide meet this recommendation (although men are somewhat more active than women). Rates of physical inactivity differ between countries, with the highest rates in the United States and the Eastern Mediterranean region and the lowest rates in the Southeast Asian region. It is clear that people differ in terms of their participation in exercise and physical activity. The question therefore arises of whether genes also contribute to this variance. Results from twin studies provide strong evidence for genetic influences on exercise behavior, with estimates in the range of 50–70% in adults of different geographic origin (Stubbe, Boomsma, et al., 2006). Interestingly, the estimates for shared and unique environmental factors differ largely between age groups, with major influences of shared environment in children (25–70%; Huppertz, Bartels, et al., 2012). Barely any effect could be found in middle and late adolescents and adults, except in girls during their early adolescence. Here, a substantial part of the variance (46%) seems to result from shared environmental influences (van der Aa, De Geus, et al., 2010) such as encouragement and receiving positive feedback from family members and peers. This complete disappearance of shared environmental effects during adolescence might be explained by the fact that actual physical skills and performance determine whether a specific exercise behavior is maintained. Furthermore, the impact of genes on the degree of physical activity becomes more important when the impact of environmental factors decreases, such as a decrease in family feedback on physical activity after having left home. Whether these heritability estimates are of similar magnitude in older adults still needs to be examined. With respect to unique environmental influence, factors such as the characteristics of neighborhoods, i.e., sidewalks, streets, and parks, showed the strongest influence (72%; Duncan, Goldberg, et al., 2008). Regarding sex-related differences in heritability estimates, genetic factors seem to play a larger role in men (>65%) compared to women (<50%). As expected, genome-wide linkage scan studies revealed suggestive linkages in regions that harbor genes related to exercise ability, i.e., muscle performance and muscle blood flow. Especially in adolescents, these exercise ability genes determine whether an individual is good at sport and therefore maintains participation in this sport. Other candidate genes, therefore, should be related to endurance, physical mobility, motor coordination, and strength. One of these genes influencing fitness and physical performance is the angiotensin-converting enzyme (ACE) gene, which degrades vasodilators and stimulates the vasoconstrictor angiotensin II, which in turn increases muscle strength for power performance. Other genes of interest are the insulin-like growth factor 1 gene, which regulates muscle mass and strength gains, beta-adrenergic receptors regulating cardiac function and metabolism,

---

[13] Medical conditions or diseases which cannot be transferred among people and are not infectious in their origin

or the alpha-actinin-3 gene playing a role in muscle contraction. With respect to the alpha-actinin-3 gene, a higher XX genotype frequency (deficiency of alpha-actinin 3 and thus impaired muscle performance) has been found in endurance athletes, while the *RR* genotype has been associated with strength and power (of relevance, for example, in sprint-related sports). Interestingly, the mutation (XX) is more common in Asian and European populations, while only 1% of African populations show this mutation. In line with this, Olympic-level sprinters have the lowest incidence of this muscle performance-impairing mutation. The ACE gene is one of the most studied genes in the context of physical performance. An insertion (I) or deletion (D) of a 287 bp fragment results in three variants (II, ID, DD), with the D allele being linked to increased ACE activity and thus higher power performance, which in turn favors strength gain from training. By comparison, the *II* genotype has been shown to be more prevalent in endurance athletes, in whom high muscle bulk is less favorable and higher metabolic efficiency is needed (Scanavini, Bernardi, et al., 2002). Further research, however, called these initial findings into question and showed no consistent effect of ACE gene variants on physical performance (Doring, Onur, et al., 2010; Hagberg, Rankinen, et al., 2011; Puthucheary, Skipworth, et al., 2011). Linkage studies identified a section on chromosome 18q being related to physical inactivity, and there is evidence that the melanocortin 4 receptor gene is proximal to this region. This gene was also shown to be involved in physical activity levels, possibly due to its role in metabolic rate and energy expenditure (see also the previous section on obesity). Other genes involved in the maintenance of exercise might be related to body composition and the acute affective responses to exercise. A gene which we discussed above in the section dealing with obesity (and thus an example of pleiotropy) also showed relations to positive mood changes during exercise: the FTO gene. However, findings did not quite fit together, since those people with the risky genotype for higher BMI values also showed the highest change of positive affect in response to aerobic exercise (Karoly, Stevens, et al., 2012). Again, the involvement of the dopaminergic reward system was also implicated in this context. The TT (A1/A1) genotype has been associated with lower physical activity as well as obesity and hypertension (Simonen, Rankinen, et al., 2003). In the future, knowledge about the effects of specific gene variants might guide the development of exercise interventions and potential adaptations, i.e., personalized exercise training. For a comprehensive human gene map for genes related to physical performance and fitness, we refer the reader to “The human gene map for performance and health-related fitness phenotypes” (most recent (seventh) update, Bray, Hagberg, et al., 2009) and the latest volume of the IOC Encyclopaedia of Sports Medicine series (Bouchard & Hoffman, 2011).

Despite the extensive knowledge regarding various genetic factors involved in physical activity, there is still little understanding of how the environment interacts with these genetic variants. Multiple features of the environment that might modify the effects of risk genes on physical inactivity have been suggested. Social environmental characteristics that support a sedentary lifestyle such as computerized work, television, and video games, natural environmental characteristics such as shopping malls located very far from the city, and architecture of the neighborhood including parks, cycle paths, and walking paths are prominent examples. Studies looking at the effects of gene variants together with influencing effects of environmental factors on the level of physical activity are underway, but it is not yet possible to draw any conclusions.

Epigenetic effects could also be important in the context of exercise behavior and physical activity. While gene expression levels and changes in overall DNA methylation status are of major importance for genetic factors being ultimately translated into disease, only a small number of studies have addressed epigenetic mechanisms in the context of physical activity. One of these studies provided evidence of lower levels of DNA methylation in sedentary individuals (<10 min/day spent being active) compared to those who are more active (about 30 min/day). The genome of physically active subjects seems to be more likely to methylate and thus harder to be switched on (Zhang, Cardarelli, et al., 2011).

This might have implications for the occurrence and development of later disease. In other words, the expression of risky genes is hampered, and thus their influence is reduced in the more physically active subjects. Furthermore, animal studies hint at an effect of prenatal malnutrition on locomotor activity. Future human studies to examine the effects of early nutrition on physical activity and exercise behaviors are clearly warranted. Turning from the effects of genes on physical activity to the effects of physical activity on genes and gene expression, physical activity is able not only to reduce the influence of genes on body composition (thus, individuals with the greatest genetic risk of developing obesity would benefit the most from physical activity) but also to alter gene expression levels. Early studies were able to show an effect of even moderate physical activity on adrenergic and metabolic-detecting receptor mRNA. Other pathways altered by short bouts of exercise are related to inflammation, stress, and apoptosis, which might therefore provide the molecular mechanism for how physical activity is related to different aspects of health.

In conclusion, physical (in)activity is influenced by (1) genes related to endurance, physical mobility, motor coordination, and strength, (2) the environment (e.g., encouragement and receiving positive feedback from family, architecture in the neighborhood such as paths), (3) epigenetic mechanisms with evidence of an effect of physical activity on methylation status and mRNA levels, and (4) there is also first evidence for how the environment interacts with genetic variants to modify the effects of risk genes.

Conclusion and Future Outlook

As outlined above, the majority of behavioral traits and diseases are influenced by many genes (polygenetic), by some genes that affect more than one trait (pleiotropy), and by epistatic effects (genes interact to form phenotypic variance). Quantitative genetic studies further highlight the effects of shared and unique environmental factors and the interaction of genes and the environment. Moreover, examples have been shown of gene-environment correlation (e.g., adolescents with high risky genotypes tend to have friends with greater substance use and select lifestyles that lead to higher exposure to environmental risk). Most recent advances in our knowledge regarding epigenetic mechanisms highlight the plasticity of genes expressed and proteins produced. Even a gene of risk need not be seen as a vulnerability factor but rather as a factor of susceptibility – both according to its “negative” meaning (i.e., under specific circumstances, higher risk of developing disease, or unfavorable behavioral trait) and its “positive” meaning (i.e., being also more sensitive to behavioral change during interventions). Accordingly, studies involving tens of thousands of subjects show that only a tiny part (1–2%) of disease or trait variance is due to direct or simple, unmoderated effects of genes.

Importantly, the field of behavioral genetics focuses on traits that appear to lie on continuous spectrums. This makes it difficult, if not impossible, to find and differentiate cases and non-cases, which in turn is necessary to conduct research on the trait’s genetic basis. Quantitative genetics (twin, family, and adoption studies) and molecular genetics (linkage analysis, GWAS) suggest some genetic links, but no single gene has been conclusively identified to affect alcohol and nicotine dependence, obesity, or physical (in) activity. In addition, the perception of environment is filtered through the individuals’ memory, emotions, and personality. It might therefore be assumed that self-report measures of environmental facets (such as interaction with parents or siblings, peer group, social support, life events, education, SES, work-related stress) also reflect an individual’s genetic makeup.

While there is some knowledge about differing prevalence rates of unhealthy behaviors (alcohol and nicotine consumption, unhealthy diet, sedentary behavior) between ethnic groups, barely anything is known about possible genetic and environmental risk factors in these groups. However, to be able to design health interventions aimed at reducing morbidity and mortality related, for example, to alcohol use, future studies need to acknowledge specific target subgroups as defined by particular risky genes, environmental risk factors, and their interactions. Importantly, the contribution of inheritance associated with specific ethnic groups and variables of the sociocultural context also need to be considered. As our understanding of the mechanisms by which biological and environmental variables interact to shape health-related behavior advance, there will likely be a strong interest to apply this knowledge to therapeutic diagnostics and interventions. Further studies are necessary to replicate current findings and, for example, to explore responsiveness to medication (pharmacogenetics) and to prevent illnesses by clarifying unhealthy lifestyles. For instance, the short allele of the 5-HTTLPR gene has been associated with poorer responses to selective serotonin reuptake inhibitors (Stein, Seedat, & Gelernter, 2006). Depending on the substance, a large amount (20–95%) of variations in responses to drugs, including adverse drug reactions, seems to be attributable to the effect of genes and gene variants (e.g., Fabbri, Di Girolamo, & Serretti, 2013). Advanced new perspectives of psychobiologically oriented genetic approaches are proteomics and metabolomics (see Table 10.3 *Recent Concepts*).

Finally, research on the role of genetic risk factors in human health and behavior also requires an ethical discussion about the opportunities and limits of behavioral genetics. Personal genetic information is highly sensitive, and dealing with this information must be subject to ethical standards. Currently, such standards are rarely created and established. Knowledge of genetic predisposition might influence not only our own identity but also how we are treated by others (i.e., stigma or parents becoming overprotective and thus restrictions in opportunities that would otherwise be available). Furthermore, scientists need to realize that, currently, only a small proportion of the population has sufficient knowledge to interpret and apply genetic information. Informed consent and the subject's decision regarding whether or not to be informed about individual study results therefore need to be based on intensive educational work prior to participation; without such educational work, many cases of consent can hardly be considered to have been "informed." Moreover, avoiding the misuse of information, e.g., reporting genetic test results to family members or insurance companies, must be part of this process. As an example of detailed discussion of these concerns, we refer the reader to the debate on prenatal and preimplantation genetic diagnosis.

Stress and Emotions

Johannes Siegrist, Silja Bellingrath,
and Brigitte M. Kudielka

Introduction

Stress and emotions are basic notions with relevance to several scientific disciplines, including behavioral medicine. At the same time, these notions are also part of everyday human experience. This interference between common types of human experience and their scientific analysis has produced some challenges to the advancement of scientific understanding, in particular in case of the stress concept. From the perspective of history of science, "stress" as a fuzzy concept almost disappeared from rigorous scientific inquiry a few decades ago, after the pioneering discoveries of Walter B. Cannon (1929) and Hans Selye (1998). This crisis was mainly due to the notion of stress as a nonspecific response of the body to nonspecific biological, chemical, physical, or social agents that were assumed to elicit a "general adaptation syndrome" via the activation of the hypothalamic-pituitary-adrenocortical (HPA) axis of the organism (Selye, 1950). However, it is not possible to define stress exclusively by an organism's physiological changes. As Herbert Weiner noted, "physiological changes cannot be separated either from the nature of the experience, the context in which it occurs, or the behavioral response of the organism" (Weiner, 1991). Thus, due to its lack of discrimination and specificity, the notion of stress almost lost its scientific significance. Yet, in the early 1970s, this situation changed due to several important innovations. In experimental psychophysiological research, it became evident that stress responses varied according to the quality of the challenge (termed "stressor") and the availability of the person's ability to cope with this challenge. A person's sense of control over a threatening challenge and over his or her ability to cope with the challenge was identified as a crucial element in the stress process, which triggered different autonomic and neuroendocrine responses (Henry & Stephens, 1977; Mason, 1975). In line with this notion, psychological stress theory emphasized the role of subjective appraisal processes as determinants of emotional and physiological responses to the experience of a challenging

situation and, thus, proposed a transactional stress concept (Lazarus & Folkman, 1984).

A further innovation came from the emerging field of social epidemiology where distinct socio-environmental stressors (e.g., critical life events, social exclusion, chronic workload) were associated with incident physical or mental diseases, using prospective population-based study designs (for recent review, see Berkman, Kawachi, & Glymour, 2014). As a result, a body of knowledge accumulated over the past 30 years across a broad spectrum of scientific disciplines that demonstrated the far-reaching impact of stressful experience and emotional responses on health and well-being. More recently, methodological progress in the field of neuroscience, and particularly brain imaging, opened a new dimension of studying the affective and cognitive processing of stressful experience.

How can this broad field of knowledge reasonably be structured in the frame of a chapter to this handbook? As mentioned above, a scientifically promising stress concept analyzes interactions between challenging extrinsic situations (stressors); the cognitive, emotional, and behavioral processes of the individual persons coping with them; and their short- and long-term consequences for bodily functioning, health, and disease.

In the *first section* (section "Social Stressors and Stress-Related Diseases"), we deal with those (mainly social) stressors that were shown to increase the risk of incident stress-related physical and mental diseases. Two such diseases are chosen as exemplary cases, cardiovascular disease (CVD) and depression. Three main reasons justify this choice. First, CVD and depression are likely to remain the leading causes of premature mortality and disability worldwide over the next few decades (Lopez, Mathers, et al., 2006). Any new knowledge with relevance to the prevention and treatment of these disorders is therefore highly relevant. Second, international research linking stress with the development of these diseases is particularly well developed, thus allowing for comparative analysis, accumulation of evidence, and new insights into psychobiological processes underlying these associations. Third, CVD and depression are not independent entities but are intertwined in complex ways, thus illustrating the complexities and comorbid processes underlying major chronic diseases in modern societies.

The *second section* (section "Person-Related Factors in Stress and Emotion Research") is concerned with individual appraisal and coping processes, with a special focus on emotions, their modification by personality attributes, and the biological processes linking emotional experiences to physiological stress responses. Again, instructive examples of major research findings are discussed with relevance to CVD and depression.

In the *final section* (section "Implications for Behavioral Medicine and Concluding Remarks"), we briefly discuss future directions of research with relevance to behavioral medicine and provide some concluding remarks. Many topics of this chapter will be dealt with in more detail in later parts of this handbook.

Social Stressors and Stress-Related Diseases

Theoretical Background

How are stressors classified in terms of their quality, duration, and intensity? An obvious distinction concerns natural occurrences, including biological, physical, and chemical hazards and disasters (e.g., earthquakes), on the one hand and man-made stressful conditions on the other hand. Although the former ones may have a long-lasting adverse impact, man-made stressors often produce more pervasive effects due to their specific *quality* and long duration. Main man-made stressors occur in a social context and are experienced as part or consequence of interpersonal relationships. This is most obvious in case of physical violence, power relationships, deception, humiliation, and loss. Therefore, social stressors are considered potent determinants of stress-related disorders and have been subject to extensive research (Weiner, 1991). Based on this argument, the focus of this section is put on social stressors.

Further on, stressors are classified according to their *duration*. In this regard, Segerström and Miller (2004) propose five different types of stressors: (1) acute time-limited stressors (e.g., a mental arithmetic task as a laboratory challenge); (2) brief naturalistic stressors (e.g., an academic examination); (3) stressful event sequences (often termed "acute or subacute life event") where a crucial event (e.g., loss of a spouse) elicits major changes and adaptations; (4) chronic stressors, characterized by their stability over time and their impact on core social roles (e.g., social isolation, chronic workload); and (5) distant stressors that occurred in an early stage of the life course but have a long-lasting impact (e.g., sexual abuse in childhood as a cause of posttraumatic stress disorder). Research in this field has mainly explored chronic social stressors, including traumatic events in early life and including those chronic stressors that originated from a critical life event (e.g., unemployment).

It is more difficult to classify stressors according to their *intensity* or severity because the experience of intensity is moderated by individual appraisal and coping processes (see below section "Person-Related Factors in Stress and Emotion Research"). However, at a general level, the intensity of a stressor depends on the level of threat evoked in the exposed person, that is, on the severity of a potential loss following failed control or mastery (loss of life, loss of social status, etc.). Subjectively appraised importance, novelty, and controllability (including avoidance) are relevant parameters of experienced stressor severity.

In order to provide a *theoretical framework* for the explanation of health-adverse effects of major chronic social stressors, their impact on basic needs of a person's self-regulation must be considered. At least three basic needs of successful self-regulation are eventually threatened by social stressors, and these threats may elicit recurrent negative emotions and enhanced autonomic arousal (Siegrist & Marmot, 2004). The first one is the need of belonging to a social network, of being affiliated with significant other persons. As social animals, humans are essentially dependent on communication and interpersonal exchange. Conditions which deprive them from realizing this need are experienced as stressful, as is the case in people who are socially excluded and isolated, or who lost significant others and whose important social ties were destroyed.

A second basic need of successful self-regulation concerns a person's ability to act and perform, to realize his or her potential, and to make a meaningful contribution to life. Here, agency in terms of autonomy and self-efficacy is crucial, and core social roles are available in every society to meet this need. Yet, opportunities to develop one's own capabilities and to acquire and maintain one or several appropriate social roles that provide autonomy and self-efficacy are limited. Being "locked in" a deprived socioeconomic position, being excluded from work or from reproduction, or having a boring job with little control and skill discretion are examples of social stressors that prevent this need of successful self-regulation and, thus, trigger enhanced stress reactions.

Third, people strive for positive self-experience in terms of favorable self-esteem. As self-esteem to a large extent is contingent on appreciation received from significant others, lack of esteem and recognition is often experienced as stressful, in particular if own achievements have been invested in exchange of expected rewards. Therefore, reward frustration in core social roles acts as a powerful social stressor due the emotional afflictions exerted on people's self-esteem.

In the next paragraph, these three types of social stressors are more closely defined in terms of theoretical models, and these models are linked to elevated risks of the two stress-related disorders under consideration, CVD and depression. Before doing so, it is important to mention that social stressors can be identified at more distant or more proximate sites of a societal structure. For instance, an urban region or a deprived neighborhood may be considered a more distant social stressor that is identified at the level of aggregate data. In these instances, a social context matters for health, even if characteristics of individuals living in this context are taken into account. There is some convincing evidence available from studies applying multilevel statistical approaches that indicate elevated risks of individual ill health within such contexts (Diez Roux, Merkin, et al., 2001; Kawachi & Berkman, 2003). Yet, in view of the strength of scientific evidence and having in mind the paradigm of behavioral medicine, we consider more proximate social stressors that are identified at the level of individual persons where their direct effects on emotions and stress reactions can be studied.

Effects of Stressful Experience in Core Social Roles on CVD and Depression

In terms of methodology, best available evidence of associations of all three types of social stressors (related to belonging, self-efficacy, and self-esteem; see above) with health outcomes derives from prospective epidemiological cohort studies. This type of study is considered a gold standard because of its temporal sequence (exposure assessment precedes disease onset), its sample size (based on statistical power calculation and allowing for adjustment in multivariate analysis), and the quantification of subsequent disease risk following exposure (odds ratio [OR] of disease in exposed versus nonexposed individuals). Therefore, mainly results of cohort studies are summarized here.

Social Isolation and Lack of Social Support

Two dimensions of experiences related to the need of belonging are distinguished, a structural and a functional dimension. The structural dimension describes the availability of one or more stable social ties (e.g., living alone or with partner, size or density of a social network), whereas the functional dimension describes the utility of social relationships (availability and quality of social support). Both dimensions matter for health, but in case of social support, an additional qualification is important. If support is needed but not available, this type of social stressor reduces health, similar to the effect of social isolation. If support is needed and available, it may not only have a direct favorable effect on health, but may additionally act as a protective resource, buffering the intensity of stressful experience evoked by other types of adversity (Berkman & Krishna, 2014; Kawachi & Berkman, 2014). A meta-analytic review summarized the current state of knowledge about the effects of structural and functional aspects of social relationships on mortality risk (Holt-Lunstad, Smith, & Layton, 2010). Although the majority of the 148 studies included in this review used all-cause mortality as an outcome measure, several investigations were restricted to CVD mortality. As these latter findings paralleled those of all-cause mortality and as cardiovascular disease is the leading cause of adult mortality, results may be valid at least for fatal CVD. Unfortunately, no information on depression-related mortality is available as studies in which mortality was a result of suicide were excluded. In this meta-analysis, the likelihood of survival was calculated as a function of availability or quality of social relationships. Overall, the study found a 50% increased likelihood of survival among participants who were socially integrated or received social support compared to those who were socially isolated or suffered from lack of support. This effect size was similar in men and women, in different age groups, and in participants from different regions of the world. In more detail, the structural dimension seemed to be somewhat more relevant than the functional dimension as effect sizes were strongest for complex measures of social integration (odds ratio (OR) = 1.91) and for social network (OR = 1.45), whereas receiving social support had a weaker effect (OR = 1.22) (Holt-Lunstad, Smith, & Layton, 2010).

This conclusion of an inverse association between availability and quality of social relationships and mortality corroborates earlier findings, most importantly the pioneering Alameda County study, where men and women who lacked ties to significant others were 1.9–3.1 times more likely to die in a 9-year follow-up period than those who had many more contacts (Berkman & Syme, 1979). While some, but not all, studies report similar findings for incident nonfatal CVD, there is more solid evidence on the detrimental role of social isolation and lack of support among people who survived an acute myocardial infarction (Berkman & Krishna, 2014). For instance, a classical study of 2320 male survivors of acute myocardial infarction observed that patients who were socially isolated were more than twice as likely to die over a 3-year period than those with more social ties (Ruberman, Weinblatt, et al., 1984).

The other exemplified stress-related disorder, depression, has also been associated with poor social relationships and social isolation although fewer prospective reports are available. The fact that social isolation is associated with higher rates of suicide was discovered more than 100 years ago by one of the founding fathers of medical sociology (Durkheim, 1897). Since then, several investigations demonstrated (1) that bereaved persons without a network of friends were at greater risk of developing affective disorders, (2) that deficiencies in social support increased the susceptibility to mental disorder, (3) that emotional support from a confidant exerted a protective effect on risk of depression, and (4) that loss of a significant person (usually a parent) early in life had long-lasting detrimental effects on mental health (Stansfeld, 2006). In conclusion, the risk of suffering from one of the most widespread chronic diseases with often deleterious outcomes, CVD and depression, is significantly elevated in people who are exposed to the social stressors of isolation or exclusion and lack of social support. Importantly, in terms of effect size, the influence of social relationships on the risk of death is comparable with the one exerted by some behavioral risk factors for mortality associated with these diseases (e.g., physical inactivity or excessive alcohol consumption) (Holt-Lunstad, Smith, & Layton, 2010).

Lack of Autonomy in Core Social Roles

It was argued that agency in terms of autonomy and self-efficacy exerted in core social roles is crucial for physical and mental well-being and that these opportunities are unequally distributed across societies, leaving those in *lower socioeconomic positions* at higher risk of disadvantage. In fact, a social gradient of major chronic diseases, including CVD and depression, has been established across the whole of a society in many prospective studies (Marmot, 2004). With each step one moves down on the social ladder, the worse one's physical and mental health is likely to be. This social gradient is particularly steep in midlife where odds ratios of CVD are more than twice as high among members of the lowest as compared to members of the highest socioeconomic group. A similar strength of association was reported for depression (Lorant, Deliege, et al., 2003).

A vast literature explored major explanations of this substantial social gradient of health. In his impressive account, Michael Marmot states that distinct social stressors that are more prevalent among lower socioeconomic groups account for a substantial part of this gradient although interactions with health-adverse behaviors and with adversity in early life need to be considered as well (Marmot, 2004). Three chronic social stressors are of particular relevance: poverty (low income), unemployment, and poor quality of work, preventing agency in terms of autonomy and self-efficacy.

It is difficult to distinguish the effects of *poverty* from those of low socioeconomic position as income serves as a major indicator of socioeconomic status. However, some studies suggest that income contributes to poor health mainly through its impact on material life circumstances, such as unhealthy food, poor housing, or lack of safety measures (Glymour, Avendano, & Kawachi, 2014). Other investigations maintain that distinct psychosocial influences on health interact with material constraints due to low income, such as feelings of relative deprivation, recurrent worry, and pessimism or impaired self-worth (Wilkinson & Pickett, 2009). Chronic financial difficulties were shown to increase the risk of CVD as well as the risk of depression (Shaw, Dorlin, & Davey Smith, 2006).

Long-term unemployment is perceived as a powerful social stressor because it prevents people from maintaining a core social role in adult life, the work role. Work has primary significance as it is normally a prerequisite for regular income and as it provides opportunities for personal performance and achievement. Moreover, it is mainly through work and employment that social status in adulthood is acquired and maintained and that a core social identity outside the family is developed. These resources are lost if people are laid off and if chances of reentry into the labor market are poor. Prospective research evidence demonstrates increased all-cause and cardiovascular mortality risks of unemployed compared to permanently employed men and women (Dupre, George, et al., 2012). Depression was less frequently analyzed in longitudinal studies of unemployed people, but was identified as an important health problem in a large study that controlled for mental health at study onset (Dooley, Prause, & Ham-Rowbottom, 2000). Recent evidence demonstrates elevated suicide risks following long-term unemployment (Milner, Page, & LaMontagne, 2013). Precarious work characterized by job instability, forced temporary work, and experience of organizational downsizing equally increases the likelihood of suffering from adverse cardiovascular events and depressive episodes (Ferrie, Westerlund, et al., 2008; Siegrist & Dragano, 2012; Vahtera, Kivimäki, et al., 2004). *Poor quality of work,* preventing agency in terms of autonomy, control, and self-efficacy, was identified as a third type of social stressors that increase the susceptibility to stress-related disease. A leading theoretical model of stressful work, the *demand-control model*, is of central importance in this respect, and this model has been tested in a large number of prospective epidemiological investigations (Karasek & Theorell, 1990).

This model posits that stressful experience at work results from a distinct job task profile defined by two dimensions, the psychological demands put on the working person and the degree of control available to the person to perform the required tasks. Jobs defined by high demands and low control are stressful because they limit the individual's autonomy and sense of control while generating continued pressure ("high job strain"). Under these conditions, excessive arousal of the autonomic nervous system (ANS) is expected to occur that is not compensated by a relaxation response following the experience of control and mastery. Importantly, a low level of control or decision latitude manifests itself in two ways, first as lack of decision authority over one's tasks, and second as a low level of skill utilization, as evidenced by monotonous, repetitive work. Overall, "high-strain jobs" seem to follow a social gradient. The higher one's level of professional training and skill, the less likely is one's probability of working in a "high-demand-low-control" job.

At present, a substantial number of reports derived from prospective studies on the associations between poor quality of work in terms of the demand-control model and cardiovascular disease are available (Steptoe & Kivimäki, 2012). In summary, despite some negative findings, the majority of results indicate a moderately, but significantly elevated relative cardiovascular morbidity or mortality risk following exposure to "high strain" compared to nonexposed individuals. Findings are more consistent in men than in women and more consistent in middle-aged as compared to early old-age populations. Additional studies found partial support for associations of work stress with major cardiovascular risk factors, such as hypertension, altered blood coagulation, and the metabolic syndrome (Chandola, Britton, et al., 2008).

More than a dozen cohort studies analyzed the demand-control model with regard to depression. Again, a majority of studies found elevated risks although effect sizes were smaller and were often restricted to single components of the model (Bonde, 2008). Interestingly, one investigation assessed work stress over time and found an elevated risk for depression following a deterioration of quality of work (Wang, Schmitz, et al., 2009).

In view of a large body of knowledge, we can conclude that poor quality of work in terms of the demand-control model acts as a chronic social stressor that contributes to the burden of stress-related disorders to a remarkable extent.

Reward Frustration in Core Social Roles

Missing or inappropriate social reward can be a stressful experience, in addition to lack of control, in particular if own achievements have been invested in exchange of expected rewards. To identify reward frustration in core social roles, and specifically in the work role, a complementary theoretical model, "effort-reward imbalance," was proposed (Siegrist, 1996). This model is concerned with stressful features of the work contract rather than the profile of job tasks. It builds on the notion of social reciprocity, a fundamental principle rooted in an "evolutionary old" grammar of interpersonal exchange. Social reciprocity lies at the core of the employment (or work) contract, which defines distinct obligations or tasks to be performed in exchange with adequate rewards. These rewards include money, esteem, and career opportunities, including job security. Contractual reciprocity operates through norms of return expectancy, where efforts spent by employees are reciprocated by equitable rewards from employers. The effort-reward imbalance model claims that lack of reciprocity occurs frequently under specific conditions and that failed reciprocity in terms of high cost and low gain elicits strong negative emotions with special propensity to sustained autonomic and neuroendocrine activation and their adverse long-term consequences for health. According to the theory, contractual nonreciprocity is expected if one or several of the following conditions are given: "dependency," "strategic choice," and "overcommitment."

"Dependency" reflects the structural constraints observed in certain types of employment contracts who have no alternative choice (e.g., due to low qualification or advanced age). "Strategic choice" describes a condition where people accept high-cost/low-gain conditions of their employment for a certain time because they tend to improve their chances of career promotion and related rewards at a later stage. "Overcommitment" points to a psychological reason for a recurrent mismatch between effort and reward at work. People characterized by this motivational pattern of excessive work-related overcommitment may strive toward continuously high achievement because of their underlying need for approval and esteem at work.

This model too has been extensively applied in recent years, and a number of prospective studies were conducted to test its ability of predicting cardiovascular and affective disease. Concerning CVD, early studies reported an almost twofold elevated risk of incident fatal or nonfatal disease in working people reporting a marked imbalance between high efforts spent and low rewards received in turn, whereas this risk was somewhat lower in more recent investigations (Backé, Seidler, et al., 2012; Kivimäki, Virtanen, et al., 2006; Steptoe & Kivimäki, 2012). In addition to manifest CVD, the progression of subclinical atherosclerotic development was studied where people suffering from effort-reward imbalance at work exhibited increased carotid intima media thickness, not only in Western societies, but also in China (Xu, Zhao, et al., 2010). Moreover, some evidence points to associations with established cardiovascular risk factors, in particular hypertension (Gilbert-Ouimet, Trudel, et al., 2014).

The second outcome, depression, was strongly associated with the components of this model assessing reward frustration at work (Siegrist, 2009). A meta-analysis documented an 80% increased risk of newly manifested depression in stressed versus nonstressed employees over a mean observation period of 5 years (Stansfeld & Candy, 2006). Complementary evidence from psychobiological studies reveals increased pro-inflammatory activity and reduced immune functioning associated with this type of chronic social stress (Bellingrath, Rohleder, & Kudielka, 2010; Nakata, Takahashi, & Irie, 2011). In summary, these results and complementary findings with other indicators of poor health confirm the significance of social reward deficiency as an independent determinant of stress-related disorders.

Having discussed adverse health effects of distinct social contexts which are not adequately responsive to people's emotional needs, it is nevertheless important to stress the role of individual differences in coping with social demands and threats and in responding to them at the cognitive, emotional, and physiological level. Therefore, a more detailed study of individual variations in dealing with stress and emotion is needed. This is the task of the next section.

Person-Related Factors in Stress and Emotion Research

Different Levels of Person-Related Factors in Stress Research

When analyzing the effects of various kinds of stressors on health outcomes, it is important to consider the different levels of internal person-related factors that modulate this relationship.

Emotional States

First of all, stressful events can impact on physiological functioning by giving rise to negative emotional states such as depression, anxiety, or anger, just to name a few. These emotional states have a spectrum of different facets with different intensities. Depression includes sadness, sorrow, unhappiness, and at its maximum despair, whereas anxiety ranges from tension to dread on the extreme end of the scale. Anger can range from a subtle annoyance or irritation to feelings of fury and aggression, manifesting itself in various behaviors ranging from shouting and threatening of others to physical assaults (Smith, 2010). Such affective states should be distinguished from more enduring, mostly more dysfunctional negative attitudes toward others, such as hostility. Hostile persons seem to create and thus live in a social environment which is characterized by high levels of interpersonal conflicts and low levels of social support (Smith, Glazer, et al., 2004), contributing to increased psychosocial vulnerability which further potentiates the risk of negative health consequences. Negative emotional states as well as more enduring emotional behavioral patterns such as hostility have repeatedly been shown to play a role in the development and exacerbation of coronary heart disease (CHD) (for a recent review, see Chida & Steptoe, 2009; Frasure-Smith & Lesperance, 2010), whereas positive affective states on the other hand may serve as protective factors against cardiovascular disease risk and vulnerability for infection (Steptoe, Dockray, & Wardle, 2009).

Emotion Regulation Strategies and Enduring Cognitive-Behavioral Patterns

To some extent, people are able to influence which emotions they experience after a stressful event and how they are expressed. Such emotion regulation strategies seem to be crucial for physiological adaptation. The considerable intra- and interindividual variability in the psychological and physiological effects of stressors on health outcomes may be attributed partly to how individuals perceive and think about the stressors. Appraisal theory postulates that the way one interprets the meaning of specific events determines the emotions one experiences in reaction to this event. Psychophysiological studies of cognitive reappraisal and coping have tried to elucidate its neural basis and how changes in emotional responses can be associated with physiological outcome parameters (Harvey, Nathens, et al., 2010; Ochsner & Gross, 2005; Weinberger, Schwartz, & Davidson, 1979). For example, cognitive reappraisal used to modulate affective responses was shown to be associated with activation in the prefrontal cortex as well as goal-appropriated increases or decreases in amygdala activation (Ochsner, Bunge, et al., 2002; Ochsner, Ray, et al., 2004).

In most studies that investigate the impact of stress and coping on health, stressors are treated as discrete events followed by singular goal-directed coping strategies. However, this research strategy fails to address the fact that some events or coping strategies have prolonged effects on physiology. For some people, the impact of a stressor persists over longer periods of time as they rehearse the stressful experience in their minds, a process termed rumination. Rumination has been repeatedly shown to prolong and deepen episodes of depression (Lyubomirsky, Layous, et al., 2015; Nolen-Hoeksema, 2000), and depressive subjects have been shown to differ from healthy controls with respect to the proposed cognitive processes of rumination, namely increased attention to negative information or better memory for negative than positive stimuli as well as global deficits in cognitive control (Gotlib & Joormann, 2010; Whitmer & Gotlib, 2013). Studies on the role of metacognitions even suggest that the extended, ruminative thinking style plays a more crucial role in the development of emotional disorders than actual, negative thought content (Yilmaz, Gencoz, & Wells, 2015). The perseverative cognition hypothesis (PHC) postulates that rumination may prolong physiological activation by the amplification of acute stress responses, a delayed recovery as well as the reactivation of stress responses later in time (Brosschot, Gerin, & Thayer, 2006), which in the long run will lead to or aggravate adverse health outcomes.

Other cognitive-behavioral patterns that may impact on the way we cope with stressful situations are certain trait aspects such as perfectionism (Wirtz, Elsenbruch, et al., 2007) or overcommitment at work (see above) (Siegrist, Starke, et al., 2004). In a number of studies, evidence has been accumulated linking levels of perfectionism with stress-related health outcomes such as depression, anxiety, or eating disorders (Egan, Wade, & Shafran, 2011).

Personality Traits

Neuroticism finally is a broader personality characteristic, which is generally defined as "the tendency to experience distress, and the cognitive and behavioral styles that follow from this tendency" (McCrae & John, 1992). As a global trait, neuroticism includes several more specific characteristics such as anxiety, depressive symptoms, worry, anger, and irritability but also nonaffective aspects such as self-consciousness and low self-esteem. In their taxonomy of personality traits, Watson and Clark (1984) describe a trait very similar to neuroticism which does not include the above-mentioned nonaffective aspects which they labeled negative affectivity. It is important to note that in the literature on health effects of personality, the labels neuroticism and negative affectivity are often used interchangeably. High levels of neuroticism are commonly seen in anxiety and mood disorders (Weinstock & Whisman, 2006), and it has been proposed that biased cognitive processing is the underlying mechanism for this association (Canli, 2008). A large body of research supports the notion that neuroticism is also associated with serious physical health problems, most prominently CHD (Suls & Bunde, 2005). Studies lend support for the assumption that about 50% of the variance for neuroticism is of genetic origin, whereas the remaining variance can be explained by environmental and unknown factors (Canli, 2008). Concerning the molecular genetics of neuroticism, most work has focused on a gene variant in the regulatory region of the serotonin transporter gene (5-HTT). A common deletion of a 44 base pair in the regulatory region of 5-HTT produces a gene variant that is physically shorter than the 44-base-pair insertion variant. The short variant produces less of the transporter than the long variant. Lesch et al. (1996) demonstrated that individuals who carry one or two copies of the *5-HTT* short variant have higher levels of neuroticism than individuals who carry only the long variant.

The "distressed" or Type D personality is a concept closely related to neuroticism, mostly studied in patients with CVD. A line of studies with both cardiovascular patients and healthy individuals demonstrated that Type D personality is a general propensity to psychological distress that affects cardiovascular outcomes (Denollet & Conraads, 2011; Denollet, Schiffer, & Spek, 2010; Widdershoven, Kessing, et al., 2013). Type D individuals are inclined to experience negative emotions and to inhibit self-expression in social interaction. In line with the results on neuroticism, heritability of Type D personality has been estimated to vary between 34% and 50% (Kupper, Boomsma, et al., 2011; Kupper, Denollet, et al., 2007).

Psychiatric Disorders

Finally, one should differentiate between negative affectivity within the normal range of emotional experience and diagnosable emotional disorders with psychopathological significance such as mood and anxiety disorders.

Next to the above-discussed environmental and psychological factors, the importance of genetic factors for the development of emotional disorders has been convincingly demonstrated in family and twin studies. Kendler et al. (2006) recently showed that 38% of the susceptibility to develop major depression is due to additive genetic factors. However, during the last years, several genome-wide association studies (GWAS), which allow the simultaneous analysis of many common SNPs, instead of a single candidate gene, failed to find a genetic variant that achieved genome-wide significance in predicting depression (Major Depressive Disorder Working Group of the Psychiatric GWAS Consortium, 2013). When looking at the impact of genetic factors in interaction with environmental events on the other hand, a seminal study published by Caspi et al. (2003) demonstrated that the association between the number of *5-HTT* short variants and later depression is a function of life stress history, a finding which was later confirmed in a study by Kendler et al. (2005). Finally, new insight has been gained by recent approaches studying epigenetic changes induced by environmental factors, contributing to changes in neural circuits and endocrine systems that are associated with stress-related diseases such as depression (Menke & Binder, 2014). It has been shown that early adversity impacts on gene expression patterns by changing DNA methylation and histone modification, thereby most likely increasing disease risk (Mill & Petronis, 2007; Tsankova, Renthal, et al., 2007). Thus, the occurrence of emotional disorders is closely linked to stressful life events and as a consequence to alterations in the regulation of various stress-sensitive physiological systems, such as the hypothalamus-pituitary-adrenal (HPA) axis or the locus coeruleus-norepinephrine (LC/NE)/autonomic system (see below). It is therefore not surprising that affective disorders are a common risk factor for physical disease, most prominently CVD (Nabi, Shipley, et al., 2010; Seldenrijk, Vogelzangs, et al., 2015).

Biological Mechanisms Linking Emotional Factors to Stress Responses

To better understand how emotional factors such as affective states or more enduring individual trait aspects may lead to an increased susceptibility to disease, a detailed understanding of possible underlying biological mechanisms is essential. The following section will briefly elaborate the physiology and regulation of two major stress-sensitive systems, the hypothalamus-pituitary-adrenal (HPA) axis, which represents the slow arm of the stress response, and the locus coeruleus-norepinephrine (LC/NE)/autonomic system, representing the fast arm.

The Hypothalamus-Pituitary-Adrenal (HPA) Axis

The HPA axis serves as a central control system of an organism, connecting the central nervous system (CNS) with the endocrine system. The HPA axis is vital for the support of normal physiological functioning and enables organisms to maintain homeostasis under acute stress. Incoming stress signals from higher centers of the brain are integrated in the hypothalamic paraventricular nucleus of the hypothalamus (PVN), which then coordinates the immediate behavioral, autonomic, and neuroendocrine responses to a stressor. In the face of challenge, neural stimulation of the PVN leads to the release of corticotropin-releasing hormone (CRH), which then initiates the secretion of adrenocorticotropin (ACTH) from the anterior pituitary. The primary target of ACTH is the adrenal cortex, where it triggers the secretion of glucocorticoids (GCs) and to a lesser extent mineralocorticoids and adrenal androgens (Chrousos & Gold, 1992). GCs are among the most versatile of hormones with a wide range of physiological effects. The best studied are those on carbohydrate metabolism and immune function. In order to adapt to the increased metabolic demands under acute stress, GCs enhance circulating levels of energy substrates like glucose, free amino acids, and free fatty acids (Chrousos & Gold, 1992; McEwen, 2003).

The acute stress response also entails the activation of the immune system to respond to challenges such as wounding and infection that (in evolutionary terms) are likely outcomes of a stressor. The rapid recruitment of leukocytes into sites of surgery, wounding, infection, or vaccination is essential for an effective immune defense network. In case of chronic stressors, GCs generally dampen immune and inflammatory responses. Additionally, GCs have important regulatory effects on the cardiovascular system, on response to hemorrhage, as well as on behavior, appetite control, and affective and cognitive processes, like learning and memory (McEwen, 2003). Dysfunctional regulation of the HPA axis has been associated with various psychosomatic and stress-related pathologies (for reviews see Heim, Ehlert, & Hellhammer, 2000; Raison & Miller, 2003).

The Locus Coeruleus-Norepinephrine/Autonomic System

The locus coeruleus-norepinephrine/autonomic system is located in the brain stem and centrally regulated by the hypothalamus and the locus coeruleus (LC). It functions globally as an alarm system, and when activated, it initiates the discharge of norepinephrine from an extremely dense network of neurons throughout the brain. This results in enhanced arousal, vigilance, and increased anxiety. The sympathetic division of the autonomic nervous system plays an important role in the adaptation to stressful situations, via its peripheral effectors: the sympathetic nerves and the adrenal medulla (Chrousos & Gold, 1992). The parasympathetic division of the autonomic nervous system typically acts to oppose the effects of the sympathetic nervous system (Tsigos & Chrousos, 2002). The adrenal medulla responds with the systemic secretion of catecholamines (predominantly epinephrine). The sympathetic nerve terminals, which line the vasculature, release norepinephrine. In the face of challenge, catecholamine secretion leads to a rapid mobilization of energy stores (through increased supply of free fatty acids and glucose by glycogenolysis and lipolysis) as well as a downregulation of less important organ functions (e.g., those of the gastrointestinal tract and reproductive systems). Furthermore, catecholamines have a substantial impact on cardiovascular functioning during stress, increasing heart rate, cardiac output, and blood pressure. Other effects include enhanced respiratory extraction of oxygen via airway dilatation, enhanced platelet aggregation, and reduced clotting time (Kudielka & Kirschbaum, 2007). Norepinephrine also activates the amygdala, the principal brain locus for fear-related behaviors, and enhances the long-term storage of emotional memories in the hippocampus and striatum. Reciprocal neural connections exist between the HPA axis and the locus coeruleus-norepinephrine/autonomic system. CRH and norepinephrine stimulate each other primarily through α1-noradrenergic receptors. Thus when working in concert, the HPA axis and the LC/NE system can produce short-term and more sustained stress responses (Tsigos & Chrousos, 2002).

Exemplary Evidence Linking Emotional Factors and Stress-Related Health Outcomes

Scientific evidence for the role of psychological stress and related emotions in disease processes has been accumulated by several distinct lines of research, which include acute stress experiments, cross-sectional observational (field) studies, as well as prospective longitudinal studies trying to predict future disease risk. The following section will summarize exemplary evidence from various studies with different methodological approaches on a continuum of emotional experience with increasing severity. First, the effects of a distinct negative emotion such as anger as well as the effects of the more enduring negative attitude hostility on health outcomes will be outlined. In a next step, evidence on stable personality characteristics (neuroticism and Type D) will be highlighted and finally the impact of negative emotions with pathological significance, that is, clinical depression on health will be summarized. As was already noted in the introduction, we decided to focus on CVD and depression as disease outcomes. With respect to depression, it is important to notice that it can be seen as both, a disease outcome in itself and a predictor of physiological disease outcomes such as CVD. When it comes to physiological alterations that may precede the development of CVD and depression, we will outline exemplary results on changes in HPA axis regulation, alterations in the functioning of the locus coeruleus-norepinephrine/autonomic system, and changes in immune parameters.

The Association Between Anger, Hostility, and Health Outcomes

The idea that a hostile attitude toward others and related affective experiences can have a negative impact on physiological functioning has a long history in behavioral medicine research (Barefoot & Williams, 2010). Dysregulation of the HPA axis is one potential mechanism that could explain the negative health outcomes associated with hostility and anger. A finding by Steptoe et al. (2000) supports this notion. In a study with school teachers suffering from high job strain, anger expression has been demonstrated to predict elevated levels of early morning salivary cortisol. Looking at HPA axis regulation after acute stress, however, current data draw a different picture. In a recent study by Brydon et al. (2010), hostility was not related to cortisol reactivity to stress, a finding which is in line with results from a meta-analysis, investigating the association between different emotional and psychosocial factors and physiological responses to laboratory-induced stress in healthy populations by Chida and Hamer (2008). With respect to autonomic nervous system dysregulation, the authors found hostile individuals to be more prone to react with larger and more prolonged increases in heart rate and blood pressure to laboratory mental stress. High levels of hostility and anger have also been shown to be associated with greater blood pressure reactivity (Christensen & Smith, 1993) to social stress and less nocturnal blood pressure dipping (Thomas, Nelesen, & Dimsdale, 2004). Interestingly, anger suppression (anger-in) compared to anger expression (anger-out) has been shown to be a significant determinant of carotid artery stiffness, a major risk factor for cardiac events, independent of blood pressure (Anderson, Metter, et al., 2006).

The immune system is another stress-sensitive system that seems to be affected by the experience of hostility and anger. Suarez et al. (2002) demonstrated that in a sample of 62 healthy men, hostility was positively associated with lipopolysaccharide (LPS)-stimulated expression of tumor necrosis factor-alpha (TNF-α), a pro-inflammatory cytokine. In a study that was aimed to assess how hostile marital behaviors modulate wound healing, as well as local and systemic pro-inflammatory cytokine production, Kiecolt-Glaser and coworkers (2005) observed that higher levels of hostile behaviors were associated with a significantly reduced wound-healing rate as well as to larger increases in plasma IL-6 and TNF-α values in the morning after a conflict compared to a social support interaction. Furthermore, the interaction between depressive symptoms × hostility has been also shown to be associated with increases in IL-6 and C-reactive protein (CRP) in a sample of 316 healthy older adults (Stewart, Janicki-Deverts, et al., 2008). In the presence of depressive symptoms, hostility may augment inflammatory processes relevant to CVD. In a recent study by Brummet and colleagues (2010), a similar effect was shown for an acute stress condition. The interaction term depressive symptoms × hostility predicted the CRP response to an emotional recall task. Those subjects with the combination of high symptoms of depression and hostility had the largest CRP response. Hostility is also associated with platelet reactivity, a key pathophysiological pathway in the onset of CVD (Shimbo, Chaplin, et al., 2009), and has been shown to be associated with endothelial dysfunction as an early indication of atherosclerosis (Raikkönen, Matthews, et al., 2004). To summarize, there is a multitude of findings that indicate a direct link between affective states such as anger and biological alterations that are responsible for an increased susceptibility for disease endpoints like CVD. A recent meta-analysis by Chida and Steptoe (2009) demonstrated the relationship between anger and hostility and increased cardiac events even in initially healthy populations. Anger and hostility were furthermore associated with a poor prognosis in patients who already suffer from coronary heart disease (CHD). The latter effects were even stronger, suggesting that patients who score high on the trait hostility might experience more frequent anger episodes, which could accelerate the recurrence and perpetuation of the disease. Interestingly, a gender difference in respect to vulnerability was observed in the healthy populations. Here, the association between anger and hostility and CHD events was stronger in men than in women. This sex effect is in line with results from the above-mentioned meta-analysis from Chida and Hamer (2008), where anger and hostility were related to stronger cardiovascular responses to psychological stressors in men than in women. Thus, the repeated experience of increased stress reactivity in daily life might be of pathophysiological significance for CHD in men.

However, according to this review based on observational studies (Chida & Steptoe, 2009), anger and hostility lost their predictive power for the occurrence of CHD events in healthy populations as well as in patient populations when a variety of behavioral covariates such as smoking, physical activity, body mass index (BMI), and socioeconomic status were fully controlled for (Chida & Steptoe, 2009). Thus, next to the above-described physiological pathways, it can be hypothesized that effects are also mediated via behavioral pathways, especially since there is considerable evidence that hostility is related to a variety of adverse health behaviors such as poor diet, reduced physical activity, or smoking (Bunde & Suls, 2006). This reasoning is in line with a prospective study in which Siegler et al. (1992) followed up over 4000 college graduates for 25 years. Those with higher hostility scores at age 18 later reported lower exercise rates, higher alcohol consumption, smoking rates, as well as higher body mass indices.

The Association Between Neuroticism, Type D Personality Traits, and Health Outcomes

As already outlined above, there are stable differences in the experience of distress and negative affect, and several mechanisms could explain the relationship between the personality traits capturing this tendency, such as neuroticism or Type D personality, and the development of CVD. It might be assumed that neuroticism, as it reflects the tendency to experience increased stress levels, is associated with increased basal HPA axis activity reflected in increased cortisol levels throughout the day. However, studies which investigated the association between neuroticism and HPA axis activity rendered inconclusive results. Two recent studies used a momentary assessment measurement approach to investigate the association between neuroticism and diurnal cortisol levels. Hauner et al. (2008) observed flatter cortisol profiles in male adolescents with high levels of neuroticism, whereas Nater et al. (2010) demonstrated a positive association of neuroticism with cortisol levels throughout a measurement period of six days. Schommer et al. (1999) on the contrary found no association between circadian salivary-free cortisol patterns as well as cortisol responses to acute psychosocial stress and levels of neuroticism. In a recent gender-specific analysis by Oswald et al. (2006), higher neuroticism scores have however been shown to be related to a blunted cortisol response to acute stress only in women. In their meta-analysis on the influence of chronic psychosocial factors on responses to acute laboratory stress, Chida and Hamer (2008) did not find an association between neuroticism and HPA axis reactivity.

Looking at changes in autonomic functioning however, the meta-analysis by Chida and Hamer (2008) reported a decreased cardiovascular reactivity, and furthermore poor cardiovascular recovery in response to acute psychosocial stress, to be related to neuroticism and negative affectivity. In accordance with the findings on the relationship between anger and immune system regulation, also neuroticism was shown to be associated with alterations in inflammatory markers (Kiecolt-Glaser, McGuire, et al., 2002). In a recent study by Sutin et al. (2010), high levels of neuroticism were associated with higher levels of the pro-inflammatory cytokine interleukin-6 (IL-6) in a population-based sample controlling for relevant covariates.

Similar to neuroticism, Type D has been associated with various health outcomes in healthy subjects. Williams et al. (2009), for example, demonstrated in a study on 84 healthy young adults that Type D personality was associated with increased cardiovascular stress reactivity, including higher heart rate, blood pressure, and cardiac output. Type D however has been primarily studied in patients with CVD. In survivors of acute cardiac events, it was shown to be related to increased cortisol levels (Molloy, Perkins-Porras, et al., 2008; Whitehead, Perkins-Porras, et al., 2007), and in chronic heart failure patients, Type D was associated with an increased activity of pro-inflammatory cytokines (Denollet, Schiffer, et al., 2009). With respect to the long-term prognosis of health outcomes, including revascularization, myocardial infarction, as well as cardiac death, the pooled effect size of nine prospective studies indicated that Type D personality was associated with a more than threefold increased risk of poor long-term prognosis (Denollet, Schiffer, & Spek, 2010). To sum up, physiological changes in major stress-sensitive systems have been shown to be associated with the tendency to experience negative emotions, captured through the personality traits neuroticism and Type D personality, which pose these individuals at a greater risk to develop CVD. However, also behavioral factors seem to play an important role, when trying to explain the adverse effects of neuroticism and Type D on health. Both constructs have been shown to be related to negative health behaviors such as unhealthy lifestyle (poor diet, smoking status) or low adherence to medical treatment (Mroczek, Spiro, & Turiano, 2009; Williams, O'Connor, et al., 2008).

The Association Between Clinical Depression and CVD

As pointed out above, there is a substantial overlap between personality traits related to emotional distress and diagnosable psychopathology. Here, exemplary evidence on the relationship between stress-related physiological dysregulation, major depression, and CVD will be summarized. However, also other subtypes of depression such as seasonal affective disorders (SAD) (Thorn, Evans, et al., 2010), atypical depression (Gold & Chrousos, 2002) or bipolar disorder (Daban, Vieta, et al., 2005) have been linked to various alterations in the regulation of stress-sensitive systems such as the HPA axis or the autonomic nervous system.

One of the most reliably reported neurobiological alterations in psychiatry is a hyperactivity of the HPA axis (Stetler & Miller, 2011), involving elevated secretion of corticotropin-releasing hormone (CRH) in major depression. A significant percentage of depressed patients have been shown to hypersecrete cortisol, as manifested by increased 24-h urinary free cortisol and elevated plasma and cerebrospinal fluid concentrations of cortisol, nonsuppression of cortisol and ACTH following dexamethasone administration, and increased volume of the pituitary gland and of the adrenal glands (Holsboer, 2001; Pariante, 2009). Hypercortisolism has been discussed to be one of the main biological mechanisms explaining the link between major depression and CVD because it increases the risk of hypertension; it weakens endothelial repair mechanisms and contributes to increased levels of cholesterol and triglycerides (Musselman, Evans, & Nemeroff, 1998; Whitworth, Williamson, et al., 2005). Altered activity of the autonomic nervous system (ANS) is another pathway implicated in the development of major depression. Cross-sectional studies have demonstrated that depressed patients with CHD as well as patients with the melancholic subtype of depression are more likely to have decreased heart rate variability (HRV) (Carney, Freedland, et al., 2002; Kemp, Quintana, et al., 2014). Furthermore, reduced baroreflex cardiac control also has been shown to correlate with depressive symptom severity in CHD patients (Watkins & Grossman, 1999).

Increases in biomarkers of inflammation in both the periphery and the brain have also been observed in depressive patients in numerous studies (Raison, Capuron, & Miller, 2006), and a state of chronic low-grade systemic inflammation is significantly increased in clinical depression (Carney, Freedland, et al., 2002). Such low-grade systemic inflammation, characterized by an increase in circulating levels of pro-inflammatory cytokines and acute-phase reactants, such as TNF-α, IL-6, and CRP, and by a decrease in the levels of anti-inflammatory cytokines (such as IL-4 or IL-10), crucially contributes to the development of atherosclerosis (Kilic, Ural, et al., 2006). Finally, depressive symptoms are associated with increased risk of cardiac events and are furthermore associated with worse outcomes in patients with diabetes and rheumatoid arthritis (Rosengren, Hawken, et al., 2004; Rugulies, 2002).

Implications for Behavioral Medicine and Concluding Remarks

The fact that extrinsic stressors and social contexts interact with individual coping strategies and emotional experiences, thereby inducing a variety of potentially harmful physiological responses, has direct implications for behavioral medicine. First of all, additional experimental research demonstrates that the major social stressors discussed so far in an epidemiological framework in section "Social Stressors and Stress-Related Diseases" can be – comparable to the intrinsic factors – directly linked to indicators of psychobiological pathways possibly underlying the observed statistical associations with disease endpoints. These indicators include cardiovascular and hormonal responses, markers of immune function and inflammation, or measures of allostatic load. Reviews are available for social isolation and lack of social support (Uchino, 2006 and Uchino et al, infra), for low socioeconomic status (Seeman, Epel, et al., 2010), and for the two work stress models (Chandola, Britton, et al., 2008; Siegrist, 2009). Thus, there is some credibility in assuming a causal relationship between social stressors and disease susceptibility, which may be relevant in terms of probabilistic risk assessment in individual persons. In fact, several screening tools were proposed for risk assessment among groups of vulnerable people.

Second, despite the difficulties of conducting randomized clinical trials in this field, preliminary findings from intervention studies indicate that reduction of a social stressor can exert favorable effects on the health and well-being of exposed people. This was documented in work settings using the two work stress models discussed (Bourbonnais, Brisson, & Vezina, 2011; Limm, Gundel, et al., 2011; Theorell, Emdad, et al., 2001) and, with mixed results, in studies that increased social support (Holt-Lunstad, Smith, & Layton, 2010). Third, as the majority of interventions in behavioral medicine, whether in primary or secondary prevention, take place in therapeutic settings, the improvement of individual skills and capabilities of coping with social stressors defines a primary goal of intervention. In addition to the more general techniques of relaxation, meditation, stress inoculation, anger management, and self-assertiveness, a specific cognitive-motivational intervention can be derived from the theoretical framework outlined. It concerns the modification of work-related attitudes of achievement and commitment. We mentioned that overcommitted people contribute to recurrent experience of reward frustration by overtaxing their resources without considering their long-term consequences. Cognitive-behavioral change attempts at reappraising work demands and motivations for excessive engagement. In line with a more realistic assessment of "cost-gain" relations at work, the ability to observing some mental distance from one's involvement in obligations is strengthened. People are trained to decline inappropriate demands and to experience self-esteem from sources other than work and achievement (Aust, Peter, & Siegrist, 1997). In a further intervention study based on the model of effort-reward imbalance, a significant reduction of perceived stress reactivity after 1 year was achieved (Limm, Gundel, et al., 2011). These are just a few examples illustrating the possible benefit of behavioral interventions that contribute toward strengthening people's sense of belonging, to reinforce their self-efficacy, and to support their self-esteem even if social contexts are not fully responsive to these needs.

Finally, a few studies investigated the effects of stress management not only on behavioral outcome measures and subjective stress ratings but also on the physiological stress markers discussed above. Gaab et al. (2003), for example, demonstrated that cognitive-behavioral stress management training following the principles of the stress inoculation training developed by Meichenbaum (1985) can influence endocrine responses and cognitive appraisal under acute laboratory stress in healthy male adults. The reduction in the cortisol stress response to the Trier Social Stress Test (TSST) in the treatment group compared to a wait control group was related to a different cognitive appraisal of the situation. Subjects in the treatment group appraised the situation as less stressful and generally coped better with it. The authors argue that the stress management training exerted its effects through the modulation of the cognitive and affective processing of stressful stimuli. In a follow-up study, the same group set out to investigate whether the effects of the stress management training were stable over time and generalizable to both genders. The previously observed attenuation of cortisol stress responses 2 weeks after the stress inoculation training was also observed after a time interval of 4 months. Furthermore, the attenuation of the cortisol response to stress could be observed in both men and women (Hammerfald, Eberle, et al., 2006). Also, a more resource-oriented form of stress management training, according to the Zürich resource model, was shown to modulate cortisol stress responses to the TSST, 3 months after the training in healthy male subjects (Storch, Gaab, et al., 2007). Gaab et al. (2006) also observed effects on stress hormone regulation with regard to real-life stress, that is, an academic exam. University students received a cognitive-behavioral stress management training 8 weeks before an important exam. Subjects in the treatment group compared to a wait control group reported less anxiety and lower levels of somatic symptoms throughout the period prior to the exam. Interestingly, on the day of the exam, subjects in the wait control group displayed attenuated cortisol awakening responses, which did not match with the cognitive appraisal of the upcoming stressor. It is speculated that the observed dissociation between the psychological and biological stress responses, namely high subjective stress combined with the inability to mount an adequate physiological stress response in the control group, might be an indication of a dysregulated HPA axis, probably as a consequence of chronic stress. With respect to patients suffering from CVD, Blumenthal et al. (2005) demonstrated in a large randomized control trial that exercise in combination with a stress management training reduced emotional distress and improved markers of cardiovascular risk more than usual medical care alone.

Finally, mindfulness-based stress reduction (MBSR) has received growing attention in clinical research, and recently biomarkers have been included to validate the self-reported benefits of the program (Matousek, Dobkin, & Pruessner, 2010). However, results regarding potential effects on HPA axis regulation are still mixed (Brand, Holsboer-Trachsler, et al., 2012; Creswell, Pacilio, et al., 2014; Lynch, Gander, et al., 2011; Stefanaki, Bacopoulou, et al., 2014), which may in part be explained by differences in program structure, sample characteristics, and the fact that both basal cortisol levels and the cortisol response to acute stress have been studied. While intervention research continues to be a task of primary importance to behavioral medicine, innovative research directions are equally relevant. One such promising approach concerns the study of positive affective states and their effects on health and well-being. There is growing evidence that positive well-being may be linked to health-buffering effects. Analyses of associations between positive affect and neuroendocrine, cardiovascular, as well as inflammatory activity documented lower cortisol output over both a working day and a leisure day and lower heart rate assessed by using ambulatory monitoring methods over the day (Steptoe, Wardle, & Marmot, 2005). Moreover, the plasma fibrinogen response to acute stress was smaller in individuals who reported higher levels of positive emotions (Steptoe, Dockray, & Wardle, 2009). Enhanced parasympathetic cardiac control may be a process through which positive emotions can protect against CVD (Bhattacharyya, Whitehead, et al., 2008; Raikkönen, Matthews, et al., 1999). To sum up, a number of studies demonstrated that positive affect is significantly associated with psychobiological alterations that could have protective effects against stress-related diseases. Finally, positive affect and positive traits such as optimism and hopefulness were also shown to relate to reduced mortality with stronger effects in healthy populations than in those with existing illnesses in a recent meta-analysis of prospective studies by Chida and Steptoe (2008).

Furthermore, alternative methods of measuring emotions, not retrospectively but in daily life, such as ambulatory assessment, allow the investigation of subjective experiences linked to a particular time and context. Growing evidence seems to suggest that this approach is especially well suited to study associations between emotional states and various biomarkers compared with traditional self-reported traits (Conner & Barrett, 2012; Kudielka, Gierens, et al., 2012). In conclusion, rich evidence on associations between emotions and stress offers new insights into the biopsychosocial dimensions of human health and disease. At the same time, new opportunities are given to reduce the burden of disease and to promote health, at both the individual and population levels.

Social Support and Physical Health: Models, Mechanisms, and Opportunities

Bert N. Uchino, Kimberly Bowen, Robert Kent de Grey,
Jude Mikel, and Edwin B. Fisher

Scientists have long-noted an association between social relationships and health. More socially isolated or less socially integrated individuals are less healthy psychologically and physically, and more likely to die.

(House, Landis, & Umberson, 1988, p. 540)

The statement by House and colleague (1988) over 25 years ago has survived the test of time. Social relationships are reliable predictors of all-cause mortality rates, as well as more specific physical health outcomes such as cardiovascular and infectious disease (Berkman, Glass, et al., 2000; Cohen, 2004; Holt-Lunstad, Smith, & Layton, 2010; Uchino, 2004). These epidemiological studies typically rely on the broad distinction between structural and functional aspects of support (Cohen & Wills, 1985). Structural measures tap into the extent to which a person is situated or integrated into a social network (e.g., married, contact with family members). Functional measures are based on the particular supportive functions served by our relationships such as emotional support (e.g., expressions of caring). These functional support measures can be further differentiated based on whether that support is perceived to be available or actually received by the recipient (Barrera, 1986).

In this chapter, we first briefly review evidence linking structural and functional measures of social support to physical health outcomes. We then present an interdisciplinary, multilevel model that incorporates the mechanisms responsible for such links. The evidence for primary pathways in the model is discussed followed by emerging perspectives and issues. Finally, we discuss the intervention, practice, and policy implications of the work linking social support to physical health outcomes.

Social Support and Physical Health

Researchers have examined links between social support and more general (e.g., mortality rates) and specific (e.g., cardiovascular disease) indices of health. Two early studies were particularly important in stimulating work in this area. In 1979, Berkman and Syme examined thousands of participants from Alameda County, California. They found that structural measures of support (i.e., social integration) predicted lower mortality rates even when considering standard control

variables like initial health status. Several years later, Blazer (1982) studied a community sample of older adults in Durham County, NC. Even when considering standard control variables such as physical health status and smoking, perceptions of functional support predicted lower mortality rates. These results held even when considering structural measures of social integration such as those utilized by Berkman and Syme (1979), thereby showing an independent association between functional and structural support with physical health.

Since these seminal studies, there have been many others that have linked social support to physical health. In a recent meta-analysis, Holt-Lunstad, Smith, and Layton (2010) examined 148 studies comprising over 300,000 participants from around the globe including the United States, Europe, Asia, and Australia. They found that social support overall was associated with a 50% increased likelihood of survival (OR = 1.50). Importantly, the link between social support and mortality was consistent across age, sex, initial health status, cause of death, and follow-up (Holt-Lunstad, Smith, & Layton, 2010). Indeed, effect sizes for these associations were comparable to standard biomedical risk factors including smoking, alcohol consumption, and physical activity. To put it plainly, social support appears to be as important for life expectancy as not smoking.

Although these structural and functional measures of support predict mortality, it is not the case that all measures are consistently predictive of health outcomes. In the recent meta-analysis, there was significant variability on mortality based on how support was operationalized (Holt-Lunstad, Smith, & Layton, 2010). These authors found that simple structural measures of support such as living alone/with others were not significantly related to survival. However, composite structural measures of support (i.e., aggregated across marriage, close friends, volunteer work) showed strong links to greater survival (OR = 1.91). This finding is consistent with the English Longitudinal Study of Ageing which found that a composite measure of social isolation significantly predicted lower mortality rates (OR = 1.26) after adjustments for a comprehensive set of covariates including demographic factors, health status, and depression (Steptoe, Shankar, et al., 2013). Overall, these data suggest that there is not one key determinant or source of social support that impacts on health. It may be the case that support from different sources is interchangeable as long as one has access to individuals to talk with about intensely important and personal matters (Miller & Ingham, 1976).

Measures of functional support also showed variable links to mortality rates. In prior work, the concepts of perceived and received support have been used interchangeably with the assumption that individuals high in perceived support also received more support (Barrera, 1986; Dunkel-Schetter & Bennett, 1990; Uchino, 2009). However, measures of perceived and received support are only moderately correlated and hence seem to represent distinct constructs (Haber, Cohen, et al., 2007). In the meta-analysis, perceived support was significantly related to increased survival (OR = 1.35), whereas measures of received support did not predict survival (Holt-Lunstad, Smith, & Layton, 2010). In fact, several epidemiological studies examining received support (especially tangible support) found it to be associated with *higher* subsequent mortality rates (Forster & Stoller, 1992; Krause, 1997). We will return to this important issue later in the review, but these findings parallel a growing literature showing that under some conditions receiving support may be related to negative mental health outcomes (Wills & Shinar, 2000).

The literature linking social support to specific causes of disease is smaller. Although there are numerous studies linking social support to pre-disease biological processes (see next section), specific chronic diseases are determined by multiple factors so research that also shows a direct link to clinically significant outcomes is needed (Barth, Schneider, & von Kanel, 2010; Pinquart & Duberstein, 2010; Tay, Tan, et al., 2013). Preliminary evidence for a role of social support on the development of cardiovascular disease can be found in studies utilizing imaging techniques. Several of these studies have shown that social support predicts less underlying atherosclerosis (Angerer, Siebert, et al., 2000; Wang, Mittleman, & Orth-Gomer, 2005). For instance, women with established coronary artery disease who were low in emotional support showed faster disease progression as indexed by angiography over a subsequent 3-year period (Wang, Mittleman, & Orth-Gomer, 2005).

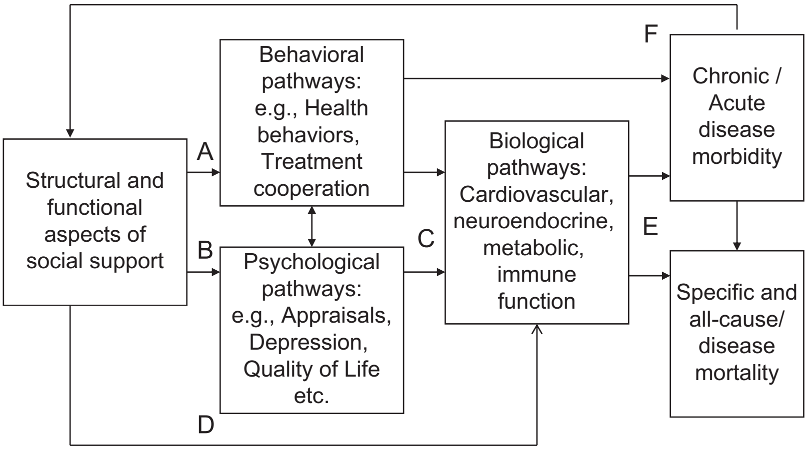
A number of studies have examined survival following the diagnosis of cardiovascular disease and cancer. Results of a meta-analysis focusing on cardiovascular disease found that functional, but not structural, measures of support predicted lower cardiovascular mortality (Barth, Schneider, & von Kanel, 2010). However, both structural and functional measures of support have been linked to lower cancer mortality in another meta-analysis, although these links are moderated by factors such as participant age and type of cancer (Pinquart & Duberstein, 2010). Finally, although we know of no recent meta-analysis linking social support to infectious diseases (e.g., HIV, vaccinations), qualitative reviews suggest that social support has beneficial influences on biologically significant infectious disease outcomes (Uchino, Vaughn, et al., 2012a).

A Broad Multilevel Model Linking Social Support to Physical Health

Although social support predicts significant health outcomes, the testing of a broad theoretical model would be useful to incorporate existing findings and guide relevant interventions. In this section, we focus on an interdisciplinary model highlighting the mechanisms by which social support can influence health outcomes (see Fig. 12.1). There are certainly sub-models (e.g., stress-buffering, direct effect models), and these will be highlighted when relevant. For instance, the stress-buffering model suggests that social support is primarily effective when individuals are under high levels of stress, whereas the direct effect model highlights the role of support regardless of stress (e.g., positive affective experiences). As shown in Fig. 12.1, structural and functional aspects of social support are grouped as indices of the global support construct. By doing so, we assume that structural features of the social environment provide the context by which functional support emerges, is maintained, and changes over time (e.g., family context, Graves, Wang, et al., 1998; Repetti, Taylor, & Seeman, 2002).

Social support is hypothesized to first impact several potential pathways that can influence disease. Path A depicts behavioral processes linking social support to health and includes factors such as health behaviors and cooperation with treatment regimens (DiMatteo, 2004; Shankar, McMunn, et al., 2011). Path B depicts psychological pathways including stress appraisals, depression, and quality of life (Berkman, Glass, et al., 2000). Although depicted as mediators, these psychological and mental health processes are also important outcomes in their own right (e.g., Diener & Chan, 2011). However, given the focus of this chapter is

Fig. 12.1 Broad model highlighting major mechanisms linking social support to physical health



on physical health outcomes, we primarily discuss their role as potential mediators. It is also important to note that the psychological and behavioral pathways are related to each other as stress appraisals can negatively influence health behaviors and health behaviors such as exercise can positively influence psychological processes (Ng & Jeffery, 2003; Stathopoulou & Powers, 2006).

Behavioral and psychological processes may also influence disease through relevant biological alterations (Path C). For instance, exercise is associated with lower blood pressure and greater cardiovascular efficiency (Smith & Kampine, 1990). We also postulate that there may be a direct link between social support and biological processes which in turn influence disease (Path D) as will be discussed below. The main biological pathways include cardiovascular, neuroendocrine, metabolic, and immune function. These biological processes in turn influence disease development and mortality as they play a role in the leading causes of death including cardiovascular disease, metabolic disorders, cancer, and infectious disease (Path E, Timiras, 1994). Finally, once individuals are diagnosed and undergoing treatment for chronic conditions, it can have direct links to social support by influencing support seeking from family and friends, disease-related adjustment, and in some cases support "erosion" due to distress over the adherence or health status of a close other (Path F, Reed, Butler, & Kenny, 2013).

Evidence for the Broad Model

In the following section we focus on a representative review of links between social support and the specific mechanisms highlighted in Fig. 12.1 (Paths A, B, D, & F). There is a large literature linking behavioral (e.g., exercise) and psychological (e.g., depression) pathways to biological and disease outcomes (Paths C and E, see Miller, Chen, & Cole, 2009; Rozanski, Blumenthal, & Kaplan, 1999; Smith & Ruiz, 2002), but here we will focus on the social support influences on pathways related to disease.

Path A: Social Support and Behavioral Pathways There is strong evidence linking social support to beneficial health practices. Perceived support has been associated with greater physical activity, less smoking/alcohol consumption, and better sleep quality (Ailshire & Burgard, 2012; Courneya, Plotnikoff, et al., 2000; Kouvonen, De Vogli, et al., 2011; Steptoe, Wardle, et al., 1996; Reininger, Perez, et al., 2012; Stewart, Gabriele, & Fisher, 2012; Yuan, Weng, et al., 2011). Although many of these studies were conducted in the United States, these associations have also been documented in Mexico, Taiwan, England, and Canada (Courneya, Plotnikoff, et al., 2000; Kouvonen, De Vogli, et al., 2011; Reininger, Perez, et al., 2012; Yuan, Weng, et al., 2011).

Social support is also related to better patient cooperation with treatment regimens in chronic disease populations. DiMatteo (2004) conducted a meta-analysis of 122 studies examining links between structural and functional support with patient's medical adherence (e.g., diabetes, cardiovascular, arthritis). Structural measures such as marital status (RR = 1.17) and living with others (RR = 1.41) predicted greater adherence. However, functional measures were generally stronger predictors of better adherence (RR = 1.90 for practical support, RR = 1.35 for emotional support, RR = 1.54 for general perceptions of support).

The data linking social support to behavioral pathways are consistent with several existing theoretical perspectives (Cohen, 2004; Lewis & Rook, 1999; Umberson, 1987). Social control models of support highlight both an indirect (e.g., life meaning) and direct (e.g., requests by spouse) role of others on health behaviors (Umberson, 1987). This model also makes the unique prediction that although social network members can influence us to behave in healthier ways, they may also be a source of psychological distress (Hughes & Gove, 1981). This distress can occur because people resent being directly controlled by others. Consistent with this prediction, when social control was measured from specific network members, it predicted both greater distress and healthier behaviors (Lewis & Rook, 1999).

The process of social control is often linked to the direct effect model which historically highlighted the role of structural measures of support in fostering lifestyle factors and well-being regardless of stress (Cohen & Wills, 1985). However, it is clear that functional measures of support are also linked to better lifestyle and behavioral factors (Kouvonen, De Vogli, et al., 2011; Stewart, Gabriele, & Fisher, 2012). There are also stress-related links between social support and health behaviors (i.e., stress prevention and stress-buffering models; Gore, 1981; Lin, 1986). These models are particularly important to consider because high stress has been linked to less healthy behaviors including poorer diet, less exercise, and sleep quality, as well as greater alcohol consumption and smoking (Cohen & Lichtenstein, 1990; Hall, Thayer, et al., 2007; Ng & Jeffrey, 2003). Consistent with this pathway, researchers found that tangible support decreased the association between financial stress and alcohol involvement (Peirce, Frone, et al., 1996; also see Wills & Cleary, 1996).

As highlighted by the model in Fig. 12.1, there has also been research examining if behavioral pathways are responsible for links between social support and biological/physical health outcomes (Uchino, 2004). These studies suggest that social support effects are reduced, although still significant, when considering health behaviors (Kaplan, Wilson, et al., 1994; Penninx et al., 1997; Seeman, Kaplan, et al., 1987). Controlling for health behaviors enables one to directly model its overlap with social support and health outcomes. Thus, a reduction in explanatory power as a result of controlling for health behaviors suggests that part of the link between social support and health is due to its association with health behaviors. For instance, one study found that statistical adjustments for risk factors including smoking, alcohol intake, coffee intake, physical activity, body mass, lipoprotein levels, and income reduced the mortality risk for low organizational activities by about 16% (Kaplan, Wilson, et al., 1994). Using data from the Stockholm Heart Epidemiological Program and Västernorrland Heart Epidemiological Program, it was found that disturbed sleep reduced the link between social support and myocardial infarctions in women (Nordin, Knotsson, & Sundbom, 2008). Although these studies did not use more current recommendations for mediational analyses (Rucker, Preacher, et al., 2011), they surely suggest the possibility and should receive further investigation.

Path B: Social Support and Psychological Pathways Most major theories of social support and health argue that psychological mechanisms are partly responsible for such links (Berkman, Glass, et al., 2000; Cohen, 2004; Thoits, 2011; Uchino, 2004). The stress-buffering model of support hypothesizes that social support should (a) reduce stress appraisals or (b) weaken the link between stress and adverse outcomes. The direct effect model also highlights the role of social support in fostering a sense of connection, self-esteem, and control over life due to knowing that you are cared for and supported by others (Lakey & Orehek, 2011; Thoits, 2011; Uchino, 2004). Broader perspectives also highlight psychological mechanisms that have been linked to both support and physical health outcomes in prior work (e.g., depression, quality of life, Uchino, 2004).

There is strong evidence that social support has beneficial influences on psychological and mental health outcomes. Social support has been linked to beneficial appraisal patterns (Dunkel-Schetter, Folkman, & Lazarus, 1987), as well as greater feelings of control, self-efficacy, and self-esteem (Atienza, Collins, & King, 2001; Shaw, Krause, et al., 2004; Symister & Friend, 2003). High levels of social support are also related to lower perceptions of stress, less stress exposure, and lower depression (Sarason, Sarason, & Pierce, 1990; Russell & Cutrona, 1991). Of particular interest is research linking social support to higher quality of life as this is an important indicator of adjustment to chronic conditions and life challenges more generally (Diener & Chan, 2011). To this point, social support has been related to higher quality of life among individuals with cancer (Waters, Liu, et al., 2013), HIV (Bekele, Rourke, et al., 2013), or diabetes (Glasgow, Barrera, et al., 1999).

According to Fig. 12.1, these psychological processes should partially mediate links between social support and biological/physical health outcomes. Such models were tested explicitly in the late 1990s. For instance, one study examined age-related differences in resting blood pressure as a function of perceived social support (Uchino, Holt-Lunstad, et al., 1999). These authors found that social support was associated with lower resting blood pressure in older adults, an effect that was not statistically mediated by perceived stress, depression, or satisfaction with life. Lutgendorf and colleagues (2000) also directly tested the possibility that mood states might be responsible for links between receiving social support and IL-6 in cancer patients. They found no evidence that alterations in mood were responsible for such links. In general, the available literature provides little evidence that the influence of social support on health-relevant outcomes is statistically mediated by anxiety, life stress, subjective distress, or depression (see Uchino, Bowen, et al., 2012b for a review). Although these data are inconsistent with theoretical models, we discuss later (see Emerging Perspectives and Issues) important factors that need consideration when examining this pathway.

Path C: Social Support and Biological Pathways Although behavioral and psychological factors remain the dominant mechanisms postulated to account for the social support – physical health link, there is evidence that there may also be a direct link between social support and health-relevant central and peripheral biological processes (Uchino, Cacioppo, & Kiecolt-Glaser, 1996). As noted earlier, the inclusion in statistical models of neither behavioral nor psychological factors eliminates the link between social support and health-relevant outcomes. This provides evidence for a potential direct effect.

Much work bearing on the pathways linking social support with biological outcomes has focused on the autonomic nervous system especially cardiovascular function. According to the reactivity hypothesis, individuals or situations characterized by high levels of cardiovascular reactivity (usually indexed by blood pressure or heart rate) may be related to higher risk for the development and exacerbation of cardiovascular disease (Chida & Steptoe, 2010). Thus, social support may be beneficial because it "buffers" the potentially harmful influences of stress-induced cardiovascular reactivity (Cohen & Wills, 1985). Indeed, studies that directly manipulate the supportive function of relationships appear to provide evidence for this stress-buffering hypothesis (Cosley, McCoy, et al., 2010; O'Donovan & Hughes, 2008; Thorsteinsson & James, 1999).

Social support may also be beneficial because it is associated with lower resting blood pressure or ambulatory blood pressure (ABP) during everyday life. ABP has emerged as an important outcome because it measures one's real life blood pressure over an extended period of time and has been linked to cardiovascular risk even after considering clinic blood pressure readings (Pickering, Shimbo, & Haas, 2006). One community study found that age was associated with increases in resting blood pressure. Further analysis, however, showed this was only true of individuals low in social support. Individuals high in support showed low and stable blood pressure across age categories (Uchino, Holt-Lunstad, et al., 1999). Existing studies are also consistent with a link between social support and lower ABP during daily life (Gump, Polk, et al., 2001; Rodriguez, Burg, et al., 2008; Steptoe, Lundwall, & Cropley, 2000), especially emotional support (Bowen, Birmingham, et al., 2013). Consistent with the buffering model of support, several studies also suggest that social support can buffer the link between stress and daily life ABP (Bowen, Uchino, et al., 2014; Steptoe, Lundwall, & Cropley, 2000).

In comparison to cardiovascular function, there is much less work linking social support to neuroendocrine function. The relative lack of such data is noteworthy because hormones and neurotransmitters mediate aspects of cardiovascular and immune function (Ader, Felton, & Cohen, 2001) and thus may shed light on how these diverse physiological systems are coordinated as a function of social support. There is some evidence that social support is associated with lower catecholamine levels (Seeman, Berkman, et al., 1994; Grewen, Girdler, et al., 2005) which is consistent with the beneficial effects of social support on cardiovascular function. In addition, social support is related to lower cortisol levels which is important due to its well-documented immunosuppressive effects (Floyd, Mikkelson, et al., 2007; Grant, Hamer, & Steptoe, 2009; Heinrichs, Baumgartner, et al., 2003).

One hormone of particular interest is oxytocin due to its hypothesized links with social support and with stress indicators across multiple biological systems (Knox & Uvnas-Moberg, 1998). For instance, oxytocin has anti-stress effects in both the brain and more peripheral physiological systems (Taylor, Klein, et al., 2000). In one of the few human studies, perceptions of partner support were uniformly associated with higher oxytocin levels (Grewen et al., 2005; but see Smith, Uchino, et al., 2013). Heinrichs and colleagues (2003) also manipulated social support (via a friend) and oxytocin levels (via a nasal spray) in men undergoing acute psychological stress. Consistent with the stress-buffering hypothesis, social support was associated with lower cortisol responses. These support effects were especially evident if combined with the oxytocin manipulation as such individuals showed the smallest increases in cortisol during stress. These data suggest that social support has influences above and beyond oxytocin which is testament to its powerful link across bodily systems. It is important to note that rather than being specific to trust or support in relationships, recent theoretical models suggest that oxytocin may set one's sensitivity to social stimuli – good or bad (Campbell, 2010). Thus, oxytocin can increase interpersonal trust or decrease it depending on the situational cues such as cooperation or competition (Bartz, Zaki, et al., 2011).

Most of the work linking social support to metabolic pathways has focused on diabetics. Importantly, there is evidence linking social support to better metabolic control in adolescents with diabetes (Burroughs, Harris, et al., 1997). A recent longitudinal study of adolescent diabetics also showed that the combination of high family restrictiveness and low parental support was related to poorer metabolic control (Seiffge-Krenke, Laursen, et al., 2013). Of course, metabolic pathways are complex, and more work will be needed linking social support to other patient populations and outcomes (e.g., restorative processes, Robles & Carroll, 2011).

A final physiological pathway by which social support may influence physical health is via the immune system (Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Much recent work in this area has focused on linking social support to inflammation (Costanzo, Lutgendorf, et al., 2005; Friedman, Hayney, et al., 2005; Lutgendorf, Anderson, et al., 2000; McDade, Hawkley, & Cacioppo, 2006; Wirtz, Redwine, et al., 2009). Of these studies, most have examined IL-6 which has both pro- and anti-inflammatory influences (Papanicolaou, Wilder, et al., 1998; Hawkley, Bosch, et al., 2007) and is related to a number of disease processes such as diabetes, cardiovascular disease, osteoporosis, and some cancers (Barton, 2005). The existing data are consistent with a link between social support and lower levels of IL-6 implicating this as one potential inflammatory pathway involved in the health benefits of support (Costanzo, Lutgendorf, et al., 2005; Friedman, Hayney, et al., 2005). However, the links between social support and other inflammatory cytokines have not been investigated in sufficient numbers of studies to draw firm conclusions. For instance, the association between social support and C-reactive protein (CRP) levels has only been examined in a few studies and shows weak or no associations with support (Coussons-Read, Okun, & Nettles, 2007; Loucks, Sullivan, et al., 2006; McDade, Hawkley, & Cacioppo, 2006). These data are surprising in light of links between support and IL-6 which is a potent stimulator of CRP release. However, it is possible that IL-6 may have independent links to disease processes beyond that of CRP (Ridker, Rifai, et al., 2000).

There has also been a systematic effort to link social support to more biologically relevant immune outcomes. In one of the first studies in this area, Glaser, Kiecolt-Glaser, et al., (1992) found that social support was associated with higher antibody (Ab) titers and T-lymphocyte responses to a hepatitis B vaccine. Subsequent work has shown that social support is related to clinical standards for seroconversion rates (e.g., fourfold increase in Ab titers, Glaser, Kiecolt-Glaser, et al., 1992; Phillips, Burns, et al., 2005), although social support has not been related to some vaccines (Gallagher, Phillips, et al., 2008).

There are also links between social support and aspects of immune function in cancer patients. A systematic and innovative program of research by Lutgendorf and colleagues found that perceived support was related to higher natural killer cell activity in both blood and the tumor microenvironment (Lutgendorf, Sood, et al., 2005). In addition, perceived support has been related to lower levels of growth factors (e.g., vascular endothelial growth factor, matrix metalloproteinase) in the blood and tumors of ovarian cancer patients (Lutgendorf, Johnsen, et al., 2002, Lutgendorf, Lamkin, et al., 2008). These findings are important because such growth factors play a role in tumor angiogenesis (Kerbel, 2000).

There have been a number of studies that have tested the stress-buffering model of support on immunity (Bosch, Fischer, & Fischer, 2009; Kang, Coe, et al., 1998; Kiecolt-Glaser, Dura, et al., 1991; Turner-Cobb, Koopman, et al., 2004). Cohen and Wills (1985) argued that one methodological requirement for an adequate test of the buffering model is to show a main effect of stress on the outcome; all of these studies showed such an effect. Importantly, a majority of these studies found some evidence for a buffering effect of support for individuals high in life stress on measures of immunity (Bosch, Fischer, & Fischer, 2009; Kang, Coe, et al., 1998; Kiecolt-Glaser, Dura, et al., 1991; Turner-Cobb, Koopman, et al., 2004; but see Marsland, Sathanoori, et al., 2007).

Finally, recent work is highlighting the central brain mechanisms that may be responsible for coordinating links to peripheral physiological pathways (Coan, Schaefer, & Davidson, 2006; Eisenberger, Taylor, et al., 2007; Eisenberger, Master, et al., 2011; Onoda, Okamoto, et al., 2009). Studies are heterogeneous in terms of their design and manipulations, but social support appears to attenuate responses in the anterior cingulate cortex (ACC). Studies differ in terms of findings in the ventral ACC (Coan, Schaefer, & Davidson, 2006; Onoda, Okamoto, et al., 2009) or the dorsal ACC (Eisenberger, Taylor, et al., 2007; Eisenberger, Master, et al., 2011). Nevertheless, the ACC is linked to greater blood pressure reactivity (Critchley, Mathias, et al., 2003; Gianaros, Derbyshire, et al., 2005) which provides evidence for how these diverse systems are coordinated as a function of support.

There are several neural mechanisms by which social support may attenuate activity in the ACC. Several studies suggest that increased activity in the dorsolateral prefrontal cortex (DLPFC) and ventral medial prefrontal cortex (vmPFC) may be associated with lower activity in the ACC (Coan, Schaefer, & Davidson, 2006; Eisenberger, Master, et al., 2011; Onoda, Okamoto, et al., 2009). In a recent well-controlled laboratory study, Eisenberger, Master, et al. (2011) exposed participants to pain stimuli (heat) while viewing either pictures of a romantic attachment figure, a stranger, or neutral objects. Viewing pictures of the attachment figure were associated with lower pain ratings and greater vmPFC activity which was stronger for longer relationships. In addition, activity in the vmPFC was negatively correlated with activity in the dACC. On a theoretical level, the emerging neuroimaging evidence is thus highlighting how the brain is influencing critical peripheral pathways linking social support to physical health outcomes. Across these biological systems, it should be clear that social support is having direct impacts on our bodies which may translate to health problems. Besides its theoretical value, potential applications of this biological modeling might include: (a) the tracking of pre-disease and chronic disease populations who benefit most from support interventions based on these health-relevant pathways, (b) the comparison of different support intervention approaches that might differ in their ease of implementation and cost-effectiveness, and (c) the identification of support-related biological pathways that might be amenable to pharmacological intervention. Finally, biological modeling can advance a better conceptual understanding of the conditions under which support, in all its different forms, has measureable benefits or costs. In this regard, basic laboratory research can supplement existing work by examining more precise manipulations of support and its causal links to physiological outcomes.

Path F: Changes in Support as a Function of Chronic Disease This is a relatively unique pathway as most models of social support and health do not consider such feedback loops. However, it is well known that stressors can influence the expression of both positive and negative behaviors within families (Randall & Bodenmann, 2009; Repetti, Wang, & Saxbe, 2009). For instance, husbands and wives report more marital anger and withdrawal at home following negative social interactions at work (Story & Repetti, 2006). These findings are important because coping with chronic conditions has been characterized as an interpersonal process that has cascading influences on stress and coping (Berg & Upchurch, 2007).

More generally, coping with chronic diseases can also be conceptualized as a significant stressor given the multiple treatment, lifestyle, and social/psychological issues faced by patients (Nicassio & Smith, 1995). Consistent with the stress-buffering model, social support should be helpful in fostering adjustment and cooperation with medical regimens during the course of chronic disease. Indeed, social support has been linked to beneficial mental and physical health outcomes across chronic conditions including cardiovascular disease and diabetes (Barth, Schneider, & von Kanel, 2010; Fisher, La Greca, et al., 1997; Penninx et al., 1996, Kriegsman, et al., 1996). In addition, these stressors influence not only the patient but their close relationships and hence can have a direct impact on the support process (Berg & Upchurch, 2007; Coyne & Smith, 1991). In one study, researchers directly tested this possibility by examining how support was influenced when couples attempted to cope with the diagnosis and treatment of breast cancer (Bolger, Foster, et al., 1996). These researchers found that although support was initially mobilized in response to the diagnosis, the patients' distress was related to an erosion of received support from the spouse over time (also see Alferi, Carver, et al., 2001; Northouse, Templin, et al., 1998). In theory there are additional places in the model where feedback processes might occur (e.g., behavioral processes influencing support as might be predicted by social control theorist). However, because chronic conditions influence the entire family (e.g., routines, concern over person), it is a good starting point for testing and incorporating more dynamic feedback processes that can influence the pathways depicted in Fig. 12.1.

Emerging Perspectives and Issues

The model depicted in Fig. 12.1 provides a starting point for examining broad but salient pathways based on prior work. It integrates existing work on social support and health by including mechanisms and outcomes at different levels of analysis including psychological, behavioral, and physiological processes. Most work focuses on one or two of these pathways, but the model highlights the importance of modeling their interconnections, as well as potential reciprocal pathways that exist given the complexity of links between social support and health. Although integrative, there are a number of emerging issues that will warrant increased attention in order to maximize the theoretical and applied implications of the model.

Discrepant Health Influences of Perceived and Received Support One important issue has to do with incorporating the discrepancies sometimes found between measures of perceived and received support (Kaplan, Wilson, et al., 1994; Penninx et al., 1996; Seidman, Shrout, & Bolger, 2006). We should note that the same psychological and behavioral pathways are implicated as depicted in Fig. 12.1 although their influence may be opposing in nature (e.g., received support in some cases increasing stress compared to perceived support decreasing stress). It is also important to mention that some studies do find received support to have positive influences, and so we need to be appropriately cautious in accepting this proposition too generally. For instance, received support can be of several types (e.g., informational, belonging, emotional), and few studies have looked at how specific dimensions of received support predict adjustment during stress. There is good reason to take a closer look at specific dimensions because research suggests that the receipt of informational and tangible support tend to be viewed as less nurturant and more controlling than either emotional or belonging support (Trobst, 2000). Consistent with this possibility, one study examining patients with chronic conditions found a detrimental influence of received tangible support on depression but a beneficial influence of received emotional support (Penninx, van Tilburg, et al., 1998).

When received support does have negative influences, it has been argued that contextual issues are important to consider because received support directly involves the exchange of important social resources (Uchino, 2009). As a result, stressor, provider, and recipient factors become important (Barbee, Gulley, & Cunningham, 1990; Dunkel-Schetter & Skokan, 1990; Wills & Shinar, 2000). Stressor-related factors that can influence the efficacy of received support include the type of stress and support received. As highlighted by the matching hypothesis (Cutrona & Russell, 1990), individuals may not receive the optimal type of support to cope with their stress. As a result, the support might be frustrating and/or ineffective to the recipient. For instance, receiving informational support for uncontrollable stressors (e.g., how to "move on" following the loss of a loved one) can be seen as insensitive and unhelpful. There are also some stressors that are perceived as embarrassing/stigmatizing (e.g., sexually transmitted diseases) or evaluative (e.g., important job interview), and if close others attempt to provide unwanted support, this might be associated with negative outcomes.

There are also provider-related factors that can influence whether receiving support is detrimental (Canevello & Crocker, 2011; Gottlieb, 2000). One such factor is anxiety on the part of the support provider that may interfere with the retrieval of effective support skills (Gottlieb, 2000). In addition, the type and quality of the relationship can influence such links. In a controlled test of such differences, Christenfeld, Gerin, et al., (1997) trained friends and strangers to provide the same type of support to participants. Results during a subsequent laboratory stress assessment revealed that friends had a stronger stress-buffering effect on cardiovascular reactivity compared to strangers despite providing what was objectively the same support. These findings are consistent with prior work on the quality of the relationship as those who are viewed primarily as a source of positivity are more effective support providers compared to those who are viewed as simultaneous sources of both positivity and negativity (i.e., ambivalent, Holt-Lunstad, Uchino, et al., 2007).

Another important provider characteristic is the manner in which support is provided. A distinction can be made between support that is provided in a directive (e.g., tells you what to do) or a nondirective (e.g., cooperates with you to make decisions) way (Fisher, La Greca, et al., 1997). This distinction is important because receiving nondirective support has been associated with beneficial influences across a number of domains, whereas the links between directive support and beneficial outcomes appear more contextual (Fisher, La Greca, et al., 1997; Gabriele, Carpenter, et al., 2011; Stewart, Gabriele, & Fisher, 2012). For instance, Fisher, La Greca, et al. (1997) found that nondirective support was related to better metabolic control in younger diabetics, whereas directive support was related to worse mood in older diabetics. In a weight management program delivered by email, however, directive support was more effective than nondirective, suggesting that the most effective type of support may vary by task and setting (Gabriele, Carpenter, et al., 2011).

Finally, there are several recipient-related processes that appear important. One important factor is whether support is actually chosen by the recipient (Bolger & Amarel, 2007). It has been argued that received support is more likely to be beneficial once the choice to seek support has been made (Bolger & Amarel, 2007). In the absence of the decision to seek support, simply providing an individual with it may threaten their sense of esteem by producing feelings of inefficacy, guilt, or indebtedness (Bolger & Amarel, 2007; Martire & Stephens, 2011). As a result, Bolger and colleagues (2000); Bolger & Amarel (2007) have argued that "invisible support" (i.e., support given that is not noticed as such) may be especially beneficial because it does not result in negative psychological reactions that can override support. We should note that although this is given as an example of a recipient factor, invisible support also reflects provider characteristics related to the skillful provision of nonintrusive support (Howland & Simpson, 2010).

Recipients may also differ in their preferences or goals for receiving support. Men appear more likely to benefit from informational support (Craig & Deichert, 2002; Wilson, Kliewer, et al., 1999). In addition, Phillips, Gallagher, and Carroll (2009) found that women had lower cardiovascular reactivity when receiving emotional support from male friends, but higher reactivity when receiving emotional support from female friends. These results were interpreted as reflecting heightened evaluation from a close, similar other (Phillips, Gallagher, & Carroll, 2009). More generally, these studies are consistent with contextual influences of social support due to the importance of socialization on gender-appropriate support behaviors (Flaherty & Richman, 1989; Rosario, Shinn, et al., 1988).

The fact that received support has less consistent influences on outcomes suggests that there may be crucial moderators at work. One important moderator appears to be perceptions of responsiveness by the recipient (Maisel & Gable, 2009). Perceived responsiveness reflects an appraisal that others are being supportive of one's important values, goals, and preferences (Reis, 2007). A recent study from the Midlife in the United States Study (MIDUS) found that receiving emotional support was related to greater mortality only if it was perceived as not responsive to the individual (Selcuk & Ong, 2013). As such, perceptions of responsiveness could reflect the fact that the optimal conditions for receiving support were met (e.g., support that is a good match to stressor). It is also possible that responsiveness may reflect an appraisal of intent which could override any of the problems associated with stress, provider, and recipient factors (e.g., intention was good although misguided).

The issues surrounding received support also beg the question of why perceived support is so beneficial for health outcomes (Uchino, 2009). Interestingly, perceived support is remarkably stable over time, and hence researchers have argued that such perceptions have their origins in early family environments that are caring and nurturant (Sarason, Sarason, & Pierce, 1990). Studies do suggest that individual's perceptions of their early familial experiences are related to their subsequent perceptions of support (Flaherty & Richman, 1986; Mallinckrodt, 1992). Such family contexts may operate via the development of basic social competencies that facilitate the formation of supportive social networks (Cohen, Sherrod, & Clark, 1986; Repetti, Taylor, & Seeman, 2002). Consistent with this possibility, several longitudinal studies have now found that warm family environments predict better relationship function over time (Ackerman, Kashy, et al., 2013; Graves, Wang, et al., 1998).

There are several reasons why perceived support is consistently beneficial to health. First, individuals high in perceived support can use those perceptions as a "safety net" and hence eliminate the possibility of receiving support that may be unhelpful, intrusive, or insensitive (Uchino, 2009). Having the perceptions that others are there for you if needed also fosters feelings of personal control which may be beneficial to health (Shaw, Krause, et al., 2004). Given the early family contributions to perceived support, it has been further argued that such individuals codevelop positive psychosocial profiles which include better social skills, lower hostility, and secure attachment styles which can produce cumulative benefits over time (Uchino, 2009). Future research will be needed to test these possibilities which will inform the pathways depicted in Fig. 12.1.

Antecedent Processes Influencing Social Support The model in Fig. 12.1 is process-oriented but does not designate the antecedent processes that give rise to structural and functional aspects of support. As noted above, perceived social support can be established early in life and highlights the importance of the family environment as one important antecedent process (Flaherty & Richman, 1986; Graves, Wang, et al., 1998). In addition, given the contextual nature of received support, different antecedent processes including the anxiety level or social skills of the support provider, the cultural orientation or personality of the support recipient, and evaluation potential of the stressor context will be important to consider.

The field of relationship science is particularly relevant to addressing questions related to antecedent processes because it is interested in the factors that influence the development, maintenance, and dissolution of social ties. In fact, there are several constructs from relationship science that are particularly promising as antecedent processes for social support. First, individual differences in attachment style appear to arise from early interactions with a primary caretaker (Bowlby, 1982). If these interactions are positive, infants can come to rely on the caretaker as a reliable source of protection and support and hence develop a secure attachment style. However if these interactions are inconsistent or negative, infants may develop more less secure attachment systems (Ainsworth, Blehar, et al., 1978). Consistent with this perspective, attachment styles appear important to support and conflict negotiation in adulthood (Pietromonaco, Uchino, & Dunkel-Schetter, 2013). Securely attached individuals provide responsive support and are better at managing negativity in their close relationships that can interfere with support compared to less securely attached individuals (Kane, Jaremka, et al., 2007).

Several additional concepts from relationship science may also be important as antecedent processes to good quality support. Although often neglected in relationships and health research, sexual behavior also has an important influence on support processes (Diamond & Huebner, 2012). Sexual behavior (e.g., frequency of intercourse) is linked to relationship positivity and maintenance, as well as lower risk for physical health problems (Diamond & Huebner, 2012). Finally, the knowledge that partners have about each other's preferences can help them provide more responsive support. In one study, the more familiar a person was with their partner's attitudes, the more responsive they were toward them and the lower their daily life ambulatory blood pressure (Sanbonmatsu, Uchino, & Birmingham, 2011).

It may not be the case that all antecedent processes associated with social support will prove to be health relevant. However, in the absence of a clear understanding of the factors that influence support to begin with, we will not know if the aspects of support that predict health outcomes are simply more proximal factors in the chain of events (Cohen, Sherrod, & Clark, 1986). For instance, social skills may influence one's ability to effectively mobilize one's network by influencing the choice of support providers and appropriate disclosure. Ultimately it may be the receipt of emotional support that proves health relevant, but the role of social skills should not be ignored in our thinking about social support processes or in developing interventions. Our ability to model these processes, however, will be dependent on our understanding of the antecedent processes influencing the development and maintenance of social support over time.

Direct Evidence for Mediational Pathways Prior research has focused primarily on linking social support to physical health outcomes, especially biological (e.g., blood pressure) and disease-related (e.g., mortality) endpoints (Holt-Lunstad, Smith, & Layton, 2010; Uchino, 2004). There is also strong evidence linking social support to behavioral and psychological processes implicated in health (Stewart, Gabriele, & Fisher, 2012; Lakey & Orehek, 2011). However, such links are necessary but not sufficient for establishing causal models. Finding a link between (a) social support and depression and (b) social support and cardiovascular disease does not logically imply that depression is a causal pathway because both depression and cardiovascular disease are multiply determined by factors other than social support. Causal inferences are best made via appropriate design considerations, but there have been recent advances in statistical mediational analyses that can guide the modeling of mechanisms in this area. (e.g., Rucker, Preacher, et al., 2011). These mechanistic issues are important to address due to the relatively large body of epidemiological research available compared to the dearth of studies formally modeling pathways.

Although there is some evidence suggesting that health behaviors partially mediate links between social support and health outcomes, there is very little evidence for relevant psychological pathways. There are a number of methodological, statistical, and conceptual reasons that might explain this lack of evidence (Uchino et al., 2012b). We do not know of any studies that have included more recent and powerful tests for mediation (e.g., bootstrapping, Rucker, Preacher, et al., 2011). Given the complexity of social support and health links, stronger evidence for mediation might also be obtained by modeling multiple psychological processes simultaneously (e.g., covariance structural modeling). Finally, conceptual issues include the need to consider contextual processes (e.g., sources of support and match to support needed; Thoits, 2011) as well as an extended set of psychological processes linked to relationships (Pietromonaco, Uchino, & Dunkel-Schetter, 2013). Alternative tests of psychological mechanisms that do not rely on self-reported psychological states may also be important such as brain imaging methodologies (Eisenberger, Master, et al., 2011) and paradigms that tap into less conscious relationship representations (Carlisle, Uchino, et al., 2012; Smith, Ruiz, & Uchino, 2004).

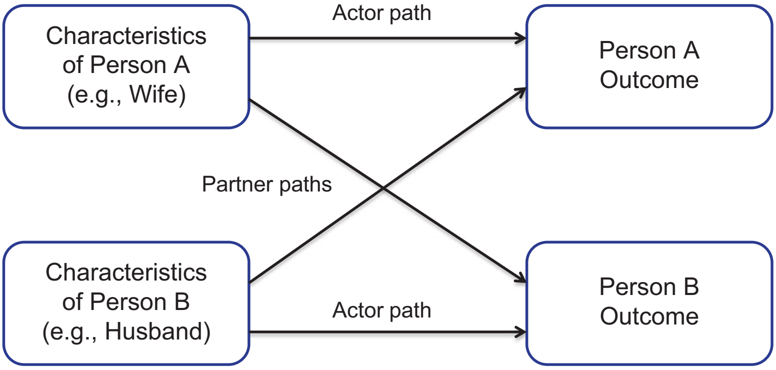
Modeling Dynamic Changes/Pathways Over Time Most models of social support highlight the direct influence it has on health. However, chronic conditions develop over significant periods of time. Testing dynamic/reciprocal influences in the model may thus be important for future work in the area. For instance, decreases in functional support in women over a 9-year period were subsequently associated with the development of hypertension (Raikkonen, Matthews, & Kuller, 2001). Such studies raise the question of where these dynamic processes occur in the model depicted in Fig. 12.1. Although one such pathway is depicted (e.g., Path F), there is very little direct work on this issue which has hindered its incorporation into health-relevant support models.

The importance of dynamic processes over time can also be seen in work on the stress prevention model (Gore, 1981). According to this model, supportive others may actually lower one’s exposure to stressors (in contrast to dampening stress reactions) which can have cumulative benefits over the lifespan (Gore, 1981; Lin, 1986). The stress prevention model is the least tested of all social support models in the health domain despite the fact that existing longitudinal studies are consistent with its basic premise. For instance, the combination of community level and individual support was associated with less exposure to negative life events during a 1-year study period (Lin, 1986; also see Russell & Cutrona, 1991).

There are a number of intriguing ways by which social support may reduce stress exposure over time. First, social support may act to influence cognitive processes such that benign appraisals occur (Cohen, 1988). Second, social support (e.g., informational support on planning for a rainy day) can help individuals make informed decisions that minimize their subsequent stress exposure via proactive coping (Aspinwall & Taylor, 1997). Finally, adequate social support may help decrease exposure to “secondary stressors” (Pearlin, 1989). For instance, stress at work can lead to conflict at home (Repetti, Wang, & Saxbe, 2009). However, if spousal support buffers worksite stressors, it may effectively eliminate potential spillover into marital interactions (Pearlin, 1989). Future direct work testing the stress preventative functions of support on health-relevant processes can thus inform more dynamic models of social support and health.

Finally, social support is often viewed as an individual level factor representing either the perception or receipt of support (Uchino, 2004). More dynamic (and accurate) views of social sup-

Fig. 12.2 Conceptual representation of actor-partner interdependence models



port should conceptualize it as an interpersonal process that involves at least dyadic level processes. An important framework for examining such dyadic processes is the actor-partner models developed by Kenny, Kashy, and Cook (2006). A conceptual representation of actor-partner influences is depicted in Fig. 12.2. Given appropriate data collection, this framework can test if one's own characteristics (actor paths) or a partner's characteristics (partner paths) predict one's outcomes. In addition, one can model actor X partner influences which highlight how a dyad's characteristics combined influence one's health outcomes. For instance, a recent application of this model in married couples showed that partner supportive ties were linked to lower levels of one's own ambulatory blood pressure independent of one's own supportive ties. In addition, couples who had more socially supportive ties combined showed the lowest levels of ambulatory blood pressure (Uchino, et al., 2013a). In general, incorporating dyadic processes when studying links between relationships and health promises conceptual insights that will inform models and interventions (Pietromonaco, Uchino, & Dunkel-Schetter, 2013).

Cross-Cultural Influences on Social Support It is also evident that the links between social support and outcomes may depend on the cultural context (Chen, Kim, et al., 2012; Dressler & Bindon, 2000; Dutton, 2012; Litwin, 2009; Taylor, Welch, et al., 2009). At a broad level, research on cultural differences in support highlights the importance of culturally appropriate forms of support (Brannan, Biswas-Diener, et al., 2013; Dressler & Bindon, 2000). For instance, familial sources of social support may be more directly relied upon and hence more important than friend support in many collective cultures (i.e., where one's identity significantly overlaps with close others as is often the case for Asian, African, and Latin American cultures) compared to individualistic cultures (i.e., where one's identity is viewed as distinct from others as is often the case for American and Western European cultures).

Most of the work on culture and support has focused on differences between individualistic and collective (especially Asian) cultures. Some research suggests that individualistic cultures show a weaker relationship between social support and psychological outcomes compared to collective cultures (Park, Kitayama, et al., 2013; Uchida, Kitayama, et al., 2008). One important distinction in this area is between explicit (i.e., seeking and using support) and implicit (i.e., the comfort of simply having close relationships) support (Taylor, Welch, et al., 2007). Due to relational concerns (e.g., concern about placing a burden on family who are obligated to be helpful), individuals from more collective cultures may benefit more from implicit forms of support during stress in which they simply feel more connected with others (Taylor, Welch, et al., 2009). Such cultural processes may also interact with genetic indicators of social interactions (i.e., oxytocin receptor polymorphism) to influence support seeking (Kim, Sherman, et al., 2010). One study found that, among Americans under stress, those who also had the oxytocin receptor polymorphism reported seeking more social support, whereas no such link was found in Koreans (Kim, Sherman, et al., 2010). One limitation of prior work, however, is that it has mostly focused on Asian cultures, and whether the same pattern would be found in other collective cultures is less clear. For instance, evidence indicates that African Americans indeed benefit from receiving explicit social support (Ford, Tilley, & MacDonald, 1998; Norbeck, DeJoseph, & Smith, 1996).

There is also some cultural work focusing on support differences between Eastern European and European American samples. Dutton (2012) argues that directive social support may be viewed positively in Russian culture which places an emphasis on mutual responsibility in problem-solving. As a result, "butting in" is not seen as threatening a person's sense of autonomy as might be the case for European Americans. In a test of this, nondirective support was interpreted positively by both Russian and European American participants. However, Russian participants were more satisfied with directive support compared to European Americans. These data highlight the importance of looking at more specific cultural groups based on their unique sociocultural history.

Technology and Social Support Technology is changing the way in which social support is communicated. Most homes in the United States now have Internet access, and smart phones are a primary communication device, especially for adolescents and young adults. As a result, many individuals have easy 24/7 access to social networking sites and instant messaging. Early conceptualizations of online social support mostly focused on the deficiencies of computer-mediated communication relative to direct support exchanges, suggesting that the lack of physical presence and emotional cues might negatively impact relationship processes (Jones, 1999; Rice, 1987). However, recent research is now exploring both equivalencies with face-to-face communication and the potential unique benefits of connectivity in increasing support transactions and reducing stress.

There are a number of advantages of online, compared to face-to-face support. For example, while seeking direct support for stigmatized conditions can be embarrassing, Internet-mediated support allows users to seek support anonymously (Malik & Coulson, 2008; Walther, 2002). Internet support may also circumvent social anxiety that otherwise may keep some from seeking or accepting social support. The exchange of support may be perceived as burdensome to the support provider or may require the observation of social obligations on the part of the support recipient (Bolger & Amarel, 2007). However, online forums allow users to search through old posts for informational and emotional support around a specific topic thereby reducing the burden for both provider and recipient (Wright & Bell, 2003). Linking individuals across geographic distance also allows users to create support networks around specific support needs, rather than simple geographic proximity thereby increasing the match between support needs and support availability (Rainie & Wellman, 2012). Finally, the lack of extratextual cues allows the Internet to effectively break down social and communicative barriers that may exist in face-to-face communication due to status, language, or cultural difference (Mikal, 2012; Wellman, Hasse, et al., 2001).

Given these potential advantages, studies now suggest that online support can decrease stress and /or increase psychological well-being. Most universally accepted within the literature on Internet-mediated support is the utility of communicating informational and emotional support (Dare & Green, 2011; Dutta-Bergman, 2004; Leung, 2003; Morgan & Cotten, 2003). More recently, evidence has emerged that simple participation in the broader social network available online can promote well-being and provide a buffering effect during times of stress (Dutta-Bergman, 2004; Nicholas, Picone, et al., 2009). While the majority of studies linking technology and social support have focused on the activation of support networks in the presence of a stressor, empirical studies have also demonstrated that having access to the Internet, and thus a link to physically distant networks of support, can increase the perception of available support (Mikal & Grace, 2011). Of course, there is the potential for Internet-mediated support to undermine health given the issues previously discussed for received support. Future research that directly examines the links between perceived/received Internet-mediated support and physical health outcomes will be needed to make this final link.

The Contextual Nature of Support Finally, a theme that cuts across many of these emerging research directions is that social support is not a monolithic concept and that the context can play a major role in how support is perceived and received and ultimately influences health. These contextual processes can operate early in life (e.g., family) and potentially set the sensitivity of stress-related biological systems. For instance, in a seminal program of research, Michael Meaney and colleagues have shown that pups who were exposed to more licking and grooming from their mothers showed lower adrenocorticotropin and corticosterone levels, increased glucocorticoid messenger RNA expression and receptor sensitivity, as well as epigenetic changes in DNA methylation (Liu, Diorio, et al., 1997; Zhang, Labonte, et al., 2013). Importantly, these differences were reversible by exposing pups of low-licking and low-grooming mothers to high-licking and high-grooming mothers (Weaver, Cervoni, et al., 2004). Thus, social interactions that arise early in life can be an important context for the development of biological vulnerability or resilience. The contextual role of social processes on health-relevant biological systems is also highlighted by recent theoretical arguments that the hormone oxytocin is not specific to positive relationship processes but sensitive to the valence of social situations (Campbell, 2010).

The literature on received support and health also highlights the role of contextual factors. These contextual factors include stressor (e.g., type of stress), provider (e.g., nondirective support), and recipient (e.g., preferences for support type) characteristics. Dyadic level processes also provide a specific context for understanding support processes as it involves a consideration of both actor and partner characteristics that may influence the efficacy of support transactions. At a broader level of analysis, cultural factors appear to influence the efficacy of support (Dressler & Bindon, 2000, Dutton, 2012; Taylor, Welch, et al., 2007; Uchida, Kitayama, et al., 2008). Chief among these are differences that might emerge between more collective and individualistic cultures (Taylor, Welch, et al., 2007); however, there appears to be value in focusing on more specific cultural groups that may differ in their reactions to support based on their unique history (Dutton, 2012). Finally, technology places support processes in a unique context (e.g., relatively anonymous, less geographical barriers) and hence may be an effective means by which to mobilize and receive support.

More generally, the emerging focus on contextual factors is theoretically important because it can influence the more specific antecedent processes and mechanisms that link social support to health outcomes. In the absence of this understanding, our support interventions may be ineffective or perhaps even harmful. These contextual issues can thus highlight multiple points for entry depending on the intervention goals (e.g., primary or secondary prevention).

Intervention, Practice, and Policy Implications

Given the reliable links between social support and physical health outcomes, it is no surprise that much work has been done to test its applied implications. Most of this applied work has focused on interventions aimed at altering social support to promote positive outcomes (Hogan, Linden, & Najarian, 2002; Martire, Schulz, et al., 2010). However, these findings also raise important practice and public policy issues that need consideration given the evidence to date. Although there is a growing literature on interventions using community health workers, many of which provide support functions, we will not review this literature given it is covered elsewhere in this volume (see Intervention chapter).

Intervention Approaches There is a relatively large literature examining support interventions (Allen & Dennison, 2010; Hogan, Linden, & Najarian, 2002). These interventions have mostly been conducted in North America and Europe, with a few studies conducted in Asia. They have included a range of different outcomes indicative of mental (e.g., loneliness) and/or physical (e.g., blood pressure) health. These support interventions take several forms including support from professionals or peers, as well as efforts to mobilize existing network support (e.g., skills training, Gottlieb, 1988).

One of the most common support interventions from professionals is some form of educational intervention by formal support sources such as physicians, nurses, dieticians, and physical therapists (Allen & Dennison, 2010; Helgeson & Cohen, 1996). Such educational interventions serve as a form of informational support and provide the patient with greater knowledge regarding the disease, its symptoms, and subsequent treatment. Such interventions may also address the stress-buffering and prevention aspects of support as patients diagnosed with a chronic condition may need help coping with the accompanying feelings of uncertainty and loss of control (Frasure-Smith & Prince, 1985). A review of such interventions suggests that they were effective in increasing patient knowledge and fostering adjustment to cancer. In fact, such interventions appear at least as effective as peer support groups (Helgeson & Cohen, 1996; Helgeson, Cohen, et al., 2000). These beneficial effects of educational interventions with professional sources of support have also been demonstrated with specific health-related behaviors and outcomes, including exercise patterns, diet, and body mass in at-risk populations (Allen & Dennison, 2010). In fact, this is one intervention context in which directive support appears especially effective given the combination of an expert source and an individual's willingness to change (Gabriele, Carpenter, et al., 2011).

Even more general professional intervention sources can be important support resources to help individual cope with stress. For instance, it has been argued that psychotherapists engaged in formal helping behavior are also important sources of support. Similar characteristics (e.g., honest, warm, open) are associated with good quality relationships in therapy as in other informal relationship contexts (Ackerman & Hilsenroth, 2003). Although the literature on therapeutic support and social support have progressed relatively independent of each other (Barker & Pistrang, 2002), integrating their different emphases can lead to a better understanding of how both formal and informal support interventions work (e.g., process questions related to disclosure, alliance-building, Barker & Pistrang, 2002).

Many interventions have also focused on peers and developing friendships as important support sources. Simply mobilizing peers as a support intervention is related to less consistent influences on outcomes (Heller, Thompson, et al., 1991). Greater attention to factors that increase the quality of the relationship may thus be important for such interventions (Harris, Brown, & Robinson, 1999; Thoits, 1986). For instance, experiential similarity revolves around having common experiences that can help in the friendship formation process and the communication of empathic emotional support (Suitor, Pillemer, & Keeton, 1995; Thoits, 1986). Such interventions built on this premise are associated with beneficial influences on outcomes (Kulik, Mahler, & Moore, 1996), although they may be more effective when individuals naturally form their own relationships (Thoits, Hohmann, et al., 2000). "Befriending" specifically focuses on the friendship formation processes by recruiting outside relationships to serve as the basis for affirming social support over time (Harris, Brown, & Robinson, 1999). A recent meta-analysis suggests a modest effect for such interventions in improving outcomes in different patient populations (e.g., caregivers, prostate cancer patients, Mead, Lester, et al., 2010).

An important peer intervention is related to support groups. These support groups are now an established part of how many patients attempt to maintain behavioral change or cope with diverse medical conditions (Davison, Pennebaker, & Dickerson, 2000). Although many support groups are facilitated by professionals (e.g., making sure everyone shares their experiences), the primary emphasis is on experiential similarity and what the peer group experience can bring to each individual. Such support groups with peers can serve multiple functions such as reassurances of the person's worth (emotional support), sharing of useful information (informational support), and a place to go and be themselves (belonging support).

Interventions examining peer support groups suggest beneficial effects on adjustment and well-being (Hogan, Linden, & Najarian, 2002). In addition, many of these studies documented that the intervention was successful in altering participants' levels of support. These positive findings have been observed with older adults (Andersson, 1985), HIV patients (Kelly, Murphy, et al., 1993), and breast cancer patients (Goodwin, Leszca, et al., 2001). Support groups among cancer patients had beneficial effects (Hogan, Linden, & Najarian, 2002), although this might depend on the extent of existing support (Helgeson, Cohen, et al., 2000). Researchers have also found that participation in support groups seems to influence the size and composition of one's social network. For instance, studies of individuals with substance abuse problems suggest that self-help groups result in decreased contact with drug-using network members and increased contact with support group friends (Humphreys & Noke, 1997). These network members then become crucial sources of support in offering advice and guidance to help individuals remain abstinent (Humphreys, Mankowski, et al., 1999).

Finally, many support interventions attempt to mobilize existing network members by: (a) teaching participants the skills to acquire support from their network, (b) bringing a significant other to treatment to help in the adjustment process, or (c) teaching social network members how to be supportive. Overall, these strategies appear promising in fostering adjustment and outcomes across a variety of patient populations (Hogan, Linden, & Najarian, 2002). Teaching individuals the skills to elicit support from their network has been successfully conducted with adolescents, psychiatric patients, and individuals with chronic diseases (Cutrona & Cole, 2000; Hogan, Linden, & Najarian, 2002). In one intervention, adolescents were assigned to enroll in a semester long course that focused on friendship development and positive peer and teacher relationships (Eggert, Thompson, et al., 1994). Students also learned how to elicit support regarding personal problems. Results of this study showed that individuals in the intervention had an increase in their friendships and in self-esteem. Moreover, compared to adolescents not provided with the intervention, individuals with social skills training showed a trend toward less drug use, a decrease in drug-related problems, and an increase in their grade point average.

One of the most comprehensive social support interventions focusing on skills for acquiring support from participants' networks was the multisite Enhancing Recovery in Coronary Heart Disease (ENRICHD) clinical trial (The ENRICHD Investigators, 2003). In this intervention, myocardial infarction patients with low social support and/or depression were randomized to cognitive-behavioral therapy that individually addressed problems related to depression/social support. Results of this study revealed a statistically significant increase in social support after 6 months for participants given the intervention. However, after about 29 months, there were no differences in survival between the support and usual care groups. There were several potential explanations for these findings (The ENRICHD Investigators, 2003). At the 6-month period, there was approximately a 9% difference in support changes that favored the intervention. However, there was no longer a significant difference between the intervention and usual care groups at the 42-month follow-up (due mostly to unexpected improvements in social support for the usual care group). Overall, the initial support differences may have been too small or not maintained over a long enough period of time to influence the main cardiovascular outcomes. It may thus be necessary to increase the effect size associated with support interventions on such disease outcomes by directly incorporating close others into the intervention (see below). It should be noted that post hoc analyses of these data have shown beneficial influences for some patient subgroups (Burg, Barefoot, et al., 2005; Schneiderman et al., 2004).

Interventions with existing network members have also reached out and directly mobilized the person's network. The challenge here is providing the network members with the understanding and skills to be supportive (Thoits, 2011). The "training" of network members to provide support in many cases focuses on family members and more specifically the spouse as they are an important source of support for married individuals (although friends can also play a role in the support process and facilitate healthy behaviors, Wing & Jeffrey, 1999). Early interventions with hypertensive patients successfully utilized spouses by increasing their understanding of hypertension and how to better manage the patient's condition (Levine, Green, et al., 1979). A recent meta-analysis found that couple-oriented interventions were associated with beneficial patient outcomes (e.g., lower depression, Martire, Schulz, et al., 2010). It is also important to note that spouses experience a considerable amount of anxiety and stress in such situations and interventions focusing on the needs of a spouse also appear promising (Bultz, Speca, et al., 2000; Gottlieb, 1988). One intervention specifically focused on spouses of cancer patients and provided them with a 6-week psychoeducational intervention (Bultz, Speca, et al., 2000). As a result of the intervention, spouses showed improved coping 3 months later. Importantly, the patients themselves also reported greater support and marital satisfaction. A more recent couple-based intervention for women with breast cancer also found that relationship enhancement for coping with cancer (e.g., communication, sharing feelings) was associated with better relationship functioning and less medical symptoms over a 1-year period (Baucom, Porter, et al., 2009).

The fact that existing network members have a rich history with the person needing support also needs to be addressed. In some cases, the history may be overwhelmingly positive and thus presents little problem in that person being a support provider. In other cases, network members may be a source of ambivalence and contain a mix of both positive and negative experiences and feelings which have been linked to poorer quality support and negative health outcomes (Reblin, Uchino, & Smith, 2010; Uchino et al., 2012c). The important implication here is that under some circumstances, dyadic counseling may be needed to help individuals resolve ambivalence in their relationships so that they may provide more effective support to each other.

Future Intervention and Practice Directions Although the results of support interventions are promising, there is certainly room for improvement. For instance, existing interventions are heterogeneous in terms of altering support and some studies did not include manipulation checks to verify that social support was indeed improved (Hogan, Linden, & Najarian, 2002). One general area where much more work is needed is on the efficacy of support interventions for primary prevention. Most interventions focus on individuals who already have health problems. These are often referred to as secondary prevention efforts which stand in contrast to primary prevention that focuses on healthy individuals. In a compelling analysis, Robert Kaplan (2000) argued for the promise of primary prevention efforts, especially in light of the more limited public health benefits that seem to arise from secondary prevention.

An alternative way of thinking about support interventions is thus as a form of primary prevention that reduces the incidence of health problems by providing a greater sense of connection and control and/or reducing the number or impact of stressful events (see Paths B of Fig. 12.1). For instance, increasing feelings of control in adolescents might lower stress appraisals such that certain events are no longer seen as stressful. Rena Repetti, Shelley Taylor, and their colleagues (2002) have argued that early familial interventions are an important starting point and may pay large dividends in the long term. A focus on primary prevention also raises the interesting possibility that support interventions aimed at improving relationship functioning may be useful if applied early on with children and adolescents to place them on healthier trajectories. Preliminary evidence suggests that such interventions result in more positive adolescent social, academic, and mental health outcomes (Dirks, Treat, & Weersing, 2007; Waddell, Hua, et al., 2010).

As research on support interventions progress, it will be extremely important to document the aspects of social support that are most beneficial, for which populations, on what particular outcomes, and for how long. A more thorough future framework for support interventions can be described by asking the question: "Who is providing what to whom and with what effect?" The "who" aspect of this statement is meant to characterize the identity of the provider, their existing support skills, and also the nature of the relationship between the provider and recipient of support. It can range from relatively new relationships such as between patients and practitioners to already established support members such as family and friends. The second aspect of this statement concerns "what" is being provided. It may be the provision of emotional support or the acquisition of new social skills to obtain needed support based on a contextual analysis of the challenges facing a person. The "whom" aspect refers to the recipient or target population of the intervention and can be healthy individuals or specific groups (e.g., depressed or chronic disease patients) and also considers the needs of the support recipient (e.g., their objectives) and other sources of support available. Finally, "with what effect" has to do with the pathways and outcomes that the intervention is attempting to modify. More generally, this framework highlights the key points that support interventions should try to address in order to heed the important support doctrine to "Do no harm" because poorly planned support intervention may result in individuals receiving ineffective help, feeling let down by the support provider, and greater perceptions of stress (Cutrona & Cole, 2000).

An important practice issue is should healthcare professionals screen to identify people who are low in support or socially isolated to facilitate treatment outcomes (Lett, Blumenthal, et al., 2007)? Critics of such an approach would argue that we do not know enough regarding what screening measures to use, what would be an appropriate cutoff score, and perhaps more importantly what exactly we can do to help them (Bucholz & Krumholz, 2012; Thombs, 2008). Proponents, on the other hand, argue that there are scales based on the available epidemiological evidence that could be developed for such purposes and promising treatment protocols (e.g., cognitive-behavioral therapy, Butler, Chapman, et al., 2006; Lett, Blumenthal, et al., 2008; The ENRICHD Investigators, 2003). Even if we might have difficulty treating low support, it can still be assessed for prognostic or predictive purposes along with other factors like age, sex, and family history (Lett, Blumenthal, et al., 2008). In fact, regardless of its treatment, such information might be used to inform individualized treatment protocols such as more intensive monitoring or follow-ups.

We do not know any current guidelines for assessing low general support or social isolation in clinical settings. However, there are several issues that will need strong consideration. First of all, the links between social support and health outcomes are strongest for general perceived support and composite measures of social isolation, so such scales should be used to identify people. There are several questionnaires that are good candidates including the 7-item ENRICHD social support instrument (Mitchell, Powell, et al., 2003), the 16-item version of the interpersonal support evaluation list (Payne, Andrew, et al., 2012), the recently developed 16-item NIH toolbox social relationship scales (support items, Cryanowski, Zill, et al., 2013), as well as the social network index (Berkman & Syme, 1979). Focusing on specific scales that contain items that have been related to physical health outcomes can inform potential diagnostic cutoff points that likely vary as a function of age, gender, and culture. Even simply asking if individuals lack a confidant that they can speak to about personal and health-related problems may prove useful for identifying individuals who are at risk for negative outcomes after the diagnosis of a chronic condition (Williams, Barefoot, et al., 1992).

In many cases, the focus of screening might be on specific relationships that we know to be important in the management of chronic conditions (e.g, spouses, Robles, Slatcher, et al., 2014; Rohrbaugh, Shoham, & Coyne, 2006). There are clinical cutoff scores for validated marital satisfaction measures that distinguish distressed marriages and could prove useful in identifying at-risk couples following chronic disease diagnosis (Crane, Middleton, & Bean, 2000). Although not developed as a screening instrument, we have utilized the social relationships index (Campo, Uchino, et al., 2009) to examine positivity and negativity from any specific relationship (e.g., spouse, friend, coworker). Moreover, we have consistently used specific cutoff points to separate supportive (supportive only) from ambivalent (supportive and upsetting) ties which is important as ambivalent ties predict a range of negative biological outcomes such as higher daily life ambulatory blood pressure, greater inflammation, and even increased cellular aging (Holt-Lunstad, Uchino, et al., 2003; Uchino et al., 2012c; Uchino et al., 2013b). Pending more work, the evidence from the social relationships index suggests some promise as a general relationship-specific assessment device that could be developed into a screening instrument (Campo, Uchino, et al., 2009).

Given the evidence to date, it might even be argued that it would be unethical to not screen for low support or social isolation as has been argued in the case for depression (Sheehan & McGee, 2013). In fact, the literature on screening for depression has a longer history and might be used to inform future work in this area. As recommended for depression, given that some degree of error will likely exist in any diagnostic criteria, individuals who initially screen low in support or high in isolation can be referred for more detailed screening and evaluation. In the case of depression, it also appears that screening is beneficial primarily when there is adequate staff available for treatment (O'Connor, Whitlock, et al., 2009). In fact, it has been argued that in the absence of collaborative care involving integrated services (i.e., medical and mental health), it is difficult to justify depression screening as it might lead to harmful labeling, as well as inappropriate additional testing and treatment (Nimalasuriya, Compton, & Guillory, 2009). Future work addressing these important practice issues deserve immediate attention because according to Holt-Lunstad, Smith, and Layton (2010) low social support appears to be as important a risk factor as cigarette smoking and a lack of exercise. Of course these health behaviors are standard assessments in medical settings which underscore the need to also develop and test relevant support screening instruments.

Policy Implications It is also important to point out that the research on social support may carry important policy implications (Umberson & Montez, 2010). Relevant policy can help escalate much needed funding priorities, bolster public perception, and increase dialogue on future policy implementation. These health policy implications are made salient by the work reviewed above, as well as the potential cost-effectiveness of social support interventions. For instance, a combined 1-year educational and support group intervention for osteoarthritis patients yielded an average cost savings during the subsequent 2 years of $1279 per participant a year compared to a control condition (Cronan, Hay, et al., 1998). This difference was primarily due to a lower number of days spent in hospitalization for the intervention groups. In fact, it has been estimated that if support groups participation was at 3% among the 32 million arthritis sufferers, the 4-year cost savings would be around 650 million dollars (Davison, Pennebaker, & Dickerson, 2000)! With increasing emphasis on medical cost containment, the health-care policy implications of social support may be considerable if future work can clearly document such savings across a number of chronic conditions (but see Wilson, Thalanany, et al., 2009).

Public policies can thus be aimed at increasing funding for understanding the more specific nature of such links or at fostering better interpersonal functioning (Brownell & Shumaker, 1985; Umberson & Montez, 2010). As an example, the Deficit Reduction Act of 2005 devoted significant funds to the Healthy Marriage Initiative (HMI) to help build stronger, stable marriages. The HMI focuses on research and demonstration projects regarding relationship education and skill building (e.g., listening, problem-solving) which have thus far yielded promising effects on relationship quality and communication patterns. Most recently, the importance of social relationships was acknowledged explicitly in Healthy People 2020 which is a nationwide health promotion plan as well as the Affordable Care Act which highlights the role of community health workers in disease prevention and treatment.

Another important policy implication of research on social support and health is the need to anticipate policies that might disrupt social support and plan/allocate funds for their amelioration or at least minimizing its potential influences (e.g., urban renewal projects that may result in gentrification, Brownell & Shumaker, 1985). More generally, it would be important to evaluate future policies in terms of their impact on support processes or the quality of people's social relationships as these are important determinants of stress management and health outcomes. For instance, end of life planning issues may influence not just the stress of the dying person but also the survivors (Carr, 2012).

A general policy implication goes back to the early pages of this chapter: *social support has very real influences on health*. It has enormous impacts on life and quality of life, comparable to those of cigarette smoking. Its association with morbidity/mortality is not because it is accidentally or coincidentally associated with the "real causes." Rather, the aggregate of evidence reviewed here shows that social support has an important influence on behavior, biology, risk factors, social interactions, and disease management, all of which have major impacts on health and illness. At the same time, social support is not simple. The paradoxical role of received support in sometimes being associated with worse outcomes makes clear that good intentions are not sufficient to guarantee good support. Thus, social support is worthy of serious investment by our culture, investment in research to enhance our understanding of this very important area of human behavior and experience, and investment in high quality interventions to enhance it.

Conclusions

It is clear that social support is a strong predictor of physical health outcomes (Holt-Lunstad, Smith, & Layton, 2010). These links are often independent of traditional demographic, lifestyle, and biological risk factors (Berkman, Glass, et al., 2000; Cohen, 2004). The mechanisms responsible for such links at different levels of analysis are being elucidated through interdisciplinary work, including psychological, behavioral, and biological pathways. It is likely that social support will play a major role in behavioral medicine over the next 20 years as it is one of the most well-documented psychosocial risk factors with over 35 years of epidemiological research in North America, Europe, Asia, and Australia (Holt-Lunstad, Smith, & Layton, 2010).

There are several reasons why social support research will continue to play a major role in behavioral medicine. First, risk factor models must continue to examine this construct and associated pathways given the evidence to date. Despite the tremendous body of work, we know very little about mechanisms which will be critical for designing cost-effective interventions. Second, social support may be part of a positive psychosocial profile that includes other important constructs in behavioral medicine such as optimism, attachment, and hostility (Uchino, 2009). Many of these factors have their origins in the early family environment which is being increasingly appreciated as an important protective or risk factor in itself (Repetti, Taylor, & Seeman, 2002; Taylor, 2010). Third and relatedly, social support may be an important mediator of other psychosocial risk factors such as early-life experience (Taylor, 2010), socioeconomic status (Cohen, Kaplan, & Salonen, 1999), or personality (Smith, 1992). Finally, the emphasis on patient-centered care will only increase the importance of social support for medical treatment across the health-care (e.g., physicians) and family (e.g., spouses) systems.

As a final parting shot, we sometimes assume that there is nothing we can do to encourage good relationships and the support they provide; they either happen or they don't. We sometimes assume that support will happen automatically if people have family or friends available to them. We sometimes assume that good support is common sense so that volunteers don't need training, supervision, or help to be good at providing it. We may also assume that it is none of our business to interfere in other people's social relationships. All these assumptions are wrong. Rather, if we take the data and its impact across individuals, families, and society seriously, we must find ways to identify those who lack it, take affirmative steps to get them the support they need, and do so in high quality, adequately funded programs to make the support as effective as it can be. Doing so will help our society realize the full potential of social support to help individuals live healthier and happier lives.

Social and Cultural Context: Healthy Eating and Physical Activity

Linda C. Baumann and Betty L. Kaiser

Introduction

In any place and time, cultural practices reflect the complex interplay between broad social phenomena and values, norms, and customs. When one of us (Baumann) first visited Vietnam in 1989, available foods were primarily local due to poor transportation systems and primarily seasonal because of limited food storage options. Traditional tea breaks included fresh green tea and seasonal fruits. At that time, most Vietnamese walked or used bicycles, and the bicycle was a national symbol of Vietnam. By 2003, the tea break at a diabetes training session for nurses consisted of prepackaged tea with sugar, prepackaged coffee with sugar and whitener, and little sweet pastries made in a local factory. The hosts were quite proud of the convenience and expanded consumer choices these foods represented. Bicycles are now scarce in the large cities and are overpowered by motorcycles and automobiles on congested roads that threaten pedestrian safety.

Worldwide, sweeping social and economic changes associated with globalization have precipitated changes in cultural norms related to dietary practices and physical activity behaviors. Across nations, food and physical activity environments are becoming more homogeneous, characterized by widespread access to calorie-rich but nutrient-poor foods, built environments that pose barriers to active modes of transportation, and occupational trends toward sedentary work (World Health Organization, 2003). Within nations and communities, these broad social and economic trends interact with local culture to create unique and dynamic contexts for health behaviors.

Culture shapes illness (Kleinman, Eisenberg, & Good, 1978); it also shapes health and health behaviors. The concept of "healthy lifestyle behaviors," widely embraced by public health practitioners and researchers, is a social construct that may have limited meaning within some cultures. In many low- and middle-income settings, "healthy" is not the absence of disease but the ability to work. Or it may be the ability to reproduce and to live long enough to raise one's children. In many cultures, eating practices are foremost important for promoting acceptance, kinship, socialization, and solidarity, rather than for promoting health or preventing disease (Purnell & Paulanka, 2008). The notion of physical activity as a purposive, regular health practice is prominent in Western, high-income countries, but not elsewhere. To design effective interventions that address the underlying behavioral determinants of health, it is essential to understand the cultural context of health behaviors.

Numerous definitions of culture exist, but they all imply a dynamic process (Andrews & Boyle, 2008). Moreover, there is agreement that defining culture too narrowly or too broadly makes it lose much of its significance. Giger and Davidhizar (2008) provide a useful definition, identifying culture as a meta-communication system based on values, beliefs, attitudes, customs, language, and behaviors that are shared by a group of people and passed down to generations through formal communication and imitation. Health beliefs and practices arise from collective cultural values that interact with an individual's unique experiences, beliefs, and values that have been learned and adapted to a particular context. Although health beliefs and practices of subgroups within a culture may be somewhat distinct, overarching cultural characteristics such as language, traditions, and sociopolitical experiences provide a shared and common experience.

Two predominant models used to explain beliefs and health-related behaviors within diverse cultural contexts are the self-regulation model (Leventhal, Meyer, & Nerenz, 1980) and the explanatory model (Kleinman, Eisenberg, & Good, 1978). Both of these models identify strategies for assessing beliefs about health and how beliefs influence behaviors. In self-regulation, beliefs about health concerns or conditions are assessed within the following dimensions: identity (symptoms, labels), cause, timeline, consequences/seriousness, control and/or cure, and coherence (overall understanding).

The explanatory model uses situated discourse to elicit illness stories about how people interpret the somatic, psychological, and social experience of an illness, as told within a "culture system." Explanatory models reflect social class, cultural beliefs, religious beliefs, and past experience. Lay explanatory models begin with an awareness of body sensations and feelings and are elicited by a series of questions (Harwood, 1981):

1. What do you think caused your problem?
2. Why do you think it started when it did?
3. What does your sickness do to you? How does it work?
4. How severe is your sickness? Will it have a long or short duration?
5. What kind of treatment do you think you should receive?
6. What are the most important results you hope to receive from this treatment?
7. What are the chief problems your sickness has caused you?
8. What do you fear most about your sickness?

Examination of explanatory models held by distinct social groups within a community can be revealing. In a classic study by Blumhagen (1980), explanatory models of hypertension were elicited from both lay people (mostly white, middle-aged men) and health experts. The lay group believed that the cause of hypertension was chronic stress, anxiety, and worry, while the experts acknowledged that the cause of hypertension is largely unknown, e.g., essential hypertension, but that the condition is probably exacerbated by chronic stress. Baumann and Leventhal (1985) conducted a worksite study in which healthy adults participated in twice-daily blood pressure monitoring and symptom reports for 2 weeks. Most participants held beliefs that blood pressure changes were associated with symptoms such as anxiety and stress, despite information they received that high blood pressure was not a condition with symptoms and evidence presented to them at the end of the trial that blood pressure fluctuations were not associated with these symptoms.

Theories of illness causation vary across cultures (Baumann, 2003). Folk systems classify disease as natural or unnatural, with natural illness the result of environmental exposure and unnatural conditions resulting from divine punishment. Latino cultures share common "labels" for certain illnesses, such as "mal ojo" or evil eye, reflecting a shared belief in magical causation and the impact of social disharmony on the physical health of an individual (Winkelman, 2009). Further, many disparate cultures, including Latinos and Asians, believe in the hot/cold theory of disease that explains cause of illness as well as appropriate treatments aimed at creating a balance of forces (Spector, 2009). In contrast, the focus of Western medicine is diagnosis by finding the causative organism, cure, and prevention. However, within the biomedical system, little is known about physiological variability across populations, including such characteristics as nutritional needs, physiological responses, and digestive capabilities (Giger & Davidhizar, 2008).

Most belief systems across cultures address the principles of harmony, balance, and moderation. Health as a balance between the individual and the environment is a bidirectional relationship. Practices such as healthy eating and being physically active are believed to have a positive effect on the individual, who in turn has a positive effect on the environment (Spector, 2009). A widespread cultural belief of health as achieving a balance in life allows one to engage in multiple belief systems, e.g., folk and Western medicine, most of the time, without negative consequence (Giger & Davidhizar, 2008).

Some aspects of culture are not specifically related to health behaviors but nonetheless influence them. Temporal orientation can influence how people regard health behaviors. Although many people in the USA tend to be oriented toward the future, many cultural groups are oriented to the present. Preventive behaviors to affect a long-term outcome may be incompatible with a present-time orientation (Purnell & Paulanka, 2008). Fatalism is the belief that powers greater than oneself control individual destiny. In cultures where fatalism is prominent, people may feel no sense of personal control over their health status and thus no imperative to engage in recommended health behaviors. In sociocentric cultures, as compared with individualistic cultures, people are not conceived as autonomous selves but rather as part of a family or community unit (Landrine & Klonoff, 2001). Obligations to the family supersede individual needs; thus, self-care practices such as personal health behaviors may not be a cultural norm.

As the intersections between diverse world cultures increase, recognition of cultural influences on health behavior becomes more critical to our understanding of processes that guide health behavior. By failing to adequately acknowledge culture, healthcare practitioners as well as researchers decontextualize social problems and objectify them as individual problems. Researchers often do not assess the culture of participants beyond their affiliation to a specific community or race/ethnicity, making it difficult to determine the impact of culture on behaviors (MacLachlan, 2006). However, this approach may be reasonable when the social, economic, and political contexts of communities may overshadow cultural differences. For example, in the USA, the condition of poverty may be a more powerful determinant of eating behaviors than race/ethnicity and cultural traditions.

The following overview focuses on two health behaviors: healthy eating and physical activity. As major underlying determinants of noncommunicable diseases (NCDs), these behaviors represent key targets for improving global health (Fineberg, 2011, February). The overview is grounded in an ecological framework (see Fig. 13.1) that proposes that social and physical environments as well as individual factors influence health behaviors (Baker, Brennan, et al., 2000; Booth, Sallis, et al., 2001). There is substantial overlap between research that addresses environmental influences on healthy eating and physical activity and research that specifically addresses environmental influences on obesity. In general, we focus on research that has addressed behaviors rather than the distal outcome of obesity and refer the reader elsewhere (Hu, 2008) for a thorough discussion of obesity determinants. A subsequent search at the time this volume was readied for publication (January, 2015) indicated no substantial changes from the conclusions here. We conclude with a discussion of issues related to research designs for studying the sociocultural context for physical activity and healthy eating as well as recommendations for further research.

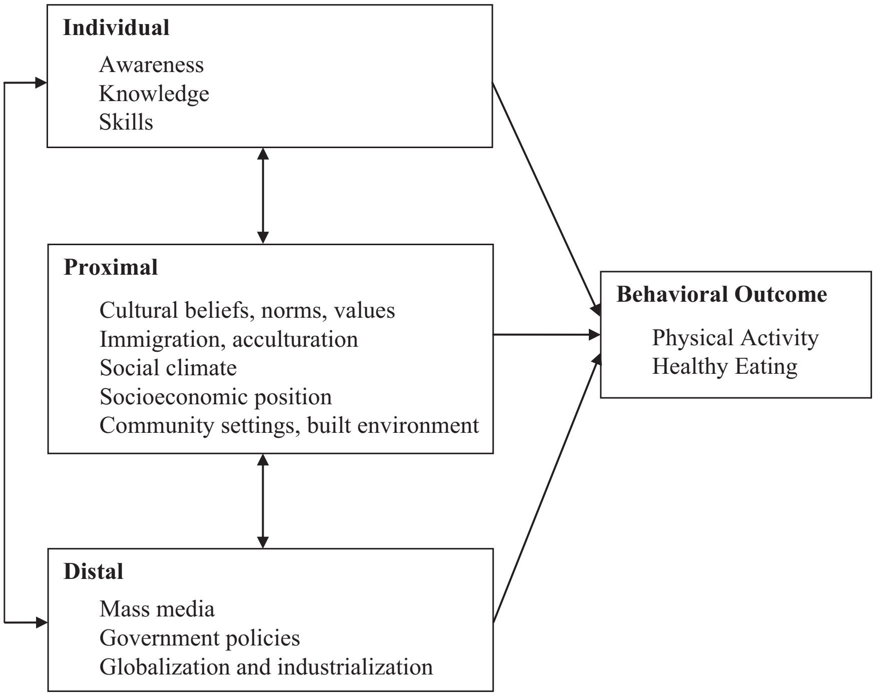

Fig. 13.1 Ecological framework of influences on physical activity and healthy eating (Adapted from Baker, Brennan, et al., 2000; Booth, Sallis, et al., 2001)

The Context for Healthy Eating and Physical Activity

Almost 20 years ago, Geoffrey Rose succinctly described the power of the social environment in shaping personal behaviors, stating:

> Personal life-style is socially conditioned . . . Individuals are unlikely to eat very differently from the rest of their families and social circle. . . It makes little sense to expect individuals to behavior differently than their peers; it is more appropriate to seek a general change in behavioural norms and in the circumstances which facilitate their adoption. (Rose, 1992, p. 135)

Rose's comments highlights proximal factors such as social and cultural norms as well as distal "circumstances" in the social environment that can support, or hinder, health-supporting behaviors. Increasingly, research on diet and physical activity behaviors is grounded in ecological frameworks that depict individuals and their behaviors at the center of a nested or interlocking structure of proximal and distal influences (Booth, Sallis, et al., 2001; Sallis, Owen, & Fisher, 2006; Story, Kaphingst, et al., 2008). Proximal influences on healthy eating and physical activity include cultural beliefs, norms, and values, immigration and acculturation, social support, socioeconomic position, and community settings and the built environment. Distal influences on healthy eating and physical activity include mass media and marketing, government policies, and globalization and industrialization. We present key concepts and evidence from studies conducted in developed and developing countries, drawing on both descriptive and intervention research.

Proximal Influences

Cultural Beliefs, Norms, and Values

In the course of clinical practice, one of us (Baumann) provided diabetes education to an African-American male and suggested that he substitute baked, skinless chicken for fried chicken. He shared that he had never in his life eaten chicken that had not been fried and that his family would not tolerate eating "diabetic food." This example suggests how eating practices are shaped by cultural preferences and perceptions that operate at multiple levels (Larson & Story, 2009). In a study on diabetes self-care behaviors of Ugandan adults (Baumann, Opio, et al., 2010), participants indicated that the word "food" refers to any carbohydrate in a carbohydrate-rich diet. These "foods" include matooke (steamed plantains), posho (cornmeal mush), millet, rice, Irish potatoes, sweet potato, and cassava. Participants expressed beliefs that green vegetables are for animals and that fruit is for children or when someone is sick. Meat and fish are not considered "food" and are eaten in small amounts and not with most meals.

Dietary practices may be influenced by cultural attitudes toward optimal body weight. Some cultures, particularly subsistence-oriented societies that experience food scarcity and poverty, view overweight as the norm or as desirable because it conveys good health (Adams, Quinn, & Prince, 2005; Marlowe & Wetsman, 2001). In sub-Saharan Africa, large body size signifies wealth and power. The consumption of luxury foods that promote weight gain, such as meat, butter, and fried foods, is a means of attaining respect and status in the community. Thinness is associated with malnourishment, disease, and poverty, and foods that are affordable to poor people, such as vegetables and legumes, have a pejorative connotation of survival food (Renzaho, 2004). Research with Latinas indicates that they prefer plumpness in children, and these preferences may affect their child feeding practices (Contento, Basch, & Zybert, 2003). In a focus group study of women from diverse cultures, African-American and American Indian women contrasted the accepting attitude in their cultures toward heavier female bodies with attitudes in white culture that establish thinness as the standard for women (Eyler, Matson-Koffman, et al., 2002). However, the women also attributed the larger body size of African-American and American Indian women to traditional diets containing high-fat foods.

In many African cultures, men prefer women with large body size (Swami, 2006). A tribe in eastern Uganda fattens a bride for a month before the wedding by force-feeding milk, often resulting a weight gain of 30 to 40 pounds. Recent research suggests that traditional non-Western attitudes favoring heavier figures, especially for women, may be changing. A study of Ghanaian women found that women were willing to change their weight if they knew of negative health consequences associated with being overweight or if requested by their spouse (Duda, Jumah, et al., 2006). Furthermore, for women willing to change their weight to comply with a spouse's request, 92% indicated they would choose to reduce their body size, suggesting a perception that husbands prefer a smaller body size. A study that examined cross-cultural differences in attitudes toward female body weight (Swami, Frederick, et al., 2010) included 7434 adults from 26 countries. Participants completed a visual rating scale for different sizes of females and items that assessed exposure to Western media. The authors concluded that cross-cultural differences in preferred female body weight were small compared to differences by rural/urban location, with heavier female figures preferred by people in rural settings. Lifetime exposure to Western media was a significant predictor of preferences for a lower female body weight, and the authors concluded that the ideal of thinness for women is becoming international due to global exposure to Western media messages (Swami, Frederick, et al., 2010).

Cultural norms and beliefs can pose a barrier to physical activity. Walking is the default form of transportation for poor people; consequently, walking may be viewed as undesirable because it denotes poverty or idleness (Kiawi, Edwards, et al., 2006). Women face unique barriers to physical activity related to cultural beliefs and norms. Normal responses to physical activity, such as sweating or fatigue, may be perceived as unhealthy (Caperchione, Kolt, & Mummery, 2009) or unwomanly by some cultures. Gender norms and gender inequity have a substantial impact on women's ability to be physically active, limiting options because of concerns about appropriateness of dress, safety of certain locations, and practical challenges, such as concerns about childcare. A practical issue that is very salient for African-American women is hair care. For African-American women, concerns about the effects of physical activity on their hair can pose a major barrier to exercise, because well-groomed hair represents a substantial investment of time and money (Brown, 2009; Railey, 2000). For some women, physical activity is not a cultural norm. Latina and African-American women report that being physically active is not a norm for girls in their cultures, making it difficult to establish a habit of physical activity in adulthood (Evenson, Sarmiento, et al., 2003; Sanderson, Littleton, & Pulley, 2002).

Overeating and physical inactivity have not historically been public health issues in subsistence societies, so that many individuals may not have well-developed personal representations or understandings of what constitutes healthy eating and physical activity. Even in cultures with traditional diets that are healthier than the Western diet, such as Vietnam, rates of overweight and obesity are increasing. The traditional Vietnamese diet consists of fresh vegetables and fruits, and steaming and boiling are common cooking methods. However, people are highly dependent on refined rice as a dietary staple. Rice is a food with a high glycemic index and contributes to an increased risk of diabetes (Baumann, Blobner, et al., 2006). The carbohydrate-rich diet, coupled with less physical activity as the society transitions from an agricultural economy to one based on industry and manufacturing, creates a potential for energy surplus. Vietnam is also an example of how even traditional foods, such as *pho* (beef or chicken soup), have been supersized and contain more kilocalories per serving than 10 years ago (Ho Chi Minh City Nutrition Centre, 2002). In Uganda, the carbohydrate-rich diet reflects local food availability and limited economic resources. Reliance on carbohydrates, as well as dietary customs such as only tea for breakfast and dinner at 10 p.m., presents a challenge to healthy eating.

Social Climate

The social climate for healthy eating and physical activity is constituted by specific interpersonal relationships that confer support as well as a more generalized sense of community (McMillan & Chavis, 1986). Within families, peer networks, and other social groups, supportive relationships help to establish positive behavioral norms and link individuals to resources that can support healthy behaviors (Heaney & Israel, 2002; McNeill, Kreuter, & Subramanian, 2006). Social support entails behaviors that convey caring, give affirmation, provide role modeling, or offer resources. Numerous primary studies have identified social support as a positive correlate of adult physical activity (Anderson, Wojcik, et al., 2006; Emmons, Barbeau, et al., 2007; Wendel-Vos, Droomers, et al., 2007). Stahl et al. (2001) examined the relationship between self-reported physical activity and perceived environmental support for exercise in a study of health promotion policies in six European countries with established market economies. Major variables corresponded to concepts in social cognitive theory (Bandura, 1986) and included direct and indirect social support, community opportunities for physical activity, and health policies. Social support emerged as the strongest environmental correlate of physical activity; participants who reported low levels of social support were twice as likely to be sedentary as those with high social support.

Several recent reviews have examined the relationship of social support to physical activity in youth and adults. Ferreira and others conducted a systematic review of environmental influences on youth physical activity, drawing on 66 observational studies conducted in established market economies, primarily in North America (Ferreira, van der Horst, et al., 2006). They reported mixed findings for the influence of social support on physical activity. Support and encouragement from parents, friends, and significant others were not related to youth physical activity. However, modeling of physical activity by fathers appeared to be an important influence on children. In most studies in which mother's and father's level of physical activity were measured separately, levels of youth and father physical activity were positively associated.

In its systematic review of interventions to increase physical activity, the Task Force on Community Preventive Services reviewed nine studies on social support interventions in diverse adult populations (Kahn, Ramsey, et al., 2002). Most of the studies were conducted in the USA and used experimental designs. Typical intervention components included motivational and problem-solving telephone support from research staff or participants, discussion groups, and group walking or exercise opportunities. Strong evidence was provided that social support interventions in community settings are effective at increasing adult physical activity.

Social support is also associated with healthy dietary habits. In a comprehensive review of environmental influences on food choices, Larson and Story (2009) summarized findings from research examining the relationship of family environments and social networks to dietary practices. Family and group norms and attitudes influence food choices; in particular, youth and adults are more likely to eat fruits and vegetables when their peers eat them (Larson & Story, 2009). Similarly, results from a narrative summary of six systematic reviews on the determinants of healthy eating and physical activity indicated that social support and modeling were important influences on healthy eating behaviors, particularly in youth (Brug, 2008).

Most research on the social climate for health behaviors has focused on social support. Sense of community is a broader concept that encompasses belonging, trust, feeling important, and emotional connection to others in the community (McMillan & Chavis, 1986). A sense of community may influence healthy eating and physical activity behaviors and may be particularly important for health promotion with people in sociocentric cultures (Bathum & Baumann, 2007), where collectivism rather than individualism is a principal value. Hystad and Carpiano (2010) examined the relationship of belonging to community and adoption of health behaviors using data from 119,693 participants in the Canadian Community Health Survey. They identified a dose-response relationship between sense of belonging and more exercise, change toward a healthier diet, or weight loss during the previous year. These authors suggested that initiatives to enhance community belonging could be an important component of population-wide health promotion initiatives. In our research with low-income, rural adults, the community social climate emerged as an important influence on physical activity and eating behaviors (Kaiser & Baumann, 2010). Participants described how mistrust of neighbors or feeling like an outsider disinclined them to engage in physical activity. However, they also described how sharing cooked meals or home-grown produce and participating in potlucks supported healthy eating and connected them to other people in the community. When we conducted community forums to share results from this research, people attending the forums, particularly Latinas, requested regular events that would bring community members together to discuss issues related to healthy lifestyles and to support and learn from one another. One Latina talked about how grateful she was to be in a setting where she could share with others; she offered the poignant comment "We didn't think anyone cared what we think."

Immigration and Acculturation

Immigration promotes both cultural change and cultural homogeneity—societies incorporate and adapt new practices, while immigrants, to various degrees, acculturate to the practices of their new country of residence (Larson & Story, 2009). Acculturation is influenced by numerous contextual factors, making generalizability of results from diverse immigrant populations difficult (Ayala, Baquero, & Klinger, 2008). Some immigrants arrive in their new country in good health due to past employment in physically demanding occupations, reliance on active transportation, and use of low-fat, high-fiber foods in their country of origin. Others may be in poor health due to malnourishment and inactive lifestyles (Caperchione, Kolt, & Mummery, 2009). The independent effects of acculturation on health behaviors are unclear since effects of acculturation are often confounded with the effects of socioeconomic position (Satia-Abouta, 2003).

The availability, expense, and convenience of foods in the new country of residence influence dietary acculturation, a process by which immigrants adopt and adapt the dietary practices of the host country (Satia-Abouta, 2003; Satia, 2010). The process involves adding new foods to the diet, excluding some traditional foods, or finding new ways to use traditional foods. Although dietary acculturation may improve the nutritional profile of diets, acculturation to societies that are more urbanized than the country of origin typically results in diets that increase the risk for NCDs (Satia, 2010). Among Latino immigrants to the USA, greater acculturation is associated with lower consumption of fruits and vegetables, legumes, and rice and higher intake of fast foods (Ayala, Baquero, & Klinger, 2008).

New immigrants face social barriers to physical activity. Immigrant neighborhoods are often located in high-crime urban areas. Poor language skills create social isolation, discrimination or fear of discrimination, loss of social capital, lack of access to resources, and unfamiliarity with their new neighborhoods (Caperchione, Kolt, & Mummery, 2009; Satia-Abouta, 2003). When we offered a weekly physical activity and nutrition program in a low-income neighborhood in the USA, we publicized the program in Spanish and English. Many of the Latino participants told us that if our advertising had been only in English, they would have understood the information, but they would not have felt welcome to participate in the program.

Socioeconomic Position

Socioeconomic position is a powerful determinant of health and health behaviors, structuring opportunities as well as exposure to risk factors (Marmot, 2002). For 8 years, we have led a weekly exercise, health education, and social support program in a low-income neighborhood and have heard participants describe the challenges they and their family members face in developing healthier behaviors. A program participant who had been homeless described living in her car with her four children and subsisting exclusively on fast food meals for a week. In her words, “It was the most food we could get for the money we had.” A Latino adult, who accompanied program sessions with his overweight adolescent son, described how he and his wife both worked two jobs. Their schedules limited their ability to model and participate in physical activity with their son. With his parents frequently out of the home, the boy spent most of his time watching television. These scenarios highlight some of the complex interactions between proximal factors such as socioeconomic position, food resources in the local environment, and social support for health behaviors.

Socioeconomic position influences the amount of money people can spend on food and physical activity resources, the amount of time people can invest in food preparation and exercise, and the neighborhood in which people can afford to reside (Caprio, Daniels, et al., 2008). Indicators of socioeconomic position include income, educational level, occupation, and poverty status, and these indicators may be measured at the individual or geographic level (Bennett, Wolin, & Duncan, 2008). Lower household income is consistently associated with lower prevalence of moderate or vigorous physical activity (National Center for Health Statistics, 2007) and less healthy diets (Drewnowski, 2004). Authors of a systematic review on environmental determinants of fruit and vegetable consumption, drawing on results from 24 studies conducted in the USA, the UK, Australia, and Europe, concluded that both household and community income are positively related to fruit and vegetable intake (Kamphuis, Giskes, et al., 2006). Limited financial resources may preclude adherence to a diet emphasizing whole grains, fruits and vegetables, lean meats, and fish (Darmon & Drewnowski, 2008), and the lowest-cost diets are those prominently featuring foods such as refined grains, added sugars, and added fats (Drewnowski, 2009). Lower socioeconomic position may limit access to healthcare providers and services that support healthy behaviors.

Community Settings and the Built Environment

Key settings in communities that influence healthy eating and physical activity include parks and recreational facilities, workplaces, schools, and places of worship (Booth, Sallis, et al., 2001). Religious institutions can play an important role in supporting the health of communities, particularly in disadvantaged communities (Peterson, Sorensen, et al., 2002). *Project Joy* investigated the effects of a 1-year church-based program on cardiovascular risk profiles of African-American women age 40 and older (Yanek, Becker, et al., 2001). Sixteen African-American churches in Baltimore were randomized to a standard behavioral intervention, an intervention incorporating spiritual strategies, and a control intervention consisting of standard self-help strategies. Over the course of the project, women in the standard behavioral arm instituted their own spiritual strategies. Compared to the self-help group, the combined intervention groups showed statistically significant improvement in daily energy intake, body weight, waist circumference, systolic blood pressure, and fat and sodium intake. There is consistent evidence from studies conducted in the USA that interventions in African-American churches are effective in improving dietary habits and increasing physical activity. However, there are very few studies that examine interventions in other types of religious institutions or other countries (World Health Organization, 2009).

A systematic review of worksite health promotion programs examined results from 13 randomized controlled trials. The authors found strong evidence for the effectiveness of worksite programs in increasing fruit and vegetable intake and decreasing fat intake. However, the distinct effects of workplace environmental interventions such as food labeling and increasing availability of healthy foods could not be distinguished from the educational elements of the intervention, such as counseling and group education (Engbers, van Poppel, et al., 2005). This review found inconclusive evidence for the effect of workplace interventions on physical activity.

Growing evidence addresses features of the built environment that influence healthy eating and physical activity that include access to sources of fruits and vegetables (Zenk, Lachance, et al., 2009) and amenities such as sidewalks, paths, parks, and trails (Frumkin, Frank, & Jackson, 2004). Neighborhoods characterized by high residential density, mixed land use typified by a combination of housing units and retail sites, and short blocks are consistently associated with walking and cycling (Cervero & Duncan, 2003; Saelens, Sallis, et al., 2003; Saelens, Sallis, & Frank, 2003). Results from a meta-analysis of 16 studies on perceived environmental correlates of physical activity indicated that the perceived environment has a modest but significant association with physical activity. Environmental features significantly associated with physical activity included the presence of sidewalks, low levels of vehicle traffic, physical activity facilities, and retail shops and services. However, the authors note that in all of the included studies, the possibility of participant self-selection into "more supportive" environments cannot be ruled out (Duncan, Spence, & Mummery, 2005). A "review of reviews" examined 13 review papers on the relationship of physical activity and the built environment. Characteristics of the built environment that had consistent associations with physical activity included access to physical activity facilities, access to destinations, residential density, "walkability," perceived safety, access to exercise equipment, and footpaths. Several features of the built environment had inconsistent associations with physical activity, including aesthetic features of the environment, topographic features such as hills, and perceived crime (Bauman & Bull, 2007).

To summarize this section, we have presented proximal influences on healthy eating and physical activity. Although the ecological approach emphasizes the need to consider variables that reflect multiple contextual levels, these levels are highly interconnected. An ecological system is dynamic and synergistic and a means of explaining complex, nonlinear processes (Stillman, Hartman, et al., 1999). For example, evidence shows that collaborative goal setting facilitates positive behavior change. However, to support patient-provider goal setting requires a healthcare provider who is skilled in supporting behavioral change efforts and a healthcare system that provides continuity of care (Glasgow & Emmons, 2007). Cultural traditions interact with local environment to influence behaviors. In Vietnam, a sociocentric culture, it is common for groups of men and women to exercise in parks and open spaces early in the morning before the pedestrian, motorbike, and automobile traffic dominate the space. Exercise is a cultural tradition taught in schools. Modern forms of morning exercise, such as aerobic exercise classes incorporating music, are increasingly popular. By contrast, in Uganda there is not a tradition of exercise, and it is rare to see men or women jogging or exercising outdoors; a solo runner is typically a *muzungu* (white person or foreigner). Modes of transportation such as walking, taking a minibus, or riding on a motorbike reflect one's socioeconomic position more than one's commitment to physical activity.

The dynamic nature of globalization fuels more intermingling of cultures worldwide. Cultural beliefs, norms, and values will continue to evolve as people encounter new barriers and facilitators to healthy lifestyle behaviors. Evidence shows that changes in nutrition and physical activity patterns are occurring rapidly and will especially impact economic development in poorer countries (Popkin & Gordon-Larsen, 2004). Finally, the built environment and community institutions such as churches, schools, and workplaces, as well as features of healthcare systems, represent important individual and family resources for supporting positive behavior change. Many of these features of the built environment are determined in large part by local, regional, and global policies and trends. Strategies to improve health need to take into account the diversity of determinants and contexts as well as the dynamic nature of the systems within which behaviors occur.

Distal Influences

Globalization, Urbanization, and Industrialization

Globalization, urbanization, and industrialization are global phenomena with similar and overlapping effects. Urbanization increases exposure to mass media, adoption of work technologies that require low levels of physical activity, and access to an increased variety of foods (Mendez & Popkin, 2004). Many developing countries are undergoing chaotic urbanization. Air pollution, traffic congestion, and urban design favoring motorized transport have created environments that discourage active forms of transportation.

Globalization is the process by which distinctive social and cultural characteristics of diverse geographic areas recede over time (Caprio, Daniels, et al., 2008). The forces of globalization are pervasive and include the reduction of trade barriers, broad penetration of international corporations into national economies, access to Western media, and uptake of advanced technologies in manufacturing and agriculture (Popkin, 2004). These forces have far-reaching influence on human behavior. Globalization exerts direct effects on behavioral choices via marketing of energy-dense foods and indirect effects due to transitions to occupational structures that require less physical activity (Beaglehole & Yach, 2003; Mendez & Popkin, 2004).

There are benefits to globalization. Globalization can improve dietary sufficiency in areas with food scarcity and increases access to healthy food (Mendez & Popkin, 2004). However, one of the most recognizable consequences of globalization is its impact on the availability of energy-dense foods worldwide, including "fast foods." Globalization has created a worldwide culture of international food such a McDonalds and KFC. Hawkes (2006) presented a case study of increasing snack consumption in Thailand. She described how global free trade agreements have interacted in Thailand with national policies that are favorable to foreign investment to create a booming market in sweet and savory snacks; between 1999 and 2004, the value of snack sales increased 75% (Hawkes, 2006). In settings such as Uganda, intensive marketing of sugar drinks makes them the most available beverages, even more available than safe water. As we have worked in Uganda in recent years, we have been struck by the strong preference Ugandans have developed for high-calorie soft drinks, favoring the full-calorie version over low-calorie versions. In fact, a non-calorie cola beverage produced by an industry giant has been withdrawn from the country due to poor sales.

Mass Media and Marketing

Several years ago, we conducted key informant interviews with health and social service professionals as part of a project to assess influences on physical activity and healthy eating in a low-income, rural population. One of the informants was a public health nurse who described how the parents she worked with struggled with their children's constant requests for heavily marketed high-fat or high-sugar products. From her perspective, an essential parental skill was establishing a plan for responding to children's requests for junk foods or "how to say no to McDonald's."

The influence of mass media, and particularly its influence on children's food preferences, has drawn increasing attention from researchers and policy makers. Mass media can influence physical activity and diet behaviors through multiple mechanisms. Watching television or using the Internet may supplant recreational physical activities, and television watching is associated with increased consumption of food (Strasburger, Jordan, & Donnerstein, 2010). Perhaps the most powerful and pervasive effect of mass media is its effect on food preferences and purchases. In a synthesis of research on food marketing to children and youth, The Institute of Medicine (2006) found strong evidence that television advertising influences the preferences, purchase requests, and short-term food consumption of children ages 2–11 years but insufficient evidence to support similar effects on youth 12–18 years. While much of the attention on food marketing has focused on its effect on children, adults' consumption of energy-dense foods may also be influenced by advertising (Thomson, Spence, et al., 2008). In a cross-sectional study of 1495 Australian adults, more time watching television was significantly associated with consumption of fast food for dinner and snacks (Scully, Dixon, & Wakefield, 2008).

Most television advertising that targets children and youth promotes high-calorie, low-nutrient products (Harris et al., 2009). Because interventions to decrease television viewing are impractical at a population level, regulation of television marketing to children represents the most promising strategy for decreasing the influence of advertising (Swinburn & Shelly, 2008). Results from an experiment with children and youth attending a summer camp demonstrated that children will eat low-sugar ready-to-eat cereals and those children who eat low-sugar cereals tend to eat less cereal and more fruit than children who eat high-sugar cereals (Harris et al., 2011). These results have implications not only for parents but also for policy makers. For example, a requirement that manufacturers of ready-to-eat cereals devote a proportion of their cereal advertising to low-sugar cereals may be a promising policy intervention to decrease sugar consumption in children and youth.

Policy

Policy operates at a broad societal level to structure physical activity and diet behaviors. Because policy-making, particularly at the national and international levels, is distant from the daily lives of most people, its effects are not generally obvious to individuals. Policies related to road construction, public transportation, and pedestrian and bicycle access ultimately affect personal choices about using active modes of transportation. Decisions to walk or bicycle are affected by urban design and land-use policies (Heath, Brownson, et al., 2006). At a community level, effective interventions to increase walking and bicycling include zoning regulations that provide convenient access to retail and investments that improve the quality and connectivity of sidewalks.

At a street-scale level, active forms of transportation are supported by improved street lighting, traffic calming measures, and landscaping that enhances the aesthetic quality (Heath, Brownson, et al., 2006). In Bogotá, the urban environment has been transformed through policies that discourage private vehicle use, improve public transportation, promote nonmotorized transportation, and convert parking areas to attractive public spaces (Wright & Montezuma, 2004). A weekly car-free day, *Ciclovía*, was established through a city referendum, and women who participate in the event are more likely to engage in leisure-time physical activity than those who do not (Gomez, Mateus, & Cabrera, 2004).

Public policies broadly determine the type and costs of foods available to individuals. A large and complex array of agricultural, industrial, and economic policies have created the contemporary food environment in the USA and other nations. The agriculture sector represents a substantial part of the US economy; government policies support this sector through subsidies, farm credits, commodity programs, trade policies, marketing assistance programs, and sponsorship of agricultural research (Tillotson, 2004). During an era when nutrient deficiencies were common, policies to increase the food supply played an important role in improving public health. However, at the present time, these same agricultural policies support the proliferation of processed foods and conflict with national nutritional policies that guide Americans to eat more fruits and vegetables, less processed food, and a smaller volume of food (US Department of Agriculture, 2010). Tillotson (2004) questions whether targeted policy initiatives such as taxes on high-fat or high-sugar products or limits on food advertising can affect American eating habits in the absence of changes to broad agricultural policies. Similar questions can be raised for other high- and middle-income nations where national policies encourage a surplus food supply.

Until recently, distal influences on health behavior such as policies, mass media and marketing, and globalization have not been a routine area of investigation for behavioral scientists. However, it is these distal influences that have radically and pervasively changed the environment in which individuals worldwide make choices regarding food and physical activity. The development of ecological models of healthy eating and active living has helped to broaden the scope of behavioral research to the larger social and political arena and has set the stage for an era when interdisciplinary collaboration is not a rarity but an absolute requirement for conducting relevant and contextualized behavioral research.

Synthesis of Research Issues

The number of studies on environmental influences on healthy eating and physical activity has increased enormously in recent years, making it a challenge to synthesize and make sense of the evidence. Numerous narrative and systematic reviews in this area have been conducted, such that "reviews of reviews" are appearing (Bauman & Bull, 2007), and more work is needed to combine and reconcile the disparate findings in these many reviews. Systematic reviews are highly selective, and studies with sufficient rigor for inclusion in systematic reviews are most often conducted in high-income countries. Contextual evidence, such as local evaluations of community-based health promotion programs, is barred from most evidence hierarchies yet constitutes the bulk of evidence for health promotion in the developing world (McQueen, 2001). Few systematic reviews have rigorously integrated results from qualitative and quantitative studies. However, this type of methodological strategy may provide a sounder evidence summary and a more appropriate base for policy decisions related to healthy eating and physical activity than overreliance on one type of study.

There is a great need for more "contextualized" research that examines unique processes, environments, and behavioral outcomes in a wide variety of settings; there is a corresponding need for greater diversity in the design of research in this area. Randomized controlled trials in community settings are expensive, difficult to implement, and probably inadequate for measuring population-level change (Victora, Habicht, &

Bryce, 2004). "Rather than efficacy in the purposefully limited context of experimental design, more timely questions surround reach, success in engaging high priority population, or robustness and replicability of impacts" (Fisher, 2008, p. 16). The great majority of studies on the environmental context for healthy eating and physical activity are correlational in design and examine a very limited range of environmental influences; few apply multilevel modeling techniques. Most studies using an ecological framework do not address the nested nature of behavioral influences (Glasgow & Emmons, 2007). However, studies examining multiple factors at multiple levels of influence present substantial challenges to researchers, such as developing measures at multiple levels, building interdisciplinary research teams, applying advanced statistical analyses, and engaging in the political processes that lead to policy and environmental change (Sallis, Owen, & Fisher, 2008). More research on sustainability and cost-effectiveness in diverse settings is also needed (World Health Organization, 2009). Researchers should consider developing studies related to the process, output, and outcome indicators developed by the World Health Organization (2008) to monitor and evaluate environmental and policy changes related to healthy eating and physical activity. Rigorous evaluation of community-based healthy lifestyle programs is especially needed in developing countries. Finally, working closely with diverse community partners is an absolute prerequisite to designing studies that are culturally appropriate and suit the local context (Baumann, 2011; World Health Organization, 2009).

Conclusion

Decades of research on individual-level approaches to promoting healthy eating and physical activity have had no demonstrable effect on improving population levels of these behaviors. The burgeoning rates of NCDs that threaten global public health are concurrent with dramatic changes in the environmental context for healthy eating and physical activity. To counter the broad forces that predispose individuals around the world to sedentary behaviors and unhealthy diets, the World Health Organization (2004) has recommended the development of environments that enable populations and individuals to achieve energy balance, shift to unsaturated fats, increase fruits and vegetables, limit free sugars and salts, and engage in developmentally appropriate amounts of moderate and vigorous physical activity. Prevention-focused, population-based policies and programs for physical activity and dietary behaviors will be needed to achieve improved and have the best potential to substantially reduce the predicted growth of the global burden of noncommunicable disease. This climate of change provides an opportunity for behavioral scientists to make a recognizable impact on public health. As environments change and new policies are enacted, opportunities abound for natural experiments, quasi-experiments, comparative case studies, and longitudinal research. The pandemic nature of NCDs demands strategic behavioral research that is timely, moving quickly from design to dissemination of results, and targeted, reaching the opinion leaders and policy makers who lead change efforts (Brownell, 2010, August). Timely and targeted research that takes place in community settings that reach large numbers of participants will provide the best evidence for practices, programs, and policies that create a more supportive context for healthy eating and physical activity for people worldwide.

The Fundamental Role of Socioeconomic Resources for Health and Health Behaviors

Arjumand Siddiqi, Clyde Hertzman,
and Brendan T. Smith

Introduction

History suggests to us – with the most intuitive interpretation – that over the past several hundred years, as the world and its inhabitants have become more economically prosperous, their social prosperity – including their health status – has also advanced in meaningful ways. While, in many respects, this describes the overall health-wealth relationship, it is far from being a fulsome account of the dependencies between the health of individuals and populations, their economic resources, and those of the societies in which they are embedded.

Through scientific inquiry, we have learned that (a) for both people and societies, incremental improvements in economic resources (and, more completely, *socioeconomic* resources, described below) are associated with incremental improvements in health and health behaviors (HHBs), though, after a point, there are diminishing returns to greater resources; (b) while there are important "absolute" aspects of economic resources which matter for HHBs, an abundance of evidence suggests that one's relative resources – that is, resources compared to others in society – are influential above and beyond any absolute level; (c) as economic resources have grown, their distribution between individuals and societies has been increasingly unequal, which has had consequences for the distribution of HHBs; (d) growing economic prosperity has also been accompanied by other societal changes which carry health effects of their own; and (e) the mechanisms – both social and biological – through which economic resources are tied to HHBs are many and varied; the influence of economic resources on health via their effects on health behaviors is certain, but also extends well beyond.

In this chapter, we first provide a working definition of *socioeconomic resources*, a broader and more complete construct which acknowledges the interdependence of economic resources and the social or relational resources which accompany them. Next, we review the current state of evidence on the relationship between socioeconomic

resources and HHBs at the three main levels of society for which we have systematic evidence from around the world: individuals and families, communities/neighborhoods, and nations. Our review concentrates on the overarching understandings which have emerged from the scientific literature in this area and presents an emergent model to synthesize these findings. We then describe two case studies which provide a more in-depth perspective on the importance of examining the interdependencies of socioeconomic resources at each of these three levels and the ways in which the interplays have consequences for HHBs. In the first case study, we explore how, in two economically advanced countries with many societal similarities – the United States and Canada – differences in the health status of their respective populations are significant and are largely explained by differences in resource distribution at the national level and its effects on other aspects of the national context, and on the resources of neighborhoods and those of individuals and families. In the second case study, we examine changes in population health status which occurred in a set of middle-income countries – those of Central and Eastern Europe – during the late 1980s'/early 1990s' transition from a communist political-economic orientation, to a capitalist (market) orientation, a shift which altered many economic and social aspects of these societies and thus changed the resources available to individuals and families.

Concepts and Measurement of Socioeconomic Resources

Individual Socioeconomic Resources

A long tradition of sociological inquiry has guided thinking about the importance of economic resources in many aspects of daily life. Scholars have long argued about the precise characterization of resources, particularly in terms of the means through which they were acquired, distributed, and valued (Lynch & Kaplan, 2000; Marx, 1894, 1991; Weber, 1922). Overall, however, there are two particularly significant and consistent findings which have emerged from this literature: (1) there is an inextricable link between education, occupation, and income as the principal inputs or indicators of an individual's economic resources; and (2) there is an inextricable link between economic resources and social resources – namely, social status and prestige – which are also strongly implicated in the quality of everyday lived experiences. In fact, the aforementioned inputs of economic resources also contribute to social status and prestige. Collectively, this constellation of economic and social resources is widely referred to as "socioeconomic resources," though there are slight deviations, depending on the nuance one brings to the construct (e.g., socioeconomic status, socioeconomic position) (Lynch & Kaplan, 2000). Moreover, not only are economic and social resources inextricable, their association is reciprocal; while higher education, occupational position, and income result in higher levels of status and prestige, it is precisely status and prestige which beget these higher economic resources, because they open doors to opportunities (particularly for future generations) for acquiring these resources (Breen, 2004; Duncan & Brooks-Gunn, 1999; Hauser, Warren, et al., 2000; Ishida, Muller, & Ridge, 1995; Solon, 2004).

Over a long history of inquiry into the causes of health and illness the contribution of socioeconomic resources has been widely investigated. In the process of adapting this construct to the investigation of HHBs, the interpretation and measurement of socioeconomic resources has been broad and varied. At the individual and family level, the translation has been fairly direct, with the idea that both material- and status- or prestige-based aspects of resources may have implications for health status (Krieger, Williams, & Moss, 1997). As such, measures of socioeconomic resources include both material assets, such as income and wealth, and social resources, which provide prestige, such as educational attainment and occupation (Krieger, Williams, & Moss, 1997).

On the one hand, as these different indicators attempt to measure the same overall construct, there is some overlap between them, both conceptually and empirically. On the other hand, the health literature has demonstrated that each indicator has a unique pathway through which it is hypothesized to influence HHBs (Lynch & Kaplan, 2000). As such, the working theory is that each indicator represents a unique dimension of socioeconomic resources. There is now abundant evidence that considering multiple measures of socioeconomic resources is necessary to capture the full association between this construct and HHBs (Braveman, Cubbin, et al., 2005).

Communities/Neighborhood Socioeconomic Resources

As research on the influence of socioeconomic resources has progressed, a major insight has been that, above and beyond the socioeconomic resources of individuals and families, HHBs are also a function of the socioeconomic resources of the communities or neighborhoods in which individuals and families are embedded. While, as we will see later in the chapter, the conceptualization and measurement of individual/family socioeconomic resources in relation to HHBs has been a global phenomenon, most of the thinking and empirical work in this regard has been based in the United States, with some evidence coming from other OECD (Organisation for Economic Co-operation and Development) nations.

As such, most of the understandings which have developed are primarily rooted in the neighborhood dynamics found in the United States, though many aspects of this literature are more broadly applicable. In the context of the United States, a long history of economic, political, and social forces has led to a high degree of residential segregation – the "sorting" or "concentration" of individuals and families in accordance with their socioeconomic resources, such that US neighborhoods are marked by a high degree of socioeconomic homogeneity within neighborhoods and a high degree of heterogeneity across neighborhoods (Massey & Denton, 1993).

Not surprisingly, neighborhoods with more socioeconomic resources are often more desirable places to live, offering more services and less stressful living. Resource-poor neighborhoods often offer fewer services and often have higher crime rates, more abandoned housing, more limited access to healthy foods, and other markers of worsened quality of life (Sampson, 2003b). As such, then, residential segregation is strongly linked to inequalities in socioeconomic resource distribution, with a reinforcing mechanism whereby the most disadvantaged individuals are differentially concentrated in cheaper and less resource-dense neighborhoods (Diez Roux & Mair, 2010).

Of note, these institutional forces have also evolved to create residential segregation based on not only socioeconomic resources but also race (Massey & Denton, 1993). Racial minorities in the United States (particularly African Americans) then experience the highest degree of segregation, owing principally to two forces: historical and present-day racism which has diminished their opportunities to acquire individual and family socioeconomic resources and, historical and present-day racism which prevents them from purchasing or renting housing in neighborhoods characterized by high resource levels, which tend to have large proportions of white residents (Williams & Collins, 2001).

Relying heavily on census data to approximate neighborhood boundaries and obtain socioeconomic measures, early studies on neighborhoods and health primarily defined neighborhoods as census tracts and the socioeconomic resources of neighborhood were proxied by the socioeconomic characteristics of the residents in a census tract (e.g., average or median household income in a neighborhood (census tract)) (Diez Roux & Mair, 2010).

A second generation of neighborhood effects studies has focused on characterizing the socioeconomic resources of neighborhoods from a structural perspective: that is, a characterization of "true" neighborhood attributes rather than solely an aggregation of the socioeconomic resources of a neighborhood's residents (Sampson, 2003a). Similar to the construct of socioeconomic resources, these attributes include both physical and social factors (Diez Roux & Mair, 2010). The physical environment refers to what materially constitutes a given neighborhood. Some examples, but not an exhaustive list, of these attributes include environmental exposures (e.g., air pollution), aspects of the built environment (e.g., housing, urban design and public spaces), and access to health-related resources (e.g., health foods and places for physical activity) within the neighborhood (Diez Roux & Mair, 2010). The social environment is defined as the social organization of the neighborhood; it includes, but is not limited to, social interaction and cohesiveness, social capital, levels of safety or violence, and the presence of social norms (Diez Roux & Mair, 2010; Kawachi & Berkman, 2003).

Societal/National Socioeconomic Resources

The third main level at which socioeconomic resources have been considered in relation to their consequences for HHBs is at the level of society, more specifically, the nation. Socioeconomic resources of nations have primarily been conceptualized and measured in terms of the per capita economic production of a nation (most commonly measured as per capita gross domestic product (GDP)) (Preston, 1975; Rodgers, 1979; Sampson, 2003a). Later literature began to focus not only on the role of per capita or average economic resources in health, but also on the role of the distribution of economic resources, most often referred to as the degree of income inequality (Kawachi, 2000).

Unlike the neighborhoods literature, which has greatly evolved in terms of its conceptualization and measurement of socioeconomic resources, literature on national socioeconomic resources has largely remained focused on income and income-like measures. Other national indicators which have strayed from this pattern still largely measure aggregate characteristics of the population. A key example in this respect is the Human Development Index, which combines per capita gross national income, mean and expected years of schooling, and a measure of health, life expectancy at birth. Increasingly, the economics literature is suggesting "gross national happiness" – determined principally through surveying population perceptions of various aspects of national wellness – as a metric of a nation's socioeconomic well-being (Anand & Sen, 1994; Kahneman & Krueger, 2006).

With few exceptions, the literature has not well elucidated nor empirically tested more structural conceptions of socioeconomic resources at the national level – such as overall infrastructure, service provisions (e.g., health care, transportation, education), safety net (e.g., unemployment insurance, welfare) – which aren't only aggregations of population characteristics (Muntaner, Borrell, et al., 2011; Navarro, Borrell, et al., 2003; Siddiqi & Hertzman, 2007). Even the World Bank's often-used categories are based solely on income (as in the designations of low-, middle-, and high-income nations) or on the compositional characteristics of citizens (as in the designations of "developed" and "developing" which draw on the Human Development Index (Stanton, 2007; UNDP, 2014)). Later in the chapter, we will take a closer look at two key examples of how a wide range of national socioeconomic factors shape the population's HHBs.

Socioeconomic Resources and Their Influence on Health

Individual/Family Socioeconomic Resources and Health

Socioeconomic resources have been strongly linked to opportunities in countless spheres of life. Their association with HHBs is profound. In fact, the persistent and ubiquitous nature of this association is perhaps one of the most striking of all epidemiologic findings about HHBs. Historically, documentation first began during the nineteenth century with the work of Villerme and Virchow (Berkman & Kawachi, 2000; Krieger, 1992). In the modern era, much of the early work on this topic arose during the early 1990s from the analysis of the Whitehall study in which investigators observed a striking relationship between the employment grade of British civil servants and a variety of HHB outcomes (Marmot, Smith, et al., 1991). These studies suggested that, with each additional increase in employment grade, HHBs (such as risk of cardiovascular disease, smoking, and alcohol use) also improved.

Take, for example, the rich literature on smoking. Low levels of socioeconomic resources in childhood and adulthood are associated with higher smoking rates in adulthood in middle- and high- income countries, with some evidence of this association in poor nations (Gilman, Martin, et al., 2008; Hiscock, Bauld, et al., 2012; Jefferis, Power, et al., 2004; Lawlor, Batty, et al., 2005; Power, Graham, et al., 2005). The link between socioeconomic resources and smoking includes the influence of resources on a variety of specific aspects of smoking behavior, including initiation, prevalence and consumption, quit attempts, and cessation rates. Differences across socioeconomic groups in initiation has been linked to family characteristics (parental smoking status, decreased ability to resist peer pressure, lower awareness and underestimation of tobacco's harm, behavior problems, and poorer educational performance) during childhood and adolescence (Galea, Nandi, & Vlahov, 2004; Hiscock, Bauld, et al., 2012). While the number of cigarettes smoked is more variable (in high-income countries, lower socioeconomic status is associated with less cigarette consumption among smokers but, in most low-income settings, with greater cigarette consumption), socioeconomically disadvantaged individuals smoke each cigarette "harder" – a process that extracts more nicotine while increasing exposure to other risky components of tobacco smoke (Hiscock, Bauld, et al., 2012). There is also evidence to suggest that individuals in lower socioeconomic strata are less successful in attempts to quit smoking (Hiscock, Bauld, et al., 2012).

Similar to smoking, type of alcohol consumption is socioeconomically patterned, with lower resourced individuals consuming higher amounts of alcohol, though higher resourced individuals drink more frequently (Huckle, You, & Casswell, 2010; Kuntsche, Rehm, & Gmel, 2004). Fewer socioeconomic resources are also associated with poorer nutritional consumption, less leisure time physical activity, and more sedentarism (Beenackers, Kamphuis, et al., 2012).

These well-documented relationships between socioeconomic resources and HHBs demonstrate a graded association. That is, incremental changes in socioeconomic resources lead to incremental changes in HHBs; the relationship is one of a gradient, not of a threshold (Adler, Boyce, et al., 1994; Siddiqi & Hertzman, 2007). NB: there are, however, some studies which suggest that the "steepness" of the gradient is greater at lower socioeconomic levels and lesser at higher socioeconomic levels (Rehkopf, Berkman, et al., 2008; Rehkopf, Krieger, et al., 2010).

The pattern has thus widely come to be known as the "gradient effect" or the "socioeconomic gradient in health." There are several related implications of this finding. The first, that there seems to be no level of socioeconomic above which an individual is certain to be protected against ill-health, because the significance of one's resources is a relative matter. The second, that health is a function of the socioeconomic resources an individual possesses compared to those possessed by others in society (Adler, Boyce, et al., 1994). Put differently, for a given individual, it is difficult to predict a level of health that corresponds to a level of socioeconomic resources, because what matters in large part is the value of one's socioeconomic resources relative to others in a given time, place, or other relevant context. This notion has been reinforced through cross-national studies which have demonstrated that the quality of life and health outcomes of low-income workers – those with similar absolute resource levels – is superior in Canada, where the relative position of these workers is higher, compared to the United States, where their position is lower (owing to lower levels of socioeconomic inequality in Canada than in the United States) (Siddiqi & Hertzman, 2007; Siddiqi & Nguyen, 2010; Zuberi, 2006). Third for a population, there are two ways to characterize health differences across socioeconomic groups: on an absolute scale (the difference in health status between high and low socioeconomic groups) and the relative scale (the ratio of health status between low and high socioeconomic groups). For instance, by some accounts, the ratio of ill-health between low and high occupational categories is less favorable in Scandinavian nations than in the United States; however, the absolute levels of ill-health for both low and high occupational groups is much lower than those of the United States (Kaufman, 2009; Lynch, Smith, et al., 2006).

At one time, it was thought that socioeconomic differences in health outcomes were mainly attributable to socioeconomic differences in health behaviors. Research had rather definitively established both that behaviors are a function of socioeconomic resources (as described above, for example with smoking, alcohol use, and diet) and that health behaviors are associated with a variety of health outcomes such as cardiovascular disease, cancers, and other leading causes of morbidity and mortality (McGinnis & Foege, 1993; Mokdad, Marks, et al., 2004). However, more recent studies have provided more mixed results with some suggesting that, in fact, the role of health behaviors may be rather modest for explaining socioeconomic disparities in health, a rather counterintuitive finding indeed. Collectively health behaviors have been shown to explain between 12% and 54% of the social inequities in mortality (Stringhini, Sabia, et al., 2010). Today, we know that socioeconomic differences in health outcomes are a function of not only behaviors, but multiple other biological mechanisms, which we describe later in the chapter.

To be sure, however, many of these studies only considered prevalence of health behaviors measured at one point in time and therefore may underestimate the contribution of health behaviors to social inequalities in health (Stringhini, Sabia, et al., 2010). Moreover, as mentioned earlier, to understand the contribution of health behaviors to the social gradient in health, it is important to consider inequalities on both absolute and relative scales. For example, a study of social inequalities in coronary heart disease (CHD) found conventional risk factors (including some health behaviors such as smoking) explained 72% of the relationship between socioeconomic position and CHD on the absolute scale, but only a modest 24% on the relative scale, suggesting that there are high levels of such risk factors in every socioeconomic group, but few differences between groups (Lynch, Davey Smith, et al., 2006). Therefore, the true contribution of health behaviors to social inequalities in health may be underestimated in many contexts.

Neighborhood Socioeconomic Resources and Health

Beyond personal socioeconomic resources, those of neighborhoods are an important context in which HHBs develop. As discussed earlier in the chapter, the neighborhoods in which individuals live and work are important factors in both constraining and enhancing HHBs (Diez Roux & Mair, 2010). Neighborhood characteristics have been shown to be associated with a variety of smoking related behaviors. Compared to neighborhoods with higher socioeconomic resources, those with fewer resources are associated with higher number of retail outlets and higher rates of cigarette advertising and promotion (Hiscock, Bauld, et al., 2012). Moreover, the well-established mood-elevating and anxiolytic effects of nicotine may make those in low-income neighborhoods especially susceptible to that advertising and promotion (Services, 1998). International studies show associations between lower educational status and greater nicotine dependence (Siahpush, McNeill, et al., 2006). That greater distress among low-socioeconomic status (SES) groups may make them more susceptible to nicotine dependence is suggested by studies linking distress and dependence, for example, associations between nicotine dependence and mood and anxiety disorders (Grant, Hasin, et al., 2004). Thus, greater likelihood of dependence due to varied stressors among residents of low-income neighborhoods may reinforce greater marketing of nicotine products, which, in turn increases use and dependence.

Neighborhoods with lower socioeconomic resources also have a greater density of alcohol outlets, which is associated with greater alcohol use. Neighborhood socioeconomic resources also affect (or are correlated with) other aspects of neighborhood context, which in turn influence health behaviors. The food environments within neighborhoods have been linked to quality of diets for its residents. For example, access to retail outlets with healthy food options (e.g., supermarkets) was associated with having healthier food intake (Larson, Story, & Nelson, 2009). Moreover, the number of and proximity to fast food outlets are associated with a poorer quality diet (Moore, Diez Roux, et al., 2009). Lower levels of stress and even lower levels of asthma have been observed in individuals living in neighborhoods with increased presence of physical activity resources in parks and recreational settings (Kaczynski & Henderson, 2008) and increased neighborhood safety (Diez Roux & Mair, 2010; Wright, Mitchell, et al., 2004). There is now building evidence that neighborhood characteristics are linked to health conditions, such as obesity (Black & Macinko, 2008; Papas, Alberg, et al., 2007) and diabetes (Auchincloss, Diez Roux, et al., 2009; Ludwig, Sanbonmatsu, et al., 2011) in large part through cumulative exposures to negative health behaviors.

Societal (National) Socioeconomic Resources and Health

Socioeconomic resources of societies – in particular, of nations – also have a strong association with HHBs. At the national level, both the overall level of socioeconomic resources and the distribution of these resources have received considerable attention. Moreover, these aspects of resources have been investigated in terms of both overall population levels of HHBs and the distribution of HHBs within and across societies. For the most part, national level studies have focused on the most commonly gathered and widely available measures of population health, life expectancy, and its close correlate, mortality rates, as their metric of health. As described earlier, perhaps the most common metric of overall resources is often per capita gross domestic product (GDP).

Influence of Societal Resources on Overall Population Health

The association between per capita GDP and metrics of population health demonstrates two major phenomena (see Fig. 14.1). First, one can observe the same general pattern as the individual association between socioeconomic resources and HHBs; incremental increases in GDP result in incremental increases in life expectancy; however, at a certain point, the health returns to additional GDP diminish and then level off entirely (Rodgers, 1979). Interestingly, this leveling off at the population level appears to be much sharper and con-

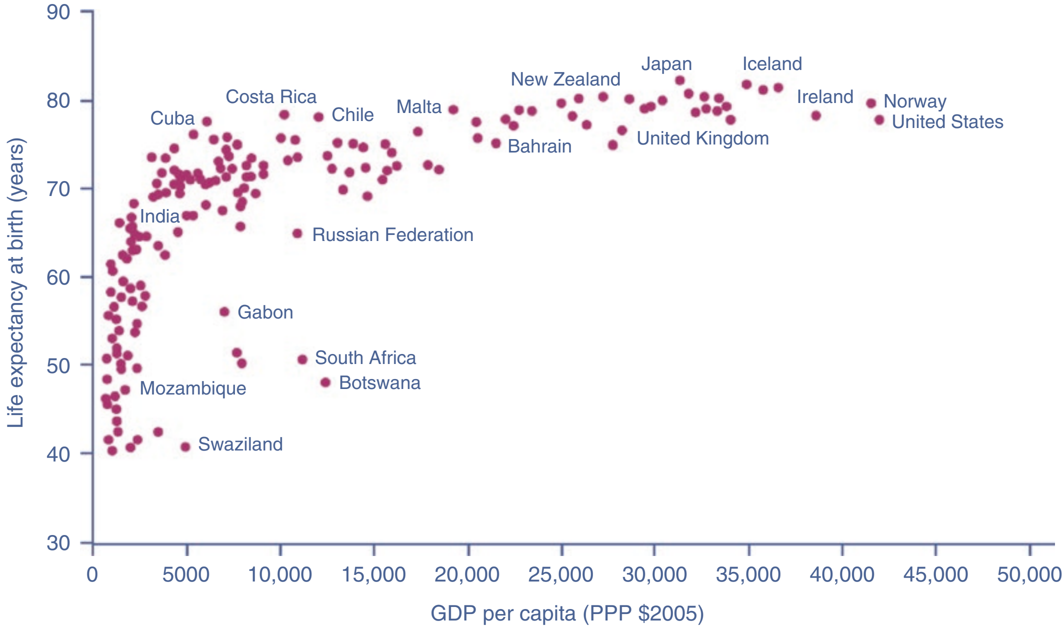

Fig. 14.1 Life expectancy at birth versus average annual income in GDP (Source: http://underpoint05.wordpress.com/category/inequality/)

sistent than that at the individual level, where nonlinearities in the socioeconomic gradient have only begun to be explored. Countries such as those of sub-Saharan Africa benefit tremendously from improvements in their national income, but by the time societies reach the level of wealth of countries such as Sweden, the United Kingdom, Canada, and the United States, there are no ostensible health benefits to becoming richer.

The initial part of this pattern – the rise in health status associated with increased resources – is largely explained by the improvements in basic health resources such as sanitation, drinking water, food security, and medical care (Preston, 1975). The latter part of this pattern – diminishing returns to life expectancy of increased national income – occurs among those countries which have a long history of basic health infrastructure, and thus have undergone an epidemiologic transition away from infectious diseases and low life expectancies to a dominance of chronic diseases which occur in later decades of life (Omran, 1971).

Among these wealthier countries then, rather than differences in absolute levels of wealth (and thus differences in basic infrastructure), variations in life expectancy are thought to be a function of the distribution of wealth and also of co-occurring societal phenomena. For instance, recent studies are beginning to show that the health outcomes of the advanced capitalist democracies (the so-called welfare state nations) are patterned by the type of social policy regime they exhibit, with more generous welfare states demonstrating stronger population health outcomes (Eikemo, Huisman, et al., 2008; Muntaner, Borrell, et al., 2011).

Second, at any given level of national resources, there is also quite a significant spread in terms of population health status; South Africa and Croatia are similar in terms of their per capita national income (South Africa, $10,700; Croatia, $10,600 according to 2003 purchasing power adjusted figures), but maintain a nearly 30-year difference in life expectancy (South Africa, 26.6 years, Croatia, 74.37 years). Moreover, the health of many poorer nations matches or surpasses that of much richer nations. Cuba's 2003 per capita GDP was $2900 and its average life expectancy was 76.8 years. By contrast, the Czech Republic with a GDP of $15,700 had a lower life expectancy, 75.2 years, and the United States at $37,800 had a life expectancy only marginally better, 77.1 years. Though not yet thoroughly investigated, these "diversions from the line of regression" are thought to be due to the provision of health resources in some countries (like Croatia and Cuba) which outpaces their level of wealth (data obtained from World Bank World Development Indicators) and sociopolitical upheaval in others, such as the epidemic of HIV/AIDS in South Africa and the postcommunist transition in the Czech Republic.

Influence of Societal Resources on Health Disparities

Evidence is also beginning to accumulate which suggests that in addition to affecting overall population health, these national characteristics (most notably, income inequality and social policy) also affect the distribution of health – health inequalities or the socioeconomic gradient – *within* a population. In fact, one hypothesis which has been forwarded suggests that health inequalities underlie the statistics on average population health; low average levels of population health are driven by large socioeconomic inequalities in health (Siddiqi, Kawachi, et al., 2007; Siddiqi, Kawachi, et al., 2013). Among the wealthy countries, those such as the Scandinavian cluster, which demonstrate lower levels of socioeconomic inequality have a correspondingly "shallower" socioeconomic gradient in health and also the highest average health status, while the United States, whose income inequality is the most pronounced among these nations, has a remarkably steep gradient effect and the lowest average health status of these nations (Mackenbach, Kunst, et al., 1997; Mackenbach, Stirbu, et al., 2008).

While the pattern of steepness (i.e., strength) in the socioeconomic gradient in health appears to be correlated with the distribution of income, it seems it is also attributable to the distribution of health resources such as education, neighborhood/living conditions, working conditions, and the like (Siddiqi & Hertzman, 2007). In some nations, where the socioeconomic gradient is shallower, policies work to provide equitable access to these resources, while in others, where the gradient is quite steep, policies to provide resource equity are either absent, weak, or even work to concentrate among the wealthiest members of society. These propositions are only beginning to be investigated.

Later in the chapter, we provide two cross-national comparative case study examples which highlight how in countries that are similar in many respects there are, nonetheless, marked differences in socioeconomic health inequalities and in average levels of population health, and which investigate the role of individual resources and societal distribution of resources in explaining these differences.

Mediating Pathways/Mechanisms Linking Socioeconomic Resources and HHBs

Over time, the bulk of research has focused on establishing the associations between socioeconomic resources and HHBs rather than deconstructing the mechanisms through which these associations arise. This may partly have been driven by the initial assumption that health behaviors were the overwhelming means through which health status was patterned along socioeconomic lines and also resulted in little emphasis was placed on exploring alternative mechanisms. Over time, as discussed above, research began to demonstrate that health behaviors explained some, but not all (maybe not even most), of the association between socioeconomic resources and health. For instance, after accounting for socioeconomic differences in smoking, drinking, and body mass index (as a proxy for diet and exercise), large socioeconomic inequalities in mortality still remain (Lantz, House, et al., 1998). More recently, then, scientific investigations have explored other major mechanisms through which socioeconomic resources are, literally, embodied and expressed as HHBs.

In the following section, we explore the now strong set of findings which suggest that, aside from affecting health behaviors, socioeconomic resources affect two additional pathways involved in shaping health (which operate distinctly, but may also be interconnected): the degree of physiological stress experienced by the body (McEwen & Seeman, 1999; Miller, Chen, & Parker, 2011) and epigenetic mechanisms (Borghol, Suderman, et al., 2012; Hertzman & Boyce, 2010).

The Role of Physiological Stress

Individuals with fewer socioeconomic resources experience both increased frequency and intensity of exposure to stress across the life course. Stressful environments in childhood, conceptualized as exposure to risky early family environment (e.g., early maltreatment, familial conflict, neglect, and cold, nonnurturing behavior (Matthews, Gallo, & Taylor, 2010; Miller, Chen, & Parker, 2011)) as well as stressful life experiences and adverse physical and social conditions in adulthood (e.g., economic hardship (Braveman, Marchi, et al., 2010)), racial discrimination (Williams & Mohammed, 2009), and low job control have been linked to poor health outcomes later in life. Individuals with few resources not only experience more of stress but also report higher levels of emotional distress compared to their more resourced counterparts when exposed to similar levels of stress (Matthews, Gallo, & Taylor, 2010). Individuals with few socioeconomic resources often lack the reserve capacity (e.g., protective resources) to deal with stressful environments. Two potential mechanisms have been proposed for this diminished reserve capacity. Relating to the stressful environment often accompanied by low levels of resources, (1) individuals may use resources more often and (2) social environment may prevent the development and replenishment of resources (Matthews, Gallo, & Taylor, 2010).

Exposure to repeated stressful experiences in low levels of socioeconomic resources can lead to physiological and behavioral dysregulations, leading to social inequalities in health getting “under the skin.” The brain plays an important role in managing stress. Exposure to stressful environments during development and aging can alter the structure and function of the areas of the brain that manage stress (e.g., hippocampus, amygdala, and areas of the prefrontal cortex) (McEwen & Gianaros, 2010). Changes in these areas of the brain, referred to as neuroplasticity, can modify the regulation, reactivity, and recovery, in both the short and long term, from physiological and behavioral stress processes, causing corresponding effects in the autonomic, cardiovascular, and immune systems (McEwen & Gianaros, 2010). Under chronic stress conditions, long-term disruptions of these systems can lead to wear and tear on the body and brain or "allostatic load."

The origins of our insights into social hierarchies and physiological dysregulation come from work done on primates (Sapolsky, 2005). Studies of baboons have clearly demonstrated that the social hierarchy in this species is associated with differential secretion of cortisol, a stress hormone; as one moves (incrementally) to baboons that have a higher social ranking, cortisol secretion in response to stressful stimuli decreases (McEwen & Seeman, 1999). These findings have now been replicated in human beings as well; individuals with greater socioeconomic resources secrete less cortisol in their stress response when compared to their lower resourced counterparts. The same is true for other aspects of the physiological stress response such as increased blood pressure (Colhoun, Hemingway, & Poulter, 1998; Loucks, Abrahamowicz, et al., 2011). In evolutionary terms, the physiological stress response is an effective means of dealing with immediate, life-threatening stressors. However, when the stress response is chronically triggered by the worries and anxieties of daily life or the vicissitudes of low social status within the group, over time, this can result in disease states such as diabetes and high blood pressure. The notion is that the stressors of everyday life are socioeconomically patterned, and so is the stress response.

The Role of Epigenetic Processes

Compelling evidence is beginning to emerge that socioeconomic resources fundamentally alter the structure of the DNA and its associated proteins, which then leads to differential long-term gene expression, and thus differential health outcomes. This process is known as epigenesis (Feinberg, 2008). Evidence among human suggests 1252 loci (i.e., "points") on the DNA molecule whose pattern of methylation (a particular type of protein alternation) is correlated with childhood socioeconomic resources. In animal models, the findings are much more robust. In mice, both prenatal and postnatal experiences affect epigenetic processes which change the health status of offspring across their life course (Diorio & Meaney, 2007; Szyf, 2003; Weaver, Cervoni, et al., 2004). For instance, maternal licking and suckling of newborn mice has been associated with decreased physiological stress response of these mice in their adulthood. The hypothesized mechanism is that epigenetic processes affect the main systems involved with the stress responses (such as the Hypothalamic-Pituitary-Adrenal axis) (Hertzman & Boyce, 2010). Epigenetic processes are also thought to affect the functioning of the autonomic nervous system and the immune system. Though these areas of research are only now beginning to gain momentum, the pool of studies conducted so far are promising.

In sum, there are three primarily distinct but interdependent ways in which socioeconomic resources affect health status: through behaviors, through physiological stress, and through epigenetic mechanisms. At the population level, socioeconomic disparities in health are created by differential vulnerability of lower socioeconomic groups to health-harming behaviors, high stress conditions, and genetic changes which lead to ill-health. At the root of these disparities, however, are the socioeconomic resources themselves. Evidence suggests that tackling any of the mechanisms we have described without addressing the distribution of socioeconomic resources and of the "life conditions" that accompany these resources will result in the persistence of the socioeconomic gradient in HHBs. As we will see later in the chapter, societies vary tremendously in the extent to which they distribute and redistribute resources across socioeconomic groups.

A Life Course Perspective on Socioeconomic Resources and HHBs

A key finding in the literature has been that the influence of socioeconomic resources on each of these mechanisms – health behaviors, physiological stress, and epigenetic processes – occurs also in the context of another dimension, that of time. Life course epidemiology is the study of the long-term effects of physical or social exposures during gestation, childhood, adolescence, young adulthood, and later adult life, which impact the development of health and disease (Kuh, Ben-Shlomo, et al., 2003). Life course studies acknowledge that individuals and environments change over time, and therefore attempt to quantify both the timing (at what period in the life course) as well as the duration of exposures (the total amount) and their corresponding risk on disease outcomes (Hertzman & Power, 2003). Individually, measures such as education, occupation, and income reflect socioeconomic resources experienced at specific periods in the life course. Using a life course perspective and combining more than one of these socioeconomic measures incorporates information on both the timing and duration of exposure and the corresponding influence on HHBs and health overall.

Three life course frameworks have been proposed to conceptualize life course socioeconomic resources (Kuh, Ben-Shlomo, et al., 2003). The "accumulation of risk" model represents the summation of effects of socioeconomic resources across the life course that accrue to increase risk for disease (Kuh & Ben-Shlomo, 2004). In contrast, the "critical/sensitive periods" model acknowledges that individuals could have heightened vulnerability to exposure to low socioeconomic resources at specific periods in the life course – many of which occur in early childhood – resulting in changes in disease risk (Kuh & Ben-Shlomo, 2004; Lynch & Smith, 2005). Finally, the "social mobility" model reflects that an individual's socioeconomic resources are dynamic throughout the life course, and incorporates the trajectory of socioeconomic mobility across a person's life (e.g., from low socioeconomic resources in childhood to high socioeconomic resources in adulthood) in determining disease risk (Pollitt, Rose, & Kaufman, 2005).

A Fundamental Cause Perspective on Socioeconomic Resources and HHBs

As the mountain of evidence has accumulated supporting the link between socioeconomic resources and HHBs, socioeconomic resources alas have come to be considered a "fundamental cause" of HHBs. In a rather influential conceptual paper, Link and Phelan identified three primary reasons for ascribing "fundamental causation" to SES (Link & Phelan, 1995).

First, the association seems to present for almost every HHB: infectious and chronic diseases; physical and mental illnesses; conditions afflicting the entire life course, from birth through death. The few illnesses that do not seem to demonstrate a gradient effect are strongly associated with a single-gene mutation, such as Down's syndrome. Others, which may show a "reverse gradient" with higher SES associated with worse health status, seem to show a flip in the gradient over time. An example is cardiovascular disease which, several decades ago, was a disease of affluence. Over time, this trend now exhibits the opposite patterning, with highest rates of disease occurring in the poorest segments of society in the wealthier nations, and evidence of the flip presently occurring in economically developing nations (Ezzati, Vander Hoorn, et al., 2005).

Second, the general gradient pattern of the association – incremental improvements in SES leading to incremental improvements in HHBs – is present in every society and every historical time period in which it has been measured. Socioeconomic gradients have overwhelmingly been studied in the context of the advanced capitalist societies where, to repeat, they are present for virtually all diseases with the aforementioned caveat. Among the middle- and low-income countries, socioeconomic gradients are apparent in the expected direction for infectious disease such as Malaria, HIV/AIDS, diarrheal diseases, and the like. For chronic conditions and their proxies (such as obesity), the middle- and low-income countries are currently in the process of a transition from reverse gradients to those which mirror the pattern of the association with infectious diseases in these countries.

Third, as earlier discussed, it is difficult to "block" the association between SES and HHBs by acting on any singular intervening mechanism. The basis for this insight is that many of the resources which accompany SES – money, knowledge, power, prestige, social support, and social network(s) – are tied to HHBs through *multiple* mechanisms. This is, perhaps, the essence of the notion that socioeconomic resources are a fundamental cause of HHBs; they lie at the origin of so many paths which lead to disease and its correlates. Interventions to date have tended to focus on intervening mechanisms (particularly on health behaviors). But, in isolation, this is largely ineffective, as socioeconomic resources simply "find" alternative pathway(s) – stress, epigenetics – through which to influence HHBs, and the socioeconomic gradient reasserts itself. That is, socioeconomic resources set forth a cascade of influences that may substitute or complement each other in ways that are only altered by altering the resources themselves. It is perhaps because public health has not addressed the fundamental (root) causes of socioeconomic gradients in HHBs – socioeconomic resources – that these gradients remain persistent and pervasive over time and space.

Next, we examine two cross-national case studies which elucidate the notion of socioeconomic resources as fundamental causes, and of the broader societal contexts which shape them and thus shape HHBs.

Case Study 1: Equity in Resource Distribution Trumps Overall Economic Prosperity

In the first case study, we examine population health in two economically advanced societies – Canada and the United States – whose many economic, political, and social similarities provide a basis for isolating and contrasting their differences. The analysis is taken primarily from Siddiqi and Hertzman (2007) and Siddiqi, Kawachi et al. (2013). In this case study, we establish that (i) differences in average levels of population health have corresponding differences in socioeconomic inequalities in health, (ii) more wealth and spending on health care does not yield better health outcomes, (iii) public provision and income redistribution have greater effects on population health, and (iv) the gradual development of public provision represents the buildup of social infrastructure that has long-lasting effects on health status. We proceed by comparing Canada and the United States on basic health outcomes and a range of determinants of health for which routine data have been collected for all or most of the period between 1950 and the present.

Health Status

Figure 14.2 depicts secular trends in life expectancy by gender (and race, which we will address later) in the United States and Canada. As of 1950, the life expectancy of Canadians and Americans was similar, with a slight American advantage for women and a small Canadian advantage for men. During the 1950s and 1960s a gap opened up, such that both male and female life expectancy in Canada increased faster than in the United States. In the late 1970s the gap narrowed considerably but starting around 1980 it opened again and continued to widen until it reached approximately 2 years by the end of the twentieth century. Although differences in infant mortality contribute to the gap, it is driven, primarily, by differences in adult mortality. A 2-year life expectancy gap may not sound like a lot, but during ages 25–64 it translates into mortality rates 30–50% per year higher in the United States compared to Canada.

A significant part of the explanation for higher average levels of health in Canada seems to be connected to lower levels of social and economic inequalities in health status. Though neither country makes data widely available from systematic

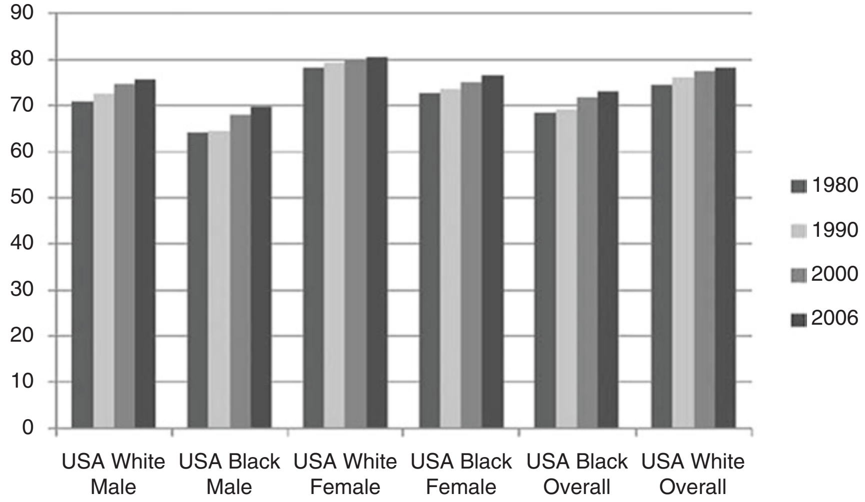

Fig. 14.2 Life expectancy by gender and race: Canada and the United States compared

monitoring of national health inequalities, studies using nationally representative samples from the 1990s and early 2000s demonstrate that the United States showed significant health disparities based on social class (Eng & Feeny, 2007), race (Siddiqi & Nguyen, 2010), and immigrant status (Prus, Tfaily, & Lin, 2010), while those differences in Canada were comparatively muted. In particular, this seems to be driven by superior health in Canada of those in more resource disadvantaged groups. For example, those in the lowest income quintile and with the lowest levels of education in Canada report a higher level of health status and health-related quality of life (as measured by the Health Utilities Index) than their US counterparts (Eng & Feeny, 2007). Other analyses have shown that the poorest 20% of Canadians enjoy the same life expectancy as Americans of average income (Singh & Siahpush, 2002; Wilkins, Berthelot, & Ng, 2002).

In both countries, people belonging to Aboriginal communities (First Nations in Canada and American Indian in the United States) are among the most disadvantaged subgroups. In relative terms, Canada and the United States show similar differentials in overall life expectancy between Aboriginal and non-Aboriginal populations (female life expectancy has a differential of 0.94 years expected life in Canada and 0.93 in the United States while the differential in male life expectancy is 0.90 in Canada and 0.91 in the United States). Interestingly, while the differentials are similar across countries, the life expectancies of both Aboriginals and non-Aboriginals is higher in Canada than in the United States, indicating better overall health in Canada among both groups. On the other hand, for several specific causes of mortality (prostate, cervical, and colorectal cancer, intentional self-harm, pneumonia, and assault), Canada demonstrates a higher relative risk for Aboriginals compared to non-Aboriginals than that observed in the United States (Bramley, Hebert, et al., 2004).

The one exception to the dearth of population-based social inequality data is the collection of life expectancy statistics by race in the United States (see Fig. 14.2) (Xu, Kochanek, et al., 2010). Indeed, these statistics demonstrate startling disparities. In 1980, the black-white female life expectancy differential was approximately 5.3 years (white female life expectancy 78.2 vs. black female life expectancy of 72.9), which increased to 5.7 years in 1990, declined to 4.9 years by 2000, and declined further to 4.1 years by 2006. The black-white male life expectancy gap in the United States was larger at all time points. In 1980, the racial gap for men was 6.7 years (white male life expectancy of

70.8 years vs. black male life expectancy of 64.1). By 1990, this gap had increased to over 8 years. In 2000, it had declined to 1980 levels and by 2006 the gap was, at 6 years, still very large. Though no directly comparable Canadian trend data are available, analysis from a 2003/2004 nationally representative survey demonstrate no significant disparities in health between whites and non-whites in Canada (Siddiqi & Nguyen, 2010).

And so the question becomes how in two countries with many similarities – both are economically advanced, democratic, have high proportions of immigrants, and are racially/ethnically diverse – are health outcomes so divergent. We next examine possible explanations. We start with the factors most traditionally associated with population health, overall economic well-being, and unemployment rates, and then move to factors that have been more recently elucidated as important correlates of population health, including the distribution of income, level of public spending, and neighborhood conditions.

Potential Explanatory Variables

Economy/Labor Market Characteristics

Purchasing-Power-Adjusted Per Capita Gross Domestic Product Gross domestic product (GDP) is an indicator of a nation's overall level of economic well-being. Adjustment for purchasing power equalizes differences across countries in the "value" of currency and expressing GDP on a per capita basis equalizes for differences in population size. From 1975 to 1988, GDP per capita adjusted for purchasing power (Purchasing Power Parity adjusted GDP) grew in Canada and the United States and tracked closely through business cycles. Throughout this period, the United States remained approximately 10% higher than Canada but from 1988 to 1993 this pattern was broken. PPP adjusted GDP per capita continued to grow in the United States, but did not grow in Canada. From 1994 to 2002, growth in Canada and the United States was, once again, in parallel, but because of the 5-year period of stagnation in Canada, its PPP-adjusted GDP per capita remained approximately 20% lower than the United States. Thus, unlike metrics of population health, overall economic well-being during this period seems to favor the United States and suggest that this variable does not explain why health of Canadians outpaced that of its American neighbors.

Unemployment Rate From the end of the Second World War until 1982, unemployment rates in Canada and the United States overlapped with each other from business cycle to business cycle, such that no systematic trend can be detected. From 1982 until 2000 unemployment rates have been consistently 2–4% higher in Canada than in the United States. Similar to GDP, unemployment trends also favored the United States, indicating that this factor is inadequate for understanding the Canadian health advantage.

Trends in Distribution of Income

Gini Coefficient In the 1970s, the Gini coefficient of income inequality, post tax and transfer, was approximately 2 points lower (i.e., more "egalitarian") in Canada than in the United States, with Gini coefficients in the "high 20s" in Canada and the "low 30s" in the United States. From then until the late 1990s the Gini stayed in the same range in Canada but increased (i.e., became more unequal) in the United States, such that there was a 5-point gap by the late 1980s and a gap of approximately 7 points by the late 1990s. In other words, over this time, the United States became an increasingly more income unequal society than Canada. Moreover, the relative redistributive work of the Canadian policies rose compared to American policies from the late 1980s to the late 1990s. The differences in redistributive policies between the countries were particularly marked in their success at poverty reduction (Zuberi, 2001). In 1974/75, taxes and transfers reduced poverty by approximately 11% in both countries. By 1994, poverty reduction had risen to 24% in Canada, but only to 13% in the United States. As indicated by prior literature, the smaller gap in income in Canada compared to the United States is consistent with higher levels of population health.

Public Spending

National Expenditure on Health During the 1960s, Canada spent approximately 0.5% of GDP more on health care than the United States. Canada's universal, single payer medicare plan was fully in place by 1971, while the United States was putting in place a plan that was universal only for seniors. Health care spending in the two countries tracked closely from 1970 to 1973, at approximately 7% of GDP. From 1973 to 1993, spending on health care in Canada rose to 10% of GDP and stayed between 9% and 10% until 2002. In the United States, spending on health care rose to 13.5% by 1993, and further to 14% by 2002. Thus, the 30-year period of universal medicare in Canada, but not the United States, has been one during which the level of spending on health between the countries diverged. Now, Canada spends 4% of GDP less than the United States. Thus, Canada's health was superior even in the face of lower health care expenditures. At the individual level, analyses of racial, immigrant, and class-based disparities have demonstrated that health insurance coverage does not explain why Canada's health is superior; higher disparities in the United States persist even after controlling for health insurance (Prus 2011; Siddiqi & Nguyen, 2010; Siddiqi, Ornelas, et al., 2013).

Public Social Expenditure In 1980 public social expenditures consumed approximately 13% of GDP in both Canada and the United States. By 1990, a large gap had opened, such that Canada was spending more than 4% of GDP more than the United States (>18% and <14%, respectively). By 1998 this difference had largely persisted, with Canada spending 18% and the United States spending slightly more than 14%. This suggests that social spending trends correlate well with population health trends in the two countries.

Neighborhood Conditions

Just as the social welfare policies differentiated the United States and Canada in terms of the extent to which basic resources for health were linked to individual/family income, so too were these nations disparate in the organization of communities and their institutions. The differences were primarily driven by two interrelated factors. First, these nations differed drastically in terms of the degree of economic and racial residential segregation. Data from the late 1980s demonstrates that both blacks and Asians in Canadian cities experienced segregation that has been described as minimal compared to the pervasive and often extreme segregation which characterized the United States (White, Fong, & Cai, 2003). Second, compared to the United States, urban planning policies of provinces and municipalities assured that key community infrastructure such as schools, community centers, parks, and transportation were maintained at a high level across all neighborhoods, not just the wealthier neighborhoods (Zuberi, 2001). Thus, the combination in Canada of greater explicit attention in local policies to equality of resources, and more economically and racially mixed neighborhoods, meant that more people had access to high-level resources irrespective of their individual characteristics or their neighborhood of residence.

Analysis

Over time, among two comparable high-income nations, trends in national-level indicators suggest that maintaining a narrower distribution of income and providing greater publicly available resources yields higher levels of population health than can be achieved through high levels of overall economic growth and investments in health care systems.

The period during which Canadian life expectancy increasingly surpassed the United States was a time when Canada's levels of public spending on social programs, the redistributive work of its social safety net, levels of maintained income equity, and levels of access to education were all surpassing the United States. Indeed, despite periods of relatively high unemployment, Canadian health status did not suffer.

The point of unemployment is especially useful for illustrating Canada-US differences. Where the labor market intersects with the social safety net, Canada's ability to support population health becomes particularly evident. Canada scores higher on the indexes of unemployment protection, labor relations, and corporate governance, constructed during the 1990s, which are designed to distinguish "liberal" from "coordinated" market economies (Estevez-Abe, Iversen, & Soskice, 2001). Unemployment protection (in part) represents the extent to which wages and benefits accrue to individuals, even in times of unemployment. The higher the unemployment protection score, the greater the wages and benefits afforded to unemployed workers. As such, unemployment protection represents a set of social policies that are designed to *transfer* income from the wealthiest members of society to the unemployed. In turn, to fund this aspect of welfare policy requires the presence of taxation policies that are progressive in nature; withholding larger amounts (as a percentage of one's income) from the rich compared with the poor. Corporate governance refers to the extent to which the state has a role in determining and enforcing the rights and responsibilities of corporations. Higher scores on this index suggest greater government input. Compared with the United States, Canada features lower wages of chief executive officers and other upper management and higher tax rates (and fewer loopholes) for large corporations.

On the other hand, Canadian health status increasingly surpassed that of the United States in a period in which economic growth in the United States moved increasingly ahead of Canada, and American unemployment rates, for the first time since the Second World War, were consistently lower, *a result that is somewhat* counterintuitive (though is consistent with their placement on the health/wealth trajectory displayed in Fig. 14.1). As mentioned earlier, research on other social processes in relation to population health came about only after cross-sectional studies showed little association between GDP per capita, health care expenditures, and measures of population health. Moreover, our data demonstrate that, even when a long view on wealth, spending on health care, and health are taken, the association is nonexistent. Even health insurance coverage seems to do little to abate cross-national differences in population health. Spending on health care in the United States increasingly surpassed Canada, during a time in which Canada had a national medicare scheme and the United States did not. (It should be noted that total government spending *per capita* on health care is greater in the United States than in Canada, despite the fact that coverage is not universal in the former.)

The Canada-US comparison is one of public provision and redistribution trumping traditional economic growth and direct health spending in producing population health. This conclusion is reinforced by the observation that, from the early 1970s to the late 1990s, socioeconomic gradients in health status did not get steeper in Canada. Over the 25-year period from 1971 to 1996, each of the income quintile groups in Canada gained equitably in terms of rising life expectancy (Wilkins, Berthelot, & Ng, 2002). The same was not true in the United States, where the highest income quintiles gained life expectancy at a faster pace than the lowest quintile (Singh & Siahpush, 2002).

Case Study 2: Health During Times of Economic, Political, and Social Transition

Our second case study examines determinants of health in the set of middle-income nations in Central and Eastern Europe (CEE) following the major (and relatively sudden) societal transition there in the late 1980s and early 1990s. It is taken primarily from an analysis conducted by Siddiqi, Bobak, and Hertzman (2009). The overall context is that, during this time, in much of the CEE, a change of guard occurred from "hardline" Soviet-style communist regimes to equally "hardline" capitalist (free market) economic approaches, a phenomenon described as "shock therapy" that was marked by a breakdown in the trade relationships among the Warsaw Pact countries, rapid economic decline, and high rates of unemployment and inflation (Brainerd, 1997; Klein & Pomer, 2001).

Health Status

Population health statistics suggest that during the first 4 years of the transition period, there were dramatic increases in mortality among males and females of working age. Among males aged 30–49, mortality rose as much as 70–80% in Russia, 30–50% in Ukraine, and 10–20% in Hungary, Bulgaria, and Romania. Among females, mortality in the same age range rose 30–60% in Russia, 20–30% in Ukraine, and more modestly in Hungary, Bulgaria, and Romania (UNICEF, 1994).

The conditions leading to this mortality increase were primarily cardiovascular disease and injuries (UNICEF, 1994). However, these were also the most prevalent conditions in working age persons at the beginning of the transition period; mortality due to these two causes was increasing even before the end of the Soviet period. Thus the working premise for this case study is that the vulnerability in this group was general: that is, a crisis in health status that simply expressed itself through the principal causes of mortality for its age group. This suggests, then, that explaining the health crisis in CEE must go beyond understanding the determinants of these conditions, and address the factors that created general risk of mortality, in particular among the working age population.

Analysis

In the analysis we present below, CEE represents a case study in which the collapse of government institutions and of civil society created for citizens conditions of economic deprivation, social isolation, and loss of control over life that, in turn, undermined the health status of the population.

Prior to rapid transformation out of communism, societies in CEE (in particular, Russia) had been depicted as having the character of an "hourglass" (Rose, 1995). This was intended to evoke the image of a society with an elite top which controlled the available economic political structures; a weak civil society in the middle (to varying degrees, depending on the country), whose capacity to buffer the stresses of daily living was limited; and at the bottom, the masses of individuals and families most of whom relied on multiple sources of support – from intimate associations to the state. During communist times, the relationship between the top and the bottom of the hourglass was stable, with a modicum of mutual obligation between the state and the individual.

Both empirical and observational accounts of the effect of the transformation yield important insights. Observationally, it has been noted that, after capitalist reforms began to be instituted in 1989, the twin ideologies of individualism and free market created unprecedented prosperity for those at the top of the hourglass and widening the social and economic distance between these elites and the masses. These new societal philosophies allowed those at the highest levels to abandon their responsibilities to those at the bottom, exposing the vulnerability of the common person – who had neither the aid of civil society nor the economic and political clout on which to depend.

In an analysis of the Russian Barometer survey, we found that people reporting higher levels of material deprivation (measured by the frequency with which people reporting going without food, heat, or necessary clothes and shoes) were more likely to report poor self-rated health (Table 14.1). Such material insecurity was rampant at the time. Polarization of the labor market had dramatically increased, as noted by a decline in the proportion of the population who were economically active simultaneous with an increase in wages for those who remained active (Forster & Toth 1998). According to sample surveys of ten countries in the region, conducted in the winter of 1993–1994, between 20% and 53% of households reported that they could not cope economically; even when resources gleaned from the informal economy were considered (Rose, 1995; Rose & Haerpfer, 1994).

For the most vulnerable members of society, this left only the intimate realm of family and informal social supports to compensate for a lack of support structures at the higher levels of social aggregation. In the same survey in Russia, respondents who reported relying exclusively on formal

institutions (employer, state, public organizations, charities, or church) were more likely to report being in poor health than those who could also rely on informal sources of support (Table 14.1). We also measured whether respondents had trust in "traditional" institutions of Russian society (e.g., police, courts, army) or in those of the "new" Russia. Those more likely to place trust in traditional institutions had poorer self-rated health. There is also supportive evidence from past research which suggests that those who were left to rely *only* on formal social capital were more likely to rate themselves as having poor health status (Abramson & Inglehart, 1995). The variations in country-level mortality support the thesis that, in those parts of CEE which had stronger civic traditions going back over the past several centuries, this tendency was less pronounced than in those places where civic traditions had never been strong. In these latter regions, life became, in Hobbesian terms, nastier, more brutish, and, for some, a great deal shorter than before.

Our analysis also revealed that these factors had a more pronounced effect on men than women, and that men who were unmarried were much more likely to report being in poor health (Table 14.1). This is consistent with earlier findings that single people were more vulnerable to declines in health status than married people during the political transition (Hertzman, Kelly, & Bobak, 1996). We interpret this result as an indication of further social disconnectedness and isolation. Taken in the context of the other results, the combination of an inadequate personal social network, and inability to rely on formal civil society (that essentially wasn't functioning) had detrimental health effects for individuals and, the fact that this was happening on a mass scale lead to detrimental population-level health outcomes.

This case study illustrates the effects on population health induced by swift and massive transformation of economic, political, and social aspects of society following the transition out of communism in Central and Eastern Europe. The dismantling of communist institutions and the rapid rise of market-based institutions brought with it both suddenly diminished national income and a drastic increase in income inequality. These new economic conditions in turn led to deleterious effects on the social fabric of society. Specifically, two (related) social shifts were induced: (1) for the majority of citizens, particularly those at the lower end of the socioeconomic spectrum, "material" security was severely compromised; and (2) social security – both that afforded by intimate relations and that by broader society – had drastically eroded. Our analyses suggest that, together, the deterioration in these factors played a major role in the decline of health status in this region.

The principal causes of death in this time period seem to point away from explanations that link this societal atmosphere to health solely through "material deprivation." This would be supported, for instance, by illness that could be traced primarily to nutritional deficiencies (e.g., wasting). Rather, our study suggests that one major way in which changes in macro-features of society led to ill-health was through the stress brought on by the rapidly changing conditions. We submit, in other words, that both material and social insecurity led to conditions such as cardiovascular disease through the well-documented physiological sequelae of stressful societal circumstances.

Based on the insights gathered from our analyses, we conclude that the root causes of major shifts in population health lie primarily at the policy level – in the case of CEE, it was the rapid economic reforms that ushered in new societal conditions – and that these policies set forth a cascade of changes at all levels of society, from national to one's most intimate connections. Our analyses also indicate that, during a time of transition to free market principles, population health is best protected by policies that maintain relative equality in income through the regulation of market institutions and systems of social protection and welfare.

A Framework for the Interdependencies Between Socioeconomic Conditions and Health and Health Behaviors

As the review and case studies we have presented illustrate, the relationship between socioeconomic resources and health status transpires – and is modified – in multiple ways and at multiple levels of society. Of course, we have not made the observations outlined in this chapter *de novo*. We build not only on the body of literature that we have reviewed and on our own contributions to this field of study, but also on preceding conceptual frameworks that have summarized the interdependencies between socioeconomic conditions and HHBs (Solar & Irwin, 2010). Sallis, Owen, and Fisher (2008) provide an excellent review of models that have been particularly influential in the study of health behavior (Sallis, Owen, & Fisher, 2008). However, such models have not fully embraced the multiple contexts – those geographically based and otherwise – nor have they incorporated the temporal dynamics – both those of individuals across their life course as well as of societies across historical time.

In Fig. 14.3, we provide an updated social-ecological model which we have modified from our earlier work (Irwin, Siddiqi, & Hertzman, 2007; Siddiqi, Vaghri, et al., 2012). Like others, the model depicts the individual as the center of a system that is affected and affects the contexts surrounding her. Also like others, each part of the system reflects many different characteristics which, for the sake of brevity we will not elaborate on. However, our model makes three primary additional contributions. First, our model portrays the development of an individual over the lifespan as a means for depicting the influence of context on the biologically and socially developing person over their life course that, as our review suggests, has been well established. Second, our model, like others before, also depicts several "nested" levels of societal aggregation. The shading and overlapping of the environments depicts their interdependencies. Moreover, the arrow through the model is intended to capture the element of historical time and thus, the accumulation of changes in societies (e.g., changes in policies) that also influence individuals. The notion is that just as individuals' life course trajectories matter, so too do the historical trajectories of societies. Finally, our model adds contexts that have previously been discussed, but not well integrated into the dominant frameworks and models in the field: the "environment" of health and other social services and the "environment" of relational communities – communities defined by social relations, such as those based on culture, religion, and even by illness status (Berkman & Glass, 2000; Fisher, La Greca, et al., 1997). While space prevents us from elaborating extensively, on these associations, both of these environments have been found to be associated with health status and socioeconomic resources (Berkman & Glass, 2000; Smedley,

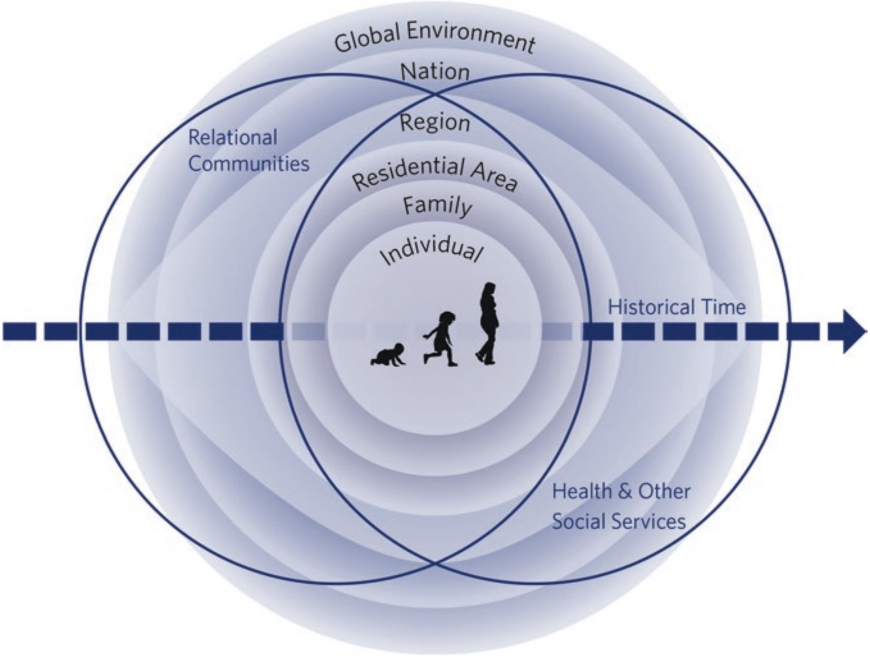

Fig. 14.3 An updated social-ecological model

Stith, & Nelson, 2003). Yet, these are not environments which are neatly subsumed by the other geographic levels described in our framework and previous frameworks. Instead, we overlay these "environments" across the geographic contexts which they touch. Our model thus depicts a broader set of contexts than has previously been captured and incorporates important dimensions of time, both of individuals and of societies. In doing so, we more fully represent the body of evidence that has thus far accumulated on the production of health for individuals.

Discussion

This chapter highlights the centrality of economic resources – and, more accurately, the cluster of socioeconomic resources – for HHBs. In fact, socioeconomic resources have come to be known as *fundamental causes* of HHBs. That is, they are tied to most every pathway through which the health of the human body is affected. They are most certainly tied to the manifestation and expression of health behaviors, but also to a variety of other biological pathways, including affecting physiological stress systems and epigenetic processes. On the other hand, the degree to which and ways in which socioeconomic resources matter seems to vary across communities and societies – socioeconomic gradients are less "steep" in some societies than others – which has led to the hypothesis that it is possible to mute or modify the effects of socioeconomic resources on health by changing resource distribution itself, or by changing the extent to which individual socioeconomic resources are needed to "purchase" opportunities for healthy living (vs. having these opportunities universally provided, e.g., by governments). We have also seen that both the community (neighborhood) and national contexts are critically important in this regard. Of note, eliminating the role of socioeconomic resources entirely seems unlikely, given that, in large part, it is the value of a particular set of resources *relative* to those of others across the socioeconomic spectrum that has importance for health status; as long as there is a socioeconomic spectrum of any span, there are likely to be health inequalities across this spectrum.

The work presented in this chapter leads to a key set of questions which will be important to further investigate: How do the socioeconomic resources of individuals/families, communities, and societies interact to produce well-being and mitigate health inequalities? How do societal level decisions about resource distribution work to address multiple aspects of human and societal well-being, including health but also extending to human development (education), a qualified work force, social cohesion, and the like? Finally, what kinds of factors allow citizens and their representatives to work toward the kinds of family, community, and societal supports that are optimal for health and well-being? Now, knowing the importance of socioeconomic resources, the future of the science in this area and of designing sound policy lies greatly in solving these complex dilemmas.

Improving Health and Tackling Health Inequities Through the Non-health Sector

William Sherlaw, Cyrille Harpet, Zoe Heritage,
and Jocelyn Raude

Introduction: Setting the Agenda

The basic message of this chapter is if you wish to markedly improve population health in an equitable way, it will be necessary to orient policy toward the non-health sector such as housing, and to take into account the environment, and especially the built environment, in which people live, work, and play. Even though some recurrent arguments can be identified in the contemporaneous public health literature about the importance of ecological factors, there is now a certain agreement among epidemiologists that the environment plays a critical role in individual and population health. Overall, the observable divergences among studies may be attributed to a large extent to the existence of competing definitions of the concept of “environment,” as some authors include social factors that affect human health while others do not. We will argue strongly in this chapter that the social, economic, and cultural conditions should be considered as a significant part of our environments. This echoes the well-known definition of social determinants of health – “the circumstances in which people are born, grow up, live, work and age” (WHO, 2008, 2010a). This comes as no surprise since the bulk of evidence from social determinant research and informed practice suggests that in order to improve health and reduce health inequalities, it is necessary to act on areas of life and activity lying beyond the health sector (Kelly, Morgan, et al., 2007; WHO, 2008, 2010a; Marmot, 2010). This also necessarily favors a broad way of defining health such as that put forward by the International Union for Health Promotion and Education, namely, *Health is a basic human need. It is fundamental to the successful functioning of individuals and of societies. (…/…) The main determinants of health are people’s cultural, social, economic and environmental living conditions, and the social and personal behaviors that are strongly influenced by those conditions* (IUHPE, 2007 as cited by Abel & McQueen, 2013). Empirically, these various factors have consistently been found to contribute to the formation and maintenance of social inequalities in health. Health inequalities, or preferably health inequities, have been classically defined by Whitehead as differences in health which are *avoidable*, *unnecessary*, and *unjust* (Whitehead, 1991).

At this stage, it is important to be clear about what we mean by health inequalities and what is

at stake for policy makers, public health practitioners, urban planners, and other non-health sector stakeholders. There will always be differences in health and indeed other differences such as educational success between individuals and groups. Beyond such personal differences, differences in environmental exposures and resources may also be found between individuals and between social groups within the population.

Crucially some differences matter more than others in that they occur systematically between different social groups or populations and may be related to loss of potential and social injustice. These are at the heart of the impact of the non-health sector and policy on health. Understanding and tackling these will offer a shape and rationale to the contents of this chapter which we will now outline.

Scope of the Chapter

First, let us give a *working definition for the non-health sector*. A working definition of a *health system*, as proposed by the World Health Organization (2000a), is a system "whose primary purpose is to promote, restore, or maintain health." We will mirror this definition and suggest pragmatically and conversely that non-health policies are policies that lie outside the health system domain (i.e., in the non-health sector) and *do not have as their primary aim to promote, restore, or maintain health*, even though, as we will argue, policies in the non-health sector may have the potential to prevent disease and improve health greatly. The case of environmental protection and environmental health lies on the borderline of such a definition, but we have chosen to examine this since it has a key role to play, and in practical terms, it is almost impossible to separate non-health areas such as housing and urban development from environmental health and protection.

Once one accepts this view, it makes a good sense to focus on what is underlying persistent good health in certain groups and persistent bad health in others, i.e., social determinants of health. Since it is obvious that people pursue their lives on the whole, with some notable exceptions, outside the health system (as usually defined), it is crucial to take into account sectors beyond the health sector itself. As Ollila (2011), citing Rose[1] (1958), states "The fact that health is largely constructed outside the health sector has been known not only for decades but even for centuries." To stress this point, one may cite René Villermé, a French physician working during the first half of the nineteenth century in Paris *Thus however one looks at it, the same result stands out; that is mortality in the different quarters of Paris is in general inversely related to the degree of 'how comfortably off' their inhabitants are*[2] (our translation, Villermé, 1830, p. 322).

We will first examine in some detail a key question which has great relevance when designing and thinking through non-health sector policies and interventions, namely, "When does a difference in health become a health inequity?" Notably, we will suggest seven principles which should be considered when addressing health differences and potential health inequities (Harpet, 2011, 2015). Following this, we will examine findings on the social gradient in health and how health and health inequities are determined, including the health inequality synthesis of the World Health Organization Commission on Social Determinants of Health. We will then go on to put forward a model of non-health sector action incorporating both structure and agency (Frohlich & Abel, Bourdieu, Sen) but also drawing on insights from environmental science, a life course perspective (Ben-Shlomo, Kuh), ecosocial theory, sociobiological embodiment (Krieger/Hertzman), and salutogenesis (Antonovsky/Lindstrom). The role of intersectoral working will be crucial for tackling health inequities and not without challenges. We turn then to examine critically the contribution of the health sector to health and briefly pause to explore why until fairly recently, the non-health sector has been

---

[1] "The fact that health is largely constructed outside the health sector has been known not only for decades but even for centuries" Rose G. A history of public health. Expanded edition. First edition 1958. Baltimore: The John Hopkins University Press; 1993.

[2] "Ainsi donc de quelque manière que l'on s'y prenne, le même résultat surgit toujours; c'est. que la mortalité dans les divers arrondissements de Paris, est. en général, en raison inverse de l'aisance de leurs habitants."

somewhat neglected. We will then go on to give an extensive range of examples drawn from the social science literature to emphasize the range of policies; the different levels of action (macro, meso, micro); the complexity of interactions, involving both social and cultural dimensions; and the role that both structure and agency may play in the impact of the non-health sector and policy on human health. Links among the economy (including the impact of globalization and recessions), labor market, employment, unemployment, work conditions, and health are explored. Particular accent is placed on how the degree of inequality in a society may itself be a factor influencing health and other social issues (Wilkinson & Pickett, 2010).

The aim of our review is to be illustrative rather than systematically exhaustive.[3] To this end we have highlighted a number of sectors and social policy issues. These include inclusive policy for disabled people and the impact of culture and religion. We will offer examples from the education sector and show how discrimination and territorial segregation may add further disadvantage to other social and environmental difficulties. We will then go on to discuss critically how contexts may determine health and health inequities. This will include work in environmental health but will go on to consider the impact of context on health, health inequities, and health behaviors within neighborhood studies. We will explore the concepts of space and place to understand context and the reciprocal relationship between the population and its neighborhood, including the argument that "people make neighborhoods and neighborhoods make people." We will review research and experimental approaches to studying space and place, including examining how people living in a community define their own community rather than only relying on objective geographical boundaries. We will focus particularly on the impact of urban life, housing, and urban planning, sectors that are particularly illustrative of non-health policy, and of how environments may impact human health and behavior. This will examine risks but also the resources available within urban environments. We will review how health practices, such as smoking, involve interactions between structure and agency such as individual capabilities, different resources, and the possibility they have to mobilize health-giving resources.

We will look at Health in All Policies and health impact assessment (Kickbusch, McCann, & Sherbon, 2008; Roundtable on Population Health Improvement, Board on Population Health and Public Health Practice, & Institute of Medicine, 2014; Kemm, 2006). In this, we will examine methodological challenges and suggest that it will be important in the future for scientists to move beyond seeking causality to embrace complexity and a science of solutions (Potvin, Petticrew, & Cohen, 2014). We will go on to sketch different strategies founded on theories of social justice that could be put forward in an attempt to improve the health of the population while at the same time taking health inequities into account. Lastly, we will further reflect and draw conclusions on the future role of non-health policy in its impact on health. It is convenient to divide such policy into different sectors since this is how the world views it and how much research on non-health policy is structured. It is, however, illusory as social determinant research shows to make a sharp separation between so-called health policy and non-health policy. Policy makers seeking lasting and long-term impact on population health should rethink the question of responsibility and health protection, promotion, and improvement to include participation, complexity, and intersectionality between the health sector and other policy areas.

What Do We Mean by "Inequity"?: Differences and Inequities in Health

A difference may be apprehended objectively or subjectively. We will consider in this chapter that a difference is a degree of dissimilarity between two states or processes. This may be expressed as

---

[3] Furthermore, we are very conscious that it is largely based on European and North American experience. For a wider perspective on worldwide urban health incorporating experience from India, South America, and Africa, readers are recommended to consult the Lancet Commission findings: Rydin et al., 2012.

either a qualitative or quantitative value. An objective measurement of this allows us to compare two states or processes. This should be contrasted with the idea of an inequality, or preferably an inequity, which is a matter of moral judgment or/and a question of social justice. So an important question for non-health sector policy and social and environmental justice is "When does a difference in health become an inequality or an inequity in health?" Recent philosophical work in environmental health justice by Harpet (2015) suggests that inequities (or unjust inequalities) which impact on freedom and the capacity to live in dignified and healthy conditions may be characterized through reference to seven principles, namely:

1. A sentiment of injustice
2. The existence of excessive differences or gaps between individuals and groups
3. Unacceptable degree of harm and prejudice undergone
4. The principle of clearly established causes and their legitimacy
5. The presence or participation of at least one third party witness
6. Infringement of dignity
7. Accumulation of burdens, inequalities and vulnerability

These seven principles offer a framework for social justice advocates and policy makers when approaching questions of health inequities since they offer a range of factors which could be referred to determine whether injustice has occurred and, if this be the case, the degree of injustice to which people are subjected.

1. *A sentiment of injustice*: From an anthropological perspective for inequities to be perceived as such, first and foremost, there must be recognition by the people concerned that alternative existences are imaginable and may be achieved through change. Life is not just a matter of preordained fate. Comparison of living conditions (notably material living conditions) of persons of different status may lead to the recognition of injustice. Injustice highlights need and foregrounds a call for justice. Absence and lacks may be considered as being as real as presences. Crucially, justice is to be seen as being one of a series of legitimate ideals and as taking the form of an unending quest rather than simply being taken for granted. Justice should not be seen as equivalent to equality since fighting injustice by imposing the norm of strict equality would not take into account diversity. Furthermore, we would run the danger of being left with a society made up of interchangeable individuals or a collective lacking singularity. In contrast to such absolute equality, Rawls's principle of justice as fairness highlights that formal equality in the eyes of the law implies that everyone enjoys the same right to exercise their freedom and the same duty to respect the same civil laws (Rawls, 1971).
2. *Excessive differences*: Secondly, the idea of injustice highlights that some degrees of difference between people may be considered to be excessive. This may result in the emergence of a feeling of guilt. The privileged members of society may feel they are partly responsible for the privation of others. Symmetrically, the underprivileged may experience feelings of envy and seek to right this. This heralds so-called distributive justice which attempts to right unequal sharing of burdens and goods. Primary inequalities are righted through ensuring that fair proportions are distributed. However, is fair distribution of social goods in itself sufficient to establish justice? The notion of capabilities teaches us that justice may not necessarily be achieved through the mere attribution of means (Sen, 2009). Thus, two individuals with different constitutions may not act in the same way even when they find themselves in similar conditions with similar resources at their disposal. Aristotle in his *Nicomachean Ethics* explicitly stresses the idea of just proportion (fair shares) as being a condition for justice and that injustice involves having too little or too much. Unfair shares are easily visible and easily measurable since they represent a deviation from the just medium. The size of the gap clearly matters.

Nevertheless, as we have previously stated, differences per se are measurable in terms of a heuristic process, while inequalities involve questions of morality and ethics. Rawls's "difference principle" in his theory of justice (Rawls, 1971) argues strongly that the greatest benefit should be attributed to the least-advantaged members of society.

3. *Inacceptable harm*: Thirdly, injustice arises with the recognition of the suffering being inflicted and perceived as inacceptable to persons of sensibility. Such suffering can be attributed to destiny, divine, or diabolic works or as a result of the actions of men. Such suffering resists objectivation. How can external environmental causes be related to a degree of personal suffering? Such self-perceived impact on one's individual physical, psychological, or moral state is eminently subjective. Within environmental health, such questions arise in the case of so-called ultra-sensitive individuals or groups, e.g., in connection with perceived impact of telephone masts and high-tension electricity pylons (SCENIHR, 2009). Nevertheless, one must be wary of dismissing out of hand such self-perceived "unscientific" suffering as being nonexistent.
4. *Establishing causes and their legitimacy*: Fourthly, to speak legitimately of injustice in the case of misfortune or suffering necessarily entails that any differences that may occur between individuals and groups must be explained through reference to clear definable causes. Furthermore, there are no contextual reasons which render such differences legitimate. Thus, if the risk of injury is greater in population (A) of young men than in another population (B) of young men of similar characteristics, it would be reasonable to seek causes of this difference and declare that a health inequity was at work. But if one takes into consideration that the first group has freely chosen to go skiing while the other group has not, then the idea of inequity would no longer be tenable (Whitehead, 1991). To establish a health inequity, the causes must be clearly established. In the case of urban health, for instance, large differences in life expectancy may occur between two city areas. There is notably a difference of 28 years in life expectancy between two areas within the City of Glasgow (WHO, 2011a). These may be considered as health inequities if one is able to show what causes these differences and that these differences can be avoided. If such differences are due to high alcohol consumption, smoking, and drug use, is it legitimate to speak of health inequities? Here another factor comes into play: the idea of responsibility. In deontic egalitarian ethics, injustice is not deemed to have occurred if no wrongdoing can be attributed to others (Parfit, 1997). Wrongdoing is generally more easily established and attributed to individuals than to organizations, institutions, corporations, and government.

Here views within the public health domain may differ between advocates of individual responsibility associated with proximal explanations and those favoring more distal explanations. The latter recognizes that the socioeconomic environments and cultural mores have great impact on people's practices and aspirations. Of course in all such agency-structure debates, the truth of the matter will lie in the interaction of people's lives with their physical and social environment. In the case of teenage pregnancies, these will occur in all strata of society (Wilkinson & Pickett, 2010). The important scientific question is not "Why do they occur?" but rather "Why do they occur more frequently in certain urban populations than others?" The answer logically lies not in some personal flaw within individuals but the different social conditions in which those individuals have developed and lived. Since in the case of Glasgow it is possible to link social inequality with health inequality, we are justified in speaking of health inequities. As Link and Phelan (1995) would suggest, the fundamental cause, "the cause of the causes," is not alcohol, smoking, or drug use but the unequal distribution of income, social conditions, and life chances. To argue otherwise would lead to becoming a "prisoner of the proximate" (McMichael, 1999).

5. *Third-party witnessing*: Fifthly, the idea of injustice will emerge if the person or group concerned can take a step back and distance themselves from their own situation. Often, such distancing will be facilitated or require a third-party witness. The witness can then offer an independent appraisal of how one group is faring in relation to another comparable population. This bearing of witness is crucial in creating and permitting a sense of injustice to emerge and crystalize, thus achieving greater legitimacy. Public health authorities and institutions have the duty to play this role of third-party witnessing thereby distinguishing legitimate differences from unacceptable differences or, in other words, inequities.
6. *Infringement of human dignity*: The sixth principle is related to the nonrecognition or infringement of human dignity. This may be due to negligence, ignorance, or deliberate oppression of others. Treating all humans with dignity ultimately implies treating them as an end in themselves rather than as a means, as in Kant’s categorical imperative. Differences in health may occur due to oppression or discriminatory practices. Under the European nondiscrimination directives, protection is offered against discrimination on grounds of sex, racial or ethnic origin, age, disability, religion, and sexual orientation. In addition other grounds such as “language,” “social origin, birth, and property” and “political or other opinions’ are featured in European court of human rights rulings (EUAFR, ECHR, & CE, 2011). Discrimination and oppression have much in common, although the latter is probably more extreme in degree. Oppression may be considered as being systemic and structural phenomenon permeating a whole society in which one group dominates another group and treats them as being less than human (Young, 1990). “No matter which definition you use, oppression is when people reduce the potential for other people to be fully human. In other words, oppression is when people make other people less human” (Young, 2004). Oppression may take several forms and not all of which involve violence or harsh treatment. Perhaps, it is at its most insidious when the people who are oppressed do not realize this, having no voice or will to change their condition. Such hegemony may also be tied to Seligman’s “learned helplessness” (Peterson, Maier, & Seligman, 1993). It is of course legitimate to speak of health inequities when it may be demonstrated that differences in health have arose due to oppression or non-respect of human rights and equal citizenship.
7. *Accumulation of inequalities and vulnerability*: The seventh principle is central to our treatment of non-health sector policy, namely, the accumulation of inequalities. One inequality is exacerbated by another, increasing the risk of further inequalities. Just as it is possible to recognize overabundance, it is also similarly possible to recognize vulnerability and the duty to act, to support, or to compensate vulnerable and disabled people. This involves a sharing or redistribution of resources from those with to those without or in need. Such acts of sharing or redistribution express and recognize our human empathy.

Inequities in Health

Differences in health may thus be seen between individuals, groups, populations, or neighborhoods. Explanations of differences between individuals may be linked to physical or psychological characteristics or individual behavioral practices. It is important to make a distinction between such individual level explanations based on comparison between individuals where responsibility is more often than not lodged in behavioral or essentialist terms and population level explanations arising from comparison and analysis of groups or populations and the impact of their living and working conditions on health (Marmot, 2000). In the former, answers are sought in behavior or individual psychological and physical makeup. This may lead to interesting and valid solutions but often neglects the impact of non-health sector policy and factors associated with the environment and the neighborhood in particular. In the latter case where differences are seen between groups, the differences in health that matter are systematic and tend to cumulate with other inequalities. More often than not, they are associated with what resources are available within the environment and the capacity of the people to access and mobilize such resources to cope with health threats and to favor and foster health-promoting practices. A study of differences between groups will not tell us who, in the groups, will fall ill, or die early, or why any particular person falls ill or dies early. It will however give us information on what factors within the physical and sociocultural environment (and this includes non-health sector policies and urban infrastructure) will favor or harm health and how these factors are distributed differently between social groups. Furthermore, through answering these questions, it will suggest solutions based on righting inequalities of resources or access. Such solutions will necessarily be systemic. They will inevitably involve not just actions and interventions located in each individual sector but also the joining together and interactions between different non-health sectors and indeed the health sector itself.

A Social Gradient in Health

Differences in health may be revealed and characterized through statistical analysis linking health and illness, disease and death, and to latent variables of social inequality such as income, education, and socioeconomic status. Typically, an inverse social gradient emerges. Increases in income, education, or socioeconomic status are associated with improved health status and decreases in mortality and morbidity across a range of diseases. Reduction in income, education, and socioeconomic status is associated with worse health and increases in mortality and morbidity across a range of diseases. Causality may occur in both directions, i.e., poor health may also lead to lower socioeconomic status, income, or education, so-called health selection. Or socioeconomic status, education, or income may lead to health status. Nevertheless, the overriding tendency and bulk of evidence tend to show that social position determines population health status, and for this reason, we may speak of social determinants of health and health inequalities (Marmot, 2010; WHO, 2010a). Three remarks may be made. Firstly, it is not just a question of those with high levels of morbidity and mortality and low economic status being solely involved, since there is a systematic relationship between health and the entire range of socioeconomic status resulting in a social gradient. Social gradients seen throughout the world in different societies are difficult to explain through evoking health selection. Secondly, where health selection does occur, this will lead to diminishing, rather than increasing, the social gradient. People of higher socioeconomic status with poor health moving down the social ladder nevertheless will tend to have better health than those further down the social gradient, and similarly upwardly socially mobile people will tend to have worse health than those within the groups they join. A smoothing out of the gradient would occur (Marmot, 2005).

Thirdly, although within the public health literature the term health inequality has become the standard, in the United States, the term "health disparities" is often employed and frequently refers to questions of access to health services. Furthermore, this term is traditionally associated with health differences found between different ethnic groups. In Europe vital statistics of social class are habitually found in censuses and surveys, whereas the situation regarding ethnic information varies, the French constitution notably outlawing the collecting of nationwide ethnic statistics. Policy will often depend on what we can count or not, within the public statistics information system (Trostle, 2005). As Frohlich and Abel (2014) maintain, health inequities should be the preferred term[4] as it places a moral emphasis on "the inequitable processes leading to these health inequalities." These may also

---

[4] The WHO website gives the following definition through answering the question "What are health inequities or inequalities?" *Health inequities are avoidable inequalities in health between groups of people within countries and between countries*. See http://www.who.int/social_determinants/thecommission/finalreport/key_concepts/en/ consulted 20 September 2015.

include discrimination of ethnic groups leading to poorer life chances and poorer health. As Tawney's writing in the 1930s, cited by Bickenbach (2009), stresses *inequality* per se, involving the endowment of different talents to different individuals is not what matters, unless it can be shown that such inequalities have their root in social and political organization.[5]

We will thus consider health inequalities/disparities, or preferably health inequities, to be systematic and concern groups and lead to lost potential of people as Braveman (2006) stresses "Health disparities/inequalities are potentially avoidable differences in health (or in health risks policy can influence) between groups or people who are more or less advantaged socially; these differences systematically place socially disadvantaged groups at further disadvantage on health."

Models

Several different models have been put forward to explain how social determinants in constant interaction are linked to health status and how they produce a social gradient of health. Certain approaches underline the importance of proximal factors (lifestyles and behaviors), while others place greater emphasis on distal fundamental or structural determinants such as socioeconomic conditions and "the causes of the causes" of health and disease (Link & Phelan, 1995). Dahlgren and Whitehead (1991), for instance, famously represent "the main determinants of health as a set of concentric arcs around the individual." Health is represented as "the outcome of a web of social influences" (Graham, 2004a). One may consider the most distal factor to be the social structure of society.

One useful way of thinking about structure is it constitutes the objective features of social life which preexist individuals, i.e., before they are born, and which typically are reproduced and outlive them. Such features include the power structures, organization of a society, and how the resources of a society are distributed (Layder, 2005). Social position may be considered as being embedded within social structure and "usually refers to an individual's location in the social hierarchies around which his or her society is built. This includes such dimensions as socioeconomic position, gender, and ethnicity" (Graham, 2004a). Gender may be of increasing importance to take into account as recent reflexion in urban health suggests (Frye, Putnam, & O'Campo, 2008). Importantly as Graham explains, social position may be considered to be "the point at which the social structure affects, and affects unequally, people's access to key resources for health" (Graham, 2004a).

The structural perspective is especially relevant to non-health sector policy, and it may be strengthened and complimented by research on developmental life course factors impacting favorably or unfavorably on future health (Ben-Shlomo & Kuh, 2002), biosocial embodiment (Krieger, 2005), agency, and salutogenesis (Antonovsky, 1996; Lindstrom & Eriksson, 2005; Lindström & Eriksson, 2009). A life course approach shows how the human organism is subject to both benefits and insults from conception to death, impact of which translates into health status and disease. The existence of different critical stages within this life course has the potential to magnify effects (Ben-Shlomo & Kuh, 2002). Thus, impacts on the developing fetus, babies, and young children should assume great importance. Firstly, these are especially vulnerable during development, but it is also during this critical period of life where the foundations of good or bad health are laid down (Hertzman & Boyce, 2010). Since we are profoundly social beings throughout our life, we are subject not only to stressors from the physicochemical environment but also from our interactions within social relationships and social situations. Calling on Durkheim's seminal work

---

[5] To criticize inequality and to desire equality are not, as is sometimes suggested, to cherish the romantic illusion that people are equal in character and intelligence. It is to hold that, while their natural endowments differ profoundly, it is the mark of a civilized society to aim at eliminating such inequalities as having their source, not in individual differences but in social and political organization Tawney (1931).

on social integration and Bowlby on attachment, Berkman, Glass, Brissette, and Seeman (2000) have conceptualized, from the macro-social to interpersonal behavior and intrapersonal biological functioning, the different mechanisms involved in the impact of social networks on health with the possibility of both positive and negative effects are arising. Complex interactions that may occur include our own perceptions and feelings about social situations and others. These may act positively or negatively on our well-being and future health prospects. As research suggests on primates, we may consider that in many ways such experience becomes embodied in our very biology (Krieger & Davey Smith, 2004; Krieger, 2005). Research on epigenesis may cast further light on important mechanisms involved (Hertzman & Boyce, 2010). As Bonnefoy, Morgan, et al. (2007) of the Measurement and Evidence Knowledge Network (MEKN) of the WHO Commission on Social Determinants of Health highlight through referring to Schutz‘s phenomenological approach, we are all unique individuals with unique life experiences. These different experiences impact on our health and well-being throughout the life course. It will be a vital part of the social determinants of health paradigm to produce evidence showing how social structuration impacts on agency and impacts on biological mechanisms translating these effects into health gains and losses (Kelly, Bonnefoy, et al., 2006).

It is important also to consider health beyond the prevention of disease and incorporate salutogenesis and resources for health and well-being favoring a sense of coherence and quality of life. Lindstrom and Eriksson (2005) renewing Antonovsky (1996) have proposed a salutogenic framework to explain the production of well-being and health and factors that favor coping and resilience to disease. More radically, Abel and McQueen (2013) and Frohlich and Abel (2014) have proposed an agenda where the starting point is the study of social context, and the outcomes considered are not just health outcomes. Such an approach emphasizes the role of social structure and agency, and how different groups and individuals have different access to capitals determining resources and are subject to different health risks.

Abel and Frohlich (2012) draw on Bourdieu’s conceptualization of different capitals at work in producing and reproducing social structure, namely, economic, social, and cultural capitals, etc. and combine this with Amartya Sen’s Capability Approach (Sen, 1999). In this second approach, the freedom and the opportunity for choice are highlighted. The combination of the two theoretical perspectives provides a powerful framework to understand how the social gradient in health is produced. Taking into account that theories of social structure generally make little accommodation for including change, Abel and Frohlich (following Hayes) distinguish between reproductive agency and transformative agency. The latter is crucial for health promotion and tackling health inequalities where health is not merely viewed as a result of choice but also as the result of a possibility of choice and availability of resources, enabling choice, or a lack of availability of resources, hampering choice. Healthy choices flying against antagonistic and unfavorable social structure will always be possible and indeed should be encouraged, but their probability from a public policy perspective will be increased, where access to health-giving resources is possible through the possession and possibility of transformation of economic, social, and cultural capitals. In our view, this is the key to understanding how different determinants of health systematically exert their effect differentially throughout the population and produce a social gradient, i.e., health inequities.

The World Health Organization Commission on Social Determinants of Health chaired by Sir Michael Marmot (WHO, 2008) has put forward a synthesis of the different models. This distinguishes three main components:

- The political and socioeconomic context (governance, macroeconomic policy, social, policy, culture, and values).
- Structural determinants linked to socioeconomic position of individuals (social stratification measured by income, education and training, employment, gender, and ethnicity).

– Intermediate determinants (material circumstances, psychosocial factors, environmental factors, behaviors, biological factors including early development, life course factors, and the health system itself). The inclusion of the health system as among the intermediate determinants that are shaped by political and socioeconomic contexts and structural determinants merits particular attention. It will also allow us to examine evidence on the respective contribution of the health and non-health sectors to health, how the health system as it exists for different groups is shaped by broader contexts and structures, and that, contrary to popular belief, the health sector is not the sole determinant of our health.

A number of frameworks and research methodologies have been proposed to explain more specifically the complex relationships of urban components and health (Whitehead & Dahlgren, 1991; Northridge, Sclar, & Biswas, 2003; Barton & Tsourou, 2004; Barton, 2009). Methodologies include a mix of research methods comprising not only ecological and multilevel analyses but also case studies and other sociopolitical methodology (De Leeuw, 2010; Gibson, Petticrew, et al., 2011). A number of models integrate social determinants of health and mirror Whitehead and Dahlgren (1991); Northridge, Sclar, and Biswas (2003); Barton (2009); and Barton and Tsourou (2004).

There is clear evidence suggesting that specific urban components at the neighborhood and city level have an impact on several determinants of health which in turn have a direct or indirect influence on the development of specific diseases or on general health and well-being (Barton, 2009, Grant, Braubach, et al., 2010, De Leeuw, 2009). Schulz and Northridge (2004) have notably put forward a model pertaining to the urban physical environment and environmental health inequalities incorporating (1) fundamental (macrolevel), (2) intermediate (meso-/community level), (3) proximate (micro-/interpersonal level), and (4) health and well-being at the individual or population level. They apply their model to four case studies involving diesel exhaust fumes, lead pollution, unintended injuries, and chronic stress. They stress the dynamic and often bidirectional nature of the phenomena modeled and the importance of fundamental factors, stressing that "environmental health promotion efforts must include the creation of structures and processes that actively work to dismantle existing inequalities and to create economic, political, and social equality." We shall echo and further illustrate their model throughout this chapter.

A Model for Framing Non-health Sector Impacts

We are now in the position to put forward a model taking into account three essential dimensions of non-health sector determinants of population health, namely, (1) environmental and sociocultural, (2) personal attributes, and (3) individual and societal development. The model draws upon a wide range of conceptual thought and thus echoes other models in the area of health promotion, health anthropology, and disability studies. More specifically, the model has been constructed from four main existing models, namely,

- The well-known model of concentric arcs of influence of Dahlgren and Whitehead (1991)
- The environmental risk analysis model, also named Driving Force-Pressure-State-Exposure-Effect-Action (DPSEEA) (Corvalán, Briggs & Kjellström, 1996)
- The burden and capacity model of the National Research Council (2009), pertaining to the work setting and the balancing point between work demands and capacities after Dempsey (1998)
- The model of Abel and Frohlich (2012) proposing a synthesis of Bourdieu's habitus and different capital theories, with Amartya Sen's Capability Approach.

We believe that our model has a number of distinctive features. Firstly, while echoing Dahlgren and Whitehead (1991) (as do other authors, such as Barton and Grant (2006)), it places great emphasis on how on one hand the physical environment and on the other hand both material and immaterial cultures constitute a heritage which can potentially impact on health. Viewed horizontally, the schema with its arrows of time highlights the fact that individuals have developmental life courses nested in societal development. Of particular importance are the transmission of values, social practices, and lifestyles. These constitute along with the physical environment a preexisting heritage into which members of the population are born and develop and bequeath in turn to subsequent generations. Viewed vertically, the nested circles highlight the different levels of organization through which health and well-being may be influenced. These range from the intrapersonal to the micro-, meso-, macro- and institutional environment. Secondly, the model portrays and emphasizes that different elements make up our environment. This goes beyond the physical environment, to include the sociocultural and economic environment, and may be declined as *constraints or freedoms* and operate symmetrically but with potentially ambivalent impacts on health. Thus, the same element or factor may constitute risks or opportunities (life chances) for human health and development, e.g., water. The sphere of constraints may be considered to be engendered by the physical, sociocultural, political, and economic environment and preexist individuals being born into the world. This represents a physical, sociocultural, political, and economic heritage. As we stress throughout the chapter, this heritage however is socially structured and is not equal. This largely explains how social inequalities persist across generations fueling health inequities. Nevertheless, the past of course not only offers constraints but also resources from which we have developed our societies and which we inherit as individuals. The past cannot be changed, although its unequal legacy may be taken into account. Nevertheless, people in the present potentially have the possibility of wroughting change in their physical, sociocultural, economic, and political environments for the current and future good. The sphere of freedoms highlights this and how individuals and groups may respond and adapt to constraints and associated pressures on human health and well-being through having access to resources for carrying out projects that have reason to value, including the mitigation of negative risks for health and the mobilization of resources for the promotion of positive health and human development. This explains why optimistically we have highlighted freedoms on the right of the schema linking this to collective and individual agency which may be theorized through capability and allied theories. Through access and use of resources, this may lead to the production of values impinging positively on the human health and environment and outcomes such as health, well-being, quality of life, sustainable development, social justice, and participation. Constraints, of course, and barriers to health may also continue to exist. Thirdly our model includes the idea that it is useful to consider this ensemble as sources of health and disease. It thus refers to *sources of health* rather than determinants. This has a double advantage. It recognizes that it may be misleading to suggest that determinants determine our health in some absolute way and that the same element may represent a source of health or disease for the population and different individuals within the population. Our world may at times be more ambivalent than we sometimes like to admit.

Although it is challenging to display graphically, we insist on the fact that the environment whether it be sociocultural or physical acts on us throughout our existence. This is the foundation of population health. Individuals from their conception onward are subjected to the negative or positive influences, but the distribution of these influences is structured socially and is unequal (Graham, 2004a). Furthermore, individuals themselves are relatively powerless to mold this environment. Burdens on health exert their force throughout the life course. Positive and negative influences act on health and are mediated through different levels of societal organization from the micro- and meso- to the macrolevels. As the nested circles attempt to portray, individuals are subject to influences from their personal attributes, their biological and genetic heritage, and their immediate surroundings and relationships. These include family, neighbors, friends, their wider sociocultural environment with its wealth or dearth of social relationships and support from social group membership or isolation, and indeed wider societal norms, rules, and regulations within a macro-socioeconomic and political context. Of course such influences impinge on individuals, but individuals and their social groups can also exert influence on their environment and the norms and policy through social and political processes in turn. However, power is not shared evenly. Government, institutions, and their apparatuses, including public health, powerful enterprises, and members of the civil society, may exert particular influence to uphold, protect, or transform both the physical and sociocultural environment in which we live (Fig. 15.1).

Central to this framework is that there are multiple determinants of health and that they may be declined as "constraints" or "freedoms." At times it would seem easy to isolate health hazards, e.g., radon, Ebola, and asbestos and treat them as purely physical, biological, or chemical hazards. These may engender risks to human populations and individuals. Nevertheless, many constituents of our world may be declined negatively as constraints creating pressures on individuals and populations or positively as freedoms creating resources available to individuals and populations. Although risk intrinsically is synonymous with chance or probability, here risk is being viewed as in the sense of a probability of an event occurring associated with deleterious consequences for health. Furthermore, we may consider that hazards become "socialized." Thus, if noise represents a physical hazard to human health Goines and Hagler (2007), exposure to noise is a profoundly social phenomenon. Individuals and populations are profoundly social beings. They occupy social positions within society and are subject to the influence of social structure. These may reproduce constraints on individuals' agency negatively influencing health and reinforcing health inequalities through leading to differential exposures to risk of disease and injury. Nevertheless, it must be recognized symmetrically that social structure and social position also may provide access for the deployment of individual and collective human agency giving access to opportunities and resources for the maintenance and promotion of health as well as resources for the mitigating risk. Furthermore, from a psychosocial perspective, pressures, such as stress at work, can also be exacerbated or

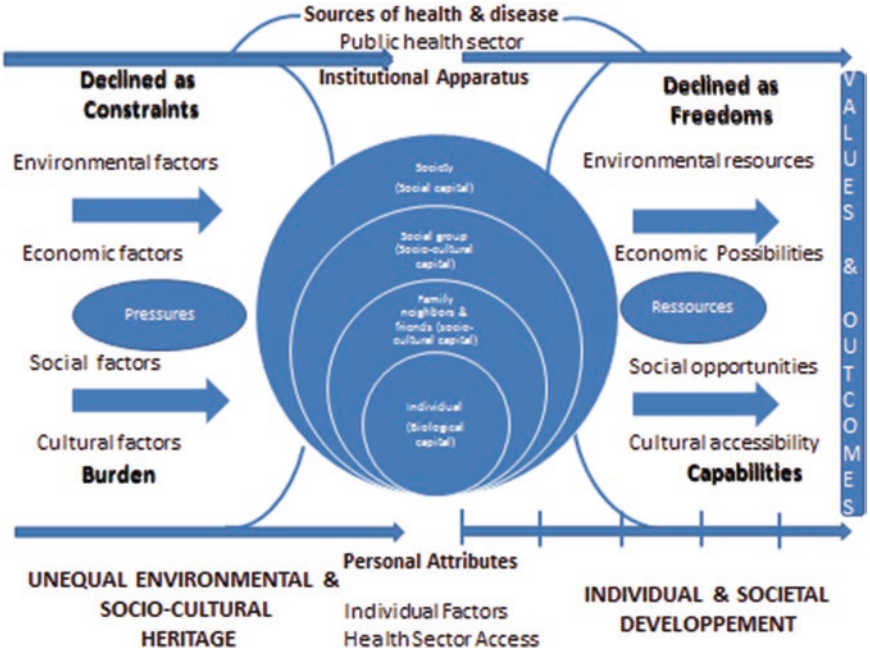

Fig. 15.1 A model for framing non-health sector impacts on health

created through overcompensation or overinvestment by the person. In response to personal ambition or of one's management, coupled often inextricably with the societal norm of individual performance or entrepreneurship, the self-setting and imposition of goals may go beyond what would normally be considered reasonable and may thus constitute a risk to health and well-being. Repeated psychosocial demands on oneself may become embodied leading to the production of chronic conditions including mental health problems.

We are confident that our model gives a good idea of how the non-health sector (such as housing and the urban environment) may impact on health. It offers insights for the design of policies and strategies ranging from acting on constraints and pressures reducing burdens, to acting on freedoms and resources promoting individual and collective agency. It allows us to consider a range of risks from the apparently "purely" physical (radon), heat waves, mold (clearly linked to income inequalities and housing status) to the deeply socialized lack of accessibility, unemployment (see Moller, 2011), health practices, smoking, drinking, etc. As may be easily appreciated, the different constraints and freedoms presented in the model together with potential resources involve a diversity of non-health sectors and stakeholders whose main activity and goals may not necessarily include health. We will now examine the particular challenges that policy makers promoting an intersectoral approach will need to face.

Emergence of the Intersectoral Health Agenda and Its Challenges

The emergence of an intersectoral Health in All Policies agenda founded on the paradigm of social determinants and health inequalities will thus necessarily involve many new non-health sector stakeholders having to work together (Kickbusch, McCann, & Sherbon, 2008). Intersectoral action on social determinants of health and the health inequity agenda coupled to implied responsibility represent a considerable challenge for policy makers and stakeholders (Exworthy, 2008). Indeed, the very attempt to link non-health sectors such as transport, industry, urban planning, education, agriculture, economy, and work with health, thus broadening the remit and responsibilities of the professionals and their services involved, may easily be greeted with a degree of astonishment, skepticism, or outright rejection. Rather than insist narrowly on health as the appropriate outcome, it will be necessary to broaden traditional indicators to take into account the environment and lived experience of the population and especially the marginalized population (Masuda, Poland, & Baxter, 2010). Thus, it may make more sense to highlight the importance of equitable services and environments adapted to all citizens. (The underlying idea for this is that services and environments that ensure social justice are most likely also to impact favorably on health, since there is much evidence that increased social justice and respect and equality are linked to well-being and less-damaging health behaviors (Wilkinson & Pickett, 2010).) Furthermore, links with the community-based participatory research, the empowerment of marginalized groups (Masuda, Poland, & Baxter, 2010), and the social participation of people with disabilities and the human rights based on the Convention on the Rights of persons with disabilities (United Nations, 2006) may be articulated.

Such an intersectoral agenda may involve both private and public enterprises and organizations. Signing up to "Health in All Policies" implies that each sector must not only analyze how its policies will impact on health, well-being, and health inequalities but also analyze how different sectors will interact with impact on health. This needs to be taken into account within policy formulation, implementation, and practice (WHO, 2010d). This goes beyond the recognition that non-health sectors can have important impacts on health and well-being and that health is not the sole concern of the health sector. Indeed ultimately it calls for the recognition that fundamentally, as, for instance, in the case of noncommunicable disease (NCDs), the conditions which determine the degree of health of population are social. As Abel and McQueen (2013) maintain "the conditions and distribution patterns, the perception of the problem, and actions taken by a society all indicate that population health issues including those on NCDs are inherently social in nature." In relation to the social determinants of health more specifically, we may speak of a "dual agenda" (Graham, 2004a). As Graham stresses "the social factors influencing health and the social processes shaping their unequal social distribution are not the same." In other words, there is an important conceptual distinction to be made between "health determinants" and "health inequality determinants" (Graham, 2004a).

Thus, in designing policies to tackle risks and behaviors, for instance, it will be necessary to demonstrate population health improvement *and* reduction or, at the very least, non-exacerbation of health inequalities. Since the latter is fueled through deep-set structural social inequalities which determine the distribution of exposure to risk and salutogenic assets, this represents a considerable political and policy challenge (Phelan, Link, & Tehranifar, 2010; Cerdá, Tracy, et al., 2014.) As the Whitehall studies demonstrated, smokers coming from higher socioeconomic groups have better health than smokers from lower socioeconomic groups. This also applies to nonsmokers. The quality of the environment such as housing, air, and water affects all people, but with rare exceptions, which argues well for keeping the above distinction in mind; the greatest risks will impact on lower socioeconomic status groups who will also tend to cumulate environmental risks and other risks as Graham (2004a) argues "…despite better health and improvement in health determinants, social disparities persist … more emphasis on social inequalities is required for a determinants-oriented approach to be able to inform policies to address health inequalities." What is more is that since policies in different sectors interact, overlap, may be in synergy, or suffer from contradictions, extensive intersectoral collaboration and policy regulation will be necessary to improve population health while at the same time to tackle health inequities. This last point in our view is crucial since experience has shown that it is all too easy to improve the health of the population while widening health inequalities. Furthermore, as we shall argue, population health should not be seen as being synonymous to health care.

Determinants of Social Gradient

The Role of the Health Sector

The inclusion of health systems within models of health determinants is in fact relatively recent. Indeed, according to Graham (2004a), in earlier models of social determinants of health, the health-care sector rarely featured prominently. Different complementary explanations may be offered. Firstly, as the bulk of research suggests, health systems do not in themselves constitute a major influence on health (Marmot & Bell, 2009). Thus, with respect to the United States, Schroeder (2007) – citing Mcginnis et al. (2002, 1993) – maintains that the health-care system has a "relatively minor role" in preventing premature deaths (10%) when considered alongside the influence of other health determinants linked to non-health policy. Similar conclusions have recently been drawn by the IOM report "For the public's health. Investing in a healthier future" (2012). (see Kaplan et al. *infra*.)

Secondly, as many have remarked, health systems are more suitably characterized as being "disease treatment systems" since they largely may be considered to be organized and designed to treat disease and repair bodies. This is a role that they often perform admirably. Nevertheless, they focus on the "negative pole" of health rather than highlighting a positive idea of health as epitomized in the WHO definition (1948). This statement may easily be substantiated through a cursory look at resources given over to prevention and health promotion. For instance, in 2006 this represented 6.4% of health expenditure in France (Fénina, Geffroy, et al., 2006). Health promotion as defined by the Ottawa Charter, and indeed in more recent health policy documents from around the world, can be properly considered in many respects to go beyond the negative pole and foster a positive vision of health and well-being.

Finally, and importantly, the social determinants paradigm linked to the health promotion movement epitomized by the Ottawa Charter emerged to counterbalance biomedical and clinically based curative approaches to health through advancing the case that the determinants of health are to be found in wider society and especially the structural inequalities within society. Hence, health-care systems simply were, rightly in our view, not considered to be a major driver of people's health (Graham, 2004a). Such a position may also be seen against the backdrop of the well-known pioneering work of Thomas Mckeown who offered evidence drawn from the analysis of historical demographic data to argue powerfully that health improvement over the last centuries was better explained by improvement of economic, social, and living conditions than by the contribution of medicine and public health and health-care services (Mckeown, 1976a, 1976b). However, the methodology and data on which the thesis was based received severe criticism and have claimed to be discredited (Colgrove, 2002; Szreter, 2002). Furthermore public health was defined rather narrowly (sanitary reforms, vaccination, quarantine) in contrast to more recent social determinants of health thinking. However, the debate is far from closed. Link and Phelan (2002) point out that social conditions are themselves linked closely to individual health-enhancing actions carried out by members of the population themselves, such as to seek good housing and go hand in hand with improvement in socioeconomic conditions. They continue to support the fundamental idea implicit in Mckeown's thesis that the contribution of medicine to population health cannot explain its dramatic improvement. Social and economic factors are the fundamental causes of health, the key to explaining population health and health inequalities (Link & Phelan, 1995; Phelan, Link, & Tehranifar, 2010). (Even if risks change over historical time, the same people at the bottom of the social ladder are those affected and who cumulate different risks.)

After perusal of the evidence, Nolte and Mckee (2004) suggest that health care may assume greater importance in more modern times since more possibilities for improving health through technology and medicines are now on offer. Nevertheless, the case of the United States would seem to present a conundrum. The United States spends more on health care than any other country and has one of the most advanced health systems in the world. As a recent IOM report reminds us "The United States is among the wealthiest nations in the world, but it is far from the healthiest. For many years, Americans have been dying at younger ages than people in almost all other high-income countries" (Committee on Public Health Strategies to Improve Health, & Institute of Medicine, 2012). Marmot and Bell (2009) offer an explanation of why the United States has poor health in spite of high health expenditure; suggesting the answer to this conundrum lies in taking into account social determinants of health. In spite of the Mckeown thesis being reevaluated and the difficulty of establishing causal relationships between percentages of GDP spent on health-care and health outcomes (Nixon & Ulmann, 2006), inequalities in health are difficult to explain by mere reference to health-care access quality and performance. In the WHO Commission on Social Determinants of Health (CSDH) framework (WHO, 2010a), the health-care sector is considered to be one of the intermediate determinants of health[6] and is put alongside material circumstances, social cohesion, psychosocial factors, and individual behavior.

Role of Non-health Sector

Non-health Sector, Policies, and Health Inequities

We believe that highlighting health inequities and their relationship to the non-health sector and policies matter. Firstly, as we have stressed, they are a concern for social justice. Indeed, health may be considered to have special moral status

---

[6] It is interesting to reflect on the Cuba paradox which suggests that combining *community health approaches* (highlighting the role of social determinants and health promotion) *with modern clinical medicine* may be the ideal mix for achieving good health outcomes (Evans, 2008).

over other goods, since it has both intrinsic and instrumental values being vital resources enabling people to carry out their life projects. Secondly, but equally importantly, health inequities and the fact that they are associated systematically with a social gradient indicate clearly where the sources of disease and good health lie: substantially outside the health sector within the fabric of society.

The view that health is largely determined by factors from outside health systems is well known and has been emphasized within the pioneering work of the Lalonde report and Ottawa Charter and indeed the WHO Healthy Cities project. More recently, official recognition in concrete policy terms of the impact of non-health sector policy on health has been forthcoming. The Adelaide Statement (WHO, 2010c; Government of South Australia & WHO, 2010) notably has argued strongly for Intersectoral Action for Health (IAH), and the logical policy follow-up to such initiatives' "Health in All Policies" highlights the necessity for intersectoral initiatives including the health sector (Baeza, Lim, et al., 2011). More pragmatically the general acceptance of environmental and health impacts assessments. Kemm (2006) also bears witness to this trend.

Non-health sectors and policy impact on people's living and working conditions through different mechanisms acting at the macro-, meso-, and microlevel (Loewenson, 2013). Lurie (2002) singles out which federal government departments may have a role to play in acting on the nonmedical determinants of health. Figure 15.2, adapted from a World Bank report of Meiro-Lorenzo, Villafana, et al. (2011), indicates how different sectors such as education, finance, urban planning, agriculture, industry, transport, and health itself may have a significant role to play in reducing risk factors for NCDs.

Addressing risk factors is important but should not blind us to the possibility of moving beyond a risk factor and lifestyle agenda to encompass a broader social and salutogenic view of health which recognizes both structure and agency and how these may interact to produce health. As recognized increasingly by such initiatives as "Health in All Policies," the non-health sector and action between non-health sectors and the health sector do not only consist of dealing with risk factors but should include an asset-based approach to health at all levels (Morgan & Ziglio, 2007). Assets for health may be found at the individual, community, and organizational level (Glasgow Centre for Population Health, 2011). Eriksson and Lindström (2007) have outlined an asset approach to healthy public policy based on salutogenesis and a quality of life perspective.

Let us now offer some illustrations of how the non-health sector and policies instigated and implemented at different levels may impact on the health of the populations and individuals through different mechanisms involving sociopolitical and political context, structure, social position and agency, and the possibility or not to have access to different capitals. We have chosen a range of examples from many different sectors whose influences on health are mediated through

	Tobacco	Poor Diet, Nutrition	Physical Inactivity	Alcohol	Unhealthy Environment	Pathogens	Injuries & Violence

different pathways. These illustrations could be easily multiplied. They range from identified environmental risks (and how such risks may accumulate with others in the case of vulnerable populations) to the impact of peoples' representations and beliefs on health outcomes and behaviors. The aim is not to be exhaustive but to be explanatory, demonstrating that whether the impact of the non-health sector and policy is conceived at a macro-, meso-, or microlevel, its effects, both anticipated and unanticipated, are likely to be mediated through social structure and position and more often than not involve interactions between levels and the accumulation of disadvantage or advantage.

Illustrations of How the Non-health Sector and Policies May Impact on Health

Macroeconomic, Political, and Contextual Influences

The relationship between the economic situation and health is complex. (See also the chapter devoted to socioeconomic influences by Siddiqi, Hertzman, and Smith, *infra*.) Often the assumption is made that economic growth = improved population health. However, Szreter argues "the human record in fact shows no necessary, direct relationship between economic advance and population health, rather a more ambivalent and contingent relationship." Increase in wealth can potentially improve population health but that will largely depend on how that wealth is used and shared (Szreter, 2003). Most often strident economic growth and great social change have had negative impacts on mortality. Indeed Szreter (2003) speaks of the four D's associated with the rapid economic and social changes of the industrial revolution – "disruption, deprivation, disease, and death" (Szreter, 1997). Such ideas are important to bear in mind when examining how worldwide macroeconomic policy and globalization in particular can impact on health.

With respect to economic globalization, it is also important to note that views may vary according to the evidence available, the countries studied, and the context, and especially economic context in which they were voiced. Thus, it has been argued that globalization has both positive and negative impacts on health (Feachem, 2001) (Dollar, 2001) (Cornia, 2001). In 2001 Feacham claimed that "Globalisation is good for your health, mostly." Dollar writing in the same year before successive financial crises and the reports of the Commission on Social Determinants of Health maintained that "the higher growth that accompanies globalization in developing countries generally benefits poor people." Furthermore that in all probability, "globalization has indirect positive effects on nutrition, infant mortality and other health issues related to income." Among negative aspects cited were the spread of disease (AIDS) due to increased migration and travel and the impact of tobacco through free trade. (Dollar, 2001). Cornia (2001) suggests that the impacts of globalization are complex but if well managed may produce positive effects on health in conditions where markets are competitive, open, and well regulated, and social safety net protection is available. Cornia states "However, the domestic and international conditions for successful globalization have been met in relatively few countries." Thus, globalization affected some countries, such as Asian countries, more positively than others (African, Latin American, and Eastern European countries). Economic development in such economies was dependent on the state of the domestic market, unequal foreign investment as well as new rules limiting access to markets of the Organisation for Economic Co-operation and Development. Furthermore globalization had particular impacts on the poor population. On the one hand, slow and uneven growth was associated with stagnation in health indicators, and on the other hand, as we will see later in more detail, economic crises in middle-income countries such as the former Soviet Union produced economic instability, sharp rises in unemployment, and dramatic effects on health and life expectancy. Of particular interest with respect to health and inequality is the observation that "high income inequality reduces the pace of growth and of poverty reduction."

Attempts have been made to model the complex effects of globalization (Woodward, Drager, et al., 2001; Huynen, Martens, & Hilderink, 2005). Huynen, Martens, and Hilderink (2005) put forward a framework for studying globalization and health which incorporates sociocultural, economic, environmental, and institutional factors intervening at different contextual, proximal, or distal levels. They point out the importance of contextual and institutional factors such as structures of global governance, global markets, global communication, and diffusion of information, mobility, and environmental change. Notably they suggest, citing Fidler (2002), that the World Trade Organization has more influence on the governance of global health than the WHO and that it is unclear whether World Trade Organization agreements may protect health.

A series of three articles by Labonte and Schreker (2007a, 2007b, 2007c) have studied the impact of globalization through a social determinants of health lens founded on work by Diderichsen, Evans, and Whitehead (2001) and have reached more negative conclusions claiming that globalization has had deleterious impacts on health and health inequities, especially in poor developing countries and among the poor households. The gains and losses due to globalization across a range of domains are not evenly distributed and tend to favor those with preexisting capital, power, and resources. This fundamentally asymmetric character of globalization does not just apply to economic development but also to the impacts of financial crises which exacerbate social disadvantage and vulnerability, for example, to environmental hazards. Different pathways involving the non-health sector leading to such asymmetric effects are singled out such as the trade liberalization, global reorganization of production and labor, debt crises and economic restructuring, financial liberalization, urban settings, and influences that operate by way of the physical environment. They conclude their three article investigation bleakly claiming that "redistributive policies of various kinds are likely to be needed to reduce health inequities within and between countries" and that "globalization tends to be associated with a long-term trend toward increasing economic inequality and increasing attachment to markets as a mechanism for allocating resources and setting policy priorities" Labonté and Schreker (2007c).

Within the developed world, the impact of economic crises and recession and the compensatory measures undertaken by governments highlight the particular importance of macroeconomic factors for health. Nevertheless these impacts are largely ignored in policy documents (e.g., *Economic Crisis in Europe: Causes, Consequences and Responses* European Commission (2009)). Recent work on austerity shows that recessions can impact on people's health negatively, as one would intuitively suspect, but also positively (Suhrcke & Stuckler, 2012). This may largely depend on whether support from social protection systems is maintained or cut. Ironically however recession in itself may have less effect than the austerity measures taken to combat it (Stuckler & Basu, 2013). Stuckler and Basu also argue powerfully that austerity measures are bad for health and can kill massively. The size of effects on health may also depend on whether a rich developed country or poorer country is concerned. Impacts of the economic situation may be masked by wider positive trends on population health. Thus, overall mortality may fall. Within the American depression, an increase in suicides was dissimulated by a bigger decrease in road accident deaths. People drove less since they could not afford cars and fuel: there was less traffic (Stuckler & Basu, 2013).

Policy matters. Different policies more often than not produce different impacts (Van de Bosch & Cantillon, 2006). Making different economic choices has implications for health and well-being. Thus, when Roosevelt's New Deal was adopted in the United States, its eventual impact very much depended on whether the policy was wholeheartedly implemented, as in certain left-leaning states, or resisted in more conservative states. Cornia, (2001) and Stuckler, King, and Mckee (2009) have highlighted the impact on health of the dramatic political and economic upheavals involving rapid privatization in Russia and certain Eastern and Central European countries in the decades following the collapse of the Soviet Union. Again where social protection system mechanisms were maintained and introduction of economic changes associated with privatization was more gradual, the negative impact on health was less pronounced. This speaks volumes in favor of the hypothesis that how economies flourish, are regulated, and buffer the possible negative effects of their functioning through social safety nets, and thereby diminish inequities, have great influence on health.

In complement to the above findings, Wilkinson and Pickett (2010) have examined how the degree of inequality within societies may impact on health and other social issues. They graphically illustrate that when comparisons are made between wealthier nations, no discernable relationship between national income per head and life expectancy is to be found. However, when one comes to examine the degree of income inequality within a wealthier country, this tends to correlate with people's health (and indeed a large range of indicators of social problems within countries). It is worth pointing out that Wilkinson and Pickett (2010) consider that income inequality is a measure, and perhaps the best measure that we currently have of how hierarchial a society is, the bigger the differences in income, the bigger the social distance and more important the social stratification. Health and a host of other social problem indicators follow a social gradient clearly related to income and social position. To quote Wilkinson and Pickett (2009): "Population health tends to be better in societies where income is more equally distributed. Recent evidence suggests that many other social problems, including mental illness, violence, imprisonment, lack of trust, teenage births, obesity, drug abuse, and poor educational performance of schoolchildren, are also more common in more unequal societies." The measure of inequality taken is how much richer the top 20 percent than the bottom 20 percent are in each country. Significantly in richer countries, what counts is not absolute wealth but whether the wealth is distributed more or less equally. As Wilkinson has stressed, it makes little difference on how a degree of equality is achieved. Countries such as Sweden and Japan are vastly different in many respects and have different social protection and fiscal systems, but their relatively low degree of income inequality correlates well with health and may be contrasted with the situation in less-equal societies. The situation with respect to inequality and health and other social indicators seen between countries is also mirrored among states in the United States. States with the highest degree of inequality (measured through Gini coefficients) also have high levels of poor social outcomes including health.

One explanation for the impact of income inequality is that status competition and status anxiety thrive in more unequal societies where social position tends to usurp social identity and common humanity. The latter receives greater recognition in more equal and more trustful societies. Humans are peculiarly sensitive to being evaluated socially, and when such social evaluative threats undermine identity and self-esteem, this leads to psychological and indeed biological stress. Such chronic social stress triggers the release of stress hormones such as cortisol with its deleterious effects on the cardiovascular and other physiological systems (Brunner, 1997). Thus, this provides one very plausible mechanism through which greater inequality within societies has impact on health and life expectancy (Wilkinson & Pickett, 2010). We would maintain that people's health is sensitive to economic forces and policies, governance, the labor market, and the degree of social and income inequality associated with social evaluative threats and stress this may engender.

Of particular importance is the labor market. Bambra (2011) reminds us that "work (paid wage labor) and worklessness (lack of paid work) are not the discreet activities of individuals, but are essential parts of the way in which the totality of society is politically, socially and economically organized." Furthermore, "the effects of work and worklessness on health and health inequalities are … mediated by political, economic and social organizations and by the welfare state regime." Health inequities are engendered by state political and economic policy which may also through social protection play a part in buffering the impact of social inequality on health. Being in work is an important condition for health, having an income and for social inclusion, but can also lead to bad health through the impact of an adverse physical or indeed psychosocial working environment. These risks follow a social gradient: lower paid workers being more vulnerable to work place hazards and accidents as well as having less control over their work and related stress in the work place. Interestingly effects especially of psychosocial working environments may differ between countries having different welfare regimes (Dragano, Siegrist, & Wahrendorf, 2011; Bambra, 2011).

Unemployment has a complex relationship with health (Bartley, 1994). Unemployment may lead to bad physical and mental health, and bad health may be related to unemployment or withdrawal from the labor market (economic inactivity). Unemployment is associated with poverty and social exclusion, and it has also been associated to greater risk of death and is linked to poor mental and physical health (Dorling, 2009; Urban Institute: Nichols, Mitchell, & Lindner, 2013). Poor health and disability also impact on the likelihood to suffer from long-term worklessness (Bambra, 2011). The effects of such worklessness are socially patterned and may lead to further social exclusion and poverty which in turn precipitate further health problems leading to a vicious circle (Whitehead, Clayton, et al., 2009).

With respect to disability, the occurrence of health problems and impairment may not only impact on social trajectories and lead to sliding down of the social gradient, but importantly and inversely, the social position of individuals and families has consequences for health. Impairments are more frequently associated with low social position, and the impact of disability on social participation is greater for the poorest and cumulative with other social disadvantages. Thus, in France not only is the unemployment rate of disabled people (15–64 years) twice that of the general population (DARES, 2012), but disabled children of working class families are seven times more likely to be cared for in full-time residential centers in France than children from professional class families (Ravaud & Mormiche, 2003). We will be examining how social policy may impact on the inclusion of people with disabilities in some detail later in this chapter.

The Impact of Supranational Policy

It is clear that economic and social policy at the national level is clearly subject to supranational and transnational influences and that these may have negative impacts on health especially in the developing world for economies in transition or crisis. Nevertheless, in spite of such conclusions, it is also clear that supranational bodies such as the European Union can also set standards and positively frame how national policy is exerted. This may have important knock-on effects in different sectors of economic and social activity. In the European Union, free movement of labor, goods, services, and persons is guaranteed under its treaty obligations. Such non-health policy has impact on the health field (notwithstanding that health falls under the principle of subsidiarity being considered to be a matter under the aegis of national governments) and has been figured as the subject of famous European jurisprudence. Since the free movement of labor, goods, services, and persons operates as the paramount principle on which European Union policy is founded, it has important effects on the health and other sectors. Notably the Kohll and Dekker cases established patients' rights to travel and be treated in different countries and to be reimbursed for treatment (Mossialos, Permanand, et al., 1996). Interestingly such a possibility was never envisaged by policy makers.

The influence of European policy on national policy is well documented, extensively studied, and permeated the national policy agenda. One example is the European Union's (EU) regulatory context on urban planning and environmental health. This includes several charters, strategies, strategic papers, and directives. In 2006, the EU adopted the Thematic Strategy on the Urban Environment in which it recognizes the problems faced in urban areas and attempts to provide guidance for better implementation of existing policies and long-term action plans. This has been followed up by the Green Paper and the Leipzig Charter which put forward an integrated sustainable urban development to overcome demographic, social, and environmental problems in European cities. Two EU directives have been implemented to address the issues related to ambient air quality (2008/50/EC) and environmental noise (2002/49/EC). The Parma Declaration (Fifth Ministerial Conference on Environment and Health in 2010) described the way forward in the work of environment and health in Europe. It sets out concrete targets to tackle the key urban environmental risk factors, paying special attention to children's health, inequalities, and emerging environmental health challenges (WHO, 2010b).

The influence of supranational policy agendas sets the scene for national legislation and implementation and can have both positive and negative effects on health. This can easily be seen in another important non-health field within Europe, namely, agriculture and food policy. The Common Agricultural Policy provides a strict regulatory framework and subsidies for farmers in Europe. This has important impacts on land use, the form of agriculture practiced, its impact on employment, the environment, and the type and price of food available favoring either health or disease (NIPH, 1996). Thus, on one hand, subsidizing beef and dairy production favors high saturated fat intake and associated disease throughout society, and on the other hand, the lack of support for fruit and vegetables favors comparatively high prices and lower consumption with obvious implications for health. Consequently, recommendations have been made for public health policy and agricultural policy goals to be aligned, matching subsidies to public health nutritional goals thus favoring higher and more equitable consumption of fruit and vegetables and less sugar, dairy produce, and meat (Birt, Faculty of Public Health, 2007; NIPH, 1996).

Similar conclusions can be drawn with respect to US farming subsidies which would also seem to conflict with US nutritional policy (PCRM, 2014). Nevertheless, sweeping changes in farming practice such as a transition from animal husbandry to the production of healthier food crops may not only lead to changes in consumption of foods with possible improvement in diet and positive impact on health but would necessarily be accompanied by huge structural and cultural changes in how agriculture and farm labors were pursued with possible negative impact on the number of people employed within agriculture and its support services and industries. For instance, according to one estimate, one man is able to cultivate 200 hectares of arable crops, but three men will be required to look after a herd on a farm of a similar acreage. Although calculating such effects is hugely complex (Whitehead & Nordgren, NIPH, 1996) and fraught with uncertainty, they may not be entirely positive for community health. Such examples demonstrate that whether it is recognized or not, macroeconomic and trade policy impact deeply on health either directly or indirectly throughout our world.

Social Policy and Inclusion

Beyond economic-related policy, social policy exerts a large impact on people's welfare and health. The macroenvironment will shape how people and families at a microlevel are represented and treated. Governments may introduce policies favoring equality between the sexes and equal rights irrespective of ethnicity, sex, and religion. Equality of this sort is often written into constitutions and documents such as *The Universal Declaration of Human Rights*. However, the straightforward monitoring of such policy involving the collection of nationwide ethnic statistics may be routine in some countries but unconstitutional in others such as France (Cédiey, Desprès, & L'Horty, 2007).

Including Disabled People in Society

Bearing in mind the relationship between inequality and disability previously mentioned, we will now consider in some detail policy aimed at favoring the inclusion of disabled people. This has been at the heart of European policy for some time but has fairly recently entered into French national policy. This illustrates well how policy, which both reflects and structures society, can have a deep influence on people's lives.

With respect to disability policy, European policy has had particular influence on national policy. In the case of France, this has led to the official taking up of nondiscrimination within French policy, notably in its landmark legislation of 2005 in favor of social participation, equal opportunities, and citizenship for disabled people.[7] Traditionally France, despite its firm belief in Republican universalism, has tended to favor affirmative action and specific treatment policies in favor of disabled people. The trend toward nondiscrimination and social inclusion of disabled people has been reinforced recently also by the adoption and ratification of the United Nations' Convention on Rights for Persons with Disabilities (United Nations, 2006). This lays down the principle of equal rights for people with disabilities in all walks of life.

One may consider that policy-promoting diversity and the rights of people with disabilities may be shaped differently to conform to two main paradigms of either favoring (a) specific treatment or (b) nondiscrimination. In the former, specific treatment or affirmative action (traditionally embedded in French practice) is designed to right (compensate) wrongs and disadvantage and lead to greater equity within the population. This may involve compensatory measures in favor of the disabled, e.g., in the provision of specific parking spaces and, within the labor market, the setting up of quota for disabled employees, e.g., 6% of the workforce in France.

Employment of disabled people is often informed by a more biomedical individual model, where the person is assessed and adaptations are made piecemeal or case by case. Furthermore, the setting up of sheltered workshops is frequent, so employment becomes very much a question for social work professionals. However, in line with European practices and the philosophy expressed in the United Nations' Convention on the Rights of Persons with Disabilities (United Nations, 2006), disability policy may alternatively be informed and built around nondiscrimination coupled to universal design and mainstream provision. Here employment of people with disability becomes primarily a question of inclusive employment rights (similar rights for all). This may involve adapting workstations, but the key principle is everyone has an equal right to work. In universal design, the idea is to render all environments and work situations open to anyone (Green, 2011); thus, toilets (rest rooms) and lifts/elevators are designed to be able to cater for all those with wheelchairs or non-wheelchair users and are equipped for all people including people with visual and hearing impairments and will incorporate auditive signals as well as Braille information and visual information. They may also attempt to cater to people with intellectual deficiency in using Makaton-type symbols. Parking spaces are not specifically designated as being for the disabled but are all made wider allowing people with wheelchairs and families with baby carriages and children to use them. Universal design also attempts to satisfy the needs of the neediest and through that process be adapted to all people. Of course in practice, the two policy paradigms are not exclusive and will frequently interact and be in tension or perhaps complement each other.

Disability policy aimed at granting disabled people with the same rights as other people may also be broadly divided into policy-shaping services and resources and the physical environment and policy impacting on the attitudes of the society toward people with disabilities. The latter has considerable importance since not only is there direct impact of attitudes on the opportunities made available to disabled people, but the very expectations of the disabled person herself and of her family, friends, neighbors, and society will tend to be integrated into the psyche and soma of the disabled person. We may make a distinction between "indifferent kinds" and "interactive kinds." In the former, a description made of an object has no impact on the structure of the described object. Hacking (2000) terms such objects as being "indifferent." The latter, termed "interactive kinds" by Hacking, is on the contrary affected by the way we describe or conceptualize. Thus, how we describe people matters. The labeling and classificatory theories we wield may become embodied by the very people being described through negative or positive feedback

---

[7] *Loi* n° *2005*–102 du 11 février *2005* pour l'égalité des droits et des chances, la participation et la citoyenneté des personnes handicapées.

loops. A positive enabling environment will empower disabled people to take their rightful place within society, whereas a hostile discriminatory environment will lead to low self-esteem and exclusion.

Of course, physical environments and adaptations also have great importance and may be enabling or disabling. The physical environment here is defined broadly to include urban planning and architectural design. The impacts of environment may result from interactions between dimensions which go beyond the impact of the sum of each individual dimension. Substantial and important work, leading to the "*Processus de production du handicap*" (PPH) Classification (Disability Creation Process) carried out in Canada by Patrick Fougeyrollas and colleagues, has resulted in increased understanding of how environments in all their different dimensions may impact on people living with impairment (Fougeyrollas, Noreau, et al., 1998).

The production of disability situations and indeed of situations in which humans are involved as developing beings may be considered to be an interaction between environmental factors, personal factors, and life habits. In principle the same schema applied to those with disabilities may be applied to all humans, their environments, and lives. The World Health Organization has drawn up the International Classification of Functioning, Disability, and Health (2001). This also considers that disability, and indeed healthy functioning, may be related to interactions between the person, her health condition, her body functions and structures, and her physical, social, and cultural environmental factors enabling or hindering the carrying out of activities and participation thus producing disablement. A situation of disability may often come about through the impact of planning and urban design informed and thought out through considering the needs of a standardized "normal" man without impairments and thus failing singularly to be adapted to a large number of humans with other needs. Architectural, physical, and environmental barriers make it impossible or difficult for people with reduced mobility to fully participate as citizens within society. Disability situations thus frequently arise due to a mismatch of the environment with the needs of people with disabilities. Environments, including sociocultural environments with their norms, may be truly disabling, e.g., lack of signing interpreters for deaf people, which may hamper their full participation or the lack of trained teaching assistants to help disabled children in schools. Thus, a well-adapted environment may bring about a huge improvement in social participation and well-being.

The mismatch between environment and ability erects barriers and obstacles toward disabled people, hampering and rendering impossible the achievement of goals which they have reason to value (Sen, 1999). These would be considered as being perfectly reasonable goals for an ordinary member of the population. Notably the United Nations Convention offers disabled people an instrument in order to pursue their rights. The convention calls upon employers and organizations open to members of the general public such as cinemas, theaters, stores, and public services to make "reasonable accommodation" so that disabled people may exert the same rights and participate equally in society. Not to do so is considered discriminatory, and organizations in breach of their obligations may be taken to court. Two points may be made. Firstly, "reasonable accommodation" is a legal, technical, and political matter. There may be tensions between the adaptations provided for different impairment groups. So, trade-offs may have to occur. Secondly, "reasonable accommodation" nevertheless should not be used as a pretext for failing to implement the principles of universal and inclusive design to the greatest extent possible. Indeed what might be the implications of more widespread promotion of inclusive environments rather than environments suited to the "normal," dutifully adjusted to accommodate others?

The United Nations Convention also has important implications for urban design and architecture and illustrates well how change in law can potentially be a powerful macroenvironmental influence on attitudes and practice. This again is well conceptualized by the Disability Creation Process (Fougeyrollas, Noreau, et al., 1998). With respect to discrimination, it is worth pointing out that specific treatment of disabled people with special needs under the convention is not considered as being discriminatory (article 5) if it favors the person's inclusion and participation in society. To such policy, especially relevant to how disabled people can thrive or have their opportunities restricted, we can add the importance of the media and the representations and discourse which structure how people behave and react toward society and others. Furthermore, representations are not just cognitive and individual, they are social and live through the norms, laws, taken-for-granted practice, physical facilities, and care and educational provision on offer. The existence of large institutional residential centers for disabled people in France will tend to structure the social protection benefit system and how disability professionals and social service workers represent and envisage life, employment, and education for people with disabilities (Sherlaw, Lucas, et al., 2014). We may consider that the representations are crystalized "in the very walls" of the residential care homes. This may militate against disabled people being accepted in society's ordinary services and facilities. Thus, it may not be a high priority for the inclusion of disabled pupils in mainstream education in spite of the existence of legislation offering disabled children the right to education in ordinary schools. Similarly, employment of disabled people paradoxically is not necessarily favored by the existence of substantial sheltered employment provision, nor is living in ordinary housing within the community, given the taken-for-granted idea, often championed by disability associations and families, that the state should provide disabled people with special residential care.

There are important vested interests at stake. Often the state or local authorities will provide funding while reaping the political advantage of delegating on the ground operational responsibilities to Disabled People's Organizations (DPO). Since a huge number of health and social service professionals are employed in DPO-managed centers, both employers and employees have a vested interest in maintaining current institutionalized practice. It is thus difficult for more inclusive policy to make headway in the face of such vested interests and alliances, despite the emergence of new paradigms and attitudes. Nevertheless, change will inevitably occur since there has been a substantial paradigm shift toward inclusive approaches throughout Europe and the world. Families through Internet and the media are also becoming more and more aware of other more inclusive possibilities on offer in other countries for their children.

Going Beyond the Social Gradient

We may speak of social structure, social stratification, and class, but we should not forget that different societies may be structured not only through social economic status but through cultural- or religious-based norms. The impact of culture is well illustrated through the example of the well-known Latino paradox (Abraído-Lanza, Chao, & Flórez, 2005). In opposition to the taken-for-granted idea that poor socioeconomic status is systematically associated with poor health, it has paradoxically been shown that recent Latino migrants to the United states have better health status in spite of their comparatively poor socioeconomic status than other more prosperous members of the Latino community who have lived much longer in the United States. It is suggested that this may be explained by the fact that recent arrivals possess better dietary habits and healthier lifestyles coupled to a greater sense of community than those Latinos that have lived in the United States much longer and who have taken on board the lifestyles and the diet of the ordinary American. Structural determinants, which may include also cultural- or religious-based norms, will determine social position, which results from the unequal distribution and use of resources.

Religion

There are many well-known examples of how religious norms of a minority community may be in tension with majority secular societal norms, e.g., the banning of wearing religiously connoted clothing or religious signs in French schools (Liogier, 2009). Another good example of how religion and norms may interact with social policy is provided by the case of school meals in France. Through offering subsidized school meals to school children, the intention is to make sure that all children eat healthily and have sufficient to eat. Poor nutrition is associated with poor health but can also lead to poor academic achievement (CDC, 2014). Policy on school meals will also largely determine whether school children return home to eat or not and favor or hinder mothers having employment. Different societies and authorities may choose to adapt menus to religious food taboos or not. An interesting study by Hermet on schools in the Parisian area illustrates how policy toward diversity may impact not only on whether subsidized or free school meals are actually taken up by children and young people from minority communities but also have unexpected knock-on effects with wider implications for social integration. It was found that meals in certain schools were not deemed culturally acceptable, and children of Moslem faith often chose to return home to eat in their families. Interestingly previous adult eating habits conforming to French norms could be modified under the pressure of their children and Moslem families readopting traditional Halal food, which had previously been forsaken, through reverse socialization (Hermet, 2001). Such overarching policy on how diversity is handled within a society although instituted at the macrolevel, including the norms associated with the policies, will impact at a microlevel on individuals and their families, their lives, and the projects that they have reason to value and that they can envisage and realize.

Further Illustrations from Education

Education provides a concrete example of how social position may be a determinant for the future life course of individuals lacking social, economic, and cultural capitals. The example is from education, which may also be considered as a structural determinant, but it illustrates well how structure and agency or rather lack of agency combine to produce their effects. Compulsory schooling in certain cantons in Switzerland is fixed at 6 years counting from May 1 or 6 years and 3 months counting from 31 August. The school year starts in September. Generally, children go to nursery school for 2 years before entering their compulsory schooling. The youngest children born in April, March, and February on entry to primary school may be less mature and hence be at a disadvantage with respect to more mature children as regards with what is considered to be an appropriate behavior and development. The influence of the birth date one would expect to be taken into account in assessments and orientations. However, as recent Swiss research has shown, some children and their families are more equal than others (Grémion, 2013). Middle professional class parents understanding the danger of a poor assessment due to a relative lack of maturity on leaving nursery school have devised strategies to protect their children from the possibility of being oriented into a special education class or *being obliged to redo* a year in the nursery school which is potentially highly stigmatizing. They postpone their children's entry into nursery school, and when their children have reached the obligatory age for primary schooling, they manage to ensure that their children, with the support of their family pediatrician who provides the seal of approval, do a second year in nursery school (doing 2 years in nursery school is considered as a right and not considered as redoing a year), so when finally they enter primary school proper, they are among the most mature children. But foreign and frequently families of lower socioeconomic status may not have access to such a fine understanding of how the educational system works. This militates against their children, who find themselves simply due to being born in the "wrong month" (April, March, or February) and thus less mature, being drawn into a downward spiral. This may end in an orientation for special schooling or institutionalization which coincidentally allows primary school teachers to be free of children from diverse backgrounds needing more attention than the others.

In this above example, we have a perfectly normal biological difference of maturity which gathers great significance due to the existence of administrative criteria and rules about how starting age for schools should be determined. This biological difference is quickly mitigated through the strategic action of middle-class parents. These parents with the welfare of their children and possessing good knowledge of the institutional system are able, through the operation of social network and economic and cultural capitals, to provide improved life chances for their children. However, parents from working class or of immigrant backgrounds may not possess such knowledge nor may they have privileged access to institutional resources or health professional allies and thus are unable to take prophylactic measures against the possible impact of a lack of maturity. Such an initial lack of maturity is quickly forgotten for the children from privileged backgrounds but may assume great importance with the intentional or unintentional complicity of the primary school teaching professionals for the life chances of children from less-privileged or immigrant background. Biology is expressed through and moderated by the social. Similarly to the case of environmental health which we will examine further, we have an apparently biological, physical, or chemical phenomenon which again may be reduced or exacerbated through the impact of social position. Furthermore, as we shall now examine, such phenomena and social position may also be impacted by territorial segregation and discrimination.

Discrimination and Segregation: Adding Further to Social Disadvantage

Discrimination may take different forms relating to gender, age, sexual orientation, disability, religion, or ethnic origin. It may frequently exacerbate health inequality. Such discrimination may be revealed within different sectors such as work, housing, and leisure activities (e.g., acceptation in restaurants, discos, or night clubs). Mirna and Simon (2014) consider that discrimination may be studied within practices, social actions, and their consequences. This is especially relevant in connection to ethnicity. One may also, as work on stigmatization of people with mental health problems has shown, make a distinction between problems of knowledge (ignorance), problems of attitudes (prejudice), and problems of behavior (discrimination) (Thornicroft, 2006). Discrimination in the last sense is linked to actions which affect individuals and groups negatively and unjustly. At first sight, such distinctions are useful but fail to appreciate that the line between attitudes and actions is a very narrow one, since attitudes tend to impact on ambient norms and people's well-being and self-esteem and as we shall see may become embodied.[8] Nevertheless, practically with respect to discrimination, the major problem is how can discriminatory behavior be characterized objectively, since, for example, unequal treatment is extremely difficult to measure (e.g., in equal employment opportunities and treatment of candidates or for patients having safety net insurance in receiving medical treatment). It should also be noted in countries supposedly "color blind," such as France, where the collection of ethnic statistics is strictly controlled, such objectivation of discrimination is peculiarly challenging (Cédiey, Després, et al., 2007).

Inequalities may also be related to the spatial distribution of the population which lives, works, and pursues leisure activities within a territorial area. Territorial segregation is at the focus of a number of significant studies carried out in sociology, urban planning, development, and geography. One of the principle findings suggests that population groups/clusters tend to cumulate disadvantage involving multiple exposures related to socioeconomic, cultural, and ethnic discrimination coupled with territorial segregation in enclaves or ghettos. Leaving aside why population clusters tend to form between people sharing features of identity, it is important to highlight in the context of discrimination the importance of the accumulation of disadvantage. This includes the lack of easily accessible neighborhood social and health services

---

[8] Furthermore, it should not be considered unjust if those who have previously be subjected to unfair treatment or oppression receive benefits and privileged treatment as a righting mechanism to favor social justice.

and from an environmental health perspective living close to potentially hazardous industrial sites, being exposed to high noise levels, air pollution, and zones liable to flooding.

A particularly important and well-documented example of segregation is that of African-American residential segregation. It is well known that there are important health disparities between African-Americans and whites. Williams and Collins (2001) powerfully argue that “racial residential segregation is the cornerstone on which black-white disparities in health status have been built in the US. Segregation is a fundamental cause of differences in health status between African Americans and whites because it shapes socioeconomic conditions for blacks not only at the individual and household levels but also at the neighborhood and community levels.” Despite methodological issues such as how one measures and defines segregation among others White and Borrell (2011), some criticism of this position and examples where segregation may protect health, the overall effect of such residential segregation is deleterious to health and in particular black pregnancy outcomes (Kramer & Hogue, 2009).

Factors linked to residency that may contribute to health inequities include educational opportunity, poverty, employment opportunities and thus income, and accumulation of disadvantage. Mismatch of work opportunities, re-siting of companies, and isolation of blacks in segregated communities takes their toll. A lack of positive role models and social networks linked to employment opportunities engenders cultures where work ethic and civic ethics are undermined and academic success undervalued, all within a context of enduring poverty. If it is clear that health disparities are primarily linked to socioeconomic status (SES), it is equally clear that such segregation usually tends to exacerbate disparities in SES and, hence, health inequities. It is important to tackle this issue since the majority of African-Americans live in urban settings and many of which remain highly segregated (Kramer & Hogue, 2009).

From a methodological perspective, additional distinctions may be drawn between spatial geographical segregations linked to the localization of habitations, work, and leisure. The fact that people may live and work and play in different geographical areas may lessen the impact of residing in an unhealthy environment favoring smoking, for example. Shareck, Frohlich, and Kestens (2014) have conceptualized and suggested people possess mobility potential which will transform into actual mobility through agency. Such mobility potential however is likely to be distributed unevenly across SES groups leading to different contextual influences on health inequalities. Mobility could buffer the effects of unhealthy residential environments, but probably the degree of conversion of mobility potential will be subject to influences such as norms and resources at people’s disposal which will be socially patterned. Nevertheless individuals, even if suffering discrimination, may be able to access resources across different urban environments, even if having an address within an urban area with a poor reputation may in itself be associated with discrimination.

There is however a crucial difference between territorial segregation and discrimination. Discrimination involves rejection and exclusion with respect to personal characteristics which may not be modified or exchanged or negotiated (one cannot change the color of one’s skin, sexual orientation, country of origin, mother tongue, etc.). Age, sex and gender, health status, accent, and mother tongue are the very characteristics which contribute toward the formation of identity and in many ways can be considered as being embodied. Discrimination thus may be defined as being an insult to such identity and human dignity. Unequal treatment is unjust since it implies domination and oppression. In order to consolidate equal rights and fight unfair discriminations, there is no question of changing and transforming individuals, but rather tackling such discrimination at a structural level implies political will and social and cultural changes in how institutions and organizations are governed and managed.

As health inequities are the biological expression of social inequities, social disadvantage related to race has a long social and political history that is sedimented in the places people dwell and the bodies, hearts, and minds of both those who suffer discrimination and those who have participated – actively or passively – in discrimination. Krieger (2012a) in putting forward an ecosocial model of embodiment has argued that it is important to study the multi-level effects of such discrimination rigorously in order to combat it and denounce it but also to give evidence of its devastating effects on people's health and lives.

We close this section on discrimination by describing a provocative study that illustrates the many complexities of the relationships among social structure and its embodiment, all as moderated by the contexts in which people live. The mean level of blood pressure in populations has been shown to vary according to different societies and social contexts. Furthermore, as has been graphically demonstrated by Gravlee (2002), cited by Russell Bernard (2006), a relation between self-perceived skin color among Puerto Ricans and blood pressure may be seen. But this is no straightforward relationship. As Gravlee has dramatically demonstrated, such effects may vary according to the socioeconomic situation of the individual and their self-esteem and pride. Gravlee measured skin color in two ways: an emic (self-perceived) rating and an etic (objective) rating with a photospectrometer. The difference between etic skin color and what people say their skin color (emic) was strongly related with blood pressure. Poor individuals in southeastern Puerto Rico who rated themselves as having a darker skin color than they really had are likely to have a higher blood pressure. For successful middle-class individuals, the relationship was inversed. They are more likely to have lower blood pressure when they rate their skin color darker than it really is. Such findings suggest that the impacts of our sociocultural environments on individuals are complex and are far from being just skin deep[9] (Gravlee, 2009). It also suggests that through changing social contexts and the socioeconomic circumstances of individuals, we may impact favorably on health and well-being.

Complex Interactions Among Contextual Determinants

In the course of the previous sections, we have identified a wide variety of determinants of health across the environment and arising from the health and non-health sectors. We now turn to a central point of our model and of most writing in these areas, the fact that different environmental or contextual determinants often interact in their influences on health.

We will take as our starting point the physical characteristics of the environment and its related exposures (Desai, Mehta, & Smith, 2004). This offers a baseline approach to considering how non-health policy impacting on and shaping environments may be explored and analyzed. In the case of ambient air quality, Deguen and Zmirou (2010) citing evidence from their extensive literature review suggest two mechanisms may be involved, namely, differential exposures to environmental agents and differential susceptibility to them. Both of these differences may be related to socioeconomic status. Firstly, populations with less resources, such as income, tend to end up living and working in unhealthier environments than other populations. However, illustrating the general point of the importance of interacting elements of context, in some settings,

---

[9] In tackling this sensitive issue, Gravlee (2009) takes the "opportunity to refine the critique of race in three ways: (1) to reiterate why the race concept is inconsistent with patterns of global human genetic diversity; (2) to refocus attention on the complex, environmental influences on human biology at multiple levels of analysis and across the life course; and (3) to revise the claim that race is a cultural construct and expand research on the sociocultural reality of race and racism." One may add however that biology of course should not be used as the one and only yardstick to measure discrimination and the impact of inequality. Other indicators may of course be used. But beyond this idea in principle, all forms of oppression and discrimination are wrong and should be fought against. Measuring them is one means to achieve that end. However, it is important to bear in mind the words of Simon Weil,

> Equality is a vital [human need]. It consists in recognition, at once public, general, effective and genuinely expressed in institutions and customs, that the same amount of respect and consideration is due to every human being because this respect is due to the human being as such and is not a matter of degree. (Weil, 1949, p. 26)

e.g., Rome, people having higher socioeconomic status have higher exposures to pollutants than poorer populations. Nevertheless, irrespective of the levels of exposure, there is a correlation between being poor and the resultant harmful effects of pollution. This would seem to be related to the second mechanism of differential susceptibility. In other words, poorer populations may, through having been exposed to repeated insults of their environment during certain periods of their life (windows of exposure) (Deguen, Petit, et al., 2015), have developed a greater susceptibility to the resultant health effects. Such susceptibility may be linked to poorer health status and developmental life course factors. As Deguen and Zmirou conclude, in the case of ambient air quality, long-term multipolar urban planning and diversity-sensitive housing policy may be the best way to tackle the environmental and social inequities and to mitigate differential health impacts.

The interactions among contextual determinants are especially apparent in research on urban areas that investigates the effect of neighborhoods on health. For example, evidence shows that obesity rates will vary between neighborhoods within cities such as New York. A range of factors would seem to be involved including the presence of supermarkets and food stores and the area income (Black, Macinko, et al., 2010). With respect to smoking, it is well known, as shown in research from Scotland and France (Lawlor, Frankel, et al., 2003; Perreti-Watel, Constance, et al., 2009), how people at the lower end of the social gradient are more likely to smoke and smoke longer than those from higher up on the social gradient. Consistent with this, better economic and social prospects and associated better health, increased life expectancy and security that goes with them will lead people not to take up smoking or to forsake tobacco (Lawlor, Frankel, et al., 2003). However, it is not only social position that will determine whether one becomes a smoker and one's smoking habits. These will also depend on which neighborhood one lives in. It has been shown that the practice of smoking is favored by the proximity and density of points of sale for tobacco (Henriksen, Feighery, et al., 2008, McCarthy, Mistry, et al., 2009, Cantrell, Anesetti-Rothermel, et al., 2015). These have often found to be concentrated in deprived areas. Van Lenthe and Mackenbach (2006) have also found that people from deprived communities are more likely to smoke but even more so if they live in stressful neighborhoods. Stressors included "physical quality (decay), required police attention, noise pollution from traffic, and population density in neighborhoods." Similarly, objective and perceived measures of neighborhood crime have also been correlated with smoking. Nevertheless, the picture is even more complex than one may suppose. Mirroring findings from a well-known qualitative study from Scotland (Stead, MacAskill, et al., 2001), Ahern, Galea, et al. (2009) demonstrate that neighborhoods with "higher collective efficacy" may either discourage smoking or favor it depending on the presence of pro- or anti-smoking norms. They point out that it will be important when intervening in neighborhoods to bear in mind such findings since increasing social cohesion, seen as being generally favorable for health, may also, depending on the norms at work within the community, lead to favoring unhealthy practices and consequent bad health.

Neighborhood effects may also depend on national contexts. Recent research by Wilson, Eyles, et al. (2010) has compared living in four different neighborhoods in Hamilton (Canada) and Glasgow. They showed that certain effects on health behaviors were shared between the two cities such as living in a low SES neighborhood impacted on likelihood to smoke or being physically inactive. However, living in a poor neighborhood favored being overweight or obesity in Glasgow but not in Hamilton. On the other hand, there were strong associations with mental health (emotional distress) seen in Hamilton but absent in Glasgow.

All such neighborhood studies of the urban environment and populations pose key questions concerning geographical space and place (Burton, Kemp, et al., (2011). In the former, effects on health may be explained through the physical characteristics of the environment and exposures occurring within that geographical space. In the latter, different spaces can have different effects on health which may not be explained completely by reference to physicochemical and biological parameters. Space may become place. Ecob and Jones (1998) citing Macintyre and colleagues suggest that place may have impacts on health through different mechanisms and distinguish between compositional, collective, and contextual effects. Compositional refers to the idea that differences between the sociodemographic characteristics of the population living in different places explain the effect; in other terms, the effect of place on health may be explained "away" through the different characteristics of the population living in the places studied (with respect to health, spaces become places, only through the fact that different populations live in them). The second refers to the possible normative social contagion ("social miasma") between people living in the same place and the last invokes the direct impact of the context. Thus, the question *do people of similar characteristics experience different health outcomes in different types of places?* may be posed. Recently, however, Oakes (2004) has raised important theoretical and methodological questions about causal inference and the possibility to neatly separate social and environmental contexts from the people who live in them. Paraphrasing Macintyre and Ellaway (2003), Oakes, Andrade, Biyoow, and Cowan (2015) remind us that "the fact is neighborhoods make people and people make neighborhoods. It is not composition *or* context, but composition *and* contexts" (authors italics).

Oakes et al. remaining fully committed to investigating rigorously the impact of social contexts on health have called for more experiments, including natural experiments, rather than observational studies. According to Oakes, Andrade, et al. (2015), such experiments are of two types: people are moved from one neighborhood to another or the neighborhoods in which people live are changed. The first category of people being moved from one neighborhood to another includes programs that give people housing vouchers to change home and neighborhood. "Moving to Opportunity" permitted families to move from public housing in high poverty neighborhoods to private housing in lower poverty or nonpoor New York neighborhoods. Moving out of the public housing/high poverty neighborhoods was associated with lower distress among parents and lower anxious/depressive and dependency problems among their sons (Leventhal & Brookes-Gunn, 2003). Similarly, a randomized environmental experimental intervention carried out in Chicago (Ludwig, Sanbonmatsu, et al., 2011) has shown that obesity and diabetes risk may be reduced by moving to different neighborhoods. Three groups were constituted. One group was offered housing vouchers provided they changed address and moved to another neighborhood. Another group was offered the equivalent sum but was given no instructions or advice on moving, and third, control group was offered neither advice nor money. Over a 7-year period, there was no significant difference between the latter two groups, but the objectively measured risks of developing obesity and diabetes were reduced in the group who moved home. Positive effects[10] were seen 10–15 years later in prevalence of obesity and diabetes (Ludwig, Sanbonmatsu, et al., 2011). Nevertheless, such programs are costly, and moving home may be no simple affair as people may identify strongly with the place they live in spite of social and economic difficulties. As Popay, Thomas, et al. (2003) have shown through comparing two Northern England towns, Salford and Lancaster, each with a high- and low-income area, there will be complex interactions involving the interplay of structure and agency and meaning of place. People will react differently depending on their socioeconomic status, biographical and narrative history, and capacity to reconcile the dissonance between "normative guidelines" of what a "proper place" to live in should be like and their own actual "lived experience of place" and the people living there. Thus, when faced with criminality, different individuals and families may take different stances, such as combatting criminal behavior through individual action and mobilizing the community or, on the contrary, protecting and shutting themselves off in their own "privatized space" from the outside world. Such realities

---

[10] See also http://www.nber.org/mtopublic/.

are important to take into account as they may structure the possibility of collective community action and social cohesion, both important for promoting health. Being aware of these issues and sociological work, such as Williams (2003), Frohlich and Abel (2014) have put forward a substantial framework founded on a synthesis of Bourdieu's theory on capital and Sen's Capabilities theory, thus combining structure and agency. They suggest that rather than study individual health-related behavior, it is more fruitful to study contextualized health practices. As we shall see, they have applied this framework to inequities in smoking. Evidence from neighborhood studies such as these implies that some neighborhoods are healthier places than others, and ultimately environments should be considered as places with both objective and subjective realties in which representations circulate rather than mere geographical space. Indeed, in line with our model, communities may be thought as having both a geographical and historical dimension.

The historical dimension of communities is illustrated well by research on lay epidemiological understandings of breast cancer (Salant & Gehlert, 2008). Focus group interviews guided by grounded theory showed that collective memory, including nostalgia for simpler lifestyles and environments, fear and social stigma of cancer, and distrust of doctors, is fed by a historical heritage of injustice and discrimination. This suggests that breast cancer-related survival and recourse to early diagnosis and treatment may be related to how black women represent the illness and how they and their families have been treated in the past. Here is a good illustration of how health may be impacted through the representations circulating within a community stemming from explicit or implicit discrimination. As Salant and Gehert suggest, research and interventions on health disparities may need not just to consider easily quantifiable indicators of belonging to a geographical community defined by objective boundaries but may need also to explore "imagined communities", that is, how the community members themselves define their own community. Imagined communities may not correspond to usual geographical definitions. Furthermore, collective representations of community can be used to "interpret the health landscape" and impact on health behaviors. This is in contrast to individual models of health responsibility (Salant & Gehert, 2008).

We suggest *in fine* that exposures to health risks and the possibility to mobilize health-giving resources by individuals and populations are socially and culturally structured. Environments are not equal for all. On the contrary, they are stratified and structured socially and culturally. Thus, conceptualizing a sharp division between risks and health behaviors depending on individual choice and passive exposure to risks is untenable. As MacIntyre (2000) suggests, the inverse care law formulated by Tudor Hart may also be usefully applied to health-promoting resources and facilities available within cities. Poor people will generally have the least resources for improving their health, whereas the richer and healthier members of the community will have the most. What is more is that hazards and risks are unevenly shared, as are the opportunities for people to extract themselves from the source of such risks. People being exposed to high levels of environmental noise linked to harmful effects on health in general will have little opportunity to choose to move home due to lack of economic, social, and cultural capitals. Such "passive" long-term exposure to sources of ill-health is generally not a question of individual choice. Public policy can of course attempt to protect habitations from high noise levels by screens or reduce noise levels through legislating for quieter motor vehicles or more radically and intelligently distancing of habitations from the proximity of major road systems. Furthermore, as we will maintain, often people from a population and specific urban district will be exposed to a accumulation of several adverse risks associated with physical agents, such as poor-quality air and noise potentially deleterious for health. These different risks will also be exacerbated, maintained, or mitigated through the sociocultural and physical environment, i.e., the conditions in which people live, work, and play.

Examples and Progress: Housing and Urban Life

We will now take a more detailed look at two of the most important non-health sector areas, housing and urban planning and development and how these impact on people's lives.

Social determinants of health have been famously defined as "the circumstances in which people are born, grow up, live, work and age." These circumstances may vary starkly from living as a rough sleeper on the city streets without a home to enjoying the luxury of a comfortable mansion. Those who are homeless suffer the highest rates of premature death (Wilkinson & Marmot, 2003). This single fact highlights the crucial importance of having a home and living conditions for health. Shaw in her 2004 review of the impact of housing on health highlights both material and immaterial attributes that are associated with having a home. We will review principal harms and benefits associated with housing in detail later. If it is reasonable to adopt a Maslowian approach to human needs by stressing the "hard" impacts of the physical housing environment as a starting point to study impact on health, it is insufficient. Impact of housing on health and well-being must also take into account psychosocial and cultural dimensions. Citing Dupuis, Shaw discusses the importance of the ontological aspects which bring the meaning of having a home to the fore. This is recognized by the WHO (2007) in their recent definition of housing as "the conjunction of dwelling, home, immediate environment and community." One should never forget that housing (if one has the chance to have a home, be it a house, an apartment, or less well-appointed dwelling) is not just a shelter where one sleeps but constitutes the daily and often yearly environment for children's play and study and adult leisure, study, and often work. Increasingly and importantly, it is well recognized that good and bad housing and living conditions are important determinants of health (Wilkinson & Marmot, 2003; Bonnefoy, 2007). Thus, access to decent housing and the type of housing policy pursued have important effects on population health (WHO, 2006a).

Housing supply may include rented social housing through the public sector or housing associations or providing rented property through private landlords or private ownership. National and local government policy with respect to issues such as mortgages, local housing taxes (rates), and rent fixing will largely determine whether the supply of social housing is high or low. Access to social housing (housing owned and rented out by local authorities to people with low incomes or specific needs) will for the most part be determined by residence in the community and recognized need such as being a lone woman with children. Since supply is restricted, competition to get on the housing register is fierce, and this in itself creates considerable tension within society among those on housing waiting lists, creating the conditions in which stigmatization and discrimination thrive especially on ethnic grounds. In France, a country with a tradition of strong social policies, it is estimated that more than 500,000 people do not have a home, and among those, 133,000 are actually homeless; others are living on sofas of friends, hostels, squats, etc. (Fondation Abbé Pierre, 2011). If the number of people living in a very "difficult housing" situation is added, the number rises to 3.6 million, more than 5% of the French population. The term "difficult housing" situation refers to those living in chronic overpopulation and dangerous buildings, with a lack of basic amenities. Moreover, another 5 million people are considered to have a very fragile housing situation (lack of house maintenance, large unpaid rents, etc.), and nearly 3.5 million face fuel poverty (Fondation Abbé Pierre, 2011). These estimates are likely to underestimate the real problem given the present economic crisis. The rehabilitation of substandard housing, both public and private owned, is a key area of intervention among French city councils (Heritage, Garchitorena-Garcia, 2013).

Even if appropriate and affordable housing has been heralded as a fundamental human right, it remains as one which is far from being upheld in many developing and developed countries alike. Homelessness has increased in many countries, including the richest, and these populations suffer the highest rates of premature death (Wilkinson & Marmot, 2003). The WHO "Closing the gap in a generation" report warns that "One of the biggest challenges facing cities is access to adequate shelter for all. Not only is the provision of shelter essential but the quality of the shelter (…). This crisis (of housing) will worsen social inequities in general, and in health in particular" (WHO, 2008). The US Surgeon General's Call to Action (2009) says that "To improve the nation's overall health, we must improve the health of the nation's homes and ensure that safe, healthy, affordable, accessible and environmentally friendly homes are available to everyone" (Meyer, 2010).

The Home Environment: A Crucible for Health and Disease

People spend the majority of their lifetime inside their homes, and therefore exposure to housing-related factors represents a considerable threat. Illustrating our earlier discussion of the roles of both exposure and susceptibility, the most vulnerable populations such as the sick, the elderly, the children, the unemployed, and the poor are also the ones who spend the largest proportion of time at home, further exacerbating the impacts of household exposures (WHO, 2007). Lower household income is associated with inadequate housing which is linked to many risk factors such as mold growth, crowding, indoor pollution, and noise (Braubach & Fairburn, 2010). Fuel poverty is also disproportionately higher in low-income groups (Braubach & Fairburn, 2010) and associated with excess winter and summer deaths due to thermal stress (Kuholski, Tohn, & Morley, 2010). Furthermore, exposure to traffic-related noise, proximity to industrial pollution sources, lack of green spaces, and lack of perceived safety due to deprived neighborhoods (litter, graffiti, etc.) are also experienced more frequently by lower income groups.

Housing Conditions and Health

Many links have been identified between housing conditions and health (see Fig. 15.3). The presence of safety devices, structural characteristics of the house, the materials used for construction, interior decoration, and neighborhood configuration can all have an influence on health. The most significant housing hazards have been quantified by the WHO Health Evidence Network (WHO-HEN). The ranking is the following: poor air quality; poor hygrothermal conditions; radon; slips, trips, and falls; noise; house dust mites; tobacco smoke; and fires (Thomson & Petticrew, 2005).

Chemical and Biological Hazards

Air pollution causes premature deaths and is associated to increased risk of coronary heart disease and many respiratory diseases such as asthma and chronic obstructive pulmonary disease, with increased susceptibility in low-income groups (Deguen & Zmirou-Navier, 2010). Indoor sources of air pollution can be caused by both chemical and biological sources.

Exposure of children to hazardous levels of lead may result in long-term effects on the brain and cognitive development among others (US EPA, 2004). Measures to reduce lead exposure have great cost-benefit ratios and result in actual savings in medical care, education, and productivity for those who are protected (Thomson & Petticrew, 2005). For instance, lead hazard control in the United States has shown to be a very effective intervention, decreasing dust lead levels by 78% over a 3-year period (Sandel, Baeder, et al., 2010).

In France, exposure to radon is the second leading cause of lung cancer after tobacco causing up to 2900 deaths per year (Ministère du travail de l'emploi et de la santé, 2008). Radon mitigation is effective in reducing individuals' risk of lung cancer and is cost-effective compared to other health-care and environmental interventions (Sandel, Baeder, et al., 2010; National Collaborating Centre for Environmental Health, 2008). Other common sources of indoor chemical air pollutants like residential secondhand smoke, pesticides used in the house, and volatile

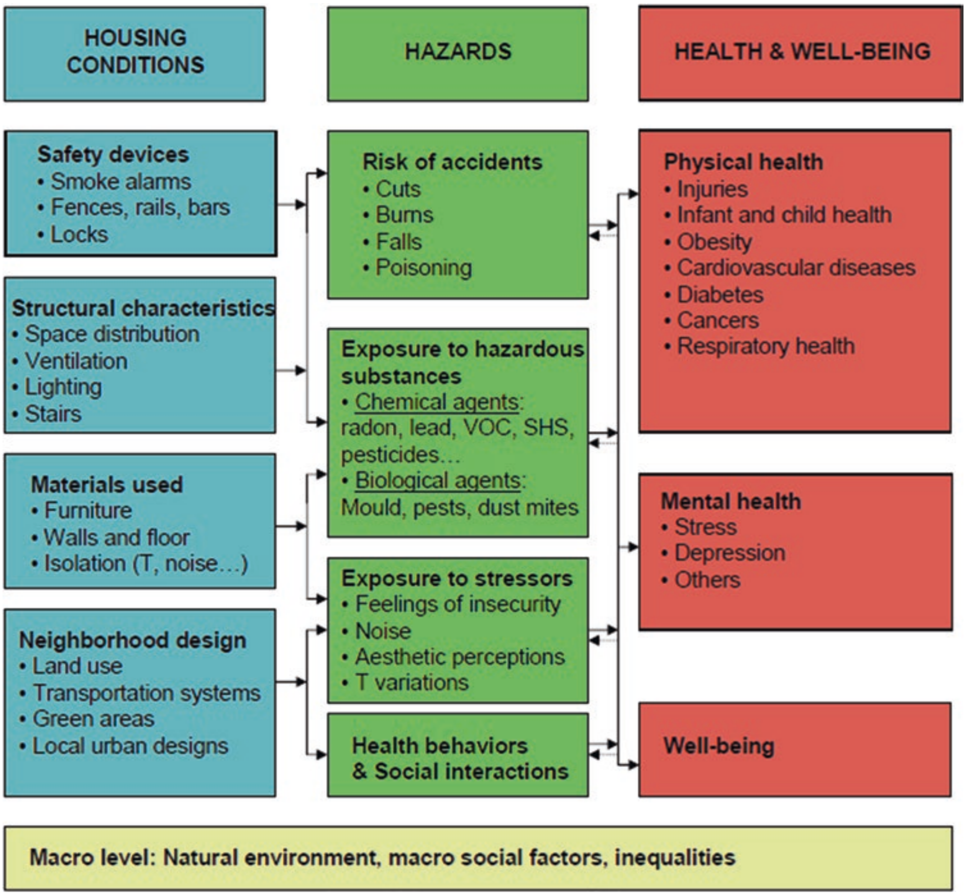

Fig. 15.3 Summary of the links between housing conditions and health outcomes (Garchitorena Garcia, 2011 adapted from Northridge, Sclar, & Biswas, 2003)

organic compounds released by many household items may result in respiratory problems and development of cancers (Sandel, Baeder, et al., 2010; WHO, 2000b).

Housing conditions may also create a favorable environment for the presence and levels of house dust mites, mold growth, cockroaches, and other pests. Overall, they represent the most common source of domestic allergens, and some of the fungal cell wall components can also irritate the respiratory tract through nonallergic mechanisms (Krieger, Jacobs, et al., 2010). They are associated with asthma development and exacerbation and other respiratory problems (WHO, 2009a). Leaks, plumbing problems, or inadequate ventilation can lead to excess moisture which attracts pests and supports mold growth (Krieger, Jacobs, et al., 2010, WHO, 2009a).

Psychosocial Influence of Housing

Housing conditions can impact not only directly on physical health but also through their influence on psychosocial factors and mental health (WHO, 2007; Grant, Braubach, & Krzyzanowski, 2010; Krieger & Higgins, 2002). They are not only associated to specific health outcomes but also to self-reported health status, well-being, and quality of life (WHO, 2007). For instance, neighborhood noise is the most frequent complaint lodged to the French municipal services (Centre d'information et de documentation sur le bruit, 2009), and it can induce stress, annoyance, sleep disturbances (WHO, 2009b), and changes in social behavior (Passchier-Vermeer & Passchier, 2000; WHO, 2011b). Other sources of stress are exposure to dampness or lack of indoor daylight (Aylin, Morris, et al., 2001). To sum up, the evidence of the link between adequate housing and both mental and physical health is irrefutable (Thomson, Thomas, et al., 2009; Jacobs & Brown, et al. 2010). Housing polices to increase the supply of affordable housing and also to improve the quality of the existing housing stock will reduce morbidity. We will now look at urban planning and development.

Urban Environmental Impacts, Planning, and Development

More than half of the human population worldwide lives nowadays in towns and cities. This is likely to increase to 60% by the year 2030. In the developing world, this is likely to lead to megacities in Asia and other large cities in Africa and 2 billion people living in slum conditions worldwide. Thus, it is important to draw lessons from the healthy cities movement to prepare for an increasingly urban world (Rydin, Bleahu, et al., 2012). In Europe and the United States, 75% and 80% of people, respectively, live in urban areas (EEA, 2011, Northridge, Sclar, & Biswas, 2003). Megapoles, cities, and other built and planned urban environments may be considered as a set of unequally structured spaces in which human populations are subject to constraints and possibilities. The existence of varied infrastructure parking lots, industrial zones, shopping areas, office blocks, road, and transport systems unequally structures the urban environment leading to health opportunities and risks. The road network and public transport systems facilitate movement but also numerous conditions that increase the likelihood of disease transmission. They also may form veritable barriers and enclaves. Cities are “plastic,” since they provide opportunities and constraints with respect to health (Raban, 2008).

Some of the challenges of the urban environment are especially pronounced for those with disabilities. Brzustowski and Jourdain (2003) found through comparing non-disabled people and physically disabled people, the latter go to the cinema 17% less than the general public. This is more than likely due to lack of accessibility of cinemas than some inherent preferences specific to disabled people. Additionally, accessibility is multidimensional and involves not just accessibility to public facilities, houses, and apartments but also the paths and roads between facilities and other dwellings as well as whether accessible transport is available and the points at which such transport services may be accessed or left (Bodin, 1999). Furthermore, provision should take into account multiple forms of impairment, each with their own particular needs.

Software is now available for analyzing accessibility (Bodin, 2005). Apps on smartphones have also been produced where disabled people may signal that a particular facility is truly accessible, thus mapping their city at low cost and to the benefit of all.[11] What is at stake in urban environments for disabled people is the possibility to benefit from the same facilities with the same rights and access as any other citizen and to carry out social activities and practices of their choosing. This has immediate implications for their health and well-being. If they cannot easily access stores and markets selling healthy food, then their health may suffer.

Disability may be a special area of interest, but its lessons hold true for other health practices with both positive and negative impacts. Frohlich and Abel (2014) suggest that urban environments and neighborhoods in particular should be thought as spaces providing resources for practices either enhancing health or harming health. Access and availability to resources are considered to be governed by four sets of rules, namely, proximity, price, rights, and informal reciprocity, e.g., gift transactions (after Godbout, 2000, 2003). Health practices, such as smoking, will occur as the result of the interaction of individuals possessing different social, economic, and cultural capitals (Bourdieu) with the resources within different domains. These domains include the physical (proximity), economic (price), institutional (rights), local sociability in community and organizational domains (informal reciprocity), and variations in how these domains are configured and in which these rules act.

---

[11] See, for instance, the collaborative initiative of Jacedde http://www.jaccede.com.

How different local configurations of domains within local neighborhoods influence health is illustrated by considering will "the local production of inequities in smoking" (Frohlich & Abel, 2014). How close are tobacco outlets? How much do cigarettes cost? Who is allowed to buy cigarettes? Who is allowed to smoke by law? And at what age? Is smoking banned in public spaces? What information resources on smoking exist? Is smoking a way to handle stress stemming from living or working conditions? What social norms are at play in relation to smoking, is it encouraged or frowned upon? Does smoking furnish a way of setting up and fostering relationships? Is smoking a way of marking out one's identity and community belonging? Are there alternative possibilities to achieve such goals within the neighborhood? Do community resources such as smoking cessation clinics exist and are they accessible to those who wish to use them? Do school-based programs exist within the community? What attitudes are taken by the school authorities to smoking? Do informal support programs set up by volunteers from the community exist? As can be easily appreciated, the above questions highlight the different domains and degree of complexity at play. Thus, physical proximity, market, institutions, and informal reciprocity involving social ties have their role to play.

Access to resources is important but insufficient to explain health practices. Depending on the neighborhood, resources will be more or lesser available, and this is not just a question of quantity. It is also a question of the capitals (social, economic, and cultural) that individuals may deploy. Although resources may be available, the ability of individuals to access these will vary. Thus, in two neighborhoods, equal health-enhancing resources may be available but their actual use may differ. Thus, mapping resources statistically is insufficient to characterize health inequities between neighborhoods. As Frohlich and Abel propose, inequities will arise at three different levels, namely, in the resources that are present in the environment, in the capitals and how these capitals relate to each other and may be deployed by individuals synergistically to access resources, and in the interaction of these levels in terms of capabilities (Abel & Frohlich, 2012). Capabilities go beyond achieving a set goal to encompass the idea that what matters is possessing the freedom to envisage and choose from a range of possibilities in relation to the projects and life plans that people have reason to value. Neighborhoods structure the health practices that people engage in, notably through the unequal distribution of resources. The idea of resources may be widened to include not just physical resources but also intangible resources which may be seen as relational processes. Neighborhoods are not just passive geographical spaces but living dialectics of structure and agency where people adapt to constraints and embrace freedoms in different domains over time and places where individuals and communities engage in practices producing health on a daily basis (Bernard, Charafeddine, et al., 2007).

Engaging in physical activity to promote health is also largely, but as our previous analysis suggests, not totally dependent on the resources within the environment. Are there safe footpaths with street lighting, green spaces, cycle tracks, gymnasium, and sports facilities? (One may have the cultural capital to engage in physical activity, but if the area is unsafe or cycle lanes inexistent, this is insufficient. Conversely, cycle lanes may exist, but cycling may be contrary to the social norms of the community, or economic capital to buy a cycle is lacking.) Is the environment isolated from the road system? Is the air clean? Are noise levels acceptable? Such matters are of course matters for local government and should be pursued actively (WHO, 2006b). (An example of the importance of the institutional domain.) Similarly, healthy eating may be seen as a health practice which is complex and favored by many factors such as personal history, education, and norms but is also very obviously dependent on the proximity, availability, and price of healthy food and unhealthy food in the local environment (Larson, Story, & Nelson, 2009; Hilmers, Hilmers, & Dave, 2012) as well as many of the neighborhood level social influences identified for smoking.

From a more physical perspective, the urban environment has also assumed considerable importance in public health terms notably due to its high population density, the size of buildings, and the existence of a considerable technical infrastructure coupled with diverse industries having high potential for different kinds of environmental pollution impacting on human health. These may aggregate or intensify the chemical and biological hazards associated with housing described above. As in our earlier mention of the diverse harms associated with noise, the degree of health impact is strongly related to the proximity of the population concerned and the source of noise emission. Thus, an increase of 10 dB of sound intensity corresponds to an increase in prescribed sleeping pills and cardiovascular disease medications (Franssen, Wiechen, et al., 2004).

The Chicago, 1996, and French, 2003, heatwaves illustrate how the urban environment may also exacerbate risks to health. Built-up environments lacking trees, hedges, bushes, and other plants tend to conserve heat (or cold). The impact of such events on mortality and morbidity is exacerbated, vulnerable isolated members of the population being trapped in veritable islands of heat within the urban environment (Klinenberg, 2003). We may also mention more extreme events such as terrorist attacks, earthquakes and other natural disasters, industrial catastrophes associated with high levels of death and injury, and chronic health problems, all of which are intensified in the densely populated urban setting. Additionally, and as noted previously, those most vulnerable are likely to have greatest exposure. In the case of industrial sites, "insult is added to injury," as very often disadvantaged populations are more likely to live close to industrial sites. Such exposed populations suffer from accumulation of long-term chronic emissions impacting on health throughout life and acute risks due to explosions and environmental contamination which may affect a large perimeter around the industrial site. Beyond the acute, immediate, traumatic injuries and deaths, disasters may also bring in their wake psychosocial consequences, such as depression. This has been seen following the major explosion of the AZF plant in the French city of Toulouse (Rivière, Albessard, et al., 2010).

The urban environment not only has direct physical impacts on health due to physicochemical risks on the human organism or as we have seen through the exacerbation of such risks but also can have indirect impacts in the form of social and behavioral effects (Whitehead, & Dahlgren, 1991; Barton, 2009). The existence of good public service provision may also contribute to mitigating such effects as indeed poor, or absent service provision may exacerbate the situation. As we have seen, people's perceptions can intensify health risks or alternatively promote healthy behaviors through reinforcing feedback loops impacting on many of today's most relevant health problems (asthma, diabetes, cancer, cardiovascular disease, depression, etc.) (Grant, Braubach, et al., 2010).

The distance to daily destinations and therefore the levels of active travel and physical activity are partly determined by the choice in urban planning of either separated or integrated land uses, the city development density, or the type of street network. Mixed land uses together with investments in good quality, accessible public transport, and reductions in the capacity of motorized transport in residential areas can reduce air pollution and traffic noise and might lead to increases in active travel and better mental health. In addition, lower speed limits in neighborhoods are associated to decreases in noise, traffic-related injuries, and fatalities (Grant, Braubach, et al., 2010).

The design of the neighborhood and the provision of urban green spaces have an impact on health risks, influencing aesthetic perceptions and physical constraints and determining the degree of social mixing. Poorly maintained and deteriorated urban environments lacking of green areas are associated with lower levels of physical activity and increased rates of overweight, partly explained through people's perception as a reaction to the aesthetic impression, which also affect mental health and social isolation. The presence of accessible municipal services, public gathering places, and green areas can counteract some of these effects. In addition, environments mimicking natural conditions (green corridors, parks, etc.) help by reducing ambient air pollution, cooling urban areas, providing a barrier against noise, and may even have an influence on preventing the development of some forms of cancer (Grant, Braubach, et al., 2010).

Given that low-income populations are disproportionately found in environments with worse urban features (less green spaces, poor urban design, etc.), many different approaches have been developed in the last decades to address health inequalities by changing the neighborhood characteristics of low-income people. For instance, programs have addressed area characteristics by moving people from high- to low-poverty neighborhoods. As we have discussed, moving to a new neighborhood can improve mental health, reduce obesity, and impact positively on some wider determinants of health (Gibson, Petticrew, et al., 2011). However, urban regeneration programs, aiming at the whole neighborhood level, are argued to be more cost-effective than the movement of individuals to better areas, since it benefits the community as a whole (Bond, Sautkina, & Keams, 2011). Yet the evidence supporting this idea is still weak. A systematic review in the UK (Gibson, Petticrew, et al., 2011) found small positive impacts on socioeconomic determinants of health but potential negative impacts as well. Mixed tenure has also been promoted in many European countries as a means to tackle social exclusion and create sustainable communities. However, the evidence is inconclusive on whether it actually promotes social cohesion and residential sustainability or improves people's perceptions of the neighborhood nor has it been found to provide better job opportunities or changes in income mix (Bond, Sautkina, & Keams, 2011).

Other interventions that have the potential to improve health and health inequalities include the demolition of distressed housing and relocation of residents, universal design standards to favor the elderly and people with disabilities, crime prevention through environmental design, smart growth and connectivity designs, zoning (regulating how a land or a site may be or not used for certain purposes, e.g., prohibiting alcohol outlets near schools), and interventions concerning green space around housing (Lindberg, Shenassa, et al., 2010).

We have presented a range of ways non-health sector factors and policies may impact on human health. We have also sketched a number of different policies that may reduce or mitigate deleterious health impacts. We have also stressed that health should be seen positively and that physical and sociocultural environments have the potential to promote and improve health. Increasingly non-health policy is taking up the gauntlet and addressing a number of these issues at the macro- and microlevel. At the macrolevel, this has been tackled notably through adapting recommendations from Health in All Policies within national and supranational government policy agendas. At the micro- or local level, numerous initiatives tackle proximal lifestyle issues. These are increasingly being proposed in tandem with more projects oriented toward distal health determinants and health inequities which recognize the impact of environments on people's practices and health. At the local level, the practice of carrying out systematically health impact assessments on new infrastructure development projects has also largely been accepted and built into law on urban renewal and industrial developments. We will briefly outline these trends giving examples of projects which recognize and reflect the importance of social determinants of health in their design.

Policies and Values

Health in All Policies and Health Impact Assessment

The idea of Health in All Policies (HIAP) is not new. The first article of the Alma-Ata declaration proclaims after defining health as a human right that

> "… the attainment of the highest possible level of health is a most important world-wide social goal whose realization requires the action of many other social and economic sectors in addition to the health sector."

The Ottawa Charter on health promotion highlights the area "Build healthy policies," "including legislation, fiscal measures, taxation and the adoption of healthy policies in non-health sectors and the development of ways to remove them."

Healthy public policy and its natural partners HIAP and Health Impact Assessment in many ways are the tool embodying the principles of healthy public policy figure prominently in WHO (2010c) and European Union policy (Ståhl, Kemm, et al., 2006). Within Europe they are also at the heart of the Healthy Cities Network. This was established at the end of the 1980s and now has around 1300 member cities. Currently the Healthy Cities Network objectives reflect a HIAP agenda incorporating both health and tackling health inequities (RFVS, 2010). Furthermore, they encompass the idea of nondiscrimination and stress a city is for all citizens. The Healthy Cities Network also recognizes that health depends on both healthy lifestyles and the living and working conditions provided to people. Good urban planning and services provide safe and healthy environments and promote health through, for example, decreasing pollution and providing opportunities for physical activity and social participation thus leading to increased well-being. Different cities and their municipal councils fix priorities and initiate projects in a wide range of environmental and health domains. In France these include projects on radon and indoor air pollution, physical and sporting activities to tackle obesity, school transport schemes encouraging walking to school or environmentally friendly vehicles, healthy nutrition, and carrying out a Health Impact Assessment in order to inform decisions about the setting up of a new crèche in an urban area.

On a global basis, the principles of Health in All Policies have also been enshrined in WHO policy by the Adelaide Statement (2010c). This stressed how cross-sector collaboration and joined up government were not only keys to better health and equity but may also be linked to sustainable development, citizen participation, and more efficient economies. The Adelaide Statement also explicitly recognizes that “the causes of health and well-being lie outside the health sector and are socially and economically formed.” The statement concludes with non-health sector examples of joined up government and its capacity to improve health and well-being (including both individual and societal well-being). The following non-health sector areas and issues are singled out: economy and employment, security and justice, education and early life, agriculture and food, infrastructure, planning and transport, environments and sustainability, housing and community services, and land and culture. As can be easily appreciated, all these areas are related to social determinants of health and tackling inequities. It is clear that the problem of introducing Health in All Policies is not for want of unclear objectives and means, since these are clearly stated, but rather lies in the fact, recognized in the Adelaide Statement, that considerable tension exists between different goals of public policy. To resolve such tension will require patience and new forms of governance and politics. As has been remarked, one measure of the success of a social innovation is whether it has managed to incorporate its most dear principles within tangible instruments or tools used routinely which become taken for granted and diffused among a wider public. As Kemm (2006) notes, “the idea of Health in All Policies is difficult to imagine without its counterpart and ally Health Impact Assessment.” In our view, Health Impact Assessment has effectively managed to incorporate a number of the key features of the Health in All Policies agenda into project design, evolution, and evaluation. As Kemm stresses however Health Impact Assessment can never be a substitute for political decision. It will give evidence on the possible consequences of policies, but it will never resolve dilemmas and tensions between different policy goals. This remains the task of policy makers who through Health Impact Assessment will be better informed about possible outcomes of their decisions affecting people’s lives. Nevertheless, there will always remain uncertainties.

Since non-health sectors largely constitute the economic and social fabric of society and non-health policies involve or impact on the people living in society, it will be necessary for all those concerned to weave common purpose in their aim to protect, maintain, improve, and address health inequities. Note that there should be no question of “us” and “them” in this, since the factors producing the social gradient in health do not only impact on those at the bottom of the gradient but act along the entire gradient. This should be done through setting up mechanisms for participation especially at the local and community level. (See chapter by Ramanadhan and Viswanath, *infra*.) This is no pious pipe dream but is based on the essential idea that humans share common needs and aspirations which go beyond culture, private, and corporate interests. In order to live in peace and prosperity in a sustainable way, it will be necessary to set up such mechanisms.

The government will need to place more emphasis on non-health policy in order to address population health. This flies in face of taken-for-granted representations of health in the general population. Health is often reduced to health care, and this is how governments and citizens traditionally represent health, dividing up the world into health and non-health. Nevertheless, recent initial French findings (You, Simons, et al., 2015) suggest that local stakeholders involved in a community project may perceive health more broadly than previously envisaged, "as a global resource for life, determined by a large number of factors (behaviors, social life, work conditions, education, transportation, etc.) and for which every local actor has a responsibility." A background paper on social determinants of health (Commission on Social Determinants of Health, 2005) highlighted the political and scientific challenges of intersectoral working and implementing policy grounded in social determinants of health agenda. Such stakeholder perceptions of health are welcome support for the idea that a robust health policy may be legitimately seen to include interventions and policies from beyond the health-care sector (Roundtable on Population Health Improvement, Board on Population Health and Public Health Practice, & Institute of Medicine 2014).

Scientific Challenges Ahead

Through engaging in work examining the impact of policies and the development of infrastructure, environmental and public health scientists have increasingly recognized that huge scientific and epistemological challenges are posed with respect to establishing causality between non-health sector factors and policies and their impacts. On the one hand, the challenges are related to the necessity for gathering high-quality data systematically. This is no easy task due to different standards, to different information systems, and to different items of information gathered in different ways, in different regions and countries, and with different degrees of priority. This last point is crucial since we are faced with a paradox. The health sector for obvious reasons gathers data about health from health sector sources. Such data frequently lacks crucial information on the circumstances of people's lives and living conditions relating to non-health policy and non-health sectors. This is almost by definition not the concern of the health sector. On the other hand, even if the non-health sector gathers data on many facets of its activities, information on health all too often will be difficult to obtain, since health, by definition again, is not a primary objective pursued by non-health policy. Thus, correlations may be difficult to establish. Geocoding by neighborhood of residence offers one approach to linking health data with other data characterizing the kinds of neighborhood and community determinants emphasized throughout this chapter. However, fundamentally gathering of such information is feasible and necessary. If it is lacking, little headway may be made and much evidence will be easy to dispute.

But even bigger challenges await researchers and policy makers. For beyond the necessity of gathering high-quality data, researchers and policy makers are confronted with the challenges of complexity and multiple pathways and feedback loops inherent within the non-health sector. It is a relatively simple matter to establish whether poor-quality or insalubrious housing can have direct proximal effects on health through, for example, dampness and associated mold increasing the risk of respiratory disease (But even here there is some degree of controversy as to the degree of impact.). However, if one attempts to further link housing to health status through studying its more indirect influence, it is immediately obvious that there are many confounding factors such as income, employment, and geographical area associated with its environmental characteristics which are challenging and difficult to unravel. As Shaw states in her 2004 review:

> Housing, health, and poverty are still empirically related and conceptually interconnected. We often become tangled in circular explanations as we attribute the effects of poverty on health to poor housing, and the effects of poor housing on health to general poverty. … This difficulty of disentangling and proving causal links is inherent to the study of social determinants of health, which tend to be multifaceted and confounded. No single factor can be identified whereby housing affects health (as with social class or socioeconomic position, gender, or ethnicity); housing is best viewed as a catch-all term for the myriad and multidimensional ways in which our conditions of living—physical, proximate, emotional, and social—can affect health. (Shaw, 2004)

Similarly Oakes and colleagues with respect to neighborhood effects stress that "Efforts to disentangle mutually constitutive, inextricably linked, synergistic, and coevolving elements are doomed to fail" (Oakes, Andrade, et al., 2015). They suggest social epidemiologists should look to solutions in ecological approaches as described by Macintyre and Ellaway (2000) and McLaren and Hawe (2005). Qualitative research may also have a significant role to play. It is perhaps illusory and ill founded to believe that such factors may be totally unraveled notwithstanding good study designs and new methodological trends in social epidemiology (Kawachi 2013, Muntaner, 2013, Galea & Link, 2013) Recent work on public health intervention research recognizes this and takes into account social theory (Hawe & Potvin, 2009). This will imply in some cases a rejection of linear logic, such as in the standard sequence of clinical medicine, that is, diagnosis, intervention, outcome, and its assessment, in favor of other models which incorporate participation, actor reflexivity, systems thinking, and complexity theory (Potvin, Gendron, et al., 2005, Livingood, Allegrante, et al., 2011).

The example of Penwerris, in Falmouth, Cornwall, UK, may be cited as a model for thinking about these issues. This socially deprived area in 1995 had the highest number of poor households, the highest proportion of children in households with no wage earners and the second highest number of lone parents. More than 50% of homes lacked central heating, and the illness rate was 18% above the national average (Durie & Wyatt, 2007). Five years on through community action initiated by two local health visitors, but carried forward by the community itself, the situation had undergone a spectacular radical transformation. Improvements of a whole series of community indicators had occurred including a 50% drop in crimes, a 42% fall in child protection registrations, and a drop of 70% in postnatal depression. Furthermore, there were no unwanted teenage pregnancies, educational achievement had hugely improved, and the unemployment rate had fallen by 71% in both men and women (Durie & Wyatt, 2007).

Durie and Wyatt carried out qualitative interviews and two focus groups to understand the process of change with its facilitators and obstacles. They suggest, through referring to complexity theory, that the downward spiral of social deprivation and urban decline was reversed through acting at a critical point, developing trust and self-confidence, favoring self-organization within the community, and leading to a reconfiguring of social relationships between those residents living in the Penwerris community, different statutory agencies, and new actors. The health visitors pinpointed 20 residents who they felt could work constructively on the estate's problems with the authorities. Five agreed to participate. The health visitors went on to initiate intersectoral action inviting the representatives of health, social services, education, local government, and the police to a series of meetings. Most importantly, in parallel with an injection of funds following a successful application for an energy improvement grant for the area, a shift in power was granted by the authorities to allow the community partnership to fix priorities and take decisions about their own community and lives. Crucially, problems were discussed and "discovered" between the actors and different solutions being explored. This was not based on classical needs analysis carried out from above but emerged and relied on local knowledge, ideas, and initiative. Regeneration was not planned from outside but emerged from within (Durie & Wyatt, 2007). This success has led to similar initiatives with other deprived communities based on similar principles of trust and self-organization being set up in other urban areas in the UK.[12] Such interventions may provide viable and effective alternatives to more traditionally planned interventions with fixed objectives based on needs analysis. It will be important to carry out intervention research to further explore and seek confirmation of this possibility.

In terms of policy outcomes, what matters is to protect, maintain, and improve health and reduce inequalities. Rather than vainly seeking complete understanding of the complex relationship between, say, housing and health, it makes more sense to humbly accept the possibility that interventions may still be effective, even if our understanding of the mechanisms by which health improvement and the righting of inequality were achieved is imperfect. In terms of population health interventions, what is important is to respect the underlying logic of the intervention and to be able to describe the different aspects of the intervention in a careful manner thus allowing transfer.

Interventions designed from a population health perspective aim to change the distribution of risk in the population in view of long-term sustainable improvements (Rose, 2001, 2008). However, there has been much debate as to whether Rose's population approach may actually widen health inequalities. It has been suggested that this may depend on whether strategies for tackling health inequities are based on structure (approaches seeking to change the context in which people live, work, and play) or agency (individual-targeted behavioral or educational interventions) (Frolich & Potvin, 2008; McLaren, McIntyre, & Kirkpatrick, 2010). The emergent consensus suggests that both agency and structure must be taken into account, and thus it is appropriate that population approaches be associated with vulnerable/high-risk group strategies (Frohlich & Potvin, 2010) and, as we will discuss later, be implemented in a spirit of proportionate universality.

Recent trends in population health intervention research also reflect this calling for a new "science of solutions" (Potvin, Petticrew, & Cohen, 2014). We may even suggest that the implicit philosophy underlying "Health in All Policies" recognizes the unpalatable fact that causality is far from easy to establish. As research on social determinants of health is increasingly demonstrating, inequality is long acting and long lasting, being embodied within individuals, its roots often being laid down early in the life course. The web of causation is complex. To tackle real-world non-health sector problems such as how housing in its wider dimensions affects health, it may well be necessary to adopt different models and forms of evaluation such as realistic evaluation (Pawson, 2006; Pawson & Tilley, 1997).

Political and Strategic Challenges Ahead

Not only are there considerable scientific challenges, there are also difficult strategic and political decisions tied up with different strategies for improving health while tackling health inequities. Firstly, it is important to revisit what we mean by a health inequity. At the beginning of this chapter, we have suggested seven principles to consider in order to determine whether we are dealing with a trivial difference in health or a health inequity. Notably it is the duty of public health professionals and academics to play a role of third-party witnessing to determine whether or not we are dealing with a case of health inequity. Secondly, policy makers and public health professionals must recognize that much health improvement and righting of health inequities is only achievable through non-health sector policies and actions since these not only impact at the heart of the conditions in which people live, work, and play but provide the resources and opportunities for access to conditions favoring health and

---

[12] See, for example, the work of *C2 Connecting Communities Ltd.* http://blogs.bmj.com/bmj/2015/02/04/jonathan-stead-on-transforming-disadvantaged-communities/.

healthy choices (Braveman, Egerter, Williams, 2011). Thirdly, different non-health sector stakeholders must come to take on board the idea that their actions, often unintendedly, have important impacts on health and well-being of the surrounding population. Fourthly, non-health sector stakeholders must realize that a social gradient in health amounts to clear evidence that everyone's health, to a greater or lesser extent, including their own is affected by their activities, and thus health becomes another dimension that needs to be considered in their policy.

How then can and should social policies aim to improve health and tackle health inequities?

Forms of Social Justice

As abovementioned, it is now clear that health inequities are frequently linked to social inequalities. In principle these may be addressed by different means involving different kinds of social justice and public health population strategies. Three main types of social justice may be singled out.

Universalism of rights. For instance, universal insurance cover may be offered to all people residing in a country, as in France, for example.

Strategies which categorize certain population groups as being at high risk or deemed vulnerable. Policy explicitly prioritizes such vulnerable groups over others thus compensating or providing more resources to the most vulnerable members of the population.

Proportionate universalism. This attempts to address health inequalities by providing more effort or resources according to how the group or individual is placed on the social gradient.

Each approach corresponds to particular public policy logic. Which form of social justice should be preferred?

Universalism of Rights

French universally oriented social policy may be considered as a good illustration of the first principle. This principle of universal coverage of needs and service provision is directly linked to an egalitarian credo. Everyone has equal rights of access to health care and services whatever their particular situation is. However, as Desrosières (2010) in his historical treatise on statistical thought and practice has explained, statistical treatment of data built around the idea of the mean and "the average man" leads to the discarding of exceptional situations and events. This favors a certain "averaging out" and standardization in line with the principle of universality. Since singularity and diversity are absorbed through the statistical mean, this may, somewhat paradoxically, lead to the necessity of deploying a second additional strategy for addressing health improvement and health inequities. Equal treatment for all almost inevitably leads to inequities since certain groups and individuals are less able to access the resources on offer than others.

Strategies for High-Risk or Vulnerable Groups

The second strategy is based on granting priority to certain, often minority, groups deemed to be suffering from deprivation, at particular risk or to be vulnerable. Such specific-targeted approaches are by their nature double edged, since they have to single out people with specific needs to be effective, but also, ultimately, run the risk of being stigmatizing. They may end up blaming the victim rather than the context that fuels inequality and need. In principle, groups at high risk may be taken into account in public policy through characterizing their living conditions in socioeconomic terms, e.g., with respect to minimum income or the poverty threshold. Through exploiting national census information, for instance, extreme situations of poverty can be characterized and classified according to percentiles. Nevertheless, all too often, the most fragile and vulnerable members of society remain "invisible" or "silent" falling outside standard statistical gathering of information. Such individuals "escape" statistical treatment. Only on the ground observation allows specific situations to be taken into account. A well-known example of this phenomenon is the Roma communities. Populations are small, statistically insignificant, poorly represented, often homeless, sleeping rough, with a wide scattering of families, and subject to wide discrimination. In order to take such populations into account, it will almost certainly be necessary to adopt preferential treatment measures in order to grant reparation and compensation for the harms and wrongs undergone by the population in question. Needless to say, such measures may be politically highly controversial but should be considered as a starting point, enabling members of the community to achieve initial successes thus laying the ground for the progressive withdrawal of the affirmative action policy.

Finally, a too simplistic and rapid reading of classical socioeconomic variables (education level, income level, size of household, etc.) gives the impression that there are typical profiles which may be considered as being deprived, even if other more statistically favorable profiles on paper, in fact, may also suffer from many of the same environmental impacts. Clyde Hertzman's work with colleagues in Vancouver on childhood vulnerability[13] illustrates this idea well (Hertzman & Bertrand, 2007). If social and education policy targets only the most vulnerable members of the community, many more families and children exhibiting features of vulnerability according to Educational Development Indicator (EDI) assessments living in apparently more favorable neighborhoods will remain untreated by the targeted policy. This argues volumes for introducing measures based on the third principle of proportionate universalism.

Proportional Universalism

Proportional universalism or proportionate universality has not yet been totally adequately theorized and may be considered to be in emergence. It is based on the idea of taking into account the social gradient and applying effort or resources according to observed need. In simple terms, universal measures are implemented but are tailored to the socially graded needs and characteristics of concern. A good illustration of how such a policy could work is afforded by the practice of providing universal after school help with homework. This is motivated by the observed needs of children disadvantaged in the educational arena. In principle, however, all children may attend. Children from more privileged backgrounds will probably need and receive less help from the homework assistance staff who will be able to focus on the children with greater need. But importantly all children will receive help and no one will be excluded. Such models may be useful for thinking through interventions for all areas of public policy, including health policy.

Scenarios for Tackling Health Inequities and Improving Population Health

Benach, Malmusi, et al. (2013) based on Rose's population health approach and Graham (2004b) has have put forward theoretical scenarios for tackling health inequities and improving population health. Four scenarios are proposed and illustrated with examples relevant for non-health policy interventions:

1. Focusing on targeted interventions and health gap, e.g., targeted neighborhood renewal
2. Universal policy with additional focus on gap, e.g., increasing childcare provision but especially in disadvantaged areas
3. "Redistributive" policy, e.g., social housing provision and decreasing residential segregation through housing vouchers
4. "Proportionate universalism" universal policy with increasing benefits through the gradient, e.g., workplace organizational psychosocial interventions which are potentially beneficial to all but bring greater benefit to lower grade employees

In the case of the environment, it is evident that the foremost policy goal is to protect and improve living conditions through reducing and controlling harmful exposures (noise, air pollution, water quality, and industrial and natural risks). But since urban spaces in particular have been planned and organized unequally leading to the cumulative effects of socioeconomic inequalities combined with environmental inequalities, it is important to

---

[13] See http://earlylearning.ubc.ca/.

attempt to right such inequities. However, this is not easily achieved, and effects on health can be insidious and persist long into the future.

Effective plans to address health inequities and improve health of communities will involve different key community players from diverse sectors such as education, housing, schooling, transport, and culture working together and working with the community of health. We believe that the "heyday" of unipolar programs based on the belief that diseases, whether they be social or biological, can be tackled through only focusing on proximal and immediate causes has long passed. Public health policy makers should take on a broader vision accepting that complexity is firmly on the agenda. This has a number of implications well spelled out by Rydin, Bleahu, et al. (2012) describing comprehensive planning of urban environments to take into account their impact on health. Three main principles taking on broad complexity are advanced. First, emphasis is placed on applying a heuristic approach involving localized pilot experimentation which enables context and the resources of local communities to be harnessed effectively. Secondly, mutual learning coupled with "strengthened assessment" involving diverse stakeholders and the community is stressed. Such assessment may be based on different forms of knowledge from statistics through to the experiential baggage of both professionals and lay members of the community. Assessment should not be seen as being imposed through the intervention of external experts. Thirdly, policy makers should recognize that attempts to improve the health of the community and to decrease risks to the urban population are value laden. They will inevitably need discussion and debate of objectives and related ethical issues with those who are concerned, i.e., the community themselves. This will necessitate the organization of forums and paying special attention to involve and sound out potentially marginal and vulnerable groups, for example, people with disabilities. What is more is that such forums will also play a key political role in protecting the interests of such groups from other more powerful vested interests at work in urban development and regeneration.

Concluding Thoughts

Ian Hacking has famously remarked "Names organize our thoughts" (Hacking, 1995). In this chapter, we have taken the decision of making a straightforward and sharp split between the health sector and policy *and* the non-health sector and non-health policy. In line with Health in All Policies, it will become more and more necessary for government, policy makers, and indeed stakeholders to accept, as in environmental health, that we all have a part to play in making the world a healthier and safer place. Such a realization however is also linked to our values and views on the sources of inequality and health. It is clear that inequality is a major source of poor health and disease. It is also abundantly clear from the evidence we have at our disposal that the non-health sector and its related policies could have a substantial role in righting such inequities. In the field of environmental health, a sea change has occurred through the recognition that we all live in the same world with finite resources, and this has opened the way for greater sustainable development and more friendly environmental policy. We believe it will be necessary for a comparable change of representations to occur accepting that the health and welfare of individuals are deeply tied to the circumstances and environments in which they work, live, and play. Indeed as Galea, Rudenstine, and Vlahov (2005) declare "There is little doubt that who we are, what we do, and to an extent even what we think, is shaped by our environment." However, different environments do not offer equal opportunities and access to resources for health. Indeed, they also are associated with different degrees of risk. We now know, but we have known this since at least Villermé's writings of the nineteenth century, that the places we live in are not equal as regards health, well-being, and indeed death. Often health policy and economic policy are construed on the basis of the independent individual, making her or his choices. This view has the merit of allowing responsibility to be allotted simply to the individuals concerned, but it flies in the face of evidence which shows that it does matter where you live, since it is likely to impact on your health and how long you are likely to live. Furthermore, it does matter where you work since similarly conditions of work impact on health and life span. And of course, if you are unlucky to be among the workless, this again has profound implications on your health and when you are likely to die.

The time has perhaps come when it will become habitual to think of people being embedded in sociocultural and economic contexts with habitual practices rather than as decontextualized individuals within statistical populations with free choice of behaviors and free choice of dwelling and neighborhood (Krieger, 2012b). Frohlich and Abel (2014), citing Sen, explain: "Sen distinguishes between two types of freedom; opportunity and process (Sen, 2009). When describing opportunity freedom, Sen draws on the structural constraints and opportunities that people have to make choices. The ability to be a certain way and live a certain life is confined, or not, by the options that are available for people to choose from. The process aspect, on the other hand, focuses on the true agency that people have to make their choices." Choice may be seen as having two components: (a) the conditions which lead to certain choices being possible or not and (b) the actual individual choosing process. It is important not to confuse the two. We now know that at least potentially, our lives are influenced before birth and may depend on what has happened in prior generations. Furthermore, Hertzman's work at Vancouver has shown that the effects of the environment, measured through indicators of educational development, are embodied through epigenetic neurodevelopmental mechanisms leading to vulnerability which varies according to neighborhood area classed by SES in which children develop and live. This vulnerability potentially may have impacts beyond early childhood. Importantly, it also graphically demonstrates that the social gradient not only concerns the children living in the poorer areas of the city but also many other children living in more prosperous areas. Social gradients demonstrate that the same underlying influences impact on people's lives and furthermore show that people's health may potentially improve in different environments with more opportunities and less risks. There are no "them" and "us." It is indeed a brave new world where genes may be switched on and off, and health is subject to influences from previous generations, prenatal, and early development, beyond the control of those they affect (Khan, 2010), but it offers us a possibility of rethinking who bears responsibility for health and health inequities. Through applying Harpet's seven principles identifying inequities, it is likely that the answer that may emerge is that those who can influence the sociocultural and physical environments in which we live, work, and play are indeed responsible. Some of us are, of course, more responsible than others. Notably, this includes our political and business leaders and policy makers, since they are responsible for the physical and sociocultural environments and their upkeep that are on offer to our fellow men, women, and children. Once this has been accepted, then the determining role of the non-health sector and the necessity for different sectors and the health sector itself to work together will be very apparent. Furthermore, the idea that insalubrious, run-down, unhealthy, unsafe, non-accessible, or segregated environments are acceptable will become unthinkable, a thing from the past.
